The interaction between the antibody and the red cells of the newborn is followed by

hemolysis with resultant **anemia, hemoglobinuria, and jaundice**. Following ingestion and absorption into the systemic circulation, antibodies bind to red blood cell membranes. Parts of the cell membrane of the antibody coated cells are removed from the circulation, probably by the spleen and associated reticulo-endothelial tissues, and affected cells are eventually lysed and release hemoglobin into the circulation. The affected animal develops **normovolemic anemia** and, if the destruction of red blood cells is sufficient, develops anemic hypoxia and dies. The reaction between red blood cells and antibodies occurs sufficiently quickly that the bone marrow is unable to compensate immediately for the loss of red blood cells. Disseminated intravascular coagulation (DIC) occurs and may contribute to the death.

Permeability of the intestine of the newborn foal to antibody disappears by 36 hours and in most cases much less. Hourly milking of the mare rapidly reduces the antibody content of the colostrum. The duration of the alimentary permeability in piglets has not been determined.

## CLINICAL FINDINGS

### Horses and mules

Pregnancy and parturition are uneventful and the foal is normal for some hours after birth. Signs appear only if the foal ingests and absorbs colostrum containing anti-red blood cell factor antibody. The severity of disease ranges from clinically inapparent to fulminant with death ensuing soon after birth.

**Peracute cases** develop within 8–36 hours of birth, and the first indication of the disease may be collapse. Severe hemoglobinuria and pallor are evident but icterus is not apparent initially. The mortality rate is high.

In **acute cases** signs do not develop until 2–4 days after birth and jaundice is marked, with only moderate pallor and hemoglobinuria.

**Subacute cases** may not show signs until 4–5 days after birth. **Jaundice** is marked, but there is no hemoglobinuria and only mild pallor of mucosae. Many subacute cases recover without treatment.

The severity of the disease is related to the type and quantity of antibody ingested. Antibodies against Aa usually produce severe disease apparent within 24 hours of birth, while ingestion of anti-Qa antibodies causes a milder disease apparent at 3–4 days after birth.

General signs include lassitude, weakness, and disinclination to suck. The foal lies down in sternal recumbency for long periods and yawns frequently. There is no febrile reaction but the heart rate is increased up to 120/min. Respiration is normal until severe anemia develops

when tachypnea (respiratory rate up to 80/min) and yawning are observed. Terminally, dyspnea and convulsions may develop. Peripheral edema does not occur and there are no signs of involvement of the central nervous system. **Bilirubin encephalopathy** or kernicterus is a rare complication of neonatal isoerythrolysis. It is apparent as altered mentation and seizures in foals with high serum bilirubin concentration.<sup>9</sup>

**Isoimmune thrombocytopenia** of foals and mules may be evident as ecchymotic hemorrhages and a tendency to bleed from relatively minor wounds. A syndrome in foals characterized by ulcerative dermatitis, neutropenia, and thrombocytopenia appears to be related to ingestion of colostrum antibodies.<sup>10</sup> Affected foals have oral and lingual ulcers, and crusting and erythema around the eyes, muzzle, perineum, trunk, and neck. There are ecchymotic and petechial hemorrhages in mucus membranes. Treatment with corticosteroids and antibiotics is associated with a good prognosis.

### Pigs

Piglets show essentially the same syndrome, being normal at birth but developing jaundice at 24 hours and weakness at 48 hours, with most affected pigs dying by the 5th day. Peracute cases occur and piglets may die within 12 hours of birth, showing acute anemia but no jaundice or hemoglobinuria. A proportion of subclinical cases also occurs in which hemolysis can be detected only by hematological examination. **Isoimmune thrombocytopenic purpura** of piglets may manifest as increased bleeding following routine management procedures such as tail docking.<sup>11</sup>

### Cattle

In calves clinical signs develop within 24–48 hours after birth and the calves die during the first week of life. Surviving calves are returned to normal health in 2–3 weeks. Peracute cases die within 24 hours, and at necropsy examination are characterized by pulmonary edema and splenomegaly.

## CLINICAL PATHOLOGY

**Hematological examination reveals acute anemia**; erythrocyte counts, packed cell volumes, and hemoglobin concentrations are low and there is greatly increased erythrocyte fragility and sedimentation rate. Depending on the severity of the disease and its duration, there can be **leukocytosis**, attributable to neutrophilia and monocytosis, and the presence of nucleated red blood cells (in piglets and calves but rarely in foals). Affected mule foals, but not horse foals, are often **thrombocytopenic**.<sup>8</sup> Isoimmune throm-

bocytopenia occurs rarely in foals and is not associated with neonatal isoerythrolysis, as it is in mule foals. In piglets, the erythrocyte count may be as low as 1 million/ $\mu\text{L}$ , the hemoglobin level below 2 g/dL, and thrombocytopenia is present. **Serum biochemical analysis reveals** an increased serum concentration of unconjugated bilirubin.

**Diagnostic confirmation** is achieved by demonstration of the presence of antibodies in the mare's serum or colostrum that cause hemagglutination or lysis of foal red blood cells.<sup>11</sup> Tests to demonstrate hemagglutination or lysis of foal red blood cells exposed to mare serum or colostrum have been developed. Of these, the standard hemolysis test appears to have the greatest utility.<sup>12</sup> However, for practical purposes a positive direct antiglobulin test (**direct Coombs' test**), confirming the presence of antibodies on the surface of red blood cells in a foal with anemia, provides a diagnosis of neonatal isoerythrolysis. False negative (foal has the disease but the Coombs' test is negative) results occur occasionally because of the hemolytic nature of the antibodies. The same principle is applicable to all species. Detection of antibodies on the surface of the neonate's red blood cells is possible using direct immunofluorescence flow cytometry.<sup>13</sup> The test identifies the presence of antibodies on red cells in some instances when the Coombs' test is negative.

The use of blood typing and other prepartum predictive tests in the prevention of the disease are discussed under control.

#### NECROPSY FINDINGS

In peracutely affected foals, there is marked pallor but only slight jaundice. The liver may be mildly swollen and friable but the spleen is greatly enlarged and is almost black due to the accumulation of lysed and lysing erythrocytes. In less severe cases jaundice is marked but pallor is only moderate in degree. The kidneys are usually pale and the urine is dark brown. The histopathological changes may include ischemic tubular nephrosis and periacinar hepatic necrosis and degeneration. Erythrophagocytosis is prominent and depending on the clinical course and therapeutic regime, there may be widespread hemosiderin deposition.

Hemoglobinuria is an important sign in piglets, and jaundice or port wine coloration of tissues occur constantly. The presence of blood-stained peritoneal fluid and an enlarged spleen is also typical of the disease in piglets.

Samples for postmortem confirmation of diagnosis

Formalin-fixed liver, spleen, bone marrow, kidney, and lymph node for light microscopic examination

#### DIFFERENTIAL DIAGNOSIS

- There are no diseases of the newborn that present the same clinical picture as that of alloimmune hemolytic anemia.

#### Differential diagnosis list for unexpected death and/or lethargy of neonates

##### Foals and calves

- Septicemia
- Neonatal maladjustment syndrome
- Uroperitoneum
- Prematurity
- Birth trauma
- Hypoglycemia
- Equine herpesvirus-1 infection

##### Piglets

- Septicemia
- Birth trauma
- Hypoglycemia.

#### TREATMENT

The aims of treatment are to:

- Prevent the deleterious effects of anemia
- Prevent or treat hemoglobinuric nephrosis
- Prevent ingestion of further colostrum
- Prevent secondary infection in severely ill animals
- Restore normal fluid, electrolyte, and acid-base status
- Provide adequate nutrition
- Minimize stress.

The **treatment of choice** for neonatal isoerythrolysis depends on the severity of the disease. The choice of treatment should be based first and foremost on the severity of the clinical signs and secondarily on the hematocrit and red blood cell count. Foals or piglets with **mild clinical signs** (minimal lethargy, mild tachycardia, slight exercise intolerance) need only protection from environmental and nutritional stresses in order to recover. However, such animals should be carefully monitored to insure that their clinical condition does not worsen.

**Severely affected** animals need a transfusion of compatible blood to alleviate the anemia and intravenous fluids to insure adequate urine flow and minimize the risk of hemoglobin-nephrosis. In general, the younger the animal at the time the disease is evident, the more severe the disease and the more likely the need for intensive treatment. See Chapter 9 for a discussion of 'transfusion triggers'.

#### Foals

Transfusion

**Transfusion** of an adequate quantity of whole blood or packed red blood cells results in dramatic resolution of clinical signs and anemia. **The decision to**

**transfuse blood** should be based on the foal's clinical condition, and not solely on the presence of a low hematocrit or red blood cell count (see Blood transfusion, in Chapter 9). In general, foals that are tachycardic, tachypneic, unable or reluctant to suck, have severe exercise intolerance or are unable to stand should receive blood. These foals will usually have a hematocrit less than 15% (0.15 L/L). Recumbent foals usually have a hematocrit less than 10% (0.10 L/L). Foals that are mildly tachycardic and tachypneic but are able to suckle vigorously and keep up with the mare generally have hematocrits above 15% (0.15 L/L) and do not require transfusion of red blood cells. The hematocrit should be monitored and foals in which the hematocrit is declining rapidly will likely require transfusion of blood or packed red cells.

The **volume of blood transfused** depends on the clinical condition of the foal and the progression of the anemia. Foals often require transfusion of 1–4 L (20–100 mL/kg body weight) of whole blood or 500 mL (approximately 10 mL/kg body weight) of packed red blood cells, and might require more than one transfusion. Blood should be administered slowly, 1 L/hour, and the foal's condition monitored closely during the infusion. Packed red cells are preferred for transfusion because of the small volume administered. Transfusion of large quantities of blood should be performed slowly because of the risk of fluid overload of the circulatory system. The half-life for mare erythrocytes transfused into foals is about 5 days.<sup>14</sup>

The **optimal donor** is a horse that does not have Aa and Qa blood group factors nor anti-Aa and Qa alloantibodies. The former should not be present as the maternal antibodies against Aa or Qa in the recipient foal's plasma will destroy the transfused cells. Similarly, donor antibodies against Aa or Qa will cause further lysis of foal red blood cells. Such donors must be identified in advance, because of the time required for the blood type testing, and are only likely to be available on large breeding farms or in specialized veterinary hospitals.

An **ideal source of red blood cells** is the **dam** because the maternal alloantibodies in the foal's plasma will not react with the mare's red blood cells. However, whole blood transfusions from the dam are contraindicated because of the presence of alloantibodies in the dam's plasma. This problem can be avoided by transfusing only the mare's washed red blood cells. Blood is collected from the mare (up to 25 mL/kg) into acid citrate dextrose or sodium citrate (10 mL of a 3.8% solution per 90 mL of blood). The mare's red cells are then washed by removing the plasma, resuspending the cells in isotonic (0.9%)

saline, thorough mixing, and subsequent removal of the saline. Plasma and red cells can be separated by large volume centrifugation or sedimentation. Adequate separation of red cells and plasma occurs by sedimentation within 1–2 hours if the blood is undisturbed.

If an ideal blood-typed donor is not available and the mare's red cells cannot be washed in time, or are unavailable, then a donor should be chosen based on routine cross-matching. The **sire** will not be a suitable donor, since the antigens against which the mare's antibodies are directed were inherited from him. A cross-match should match the foal's (or dam's) serum against the donor's red blood cells, and the donor's plasma against the foal's red blood cells. The chance of finding a suitable donor is enhanced by selecting ponies or breeds other than Thoroughbreds, Standardbreds, and Arabians, because of the higher prevalence of Aa and Qa negative animals in these breeds.

Emergency support of severely affected foals can be achieved by administration of a solution containing **polymerized bovine hemoglobin**.<sup>15</sup> This compound increases the hemoglobin concentration of blood thereby increasing oxygen carrying capacity. It is not a replacement for transfusion of blood or packed red cells, but is a useful bridging procedure while a donor is identified and blood collected. The recommended dose rate is 10–30 mL/kg administered slowly (10 mL/kg/h) intravenously. However, the cost of the compound might necessitate the use of lower doses (3–5 mL/kg).

#### Nutritional support

The foal should not be permitted to nurse the mare until it is >36 hours old. Therefore, **nutritional support** should provide approximately 100 kcal/kg per day in the form of mare's milk (10 L per day per 50 kg foal), goat's milk, or commercial mare's milk substitutes. If the foal is more than 36 hours old, then it is highly unlikely that either the mare's milk will still contain a significant quantity of antibodies or that the foal will be able to absorb them, and the foal should be allowed to continue to suckle the mare. In younger foals, an alternative feed should be supplied until the foal is at least 36 hours old. The mare should be milked out every 3–4 hours during this time to remove the colostrum.

**The fluid, electrolyte, and acid-base status** of moderately to severely ill foals should be assessed and corrected with intravenous administration of balanced polyionic fluids and sodium bicarbonate. Fluid administration should be used to insure an adequate flow of urine to prevent hemoglobinuric nephrosis.

#### Antibiotics

**Broad-spectrum antibiotics** should be administered to severely ill foals to prevent secondary infection (see Principles of providing care to the critically ill neonate).

**Nursing care** should be provided to minimize stress and prevent the development of complications such as pressure sores in recumbent foals.

#### Piglets

In pigs the prevention of sucking for periods of up to 24 hours does not prevent the disease. The safest procedure is to remove piglets from the sow, feed them artificially for 48 hours, and then return them to the sow. Frozen bovine colostrum collected as soon as possible after calving is a satisfactory substitute for sow colostrum but is improved by the addition of pig serum. When transfusion is necessary the intraperitoneal route is practical and safe.

#### CONTROL

The principles of control are:

- Identification of incompatible matings by blood group typing
- Identification of at-risk foals by testing of mare serum or colostrum for the presence of alloantibodies directed against blood factors possessed by the foal.

**Blood group typing** permits the identification of mares that are at risk of developing antibodies against Aa or Qa antigens. If an Aa or Qa negative mare is mated to a stallion that has Aa or Qa factors then there is the potential for neonatal isoerythrolysis. If the stallion is Aa and Qa negative, then there is no risk of the disease caused by antibodies to these blood groups.

**Measurement of alloantibodies** in the serum or colostrum of at-risk mares is

useful in identifying mares at increased risk of having affected foals. Serum from at-risk mares is collected during the last month (preferably 3–5 weeks before expected parturition) of pregnancy and examined for the presence of antibodies against the blood of the sire or, if a sample of the sire's blood is not available, a range of blood group factors including Aa and Qa. Mares that have such alloantibodies causing hemolysis at >1:16 are not permitted to suckle at risk newborn foals. If the titer is between 1:2 and 1:16, it is measured again 1–2 weeks before anticipated parturition to determine if the titer is rising, in which case the mare is likely carrying a foal with an incompatible blood group. Equine blood typing and detection of isoantibodies is performed by specialized laboratories in a number of countries:

- Australia – [www.aegrc.uq.edu.au/services](http://www.aegrc.uq.edu.au/services)
- New Zealand – [www.ivabs.massey.ac.nz/centres/centre\\_blood.asp](http://www.ivabs.massey.ac.nz/centres/centre_blood.asp)
- USA – [www.uky.edu/Agriculture/VetScience/textpages/epvrl.HTM](http://www.uky.edu/Agriculture/VetScience/textpages/epvrl.HTM) and <http://www.vgl.ucdavis.edu/service/horse/index.html>

The **jaundiced foal agglutination test (JFA)** is useful in determining the compatibility of mare's colostrum and foal's red blood cells (Table 34.1).<sup>16,17</sup> In this test foal red blood cells are added to serial dilutions (1:2 through 1:32) of colostrum and the presence of agglutination examined. Agglutination at dilutions of 1:16 in horses and 1:64 in mules are considered significant and the foal should not be permitted to receive the mare's colostrum.<sup>1</sup> The foal should be fed colostrum from another, compatible,

Table 34.1 Method for performing the jaundiced foal agglutination test<sup>16,17</sup>

1. Assemble eight 5–10 mL clean glass tubes. Label one as control (saline), and the others 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128
2. Place 1 mL of 0.9% isotonic sterile saline in each tube
3. Add 1 mL of colostrum to the tube labeled 1:2. Mix this tube well and then transfer 1 mL of the contents of this tube to the tube labeled 1:4. Repeat this procedure until all tubes have had colostrums added. This procedure produces serial dilution of the colostrums.
4. Add one drop of well mixed, anticoagulated blood (e.g. blood collected into a tube containing EDTA) to each tube.
5. Centrifuge the tubes at 300–500 g for 2–3 minutes
6. Pour off the supernatant and observe the red cell pellet.

#### Interpretation

If no agglutination is present the red cells will flow evenly down the side of the glass tube whereas with complete agglutination (4+) the cells remain tightly packed at the bottom of the glass tube. Strong agglutination (3+) causes the cells to form large clumps that are visible to the naked eye. Agglutination of grade 3 or 4 is considered a positive test.

If there is agglutination in the saline control tube, then the foal might have already ingested colostrum containing antibodies to the foal's red blood cells. Some authorities recommend running a parallel test using mare's red blood cells in place of foal's red cells. This provides a negative control (there should be no agglutination of mare red cells by her colostrum) and aids interpretation of results especially for inexperienced operators.

mare or from a colostrum bank. The mare should be milked out every 2–4 hours until the JFA titer is less than 1:16 or for 36 hours, after which the concentration of antibodies in the milk is negligible,<sup>1</sup> and the foal can be permitted to suckle its dam. It is critical to the successful use of this test that it is performed before the foal is permitted to suckle the mare. If an incompatibility is detected the foal should be fed colostrum from a mare that does not have a positive jaundiced foal agglutination test to the current foal's red cells.

Avoidance of vaccines based on whole blood or cellular parts of blood is recommended, and if they have to be used it should be as far away as possible from parturition and should be restricted to one injection and one booster.

## PURPURA HEMORRHAGICA

### Synopsis

**Etiology** Deposition of immune complexes in the walls of capillaries with subsequent vasculitis and extravasation of blood and plasma.

**Epidemiology** Sporadic disease of horses, and rarely cattle and pigs. The disease in horses is often associated with upper respiratory tract disease, especially *Strep. equi* infection.

**Clinical signs** Swellings of the head, limbs, and body. The swellings are usually asymmetrical, not painful on palpation and pit with gentle pressure. Tachycardia and tachypnea are characteristic. Petechial hemorrhages are present in mucosal surfaces. Skin of the limbs may slough.

**Clinical pathology** None specific. High anti-streptococcal in protein liter in serum thrombocytopenia is not present.

**Diagnostic confirmation** Clinical signs, skin biopsy.

**Treatment** Corticosteroids (dexamethasone) and antibiotics. Supportive care.

## ETIOLOGY

The disease is acute and non-contagious. The cause of the **vasculitis** that characterizes purpura hemorrhagica is likely the deposition of complexes of antigen and immunoglobulin in the walls of capillaries and small blood vessels. The disease appears to be **immune complex-mediated** and due to a **type III hypersensitivity reaction**. The common association of the disease is with *Strep. equi* infection of the upper respiratory tract. The high concentrations of antibodies to *Strep. equi* M protein in affected horses, and the presence of complexes of IgA and streptococcal M protein in sera are evidence that the disease is associated with an immune reaction to streptococcal protein.<sup>1-3</sup> The immune complexes are not found in the serum of horses recovering from *Strep. equi* infection that do not have purpura hemorrhagica. However, in many instances there is no history of streptococcal infection.<sup>4</sup> There is a suggestion that the disease might be associated with an adverse reaction to therapeutic drugs. Vaccination using modified live *Strep. equi* M protein or killed *Strep. equi* vaccines is strongly suspected of inducing the disease.

## EPIDEMIOLOGY

Purpura hemorrhagica is an uncommon, non-contagious, sporadic disease of horses. It has been recorded in pigs and cattle. Estimates of the incidence of the disease are uncommon and imprecise. There was an incidence of 27 cases in 1438 horses housed over a 3-year period in a Swedish Army remount facility.<sup>5</sup> All cases of purpura hemorrhagica followed upper respiratory infections, of which 11 were typical of strangles. Only a small proportion of horses are affected but the incidence is highest when extensive outbreaks of strangles occur, possibly because of reinfection with streptococci of horses already sensitized by previous infection.

Of 53 horses with purpura hemorrhagic treated at a referral center, 17 had been exposed to or infected with *Streptococcus equi*, 5 had been vaccinated with *Streptococcus equi* M protein, 9 had been infected with *Corynebacterium pseudotuberculosis*, and 5 had a history of apparently infectious respiratory disease of undiagnosed cause. Fifteen of 53 horses had no history of recent infectious disease.<sup>4</sup>

There is a strong suspicion among clinicians of an association between purpura hemorrhagica and vaccination.<sup>6</sup> However, vaccination against *Strep. equi* infection has not been clearly demonstrated to be a risk factor for purpura hemorrhagica. Certainly, cases of purpura do occur in horses that have been vaccinated against strangles, but presumably

there was a high probability that such horses were at increased risk of developing strangles. The consensus is that vaccination with vaccines containing M protein or avirulent *Strep. equi* is associated with increased risk of purpura. Edema of the lower limbs does occur after vaccination with streptococcal M protein and may represent a mild form of the disease.<sup>7</sup> It is recommended by some authorities that horses with high serum antibody titers to streptococcal M protein not be vaccinated against strangles,<sup>6</sup> although definitive data to support this recommendation are not available.

There does not appear to be breed, age, or sex predisposition to the disease. Horses as young as 6 months of age, and possibly younger, can be affected.

The case fatality rate with appropriate treatment is approximately 10%.<sup>4</sup> Purpura accounted for 2 and 8% of 2028 and 1245 deaths among horses shipped from Great Britain and the United States, respectively, to South Africa during the Boer War.<sup>8</sup> This mortality rate was before the advent of antimicrobials or corticosteroids which have presumably decreased the case fatality rates.

## PATHOGENESIS

The basis of the disease process is an **aseptic vasculitis** of capillary walls that is accompanied by extravasation of plasma and blood into the tissues. Thrombocytopenia does not occur, nor is there a defect in coagulation in most cases. Prolonged clotting times (activated clotting time, partial thrombin time, and thromboplastin time) occur in severely affected horses with infarctive purpura hemorrhagica.<sup>3</sup> Skin lesions predominate but other organs, including the kidney, muscles, and gastrointestinal tract, are affected.<sup>3,9</sup>

## CLINICAL FINDINGS

Affected horses are usually depressed and have reduced or absent appetite. The temperature is elevated in approximately 60% of cases,<sup>4</sup> as is the heart rate. **Extensive subcutaneous edematous swellings** are the characteristic sign of the disease. They occur most commonly about the face and muzzle, but are often present on other parts of the body and are not necessarily symmetrical in distribution. The swellings may appear suddenly or develop gradually over several days. They are cold and painless, pit on pressure, and merge gradually into normal tissue without a definite line of demarcation. There is no discontinuity of the skin, although it may be tightly distended and even ooze red-tinged serum. Swellings about the head may cause pressure on the pharynx with subsequent dyspnea and dysphagia. Lesions in the lungs are usually not clinically apparent without radiographic or ultrasonographic

examination of the chest. Extensive edema of the limbs occurs in almost all cases.<sup>4</sup> Rare cases of the disease in horses do not have edema.<sup>10</sup>

**Submucous hemorrhages** occur in the nasal cavities and mouth, and petechiae may be present under the conjunctiva in over 80% of cases. Hemorrhage and edema of the gut wall may cause colic but in most cases there is no diarrhea or constipation. Severely affected skin, and especially that of the legs, may slough and leave granulating wounds.

**Infarctive purpura hemorrhagica** is an uncommon manifestation of the disease characterized by infarction of multiple tissues including the gastrointestinal tract and muscle.<sup>3</sup> Affected horses have signs of colic and muscle swelling. The course is usually over 3–5 days and death, which is the most common outcome, is associated with severe colic and rapidly deteriorating metabolic status.

The course of the disease is usually 1–2 weeks and many animals die from blood loss, dyspnea due to laryngeal or pharyngeal swelling, and secondary bacterial infections. Relapses are uncommon among appropriately treated horses.

#### CLINICAL PATHOLOGY

There are no characteristic abnormalities detected on routine hematological or biochemical examinations of affected animals.

**Hematological changes** are typically a mild anemia (usually <32% but >20%, <0.32 L/L but >0.20 L/L) with a neutrophilic leukocytosis and hyperfibrinogenemia. **The platelet count is normal.** Hypergammaglobulinemia can be present. There is an elevation in serum activity of creatine kinase (CK) and aspartate aminotransferase (AST) in affected horses, likely a result of muscle lesions, in approximately 25–30% of cases.<sup>4</sup> Horses with infarctive purpura have marked elevations in serum activity of creatine kinase and aspartate aminotransferase, neutrophilia, and in severely affected horses, there is evidence of disseminated intravascular coagulation.<sup>3</sup>

**Diagnostic confirmation** is achieved by **skin biopsy**, especially of early lesions, and reveals leukocytoclastic vasculitis.<sup>7</sup> Immunofluorescence staining of sections of skin may reveal the presence of antibodies, antigens, or complement in the walls of small blood vessels.

#### NECROPSY FINDINGS

Echymotic and petechial hemorrhages are present generally throughout the body. The subcutaneous swellings contain plasma which may be blood-stained, or sometimes whole blood. The lungs are edematous and congested. Histologically, the changes are also dominated by bland hemorrhage but a leucocytoclastic vascu-

litis is usually observed in scattered vessels. Sample of lung, muscle, and gastrointestinal tract, in addition to skin, should be examined via light microscopy to check for the presence of vasculitis.

Horses with infarctive purpura have dark red to black, multifocal coalescing hemorrhages in skeletal muscles.<sup>3</sup> Hemorrhages also occur in the lungs and gastrointestinal tract. Histological examination reveals coagulative necrosis of muscle and other tissues. There is inflammation of the blood vessels.<sup>3</sup>

#### DIFFERENTIAL DIAGNOSIS

##### Horses

Causes of edematous swelling include:

- Equine viral arteritis and equine herpesvirus 1 or 4 infection, which do not have petechiation and are readily distinguished by their epidemiological characteristics and by serological testing
- Equine granulocytic anaplasmosis (ehrlichiosis) which can be differentiated by the presence of granular inclusions in the cytoplasm of neutrophils
- Congestive heart failure, which should be apparent on clinical examination
- Angioneurotic edema, which is not associated with petechiation
- Stachybotryotoxicosis.

Causes of petechial hemorrhages include:

- Equine infectious anemia
- Thrombocytopenic purpura
- Stachybotryotoxicosis.

##### Cattle

Hemorrhagic septicemia, poisoning by bracken fern and sweet clover, thrombocytopenia associated with bovine viral diarrhea, and stachybotryotoxicosis are more likely causes of a hemorrhagic syndrome than is purpura hemorrhagica.

#### TREATMENT

The **principles of treatment** are to reduce inflammation of the blood vessels, remove the inciting cause, and provide supportive care. Because of the possibility that the disease is due to an adverse drug reaction, administration of any drugs that the horse is receiving at the time the disease develops should be discontinued.

**Reduction of inflammation of the blood vessels** involves mitigation of the immune response and removal of the source of the antigenic stimulus. The immune response, and its associated inflammatory reaction in blood vessels, should be treated with corticosteroids such as **dexamethasone** (0.05–0.2 mg/kg, IV or IM every 24 hours) or **prednisolone** (0.5–1 mg/kg, IM or IV every 24 hours). Prednisolone might not be as effective as

dexamethasone. The dose of corticosteroid can be gradually reduced as the clinical signs improve, and the drug can be given orally. **Non-steroidal anti-inflammatory drugs** (phenylbutazone 2.2 mg/kg orally or IV every 12 hours, or flunixin meglumine 1.1 mg/kg orally or IV every 12 hours) may reduce inflammation and provide some analgesia.

**Removal of the source of the antigenic stimulus** of the disease is difficult, especially in cases when an antecedent infection or disease is not readily identified. On the assumption that purpura hemorrhagica is often a sequela to *Strep. equi* infection, and the suspicion that occult *Strep. equi* infection is present and the source of antigen associated with the disease; affected horses are usually treated with **penicillin** (procaine penicillin, 20 000 IU/kg, IM every 12 hours, or potassium penicillin, 20000 IU/kg, IV every 6 hours) until the clinical signs resolve. Treatment with antibiotics might need to be continued for as long as 20 days.<sup>4</sup>

**Supportive care** includes bandaging of swollen limbs, care of wounds, hydrotherapy, and intravenous fluid administration. Swelling of the head and pharynx may necessitate placement of a nasogastric feeding tube to permit enteral feeding of dysphagic horses. Respiratory distress can develop very rapidly and emergency tracheotomy may be required to relieve respiratory distress and prevent asphyxiation.

#### CONTROL

There are no specific preventive measures. However, control and prevention of upper respiratory tract infections in horses should lead to a reduction in the incidence of purpura hemorrhagica. Careful consideration should be given to the use of vaccines containing streptococcal M protein or avirulent *Strep. equi* in horses at low risk of developing strangles. Although the relationship between M protein containing vaccines and purpura hemorrhagica is not definitive, circumstantial evidence and the opinion of authorities in the field support such an association. Measurement of serum antibodies to M protein might be useful in determining the need for vaccination of horses in endemic areas or at high risk.<sup>6</sup> Horses with antibody titers >1:3200 should not be vaccinated.<sup>6</sup>

## EQUINE SEASONAL ALLERGIC DERMATITIS (QUEENSLAND ITCH, SWEET ITCH)

This is an intensely pruritic dermatitis of horses caused by hypersensitivity to insect bites.

### ETIOLOGY

The disease is caused by type I (immediate) hypersensitivity to salivary antigens introduced into the skin by the bites of sandflies and other insects. There may be a lesser role for type IV (cell-mediated) hypersensitivity in the disease. *Culicoides brevitarsus* is the cause in Australia,<sup>1</sup> *C. pulicaris* in the United Kingdom and Europe,<sup>2</sup> and *C. obsoletus* in Canada.<sup>3</sup> *Stomoxys calcitrans*, the stable fly, and *Simulium* spp. cause the disease. The distribution of the skin lesions is related to the feeding habits of the inciting insect. For instance, *C. pulicaris* has a predilection for landing at the mane and tail, and this is where the lesion is most commonly seen.

### EPIDEMIOLOGY

The prevalence of the disease varies depending on environmental factors, and possibly characteristics of the local horse population. Up to 60% of horses are reported affected in areas of Queensland, Australia, 22% in Israel, and 18% of Icelandic horses in Norway.<sup>4</sup> The prevalence in Switzerland is very low in regions above 1000 m and 1.6% in lower areas.<sup>5</sup>

The disease is quite common worldwide in areas where **hot and humid summer weather** favors the causative insects: Sweden, the United Kingdom, Japan, Israel, Hong Kong, North America, Australia, the Philippines, India, and France. Most cases occur during **summer** and lesions disappear during cooler weather. Lesions disappear when the horses have been stabled in insect-proof barns for several weeks or are moved outside the geographical range of the inciting insect.

The disease is characteristically sporadic and affects only a few of a group of horses. However, because the predilection to the disease is likely inherited, there may be multiple cases among related animals on a farm.<sup>5,6</sup> The prevalence of the disease increases with age; 3.4% of Icelandic horses 1–7 years of age compared to 32% of horses older than 14 years were affected.<sup>4</sup>

### PATHOGENESIS

Reaginic antibodies (IgE) produced in response to exposure to proteins in insect

saliva bind to mast cells in the skin and, when exposed to the antigen, are associated with degranulation of the mast cell. Horses with sweet itch have IgE antibodies that react with constituents of the salivary gland of *Culicoides* sp., whereas horses that do not have the disease have IgG, but not IgE, antibodies against *Culicoides* salivary gland antigens.<sup>6</sup> Horses that have not been exposed to *Culicoides* sp. do not have either antibody to the insect salivary gland antigen.<sup>6</sup> **Degranulating mast cells** and intradermal or subcutaneous lymphocytes release various vasoactive substances and cytokines that cause inflammation and accumulation of eosinophils in the skin of affected areas and eosinophilia.<sup>7</sup> The distribution of the lesions on patients reflects the insects' preferred feeding sites. Ponies with seasonal allergic dermatitis have greater numbers of circulating CD5+ and CD4+ T-lymphocytes than do normal animals.<sup>8</sup> Increased numbers of CD3+ T-lymphocytes, most of which are CD4+, and eosinophils are present in the skin of affected ponies after injection of *Culicoides* antigen.<sup>8</sup> Furthermore, eotaxin and monocyte chemoattractant protein (MCP) 1, but not MCP-2 or MCP-4, mRNA expression is upregulated in skin biopsies of sweet itch lesions, demonstrating a mechanism for accumulation of eosinophils and T-2 lymphocytes in the lesions.<sup>9</sup>

### CLINICAL FINDINGS

**Lesions** are usually confined to the base of the tail, rump, along the back, withers, crest, poll, ears and, less commonly, ventral midline. In severe cases the lesions may extend down the sides of the body and neck and onto the face and legs.

**Pruritis** is intense, especially at night, and the horse scratches against any fixed object for hours at a time. In the early stages slight, discrete papules, with the hair standing erect, are observed. Constant scratching may cause self mutilation, severe inflammatory lesions, and loss of hair. Scaliness and loss of hair on the ears and tail-base may be the only lesions in mildly affected horses.

### CLINICAL PATHOLOGY

Affected animals have **eosinophilia** and thrombocytosis.

**Diagnosis** is facilitated by skin biopsy, fungal culture, and parasitological examination of skin scrapings, and intradermal sensitivity testing. **Skin biopsy** of early lesions, before trauma masks the true picture, reveals edema, capillary engorgement, and eosinophilic and mononuclear perivascular infiltration. Fungal culture and parasitological examination of **skin scrapings** are useful only in that they rule out dermatophycosis, onchocerciasis, and strongyloidosis. **Intradermal skin testing**

demonstrates immediate and delayed sensitivity reactions to extracts of *Culicoides* and *Stomoxys* spp.<sup>1</sup>

### DIFFERENTIAL DIAGNOSIS

Infection with larvae of *Onchocerca* sp. or *Strongyloides* sp., or *Dermatophilus congolensis* can produce similar lesions. Alopecia of the tail head may be caused by *Oxyuris equi*.

### TREATMENT

The principles of treatment are removal of the inciting cause and suppression of the hypersensitivity reaction.

**Removal of the inciting cause** is achieved by preventing horses from being exposed to the inciting insects. This can be achieved by relocating the horse to a geographical region where the insects do not occur, stabling of the horse in an insect-proof stable during the periods of the day (early evening) when the insects are most active, or applying agents that kill the insect or otherwise prevent them from alighting on and biting the horse.

**Suppression of the immediate hypersensitivity reaction** or its sequelae can be achieved by administration of corticosteroids (prednisolone, 1 mg/kg every 24 hours initially then reducing to as low a maintenance dose as possible). Theoretically, hyposensitization may be effective, but the only controlled clinical trial to date did not demonstrate a beneficial effect, although the placebo effect on the owners was impressive.<sup>10</sup>

### CONTROL

Prevention of the disease necessitates protection against sandfly bites by stabling in insect-proof quarters. Continuous spraying of the horses with insecticides or repellents may be of some value. A 4% permethrin pour-on gives effective protection. Most horses need only one application a week; others need an application every second day.<sup>11</sup>

## SEASONAL ALLERGIC DERMATITIS

A disease similar to sweet itch of horses occurs in sheep in the UK.<sup>1</sup> The lesions

are similar to those in horses and are located principally on the teats, udder, and ventral midline, but also on the tips of the ears, around the eyes, and on the nose and the lips. Because of their appearance only in summer, and in senior ewes, and at a time when midges are plentiful enough to cause signs of insect worry, a cutaneous sensitivity to *Culicoides* spp., especially *C. obsoletus*, is suspected. Histologically the lesions represent the changes characteristic of immediate hypersensitivity. Cutaneous sensitivity to ground up *Culicoides* spp. was demonstrated. A very similar disease occurs in cattle in Japan. It is thought to be due to an allergy to the bite of an external parasite.<sup>2</sup>

### RECURRENT AIRWAY OBSTRUCTION (HEAVES)

#### Synopsis

**Etiology** Inhalation of barn and feed dust containing inciting agents which can include particles of molds, endotoxin, mites, plant debris, and inorganic material.

**Epidemiology** Predominantly a disease of horses stabled in poorly ventilated barns and fed poor quality hay containing molds. Occurs worldwide but more commonly in the northern hemisphere. No breed or sex predilection.

**Clinical signs** Chronic cough, mucopurulent nasal discharge, poor athletic performance, increased respiratory rate, increased expiratory effort, wheezes on thoracic auscultation, and abundant mucopurulent material in the trachea on endoscopic examination.

**Clinical pathology** Neutrophilia in tracheal aspirate and bronchoalveolar lavage fluid.

**Lesions** Bronchiolitis with mononuclear cell infiltration, epithelial, and goblet cell hyperplasia, neutrophil accumulation in airway lumens, and alveolar hyperinflation.

**Diagnostic confirmation** Clinical signs, examination of bronchoalveolar lavage fluid, and the response to treatment.

**Treatment** Remove the inciting cause by providing a dust-free environment, and administer corticosteroids. Bronchodilators are useful for treatment of acute bronchoconstriction.

**Control** Prevent exposure to inciting cause. Insure optimal air quality in stables or maintain horses at pasture.

Heaves is a recurrent or chronic disease of stabled adult horses (previously known as chronic obstructive pulmonary disease) characterized by neutrophilic airway inflammation and airway obstruction manifest clinically by the presence of

coughing, excess mucus accumulation in airways, tachypnea and increased respiratory effort, and exercise intolerance. It should be differentiated from the usually transient inflammatory airway disease of young adult horses in which there is no significant impairment of pulmonary function. The disease is included in this section because it is classically considered to have an allergic component, although this assumption is increasingly questioned.

#### ETIOLOGY

Heaves, previously referred to as chronic obstructive pulmonary disease, is caused by inhalation by susceptible horses of dust particles found in barns, bedding, and feed materials such as dusty hay. The inhaled particles include endotoxin, mites, plant debris, inorganic materials, and conidia and fragments of molds. *Faenia rectivirgula* (formerly known as *Micropolyspora faeni*), *Aspergillus fumigatus*, and *Thermoactinomyces vulgaris* are molds commonly associated with respiratory disease in susceptible horses, as evidenced by experimental studies involving inhalation of mold or mold fragments by horses.<sup>1</sup> Molds contain a number of inflammatory substances including various allergens, glucans, mycotoxins, and proteases and it is not clear which of these agents are the inciting cause of heaves.<sup>2</sup> Furthermore, dust containing mold also contains endotoxin. Endotoxin contamination of molds contributes to the airway response to inhalation of preparations of molds used in experimental studies<sup>3</sup> and inhalation of endotoxin alone produces airway inflammation and impaired respiratory function in horses in a dose-dependent manner, with heaves-susceptible horses having an exaggerated response at lower doses.<sup>4</sup> However, the response to endotoxin is less than that of susceptible horses exposed to hay dust containing endotoxin indicating that endotoxin alone is not sufficient to cause the clinical signs of heaves. Other compounds in hay dust are integral to the development of heaves.<sup>5</sup>

It is emphasized that there is not one causative agent acting alone but rather a range of agents that, when inhaled in sufficient concentration by susceptible horses, induce airway disease. It is likely that heaves is associated with the potentiating interactions among several agents present in barn or hay dust and is not simply a response to one agent.<sup>3,6</sup> The mechanisms underlying development of airway inflammation and respiratory dysfunction are provided under 'Pathogenesis'. Viral infections and 3-methylindole intoxication are not considered important causes of heaves.<sup>7</sup>

#### EPIDEMIOLOGY

##### Occurrence

Although heaves is one of the more common diseases of horses, and is a major cause of loss of performance and wastage in European horses,<sup>8</sup> there are few reports of its epidemiological characteristics. The disease is common in Europe and North America but is rare in Australia. In Germany, 83% of horses believed to be healthy at an auction were found to have clinical evidence of chronic pulmonary disease.<sup>8</sup> Inflammatory airway disease is very common in horses, with 96% of racehorses in Hong Kong examined at necropsy and 12% of horses examined in an abattoir in the northern U.S. having histological evidence of bronchitis.<sup>9,10</sup> Twenty-seven per cent of healthy racehorses in training had an increased proportion (>20%) of neutrophils in tracheal aspirate, indicating inflammatory airway disease.<sup>11</sup> However, the airway inflammation common in young athletic horses is not generally considered to be heaves, or a prodrome of heaves. The prevalence of heaves is not well documented.

The **case-fatality rate** for moderately to severely affected horses is approximately 20% over a 2-4-year period.<sup>12</sup> Most mildly to moderately affected horses respond well to treatment and continue to perform at a satisfactory level.<sup>12</sup>

##### Risk factors

###### Animal risk factors

The disease occurs in adult horses and ponies, and animals >7 years of age are 6 to 7 times more likely to be examined because of the disease than are horses <4 years of age.<sup>13</sup> There is no apparent breed or sex predisposition with the exception that Thoroughbreds are 3 times more likely to be examined for the disease than are ponies,<sup>13</sup> although this could represent a sampling bias in that owners of Thoroughbreds might be more likely to seek veterinary attention than owners of ponies. The finding of increased likelihood of Thoroughbred horses having the disease is not consistent among studies. Horses are approximately 2 times more likely to be examined by a veterinarian because of the disease in winter or spring compared to summer, suggesting a seasonality to the occurrence of the disease<sup>13</sup> perhaps as a result of increased stabling during winter.

There are horses that develop the disease and other horses, maintained in an identical situation, that do not. Development of disease is dependent upon the horse being susceptible to the inflammatory effect of inhaled dust but the reasons for this individual susceptibility are poorly understood. A familial predisposition has been suggested based on the observation that

Lipizaners and German and Swiss Warmbloods are 3.2 times more likely to have heaves if one parent was affected and 4.6 times as likely if both parents had heaves.<sup>14</sup> There is no association between major histocompatibility markers (equine leucocyte antigens) and occurrence of heaves.<sup>14</sup> However, genetic and environmental factors are often closely associated, in that horses of similar genetic background are often housed in similar situations, making elucidation of inherited susceptibility to heaves difficult.

Exposure to inciting agents is associated with a variety of environmental factors, including potentially outdoor concentrations of aeroallergens and climatic factors,<sup>15</sup> but most importantly housing and feeding practices.

#### Environmental risk factors

There is a clear association between housing, feeding of hay, and development of the disease.<sup>16,17</sup> Typically, susceptible horses are clinically normal when at pasture and develop signs of disease within hours to days of being housed in stables and fed dusty hay. Moving affected horses to pasture, or improving air quality by increasing ventilation and feeding processed feedstuffs, results in resolution of the disease.<sup>16</sup>

Development of disease is related to inhalation of **respirable particles** that gain access to the lower respiratory tract. Respirable particles are less than 5 µm diameter, the principal source of these particles in stalls is hay, and the majority of particles are fungal spores.<sup>18</sup> The concentration of particles in air of the stable is determined by the rate of release of particles from hay, which is dependent in large part on the quality of the hay, concentration of fungal spores in the hay, and the rate of clearance of dust from the stable, a function of the ventilation rate.<sup>19,20</sup> Concentrations of respirable dust particles in the breathing zone of stabled horses can be as high as 20 mg/m<sup>3</sup>.<sup>3,21</sup> The severity of increases in neutrophil count and proportion and decreases in pulmonary function in experimental models of heaves are related in a dose-dependent fashion to the amount of dust inhaled.<sup>4</sup> The presence of dust particles, and not the soluble products in hay dust, is responsible for most of the airway neutrophilia induced by inhalation of hay dust.<sup>5</sup>

**Hay** is the usual original source of spores in stable air. However, **decomposing wood shavings** are also a source of spores of fungi that multiply during degradation of plant-based materials, and housing horses in poorly ventilated stalls deeply bedded with wood shavings may be detrimental to their respiratory health.<sup>22</sup> Spores from hay enter the bedding either

directly or after dispersal through the air and multiply in the bedding if it is not removed regularly. **Diced paper** and **wood shavings**, when fresh, usually contain very few spores. Barley and wheat straw are usually free of any small spores such as *A. fumigatus* or *M. faeni*.<sup>19</sup> Bedding horses on fresh wood shavings, and feeding a nutritionally complete pelleted ration, results in a respirable dust burden 3% of that of horses fed hay and bedded with straw.<sup>23</sup> Dust burdens measured in the air of the stall underestimate the respirable particle challenge of horses because of the high concentration of particles in hay and bedding, areas from which the horse inhales while eating.<sup>23</sup>

Respiratory health of horses is related to **stable design and ventilation**, with horses in poorly ventilated barns having more respiratory disease than horses in well-ventilated barns.<sup>22</sup> See 'Control' for recommendations regarding stable design.

#### PATHOGENESIS

Susceptible horses, when exposed to adequate concentrations of respirable dust in the breathing zone, develop airway inflammation, excess mucus accumulation, and respiratory dysfunction within hours to days of exposure. The putative inciting agents include fungal spores and debris, endotoxin, and particulate matter; however, the exact role for each of these agents is unclear, partly because of the difficulty in obtaining uncontaminated material. For instance, fungal material is commonly contaminated with endotoxin which has a synergistic interaction with hay dust in inducing airway neutrophilia in susceptible horses.<sup>3</sup>

The mechanisms underlying these responses to inhalation of dust are not well defined but can be considered in the contexts of immune and inflammatory responses, mucus secretion, and pulmonary dysfunction.

Inflammatory and immune responses  
Inflammation is associated with excessive mucus production, airway swelling, and abnormal lung function.<sup>6,24</sup> The inflammatory response in horses with heaves is neutrophilic, with lesser numbers of mast cells and rarely eosinophils. The mechanisms underlying this inflammatory response have not been fully elucidated, although it involves activation of nuclear factor kappaB and there is support for an acquired immune-mediated process.<sup>25-28</sup>

The presence of allergen-specific IgE antibodies in bronchoalveolar lavage fluid is supportive of a hypersensitivity reaction, although others have proposed type 3 and type 4 immune reactions as the basis of the disease.<sup>25</sup> One proposed explanation is that heaves-susceptible horses exhibit a Th2-like immune

response to inhalation of hay or barn dust characterized by increased expression of interleukins 4 and 5 and decreased expression of interferon-γ in cells obtained by bronchoalveolar lavage.<sup>29,30</sup> Others have not detected a pure Th2-like cytokine profile finding instead a mixed inflammatory response including increases in expression (mRNA) in cells obtained from bronchoalveolar lavage fluid of affected horses of interferon-γ, tumor necrosis factor-α, interleukins 1β and 4, and interleukins 8 and 17 (potent attractors of neutrophils) but not interleukins 2, 5, and 10.<sup>31-35</sup> However, all the studies cited above were performed on crude preparations of cells obtained by bronchoalveolar lavage and the results could have been influenced by the varying proportions of types of cells in these preparations.<sup>32</sup> A study examining just CD4 and CD8 lymphocytes in blood and bronchoalveolar lavage fluid of heaves-affected horses demonstrated a general down regulation in expression of interferon-γ, and interleukins 4, 5, and 13 and no evidence of a cytokine profile consistent with either sole or predominate Th1 or Th2-like responses.<sup>26</sup> The magnitude of the inflammatory response varies depending on the challenge (i.e. nature of the inhaled material) with responses to endotoxin characteristically being less than that of hay dust.<sup>35a</sup> Regardless of the underlying mechanism, exposure to inciting agents results in airway inflammation and interference with normal respiratory function.

Following inhalation of inciting agents there is recruitment of neutrophils, but not eosinophils or platelets, into the lungs in most horses that develop changes in lung function.<sup>36,37</sup> Histologically there is peribronchiolar accumulation of lymphocytes and luminal accumulations of neutrophils in affected horses. The entry of neutrophils into the airways is mediated at least in part by IL-8 and IL-17.<sup>31,33</sup> The neutrophils of horses during episodes of heaves, but not when the horses are asymptomatic, have increased adherence *in vitro* to protein coated plastic suggesting a mechanism for the increased migration of neutrophils into airways of affected horses.<sup>38</sup> Inhibition of neutrophil phosphodiesterase-4 activity does not alleviate clinical signs of heaves or decrease neutrophil numbers in bronchoalveolar lavage fluid in affected horses suggesting that neutrophils are not primarily involved in the genesis of airway obstruction.<sup>39,40</sup> The extent to which neutrophils in the airways are activated has not been determined and their role in the development of respiratory dysfunction is unclear given that glucocorticoid administration attenuates the

respiratory dysfunction but not airway neutrophilia in horses with heaves (see under 'Treatment').<sup>41</sup>

Airway inflammation is associated with increases in concentration of inflammatory mediators including leukotriene B<sub>4</sub>, prostanoids including thromboxane, and proteases.<sup>42</sup> Activity of matrix metalloproteinase-9 is higher in horses with heaves than in unaffected horses and is induced in a dose-dependent manner by inhalation of inciting substances including hay dust and endotoxin.<sup>42-45</sup> MMP-9 is likely important in the inflammatory process associated with heaves through excessive gelatinolytic proteolysis that can contribute to lung injury, and through a role in lung remodelling.<sup>43</sup> Inflammation is also associated with increased oxidative stress in lungs of horses with heaves as indicated by elevated concentrations of epi-PGF<sub>2a</sub> and redox ratio of glutathione in pulmonary lavage fluid.<sup>24,46</sup>

#### Mucus

Accumulation of excessive quantities of mucus in the large airways is characteristic of horses affected by heaves and can contribute to nonbronchospastic airway obstruction.<sup>6,47</sup> Accumulation of mucus is attributable to decreased clearance and increased production.<sup>48,49</sup> The mucus in horses with heaves differs in both composition and viscoelasticity from that of clinically normal horses<sup>63,65</sup> and this might contribute to its decreased clearance. The viscosity of mucus can increase threefold in heaves susceptible horses stabled and exposed to hay dust.<sup>48</sup> Increased production of mucus is associated with up-regulation of the equine MUC5AC gene, which is responsible for production of mucin, in particular in small airways of horses with heaves.<sup>49</sup>

#### Airway function and gas exchange

Inhalation of inciting agents causes changes in lung function characterized by an increase in pulmonary resistance, lower dynamic compliance, altered distribution of ventilation, impaired gas exchange, increased functional residual capacity, and an altered breathing strategy.<sup>7</sup> **Airway obstruction** is a result of bronchospasm, inflammatory thickening of airways, and accumulation of mucus and cells in the airways. Bronchospasm is largely relieved by administration of bronchodilator drugs or removal of the inciting cause, but residual effects on lung function remain and are attributable to inflammation and fibrosis and bronchoconstriction of small airways.<sup>7</sup> **Bronchoconstriction** in both normal and affected horses is caused by parasympathetic activity and release of acetylcholine that reacts with muscarinic receptors on air-

way smooth muscle. However, the response is exaggerated in horses with heaves. Stimulation of airway sensory receptors results in an exaggerated bronchoconstrictive response, possibly because of the action of inflammatory mediators and/or by-products. The exaggerated bronchoconstrictive response is not specific for allergens, and any substance that activates airway sensory receptors may incite bronchoconstriction once the sensitivity of the receptors is enhanced by inhalation of the inciting allergens. Exaggerated airway responsiveness to inhaled irritants persists for up to 3 days after a single exposure to the inciting agent and is likely important in the development of clinical signs of the disease.<sup>50</sup> Bronchoconstriction increases work of breathing but hypoventilation probably contributes little to the hypoxemia of affected horses, given that PaCO<sub>2</sub> is rarely increased.<sup>51</sup>

**Hypoxemia**, which can be severe (<60 mmHg, 8 kPa), is due to ventilation-perfusion mismatches and increased dead space ventilation.<sup>51</sup> The increased minute ventilation of affected horses, a result of maintained tidal volume and increased respiratory rate, mainly supplies dead space and regions with high V/Q ratios.<sup>51</sup> Pulmonary hypertension in affected horses is probably due to hypoxia and perhaps inflammatory mediators with vasoconstrictor activity.<sup>7,51</sup>

The **elevated functional residual capacity** and characteristic breathing strategy of affected horses is due to airway obstruction. Airway obstruction causes trapping of air in alveoli and a higher end-inspiratory volume. The high end-inspiratory volume maximizes airway diameter and facilitates the high expiratory and inspiratory flow rates necessary for affected horses to maintain a normal tidal volume while increasing their respiratory rate.

**Bronchiectasis** (irreversible dilation and deformation of bronchi or bronchioles) occurs in some horses affected with heaves for a prolonged duration.<sup>52</sup> Neutrophilic inflammation is essential for the development of bronchiectasis.

#### CLINICAL FINDINGS

The degree to which horses are affected varies considerably. Minimally affected horses have airway inflammation evident on endoscopic or cytological examination of the airways, but few other signs on physical examination, whereas severely affected horses have very obvious clinical signs.

The usual **history** is that of chronic cough in a stabled horse.<sup>12</sup> Typically, the disease is precipitated by exposure to hay and stabling, and disease remission occurs in most horses when pastured and

removed from hay. There may be a history of reduced exercise tolerance.

Affected horses are usually bright and alert and have a normal appetite and rectal temperature. Severely affected horses appear anxious and have a greatly increased respiratory effort.

**Coughing** is common in horses with heaves, although it is neither particularly specific nor sensitive as an indicator of the disease. Coughing may consist of a single cough every few seconds to minutes or there may be a paroxysm of coughing. The cough can also be elicited by digital massage of the larynx and proximal part of the trachea because horses with airway inflammation have increased sensitivity of the cough reflex. Stimulation of the larynx or proximal trachea by digital massage does not elicit coughing in normal horses. The cough becomes more pronounced and wheezing with exercise. It also occurs more frequently when the horse is exposed to cold air, physical activity, excitement, and when placed in a dusty environment, or if dusty feed is offered. The amount of coughing, which must be counted over at least 15 minutes and preferably 1 hour for accurate determination of its severity, correlates closely with the amount of mucus in airways, maximal change in pleural pressure (a measure of bronchoconstriction), and neutrophil count in bronchoalveolar lavage fluid.<sup>41</sup> Coughing is more frequent in horses with heaves, and affected horses often have paroxysmal coughing especially after barn cleaning and feeding.

An intermittent, bilateral mucopurulent to serous **nasal discharge** is a common sign in affected horses.

The resting **respiratory rate** is increased from a normal of 12/min up to 24-36/min. There is a pronounced effort during expiration and markedly affected horses have an obvious abdominal component to respiration. Normal horses have a biphasic pattern of airflow during inspiration and expiration while affected horses lack the second phase of respiration.<sup>53</sup> Long-standing cases develop a 'heave-line' in the flank due to hypertrophy of the abdominal oblique musculature. It is evident as a trough or furrow along the costal arch. In advanced cases the nostrils may be visibly dilated during inspiration and the force of the expiratory effort causes the anus to protrude.

Heart rate is commonly within the normal range or only slightly increased. In horses with heaves, the heart rate is significantly higher during exercise than in healthy horses.

**Abnormal lung sounds** are one of the most frequent abnormalities detected on clinical examination and the sensitivity of this finding can be increased from 70%

to almost 90% by auscultating the thorax while the horse breathes for 60 to 120 seconds with an airtight plastic bag over its nostrils.<sup>12</sup> The bag should be large enough to enable the horse to breathe unhindered (10–15 L) and should not leak. Accumulation of carbon dioxide in the bag increases the horse's respiratory rate and tidal volume and accentuates lung sounds. Auscultation of the lungs in the early stages of the disease may reveal only a slight increase in the amplitude of normal breath sounds. Abnormal lung sounds become audible as the disease progresses. **Wheezing and crackling sounds** occur at the end of inspiration and the end of expiration. These abnormal sounds are audible over most of the lung but are usually easiest to detect over the upper one-half of both lung fields. **Auscultation of the trachea** usually reveals moist sounds characteristic of fluid in the trachea. Some affected horses have quieter than expected lung sounds.

Percussion of the thorax may reveal an increase in the area of resonance by as much as one to two intercostal spaces caudally. However, the area of resonance delineated by percussion is too labile and ill-defined to be of diagnostic value.

**Endoscopic examination** of the upper airways, trachea, and bronchi reveals an abundance of mucopurulent material in the trachea which, in severe cases, is also present in the nasopharynx. The amount of mucus can be graded on a 0–5 scale<sup>41</sup>:

- Grade 0 – no visible mucus
- Grade 1 – small blobs of mucus that are not confluent
- Grade 2 – multiple blobs of mucus some of which are confluent
- Grade 3 – mucus confluent in a stream in the ventral aspect of the trachea or multiple large blobs around the circumference of the lumen
- Grade 4 – large pool of mucus in the ventral aspect of the airway
- Grade 5 – Profuse amounts of mucus occupying more than 25% of the tracheal lumen.

Observation of tracheal mucus of grade 4 or 5 has a high specificity (92%) but low sensitivity (52%) for detection of heaves.<sup>47</sup>

**Radiographic examination** of the thorax usually reveals evidence of bronchial disease with some evidence of interstitial disease. Radiography is more useful in ruling out other diseases, such as granulomatous or interstitial pneumonia, than in confirming heaves.

Sophisticated techniques for measuring pulmonary function, such as determination of tidal flow–volume loops, nitrogen wash-out or forced expiratory flow–volume loops, may identify mildly or subclinically affected

animals but have limited day-to-day clinical utility.<sup>53–55</sup>

Measurement of **pleural pressure changes** by insertion of an esophageal balloon is relatively simple and may be useful in monitoring response to treatment. Affected horses have pleural pressure changes during respiration greater than 6 cm H<sub>2</sub>O.<sup>54</sup> Administration of atropine (0.02 mg/kg, IM or IV), isoproterenol (isoprenaline), or a  $\beta_2$ -adrenergic agonist such as terbutaline (0.04 mg/kg, PO) reduces the maximal change in pleural pressure of horses with heaves.

The **course of the disease** is dependent on the removal or continual presence of the precipitating cause. If the cause is removed in the early stages, complete recovery can occur. In the continual presence of the precipitating cause relapses occur commonly or the disease becomes progressive and affected horses become severely incapacitated. **Bronchiectasis**, evident on radiographic examination of the thorax, develops in horses with heaves of prolonged duration.<sup>52</sup> With conscientious management and adequate housing, breeding animals and hunters or show-jumpers with heaves can remain useful for many years.<sup>56</sup>

#### CLINICAL PATHOLOGY AND SPECIAL EXAMINATIONS

There are no significant changes in the hemogram or serum biochemistry of affected horses. The PaO<sub>2</sub> is below normal in moderately to severely affected horses and the PaCO<sub>2</sub> is usually normal although it may be increased in severely affected horses. Blood oxygen tension measurements should be corrected for the temperature of the animal and the altitude. At approximately sea level, PaO<sub>2</sub> values of normal horses are usually greater than 90 mmHg (12 kPa), whereas affected horses have PaO<sub>2</sub> less than 82 mmHg (10.9 kPa). With increases in altitude the values in both normal and affected horses decrease.<sup>54</sup> The normal hypoxemia that occurs in horses during intense exercise is exacerbated by heaves.

**Bronchoalveolar lavage fluid** from affected horses during symptomatic episodes has a relative neutrophil count greater than 5 to 10%, and usually over 50%, of the absolute nucleated cell count.<sup>12,57,58</sup> It is recommended that horses not be considered to have airway inflammation unless >15% of cells in bronchoalveolar lavage fluid are neutrophils. During periods of remission, the bronchoalveolar lavage fluid of previously affected horses is not different from that of normal horses. Absolute nucleated cell counts in bronchoalveolar lavage fluid of affected horses are reported<sup>12,57,58</sup> but the values depend on the collection technique used.<sup>59</sup>

The relative proportions of macrophages and lymphocytes in bronchoalveolar lavage fluid of affected horses are lower than those of normal horses. Eosinophil numbers in bronchoalveolar or tracheal aspirate fluid of affected horses may be mildly elevated (up to 10%), but are usually low (<3–5%). Higher values should raise the index of suspicion for *Dictyocaulus armfieldi* or *Parascaris equorum* infestation. Aspirates of **tracheal fluid** reveal a profound neutrophilia (>90%).<sup>57</sup>

Measurement or identification of **precipitins** in serum of horses is not useful in identifying horses with heaves.<sup>60</sup>

**Intradermal testing** using putative allergens has been investigated as a means of identifying horses with heaves or of identifying antigens with which to hyposensitize affected horses with variable or undetermined efficacy.<sup>1,61,62</sup> Retrospective examination of records of horses with a history of heaves suggests that they are more likely to react, and react to a larger number, of intra-dermally injected allergens than horses without a history of heaves.<sup>63</sup> However, reactions to individual allergens cannot be used to determine hypersensitivity to particular allergens, although it is suggested that overall patterns of reactivity, with a history of exposure of the horse to these allergens, might be useful in guiding management of affected horses.<sup>63</sup> Contrary to these results, a prospective study demonstrated that horses with heaves did not have a greater rate of reaction to intradermal skin tests than did horses not affected by heaves.<sup>64</sup> Intradermal testing did not distinguish clinically relevant reactions from those that were not clinically relevant.<sup>64</sup> Horses with heaves have greater sensitivity to intradermal injection of histamine, which is commonly used as a positive control, than horses without heaves.<sup>65</sup> Overall, intradermal skin testing is neither useful in detecting horses with heaves nor in determining hypersensitivity to particular allergens in individual horses. Results of such testing might be useful in management of horses, but this has not been demonstrated. The usefulness of intradermal skin testing and subsequent administration of preparations of antigens selected on the basis of intradermal testing, in an effort to hyposensitize horses with heaves, has not been determined. The apparent lack of efficacy of intradermal testing might be because the extent of reactivity to intradermal injection of mold preparations does not correlate with the severity of pulmonary dysfunction after inhalation of the same preparation in horses with heaves.<sup>1</sup>

**Lung biopsy** demonstrates peribronchiolar lymphoplasmacytic inflammation, goblet cell metaplasia, alveolar

fibrosis, and bronchial lumen exudate and neutrophils.<sup>12</sup> The severity of bronchiolar neutrophil and mast cell infiltration correlates well with the severity of the clinical signs.<sup>12</sup>

### NECROPSY FINDINGS

The major findings are restricted to the lungs, which are pale, voluminous, and do not collapse when the chest cavity is opened. The tissue damage is primarily centered on airways which are less than 2 mm in diameter. Microscopically, a variable degree of alveolar emphysema is accompanied by a chronic bronchiolitis featuring diffuse epithelial hyperplasia, goblet cell metaplasia, peribronchiolar fibrosis, and cellular infiltration by lymphocytes, plasma cells, mast cells, and sometimes eosinophils. Plugs of mucus with entrapped neutrophils often occlude bronchiolar lumina.

Samples for postmortem confirmation of diagnosis

Formalin-fixed lung for light microscopic examination.

### DIAGNOSTIC CONFIRMATION

Confirmation of the disease is based on the presence of a history and clinical signs consistent with the disease, in particular the response to stabling and pasturing, and demonstration of reversible airway obstruction. Objective confirmation can be achieved by measuring the response of maximal changes in pleural pressure in response to bronchodilator drug (atropine or glycopyrolate) administration.

### DIFFERENTIAL DIAGNOSIS

Horses with respiratory distress may have:

- Interstitial pneumonia
- Heart failure
- Bacterial pneumonia
- Pleuritis
- Pulmonary or mediastinal neoplasia including leiomyosarcoma<sup>66</sup>
- Parasitic pneumonia (*D. arnfieldi*).

Nasal discharge may be caused by:

- Guttural pouch diseases including empyema
- Dysphagia of any cause
- Esophageal obstruction
- Sinusitis
- Pneumonia.

### TREATMENT

The **principles of treatment** are:

- Removal of the inciting cause
- Reduction of airway inflammation
- Bronchodilation
- Correction of hypoxemia.<sup>55</sup>

Heaves is an inflammatory disease caused by inhalation exposure to inciting agents. Bronchoconstriction is secondary

to inflammation. Control of the disease is based upon preventing inhalation of inciting agents and suppression of inflammation by administration of corticosteroids. Relief of bronchoconstriction should be necessary only during acute exacerbations of the disease, and administration of bronchodilatory drugs for more than several days is not optimal treatment in most horses. Drugs used in the treatment of heaves are summarized in Table 34.2.

*It is essential that the horse is not exposed to the inciting agents and irritant substances that could provoke or worsen the disease.* Even relatively brief exposure of susceptible horses to the inciting agents, such as can occur if a horse is brought into a poorly ventilated barn to be fed, can result in airway hypersensitivity and the development or maintenance of clinical signs. Affected horses should be moved to a clean environment, **ideally pasture**, in which the concentration of airborne allergens is reduced to an absolute minimum. If the horse cannot be kept at pasture, then it should be housed in a well ventilated barn (see 'Control' for details), bedded with clean wood shavings or shredded paper, and fed a complete pelleted ration. If affected horses are fed hay, it should be thoroughly wetted to minimize the release of spores. Remission of clinical signs can be expected in 4–21 days if the environmental changes are adequate.<sup>67</sup> This may be all that is necessary to control the disease in many horses.

Antiinflammatory drugs

The disease is essentially one of inflammation of the airways and therefore one of the mainstays of treatment is administration of anti-inflammatory drugs. Nonsteroidal anti-inflammatory drugs such as phenylbutazone and flunixin meglumine are not effective. Corticosteroids including dexamethasone, prednisolone, triamcinolone, and betamethasone are effective in controlling the disease. **Dexamethasone** (0.04–0.1 mg/kg, intravenously, intramuscularly or orally every 24–48 hours) can be given to control the acute signs of the disease, and then the dose reduced and eventually discontinued as environmental alterations have their effect. Similarly, **prednisolone** (1–2 mg/kg, orally once daily), but not prednisone<sup>68,69</sup> can be given initially, then the dose reduced by approximately one half every 5–10 days as the disease is controlled. Often prednisolone or dexamethasone sodium phosphate is effective when administered every second day when the disease has been controlled. **Dexamethasone-21-isonicotinate** (0.04 mg/kg, intramuscularly) is effective

when administered every 3 days, but not when administered only once.<sup>69,70</sup> **Isoflupredone** (0.03 mg/kg, intramuscularly once daily) is as effective as dexamethasone in alcohol in control of exacerbations of heaves, although it does cause hypokalemia.<sup>71</sup> **Triamcinolone** (0.09 mg/kg, intramuscularly) administered once provides long-term (weeks) relief of signs in some horses.<sup>72</sup>

**Inhaled corticosteroids**, such as beta-methasone, beclomethasone, or fluticasone, are useful in controlling the disease.<sup>73,74</sup> Both inhaled and parenterally administered corticosteroids suppress adrenal function of horses<sup>75</sup> but 500 µg of beclomethasone propionate inhaled twice daily effectively alleviated signs of heaves and causes less adrenal suppression than doses of 1000 µg or 1500 µg.<sup>76</sup> It is important to reiterate that the use of glucocorticoids should only be as an adjunct to control of the horse's environment and reduction in the inhaled particle burden.

**Clebuterol** decreases the production of inflammatory cytokines by cells obtained from bronchoalveolar lavage fluid of horses with heaves, suggesting that clenbuterol can have anti-inflammatory effects in such horses.<sup>35</sup> The clinical applicability of this finding remains to be determined.

In summary, a number of different corticosteroid preparations are useful in the control of heaves. Drugs administered by inhalation appear to have a reduced potential for adverse effects including adrenal suppression, but are more difficult to administer and require more frequent administration than drugs administered orally, intravenously, or intramuscularly. Improvements in respiratory effort and clinical signs are evident in approximately 3 days and persist for the duration of treatment. Cell counts and the neutrophilia in bronchoalveolar lavage fluid are not reduced by administration of corticosteroids. Affected horses, after institution of appropriate measures to control inhalation of hay and barn dust, should be treated with the lowest dose that controls the disease and only for as long as necessary. The dose of corticosteroid can be reduced gradually and the frequency of administration decreased from once daily to once every second or third day (or greater, depending on the preparation) to achieve this end. Administration of the lowest effective dose is important because of the effects of corticosteroids in suppressing immune and adrenal function. It is suggested that dexamethasone and triamcinolone increase the likelihood of horses developing laminitis, but this relationship has not been conclusively demonstrated.

Table 34.2 Drugs used in the treatment of heaves in horses

	Drug	Dose and frequency	Route	Comments
<b>Bronchodilators</b> $\beta_2$ -agonists	Clenbuterol	0.8 to 3.2 $\mu\text{g}/\text{kg}$ q12 hourly	Oral or IV	Initial therapy with lowest dose. Gradual increments depending on response. For short-term therapy pending environmental control and corticosteroid administration
	Albuterol	50 $\mu\text{g}/\text{kg}$	Oral	Unknown and doubtful efficacy
	Albuterol	1–3 $\mu\text{g}/\text{kg}$ q6–12 hours	Inhalation	Has short duration of action (1 hour). Can be combined with ipratropium to prolong duration of bronchodilation.
	Fenoterol	2–4 $\mu\text{g}/\text{kg}$ as needed	Inhalation	Short duration of action.
	Pirbuterol	1–2 $\mu\text{g}/\text{kg}$ as needed	Inhalation	Short duration of action.
	Salmeterol	0.5–1.0 $\mu\text{g}/\text{kg}$ q6–12 hours	Inhalation	Longest acting $\beta_2$ -agonist available for inhalation
	Terbutaline	0.2 mg/kg as needed	Inhalation	Marked adverse effects including tachycardia. Not absorbed after oral administration.
Parasympatholytics	Terbutaline	0.01 mg/kg as needed	IV	Marked adverse effects including sweating and tachycardia
	Ipratropium	0.5–2.0 $\mu\text{g}/\text{kg}$ q4–6 h	Inhalation	Usually combined with albuterol for rapidity of onset of bronchodilation
	Glycopyrolate	0.7 $\mu\text{g}/\text{kg}$ as needed	IV or IM	Useful for short-term or emergency relief of bronchoconstriction
Miscellaneous	Atropine	0.1–0.02 mg/kg as needed	IV or IM	Useful for diagnosis of reversible airway obstruction and short term relief of bronchoconstriction. Can cause colic.
	Theophylline	5–10 mg/kg q8–12 hours	Oral	Antiquated therapy. Moderate bronchodilation, variable absorption, narrow therapeutic index, frequent adverse CNS effects. Not recommended.
Antiinflammatory drugs	Pentoxyfylline	36 mg/kg q12 hourly	Oral	Not used clinically. Experimental evidence of efficacy.
	<b>Corticosteroids</b>			
Corticosteroids	Dexamethasone phosphate or in alcohol	0.02–0.1 mg/kg q24 hourly	IV, IM, or oral	Effective at reducing clinical signs within 3 days. Gradually reduce dose and frequency to lowest efficacious dose.
	Dexamethasone-21 isonicotinate	0.04–0.06 mg/kg q 3 days	IM	Effective. Infrequent dosing.
	Prednisolone	1–2 mg/kg q24 hourly	Oral or IM	Effective at reducing clinical signs within 3 days. Gradually reduce dose and frequency to lowest efficacious dose.
	Prednisone	1–2 mg/kg q24 hourly	Oral	Variable efficacy and not efficacious in most horses. Do not use.
	Triamcinolone acetonide	0.9 mg/kg q2–4 weeks	IM	Infrequent dosing and therefore lack of ability to taper dose. Should not be repeated at <3 month intervals.
	Beclomethasone	1–3 $\mu\text{g}/\text{kg}$ q12 hourly	Inhalation	Relief of bronchoconstriction within 3 days. Lowest dose does not cause adrenal suppression and is effective in relief of bronchoconstriction.
Other	Fluticasone	2–4 $\mu\text{g}/\text{kg}$ q12 hourly	Inhalation	Potent and effective. Expensive.
	Cromolyn sodium	200 mg q12 hourly	Inhalation	Undetermined efficacy. Should be used before exposure to inciting agent.
	Montelukast	0.11 mg/kg q24 hourly	Oral	Leukotriene receptor antagonist. Not efficacious at this dose.

Modified from: Robinson, N.E. (2001) *Equine Vet. Educ.* 13, 247 and Couetil, L.L. & Hinchcliff K.W. (2004) *Equine Sports Medicine and Surgery*. Elsevier Health Sciences, p 613.

### Bronchodilator drugs

Bronchodilator drugs might be needed to provide acute relief of airway obstruction but should not be used as maintenance therapy. **Atropine** (0.02–0.04 mg/kg, intramuscularly) can be used to provide

short-term relief of bronchoconstriction, but its use is associated with gastrointestinal side-effects, including colic, that preclude its long-term use. **Glycopyrolate** (0.1 mg/kg, intramuscularly every 8–12 hours) is a potent bronchodilator

with minimal gastrointestinal effects. **Ipratropium bromide**, a parasympatholytic drug with minimal extrapulmonary effects when given by inhalation, is very effective in relieving airway obstruction in severely affected horses.<sup>77</sup>

**$\beta_2$ -adrenergic agonists** are potent bronchodilators frequently used in the management of horses with heaves. They can be administered orally or by inhalation.<sup>73,78</sup> **Clenbuterol hydrochloride** is used as maintenance therapy at a dose of 0.8–3.2  $\mu\text{g}/\text{kg}$ , orally every 12 hours, and is effective in controlling signs in 75% of affected horses.<sup>79</sup> The lower dose should be used initially and then increased in 0.8  $\mu\text{g}/\text{kg}$  increments until the desired effect is achieved or side-effects of tachycardia, muscle fasciculation, and sweating are apparent. Gradual, incremental increases in dose lessen the frequency and severity of side-effects. **Terbutaline** is not absorbed after oral administration to horses.<sup>80</sup> Terbutaline and clenbuterol can also be given intravenously, at a dose one-tenth of that given orally, to severely affected horses in which the need for bronchodilation is urgent. Side-effects of  $\beta_2$ -agonist administration include tachycardia, sweating, and apprehension.<sup>79</sup> Prolonged administration of clenbuterol is associated with potentially adverse effects on cardiac structure, alterations in body composition, and an impaired response to training.<sup>81–83</sup> Delayed parturition may occur in mares treated in late pregnancy.  $\beta_2$ -adrenergic agonists may transiently exacerbate hypoxemia in severely affected horses. Intra-tracheal administration does not produce detectable bronchodilation.<sup>84</sup>

Bronchodilators administered by inhalation to horses include the  $\beta_2$ -agonists **Albuterol, salbutamol, and salmeterol**, and the parasympatholytic ipratropium. The efficacy and duration of action of each of these drugs varies somewhat, but all are effective in producing bronchodilation in affected horses. Salmeterol produces bronchodilation in horses with heaves that persists for up to 6 hours, although onset of action requires 30–60 minutes.<sup>85</sup> Similarly, ipratropium reduces pleural pressure changes and attenuates clinical signs of airway obstruction in horses with heaves.<sup>77,86</sup>

**Theophylline** (aminophylline) is a non-adrenergic bronchodilator given at a dose of 10–12 mg/kg, orally every 12 hours. Signs of toxicity include tachycardia, excitement, and convulsions. Theophylline is not a drug of first choice for the treatment of heaves and is now used infrequently because of the availability of efficacious anti-inflammatory drugs and other bronchodilators.

Other drugs

**Sodium cromoglycate** is useful for the prophylaxis of heaves, but has no direct bronchodilatory activity.<sup>55</sup> Its mechanism of action is unclear, but it may act to prevent the degranulation of mast cells. It

can be given at a dose of 20–30 mg per 425 kg horse by inhalation once daily for 4 days, and then repeated in 1–2 weeks.<sup>87</sup>

**Pentoxifylline** at high doses improves respiratory function, but not bronchoalveolar lavage fluid cytology, of horses with heaves.<sup>88</sup> However, bioavailability after oral administration is quite variable, contributing to variations in the responses of horses to the drug.

Drugs that reduce **leukotriene** production or activity do not appear to be useful in the treatment of heaves. An experimental leukotriene D<sub>4</sub> receptor antagonist was not effective in relieving signs of heaves.<sup>89</sup> Similarly, montelukast did not improve respiratory function in 5 horses with heaves.<sup>88</sup>

**Mucolytics** are often used but their efficacy is not established and is doubtful. **Cough suppressants** should not be used as they may impair clearance of mucopurulent material from the airways.

**Antibiotics** are often given to affected horses but are probably not necessary in the vast majority of cases.

**Acupuncture** is not effective in the treatment of heaves.<sup>90</sup>

Administration of large quantities of **isotonic electrolyte solution** intravenously is associated with a decrement in respiratory function in both normal and heavy horses and is not recommended as a treatment for heaves.<sup>91</sup>

Integrated therapy

Initial treatment of affected horses usually involves changes to the horse's environment and feed in combination with administration of corticosteroids. Corticosteroids and  $\beta_2$ -adrenergic agonists can be given as combined therapy to severely affected horses until the disease is controlled, at which time therapy should consist of environmental control and, if needed, administration of the lowest effective dose of corticosteroids. Bronchodilators are sometimes used as sole therapy, but their use without correction of the housing and feeding factors, and attempts to control inflammation, is not rational. Long-term administration of bronchodilators is not optimal therapy and, given the documented adverse effects, is not recommended. Long-term control of heaves is achieved by environmental management and administration of corticosteroids.

## CONTROL

Housing horses in stalls with good air quality is essential in reducing the occurrence of the disease. **Adequate ventilation** is critical in maintaining good air quality in stalls. Few horse housing units have adequate ventilation<sup>19,22</sup> although a well-designed individual box stall can meet the needs of the horse both for air hygiene and thermal comfort.<sup>19</sup> Many

horse barns have inadequate open space for ventilation in still air conditions when the doors are closed at both ends of the building. When the release rate of spores is low, ventilation rates of 4 air changes per hour are satisfactory. However, suggested minima are 8–10 air changes per hour, airspace of 44 m<sup>3</sup>/head, and floor space of 9.2 m<sup>2</sup>/head.<sup>23</sup> In practical terms, if the upper half of the stable door is open, and faces open air and not into a barn, the natural ventilation should exceed the minimum specifications.<sup>23</sup> Hay and dusty feed materials should not be stored above stalls or in the same airspace as horses. Bedding should be changed frequently, preferably daily. Use of cardboard as bedding material is effective as part of an overall regimen to improve air quality.<sup>92</sup>

A portable slit sampler is an accurate, quick, and simple semiquantitative method of assessing the mold contamination of source materials such as hay, straw, and other feeds and bedding collected from stables.<sup>18</sup> The health hazard posed by any moldy source material depends on the types of organisms present and their abundance. The size of the respirable challenge from heated hays and straws arises from the prolificacy of the species involved and their small spore size. The highest respirable challenges are from the presence of thermotolerant and thermophilic mold species. The most critical factors in determining the microbial development in plant-based materials are water content and thermal environment. Hay baled at 15–20% moisture heats little, it is virtually dust-free and contains few spores. Baling hay with 20–30% moisture leads to temperatures of up to 35–45°C. At these temperatures, hazardous contamination may develop with the appearance of thermotolerant fungi and actinomycetes.<sup>18</sup> The heaviest contamination of hay and straw occurs with baling at 35–50% moisture when spontaneous heating up to 50–60°C may occur. Microscopically, these hays show large numbers of fungal spores in the 2–5  $\mu\text{m}$  size range.

### PASTURE-ASSOCIATED HEAVES (PASTURE-ASSOCIATED OBSTRUCTIVE PULMONARY DISEASE OF HORSES)

Summer pasture-associated heaves occurs in horses in the southeastern region of the United States and in Great Britain.<sup>1-3</sup> It appears to be a disease of adult horses that are on pasture most of the time in the summer. It occurs most commonly in the warm, humid summer months of June to September. Affected horses gradually recover during the cooler months of winter and early spring, and the disease may recur in the same horse each successive summer. Most severe signs occurred during late spring and early summer during times of high airborne pollen counts. It has been suggested that pulmonary allergy to pollens is a factor but this has not been validated. Affected horses have increased expression of interleukin-4 and interferon- $\gamma$  in cells of bronchoalveolar lavage fluid and peripheral blood mononuclear cells<sup>4</sup> but not increased concentrations of IgE in bronchoalveolar lavage fluid.<sup>5</sup> Affected horses have clinical findings typical of heaves including nasal discharge, coughing, tachypnea, labored expiratory effort, and crackles and wheezes on auscultation.<sup>6</sup> There is moderate-to-severe accumulation of mucus in the large airways evident on endoscopic examination. Lung function testing is consistent with bronchoconstriction. Bronchoalveolar lavage fluid contains large numbers of nondegenerate neutrophils and lesser numbers of lymphocytes and mast cells.<sup>6</sup> Necropsy reveals overinflated lungs that do not collapse when the chest is opened

and that retain the impressions made by the ribs.<sup>6</sup> The predominant histologic finding is accumulation of mucus in small airways. Inflammation is not severe and most inflammatory cells present are neutrophils and lymphocytes in peribronchial tissues.<sup>6</sup> Treatment includes stabling and administration of corticosteroids and bronchodilators, as discussed for heaves and Table 34.2).<sup>1,2,7</sup>

### MILK ALLERGY

Signs of allergy, principally urticaria, are often manifested by cows during periods of milk retention.<sup>1,2</sup> Most of these occur as the cow is being dried off. The Channel Island breeds of cattle are most susceptible and the disease is likely to recur in the same cow at subsequent drying off periods; it is almost certainly inherited as a familial trait.

The important clinical signs relate to the skin. There is urticaria which may be visible only on the eyelids or be distributed generally. Local or general erection of the hair may also be seen. A marked muscle tremor, respiratory distress, frequent coughing, restlessness to the point of kicking at the abdomen and violent licking of themselves, and even maniacal charging with bellowing may occur. Other cows may show dullness, recumbency, shuffling gait, ataxia, and later inability to rise. The temperature and pulse rates are usually normal or slightly elevated but the respiratory rate may be as high as 100/min.

Diagnosis of milk allergy can be made by the intradermal injection of an extract of the cow's own milk. A positive reaction occurs with milk diluted as much as 1 in 10 000, and the edematous thickening is present within minutes of the injection. Other clinicopathological observations include the development of eosinopenia, neutrophilia, and hyperphosphatemia during an attack.

Spontaneous recovery is the rule but antihistamines are effective, especially if administered early and repeated at short intervals for 24 hours. Prevention is usually a matter of avoiding milk retention in susceptible cows, but in many cases it is preferable to cull them.

### ENZOOTIC NASAL GRANULOMA OF CATTLE (ENG, BOVINE ATOPIC RHINITIS)

Of the three known clinical types of chronic nasal obstruction in cattle, two have been identified etiologically and have clinical or epidemiological features that distinguish them from enzootic nasal granuloma. One is recorded predominantly in beef cattle appears to be caused by a fungus, most commonly *Rhinosporidium* spp., or *Drechslera* spp.<sup>1,2</sup> Another is caused by the parasite *Schistosoma nasalis*.<sup>3</sup> The third type, enzootic nasal granuloma, occurs commonly in southern Australia, less commonly in New Zealand and is recorded as a sporadic disease in South America and an occasional disease in North America, Britain, and Europe.<sup>4,5</sup>

Enzootic nasal granuloma occurs sporadically in some herds but may reach an incidence of 30%. In one area, as much as 75% of herds may have the disease. Animals aged between 6 months and 4 years are most commonly affected, and the chronic disease may or may not be preceded by an attack of acute rhinitis. Most cases commence in the summer and autumn months. It is apparent that nasal granuloma develops as a continuous and progressive response to acute episodes of hypersensitivity to an allergen present in the summer months. This accords with the gradual development of the stertorous respiration<sup>6</sup> and the observations, in biopsies of nasal mucosa, of the presence of mast cells in all seasons, but the regression of eosinophils in the winter months.<sup>4</sup>

An extensive survey of Australian dairying areas showed that 22% of cattle had lesions, and that the prevalence was greater in areas where the average annual rainfall was over 70 cm, than where it was less than 70 cm; the prevalence varied be-

tween 4% and 48%; Jerseys were more commonly affected than Friesians. In New Zealand, 40% of farms and 36% of culled cattle were affected, whereas only 3.6% of young beef cattle showed lesions.

The disease has been identified as an allergic rhinitis and has been produced experimentally.<sup>7</sup> Specific antigens have not been identified as the cause but cows with nasal granuloma are much more sensitive to a number of common allergens in the environment than are unaffected cows. Bovine herpesvirus 1 is often isolated from lesions of ENG and is thought by some to predispose animals to the development of the disease. Additional possible causes include infestation of the nasal cavities with pasture mites (*Tyrophagus palmarum*). An allied condition has been described in the United States as maduromycosis but there are nasal granulomas plus multiple granulomatous lesions of the skin of the ears, tail, vulva, and thigh.<sup>8</sup> The granulomas contain many eosinophils and fungal elements identified provisionally as *Helminthosporium* sp.

In enzootic nasal granuloma acute cases are characterized by a sudden onset of bilateral ocular and nasal discharge and swelling of the nasal mucosa causing difficult, noisy breathing. Affected animals shake their heads and snort and rub their noses in hedges. As a result they commonly block their nostrils with twigs. This form of the disease is commonest in cattle of the Channel Island breeds and their cross-breeds. The nasal discharge in these breeds is usually yellow to orange in color.

Established cases of enzootic nasal granuloma have lesions, consisting of granulomatous nodules 1–4 mm in diameter and height, in both nostrils. The lesions extend from just inside the nostril posteriorly for 5–8 cm. They may be few in number or be packed closely together. Their texture is firm and the mucosa over them is normal. They have a characteristic histopathology of epithelial metaplasia and hyperplasia,

and contain large numbers of eosinophils and mast cells.<sup>4,9</sup>

The predominant clinical sign is respiratory stertor and dyspnea caused by obstruction to the air flow. The severity of these signs may fluctuate but in general they progress slowly over several months and then remain static. Although the respiratory distress may be sufficiently severe to cause a loss of condition and marked reduction in milk yield, affected animals do not die. A good proportion of them have to be culled as uneconomic units.

The clinical picture in **mycotic nasal granuloma** is superficially similar with respect to noisy breathing, respiratory distress, and nasal discharge, but there is no seasonal association. Also, the visible and palpable lesions in the anterior part of the nasal cavities are polyps up to 5 cm in diameter which occur singly or in confluent masses. Their cut surfaces are yellow to green and they are sometimes ulcerated.<sup>4,10</sup> Histologically the lesions are eosinophilic granulomas containing fungal spores and sometimes hyphae. Fungi (*Drechslera rostrata*) have been isolated from the lesions.

**Equine allergic rhinitis** is a clinically and epidemiologically similar condition, but without mucosal lesions, recorded in horses as a common cause of persistent head shaking.<sup>11</sup>

# Diseases associated with the inheritance of undesirable characters

## INTRODUCTION 1938

### DISEASES CHARACTERIZED BY CHROMOSOMAL ANOMALIES 1939

Freemartinism in calves 1939  
Chromosomal translocations in cattle 1939  
Chromosomal translocations in sheep 1940

### INHERITED DEFECTS OF THE BODY AS A WHOLE 1940

Deficiency of UMP synthase (dumps) 1940  
Inherited goiter 1940  
Inherited immunodeficiencies 1940  
Bovine leukocytes adhesion deficiency (BLAD) 1941  
Inherited deficiency of lymphocyte maturation (lethal trait A46, parakeratosis, adema disease) 1941  
Inherited deficiency of immunoglobulin synthesis 1941  
Chediak-Higashi syndrome 1941  
Pseudoalbinism and lethal whites 1942  
Fell pony syndrome 1942

### INHERITED DEFECTS OF THE ALIMENTARY TRACT 1943

Inherited defects of the mouth and jaw 1943  
Inherited rectovaginal constriction 1944  
Hepatic lipodystrophy in Galloway calves 1944  
Inherited atresia of alimentary tract segments 1944

### INHERITED DEFECTS OF THE CIRCULATORY SYSTEM 1944

Bovine hereditary dilated cardiomyopathy 1944  
Inherited lymphatic obstruction 1945  
Inherited ventricular septal defect 1945  
Inherited aortic aneurysm 1945  
Bovine Marfan syndrome 1945  
Inherited congenital porphyria 1945  
Inherited erythrocytic protoporphyria 1946  
Hemochromatosis 1946  
Familial polycythemia 1947  
Inherited bleeding disorders 1947  
Inherited anemias 1947

### INHERITED DEFECTS OF THE URINARY TRACT 1948

Inherited nephrosis (mesangiocapillary glomerulonephritis) 1948  
Chronic interstitial nephritis 1948  
Inherited cystic renal dysplasia 1948  
Inherited bilateral renal hypoplasia 1948  
Inherited renal tubular dysplasia 1948  
Inherited renal lipofuscinosis in Danish slaughter cattle 1948

### INHERITED DEFECTS OF THE NERVOUS SYSTEM 1948

Inherited lysosomal storage diseases 1948  
Mannosidosis 1948  
Gangliosidoses 1949  
Ceroid lipofuscinosis 1950  
Globoid cell leukodystrophy 1950  
Inherited nervous system abiotrophies 1950  
Caprine progressive spasticity 1951  
Cerebellar abiotrophy 1951  
Inherited neurodegeneration (shaker calf syndrome) 1951  
Inherited progressive degenerative myeloencephalopathy (weaver syndrome) 1951  
Inherited spinal dysmyelination 1951  
Inherited progressive ataxia 1952  
Inherited spinal dysraphism 1952  
Inherited spinal myelinopathy 1952  
Inherited multifocal symmetrical encephalopathy 1952  
Inherited bovine degenerative axonopathy 1952  
Inherited ovine degenerative axonopathy (neuraxonal dystrophy) 1952  
Inherited spontaneous lower motor neuron disease 1953  
Inherited maple syrup urine disease (branched chain ketoacid decarboxylase deficiency - BCKAD) 1953  
Inherited citrullinemia 1953  
Equine degenerative myeloencephalopathy 1953  
Inherited congenital hydrocephalus 1954  
Inherited prosencephaly 1954  
Inherited hydranencephaly and arthrogryposis 1954  
Inherited congenital cerebellar defects 1954  
Inherited spastic paresis (also heel) 1955  
Inherited periodic spasticity of cattle 1956  
Inherited neonatal spasticity 1956  
Inherited congenital myoclonus (hereditary neuraxial edema) 1956  
Inherited congenital posterior paralysis 1956  
Inherited congenital myotonia 1957  
Inherited hypomyelinogenesis (congenital tremor of pigs) 1957  
Exophthalmos with strabismus 1957  
Familial undulatory nystagmus 1957  
Inherited idiopathic epilepsy of cattle 1957  
Familial narcolepsy 1957  
Doddler calves 1957

### INHERITED DEFECTS OF THE MUSCULOSKELETAL SYSTEM 1957

Inherited diseases of bones 1957  
Inherited osteoarthritis 1957

Inherited osteogenesis imperfecta 1957  
Inherited dwarfism 1958  
Congenital osteopetrosis 1959  
Inherited probatocephaly (sheepshead) 1959  
Inherited atlanto-occipital deformity 1959  
Inherited agnathia 1959  
Inherited displaced molar teeth 1959  
Inherited jaw malapposition 1959  
Inherited cranioschisis (cranium bifidum) 1959  
Inherited craniofacial deformity 1959  
Inherited arachnomelia (inherited chondrodysplasia) 1959  
Complex vertebral malformation in Holstein calves 1960  
Inherited acroteriasis (amputates) 1960  
Inherited reduced phalanges (amputates, acroteriasis, ectromelia) 1960  
Inherited claw deformity 1961  
Inherited multiple exostosis 1961  
Inherited congenital hyperostosis (thick forelimbs of pigs) 1961  
Inherited rickets 1961  
Inherited taillessness and tail deformity 1961

### INHERITED DISEASES OF JOINTS 1961

Inherited arthrogryposis (inherited multiple tendon contracture) 1961  
Inherited multiple ankylosis 1962  
Inherited patellar subluxation 1962  
Inherited hypermobility (laxity) of joints 1962  
Inherited hip dysplasia 1962

### INHERITED DISEASES OF MUSCLES 1962

Generalized glycogenosis (glycogen storage disease Type II) 1962  
Glycogen storage disease Type V (muscle glycogen phosphorylase deficiency) 1963  
Familial polysaccharide storage myopathy (equine rhabdomyolysis syndrome) 1963  
Inherited diaphragmatic muscle dystrophy 1963  
Congenital myasthenia gravis 1963  
Bovine familial degenerative neuromuscular disease 1963  
Inherited umbilical and scrotal hernias, cryptorchidism, and hermaphroditism 1963  
Myofiber hyperplasia (double muscling, doppelender, culard) 1964  
Pietrain creeper pigs 1965  
Inherited progressive muscular dystrophy 1965  
Inherited spinal muscular atrophy 1965  
Inherited splayed digits 1965  
Equine hyperkalemic periodic paralysis 1965

Recurrent exertional rhabdomyolysis in thoroughbred horses (azoturia, tying up, chronic intermittent rhabdomyolysis) 1966  
 Porcine stress syndrome (PSS; malignant hyperthermia) 1968

#### INHERITED DEFECTS OF THE SKIN 1973

Inherited symmetrical alopecia 1973  
 Inherited congenital hypotrichosis 1973  
 Inherited hair coat-color-linked follicle dysplasia 1974  
 Inherited birthcoat retention 1974

Inherited leukoderma 1974  
 Inherited albinism and lethal white foal syndromes 1974  
 Inherited epidermal dysplasia (baldy calves) 1974  
 Inherited parakeratosis (lethal trait A46, adema disease) 1975  
 Inherited dyserythropoiesis-dyskeratosis 1975  
 Inherited congenital absence of the skin 1975  
 Inherited crop ears 1975  
 Inherited hyperbilirubinemia and photosensitization 1975

Inherited congenital ichthyosis (fish-scale disease) 1976  
 Inherited dermatosis vegetans 1976  
 Dermatosparaxis (hyperelastosis cutis) 1976  
 Inherited melanoma 1976  
 Inherited hyperhidrosis 1976

#### MISCELLANEOUS INHERITED DEFECTS 1976

Inherited eye defects 1976  
 Inherited prolonged gestation (adenohypophyseal hypoplasia) 1977

## Introduction

### GENERAL

Genetic disorders are a small but important cause of wastage in farmed animals. Most occur in pure-bred animals and are inherited as autosomal recessive traits because dominant disorders tend to be self limiting, or affected animals are excluded from the breeding pool. Incomplete dominants occasionally occur in which there are three potential phenotypes, i.e. normal, affected, and more severely affected. The classic example is in the original Dexter cattle where the slightly dwarfed Dexter phenotype is dominant to the normal and is selected for. Animals homozygous for the gene abort with a non-viable 'bulldog' type fetus.<sup>1,2</sup> Sex-linked disorders may occur but are uncommon. Some monogenic disorders may arise *de novo* due to new mutations of germ plasm. Those with a dominant mode of inheritance are present in offspring of the animal in question, usually affecting genes for structural proteins such as collagen. A new mutation should be considered with disorders such as *osteogenesis imperfecta* or skin fragility.<sup>3</sup> The proportion of offspring with the defect may vary depending on what stage of gametogenesis the mutation occurred.

In-breeding, knowingly or unknowingly practiced, is an important feature in the manifestation of most outbreaks of a recessive disorder. Founder effect is an aspect of this that has been important when new breeds have been introduced to a country by importation of genetic material from a small number of individuals. Artificial breeding on a large and international scale has sometimes exacerbated this, particularly in cattle.

Genetic disorders may be manifested as disease or bodily malformation. When diagnosed, an entity may reflect the tip of an iceberg only and it can be expected that many other cases go undiagnosed. Spread across an industry their economic importance may be limited, but as particular disorders tend to be concentrated

in certain herds/flocks they may have considerable importance to an individual breeder, particularly those involved with pedigree breeding. Animal welfare is also a concern to be addressed, being driven by a greater awareness of ethical standards in livestock production and by potential market access requirements.

The two main problems for the clinician investigating a suspected inherited disorder are to confirm a primary genetic cause and then to institute control in a cost-effective manner.

### DIAGNOSIS

For a number of inherited diseases or malformations known to occur in a breed, morphology or histopathology may be so characteristic as to be essentially pathognomonic. However, for some disorders environmental agents (teratogens) may cause similar morphological anomalies, e.g. arthrogyposis, so care should be taken. Pedigree analysis may help if there are sufficient animals of known breeding to show that the incidence of the disorder follows a Mendelian pattern. However, in many herds/flocks animals may be closely related and pedigree analysis can sometimes be misleading and produce a fictitious relationship between inheritance and disease. As the biochemical anomaly is now known for many diseases, or perhaps can be deduced from histopathological lesions, laboratory tests may confirm a presumptive diagnosis. Test mating of a sire to daughters, related females, or females that have given birth to an affected animal is the ultimate confirmation of the genetic nature of a disorder, provided the appropriate numbers of progeny are generated. Disproving a genetic cause of a disorder may be as important as proving it. Matings of a sire to produce a minimum of 24 progeny from his daughters or 12 from putative heterozygotes (females that have given birth to affected individuals) are usually considered satisfactory numbers to exclude a likely inherited cause if no affected individuals are born ( $P < 0.5$ ). The birth of a proportion of affected off-

spring is strong evidence of inheritance. The use of super-ovulation and embryo transfer techniques may facilitate this, particularly if insufficient daughters or putative heterozygotes are available. The time to accomplish this may be decreased by caesarian section of the surrogate dams if the defect can be detected in the fetuses.

The degree of in-breeding is an important indicator of whether a congenital disorder is inherited or not. Consistency of the defect is a characteristic of inherited disorders but there may be some variation in age of onset or expressivity of lesions. Other epidemiological factors include the occurrence of the defect over more than 1 year and occurrence or repetition of it in the same mating group, but not in others on the property.

### CONTROL OF INHERITED DISEASE

Appropriate control measures may vary, depending on the importance of the disorder and may be aimed at the herd/flock level or at the breed as a whole. It may be prospective but, at the farm level, it is mainly reactive with the purpose of preventing further losses by immediate action. This should include not breeding from putative heterozygous sires or females which should preferably be culled. Replacement sires are best acquired from another breeder but, if the defect is common in the breed, then the risk may remain and cross breeding with a sire from another breed may be considered if the type of farm operation permits it. If a test is available for detecting heterozygous animals then this can be used in new sire selection.

Control of genetic disorders in pedigree herds is more complex and to be effective depends on ability to detect heterozygotes or prove animals do not carry the recessive gene in question. Test mating is time consuming, expensive, and of limited application. The explosion of knowledge concerning the biochemical and molecular genetic basis of inherited diseases across species has opened up effective means of diagnosing genotype

for many of them. Control may be at an individual herd/flock level or applied to all at risk. It is best instigated with the help of breed societies who may exert control over the fate of animals diagnosed as heterozygous through control of registrations. Apart from the accuracy of genetic tests in genotype diagnosis, there is the added advantage that particularly valuable animals may be kept within the herd/flock for breeding as their offspring can in turn be tested as normal or heterozygous.

The first generation of tests for heterozygotes was biochemical being based on knowledge of the enzyme deficiency and the gene dosage phenomenon. Heterozygous animals having one normal and one mutant gene have enzyme values midway between normal and diseased values, although there may be some overlap. Supplementary tests or knowledge of the parents' genotype may assist with clarification of equivocal results. Such tests were used to control the economically important lysosomal storage diseases  $\alpha$ -mannosidosis in Angus and Murray Grey cattle in New Zealand and Australia<sup>4</sup> and Glycogen storage disease type II in Shorthorn and Brahman cattle in Australia.<sup>5</sup> These have now given way to more accurate second-generation technology based on DNA for these diseases as well as a number of others.<sup>6-8</sup> Such tests may be performed on blood samples but are increasingly being done on hair roots.

The genome for the major farm species is essentially known and, given the will and enough affected families, the technology exists to develop tests for most disorders. If the disorder in question is poorly defined biochemically, then tests are still possible by finding a closely linked polymorphic gene marker. This is usually the first step in investigating the molecular genetics of an unknown disease but it is expensive. In contrast, if a candidate gene can be deduced from the pathology of the disease, then it is much simpler to define the mutation and through polymerase chain reaction (PCR) technology develop a DNA based test.

Artificial breeding techniques have the capacity to spread undesirable genotypes widely before they are recognized. Many artificial breeding organizations involved in the dairy industry prospectively screen for genetic disorders by mating prospective sires over a proportion of their daughters. This is possible because of the time taken to prove a sire before he enters the industry on a large scale.

disorders and traits in animal species (other than human and mouse) authored by Professor Frank Nicholas of the University of Sydney, Australia, with help from many people over the years. The database contains textual information and references, as well as links to relevant records from OMIM, PubMed, Gene, and soon to be NCBI's phenotype database.

### Diseases characterized by chromosomal anomalies

The principal advance in cytogenetics in agricultural animals has been in the field of fertility in cattle but freemartinism and structural translocations are the only groups to have been well documented. Other chromosomal abnormalities in other species are recorded but not in sufficient numbers to make a coherent account possible; details of them should be sought in the theriogenology literature. Besides the many identifications of individual infertile males and females by this means there is the probability that chromosomal aberrations characterized by aneuploidy are the cause of many stillbirths and multisystemic anomalies that make neonates non-viable.<sup>1,2</sup> A true hermaphrodite in a horned goat with 60 XX/60 XY chimerism has been described.<sup>3</sup>

Chromosomal analysis techniques are based on tissue culture using leukocytes collected in a highly aseptic manner. The blood is placed in tissue culture medium containing a stimulant to cell division.

After brief incubation, cell division is arrested by the addition of a cytotoxic agent and the cells are then swollen osmotically by treatment with a hypotonic solution, then fixed and dried onto slides and stained. Microscopic examination of dividing cells allows the total number of chromosomes in each cell to be counted, and the sex chromosomes and abnormal chromosomes identified. The individual chromosomes are cut out from photographic prints, paired, and stuck onto cards to create the document used for identification – the **karyotype**. The number of cells subjected to chromosomal analysis in each case is usually 10–20, but 50 are recommended for satisfactory accuracy.

#### FREEMARTINISM IN CALVES

A freemartin is defined as a sterile female partner of a pair of heterosexual twins. In cattle, 92% of females born co-twins to males are freemartins.

In normal calves the chromosomal identification of females is 60 XX (60 chromosomes, both X chromosomes) and of males is 60 XY (the Y being smaller and not readily paired with its opposite X chromosome).

The freemartin is the classical example of the chimera in cytogenetics. They are the individuals which contain two or more cell types which originated in separate individuals. The only way in which chimera can develop is via the fusion of circulations or zygotes *in utero*. Sex chromosome chimerism is also reported in goats, sheep, and pigs, and, although the male partners of female twins are usually anatomically normal, they often have reduced fertility. Bulls born co-twin with freemartin females may also be chimeric and have low reproductive efficiency.

The diagnosis of freemartinism has been based on physical examination, karyotyping, or blood typing and each has its limitations. There is variation in the degree of reproductive tract abnormalities in freemartins. The external genitalia may appear normal, the vulval hair may be coarser than usual or the clitoris may be enlarged. The vagina is generally expected to be shorter than normal. The cervix, uterus, uterine tubes, and ovaries may be absent, present in underdeveloped form, or may appear normal on rectal palpation.

Special cytogenetic techniques are also available which facilitate the diagnosis of freemartinism in a female calf of a male-female twinning. In freemartins (phenotypically female, but carrying also male cells) there is a mixture of mostly 60 XX chromosomes to a cell, and a small proportion of 60 XY cells. A large number of cells need to be analyzed if only the

#### ONLINE MENDELIAN INHERITANCE IN ANIMALS (OMIA)

Online Mendelian Inheritance in Animals (OMIA) is a database of genes, inherited

freemartin calf is available because the proportion of abnormal cells present may be as low as 2%. It is, however, possible to make a diagnosis on the examination of 10–20 cells, provided the male twin is also analyzed; the female may have very few XY chromosomes but the male will have a very high proportion of XX chromosomes. The technique is much more accurate than blood group analysis, or clinical observations of a short vagina, enlarged clitoris and the presence of a vulval tuft of hair. Karyotyping is a definitive method of freemartin diagnosis but it is tedious, time consuming, and expensive. Blood typing analysis may be performed on both the male and female co-twins in order to demonstrate two blood group populations, but it is expensive and requires blood samples from both co-twins.

The **polymerase chain reaction (PCR)** method of freemartin diagnosis using sex-specific DNA sequences is rapid, accurate, relatively simple, and inexpensive to perform and a blood sample is required only from the female co-twins.<sup>4</sup> It allows for the accurate decision of freemartinism down to a level of 0.05% of male chimeric cells present.

### CHROMOSOMAL TRANSLOCATIONS IN CATTLE

When two chromosomes which have previously been broken have fused to form a morphologically distinct chromosome this is known as a translocation. It is further identified by the chromosomal series involved. Thus a 1/29 translocation represents a fusion between a chromosome of each of the pairs numbered 1 and 29.

**Translocation 1/29** has been identified in many breeds of cattle and has been associated with significant reductions in the fertility of cows bred by artificial insemination (AI) services. Early embryonic death occurs in embryos produced by fertilization of affected gametes or fertilization of normal gametes by spermatozoa carrying the 1/29 translocation. There is no abnormality of serving behavior or semen quality. The translocation has been shown to be inherited in most European beef breeds including the Blonde d'Aquitaine, Swedish Red and White, Charolais,<sup>5</sup> Danish Limousin,<sup>6</sup> British Friesian<sup>7</sup> and Red Poll breeds and in the wild British White cattle. In Bolivian Creole cattle breeds, the Creole-like cattle, the average frequency was 10.42% with a variation from 0 to 28.2%.<sup>8</sup> In contrast, Yacumeno and Creole-type cattle did not show the centric fusion. The highly significant differences between Creole cattle breeds in relation to the 1/29 translocation could be the consequence of factors such as founder group, genetic drift, and selection.

The low frequency observed in the Saavendreh Creole dairy cattle might be due to breeding under a more intensive system, and selection according to milk yield and fertility traits. The frequency of affected animals in a breed may vary between 1 and 20%. Karyotyping and culling of abnormal bulls in most artificial breeding centers has reduced the impact of the defect.

**Translocations 1/21, 2/4, 14/20, and 13/2** have also been identified in bulls, the 1/21 in Holstein Friesian cattle,<sup>9</sup> and the latter two seeming to be widespread in Simmental cattle.<sup>10</sup> None of them has been linked with a disease but it is becoming accepted practice not to use such animals for artificial insemination, and in some countries to refuse their importation.

A cytogenetic survey of Holstein bulls at a commercial AI unit to determine the prevalence of bulls with centric fusion and chimeric anomalies found that chimeric fusion is extremely rare in Holstein blood lines available by AI in the United States.<sup>11</sup> However, chimeric bulls are more common and reportedly have decreased reproductive performance. Because of the possibility of de novo onset of chimeric fusion at any time, early cytogenetic screening should be encouraged for prospective bulls intended for AI programs.

**Translocation 27/29** is suspected of being associated with reduced fertility in Guernsey cattle. These and other abnormalities of chromosomal structure were detected in an examination of a large number of infertile dairy heifers.

### CHROMOSOMAL TRANSLOCATIONS IN SHEEP

The literature on chromosomal aberrations in sheep has been reviewed.<sup>12</sup> Centric-fusion (Robertsonian) translocations have been described in sheep in New Zealand. There is no evidence to suggest that these centric-fusions, in a variety of combinations, affect the overall total reproductive performance of domestic sheep, as unbalanced spermatids failed to mature and take part in fertilization.

### Inherited defects of the body as a whole

Many inherited defects, other than those listed in this section, probably have a metabolic defect as their basic cause, for example the abiotrophies, but they are listed elsewhere because of lack of certainty about their exact cause. Three known inherited enzyme deficiencies – bovine citrullinemia, bovine protoporphyria – are described in system groupings where their clinical signs are most prominent. Inherited vitamin C, D, and E deficiencies are dealt with in the chapter on nutritional deficiency diseases. Inherited immune deficiencies are listed in this section.

### DEFICIENCY OF UMP SYNTHASE (DUMPS)

This is a partial deficiency of an enzyme which is involved in the conversion of orotate to uridine 5'-monophosphate (UMP) as a step in the synthesis of pyrimidine nucleotides. It is recorded at a high prevalence in Holstein Friesian cattle in the US and is characterized by an autosomal recessive form of inheritance and the secretion of high levels of orotate in the milk. Heterozygous animals have a partial deficiency of UMP synthase<sup>1</sup>; they have no individual or herd clinical abnormalities but can be detected biochemically by their half-normal levels of erythrocyte UMP synthase. Bovine homozygotes die at about the 40th day of pregnancy.<sup>2</sup> Embryonic mortality is the only form of loss.

### INHERITED GOITER

This disease is recorded in Merino sheep, Afrikaner cattle, crossbred Saanen dwarf goats, Boer goats, possibly Poll Dorset sheep, and pigs,<sup>1</sup> and appears to be inherited as a recessive character. The essential defect is in the synthesis of abnormal thyroid hormone leading to increased production of thyrotropic factor in the pituitary gland, causing in turn a hyperplasia of the thyroid gland. In Afrikaner cattle the defect stems from an abnormality of the basic RNA, and

heterozygotes can be identified by blot hybridization analysis.<sup>2</sup>

Clinically in **sheep** there is a high level of mortality, enlargement of the thyroid above the normal 2.8 g, but varying greatly up to 222 g, and the appearance of 'lustrous' or 'silky' wool in the fleeces of some lambs. Other defects which occur concurrently are edema and floppiness of ears, enlargement of, and outward or inward bowing of, the front legs at the knees, and dorsoventral flattening of the nasal area. The thyroglobulin deficiency in the neonatal lamb may result in defective fetal lung development and the appearance of a neonatal respiratory distress syndrome; there is dyspnea at birth.

The clinical picture in **goats** is the same as for lambs. It includes retardation of growth, sluggish behavior, rough, sparse hair coat, which worsens as the goats get older, and a thick scaly skin.

In **Afrikaner cattle** most of the losses are from stillbirths or from early neonatal deaths. Some are caused by tracheal compression from the enlarged gland. It is the calves with the largest glands that have the greatest mortality. In these cattle there may be a concurrent inherited gray coat color, a defect in a red breed.

In **pigs** hairless and swollen piglets with enlarged thyroid glands occur, in the proportions with normal piglets consistent with an autosomal recessive mode of inheritance.

## INHERITED IMMUNODEFICIENCIES

Many of these diseases have been previously characterized as diseases of other body systems but are now correctly classified by the wider acceptance of clinicopathological examinations, especially those involving immunological studies. The group is probably still in a period of transition (see Chapter 9).

## BOVINE LEUKOCYTE ADHESION DEFICIENCY (BLAD)

This granulocytopenia is inherited as an autosomal recessive trait in Holstein-Friesian cattle. Homozygotes are not viable because of their low resistance to infection. Heterozygotes are unaffected. Signs are observed first between 2 weeks and 8 months, and are characterized in most cases by bouts of infectious disease, e.g. persistent fever, diarrhea, cough,

dyspnea, delayed wound healing, and stunted growth.<sup>1</sup> Some cases exhibit a striking periodontal gingivitis with marked retraction of the gingiva, and severe resorption of mandibular bone causing premature teeth loss.<sup>2</sup> In a small proportion of cases the signs are limited to unthriftiness.<sup>3</sup> Severe ulcers on oral mucosa, severe periodontitis, loss of teeth, chronic pneumonia, and recurrent or chronic diarrhea are common.<sup>1</sup>

The clinical pathology is characterized by a severe and persistent neutrophilia, without a left shift, and a significantly increased cellularity of bone marrow.<sup>4</sup> At necropsy there are very large numbers of intravascular neutrophils in all tissues, especially the spleen, but not in infected tissues, which may include bronchopneumonia, pseudomembranous or necrotizing enteritis, and granulomatous gingivitis.<sup>5</sup> Intestinal ulcers are an essential part of the pathogenesis of the disease in chronically affected animals which receive intensive medical care.<sup>6</sup> Affected animals are stunted and unlikely to live as long as 2 years.

The gene frequency is widespread in the Holstein-Friesian breed. The genetic basis for the disease is a single point mutation in the gene coding for CD18, a subunit of the  $\beta_2$  integrins, surface glycoproteins which are important to cell adhesion processes, causing a deficiency of adhesion on the surface of leukocytes.<sup>7</sup> Neutrophils from BLAD cattle have impaired expression of  $\beta_2$  integrin (CD11a, b, c/CD 18) of the leukocyte adhesion molecule. The biochemical basis for the disease is a deficiency of interaction between receptors on the leukocytes with adhesion glycoproteins in the mediation of immunological functions.<sup>8</sup> A polymerase chain reaction test is available for the detection of heterozygotes<sup>9</sup> and an eradication program is operating in Japan<sup>10</sup> and the US.<sup>11</sup> Heterozygotes have poorer feed utilization and growth rates than non-carriers of the inheritance.<sup>12</sup> Control of BLAD in Holstein cattle requires publishing the genotypes and avoiding the mating between BLAD carriers which is successful.<sup>1</sup> Heterozygote calves are not affected.<sup>13</sup>

## INHERITED DEFICIENCY OF LYMPHOCYTE MATURATION (LETHAL TRAIT A46, PARAKERATOSIS, ADEMA DISEASE)

This defect is recorded in Black Pied Danish cattle but probably occurs in a number of European breeds of cattle, including Friesian-type cattle, and in beef Shorthorn calves in the US.<sup>1</sup> It is a defect of lymphocyte maturation and is inherited as an autosomal recessive character.

Calves are normal at birth and signs appear at 4-8 weeks of age; untreated animals die at about 4 months of age. There is exanthema and loss of hair, especially on the legs, parakeratosis in the form of scales or thick crusts around the mouth and eyes, under the jaw, and on the neck and legs, and a very poor growth rate. Lymphocyte numbers and function are reduced when the patient is in a zinc-deficient state,<sup>2</sup> and antibody responses are suppressed.

At necropsy the characteristic skin lesion is acanthosis and hyperkeratosis and there is atrophy of the thymus, spleen, lymph nodes, and gut-associated lymphoid tissue.

There is a significant response to oral treatment with zinc (0.5 g zinc oxide/day) and an apparently complete recovery can be achieved in a few weeks if treatment is continued. The disease reappears if treatment is stopped. The dose rate needs to be increased as body weight increases. It is thought that the disease is an inherited excessive requirement for zinc and that the thymic hypoplasia is due to the dietary deficiency. Absorption studies with radioactive zinc have shown that there is impaired absorption of the element.

## INHERITED DEFICIENCY OF IMMUNOGLOBULIN SYNTHESIS

An inherited complete deficiency of IgG<sub>2</sub> occurs in Red Danish cattle at a low level of incidence. Affected animals are unusually susceptible to severe infections including gangrenous mastitis and pneumonia.

## CHEDIAK-HIGASHI SYNDROME

This inherited disease occurs in humans, in mink, and in Hereford, Japanese Black, Brangus cattle,<sup>1,2</sup> and possibly other breeds of cattle. Clinically affected animals grow poorly; they are incomplete albinos with generalized oculocutaneous hypopigmentation, e.g. pale gray hair, ocular iridal and fundic hypopigmentation, photophobia and lacrimation, and have anemia, enlarged, edematous lymph nodes, and a defect in immune defense mechanisms so that they often die of septicemia. Their average life span is about 1 year. The immunological defect has been identified as one of insufficient bactericidal activity within abnormal leukocytes. The clinical, morphologic, and biochemical characteristics of Chediak-Higashi syndrome in Japanese cattle has been described.<sup>2</sup>

A mutation in the Chediak-Higashi 1/LST gene is likely responsible for the disease in Japanese Black cattle.<sup>3</sup> The LYST gene responsible for the mutation has been cloned.<sup>4</sup>

The disease is readily diagnosed by the detection of anomalous enlarged cytoplasmic granules in neutrophils, lymphocytes, monocytes, and eosinophils. The granules are swollen lysosomes, and the disease is a lysosomal storage disease. There is also a defect in blood clotting, and this has been identified as a metabolic defect within structurally abnormal platelets. The platelets have a storage pool deficiency of dense granules and produce much less serotonin, ATP, and ADP than normal platelets. The platelets also fail to aggregate normally in response to the presence of collagen.<sup>5</sup> The disease is conditioned by a factor inherited as a single autosomal recessive.<sup>6</sup>

A DNA diagnostic system using allele-specific PCR for detection of the nucleotide substitution has been developed as an effective DNA diagnostic aid.<sup>7</sup>

## PSEUDOALBINISM AND LETHAL WHITES

There are a number of forms of pseudoalbinism in domestic animals. There is a non-lethal form in cattle and a lethal dominant in horses in which 25% of conceptions produced by mating dominant white

horses die *in utero* in early gestation. The only pigment in the affected foals is in the eyes.

The disease in **cattle** occurs in Angus, Brown Swiss, Holstein, and Hereford cattle. The Angus cattle have a brown coat and two-tone irises with an outer pale brown ring and an inner blue one. There appears to be no defect in digestion or metabolism. Hereford incomplete albinos have the Chediak-Higashi syndrome. The other breeds do not appear to have defects other than in pigmentation and the defect in Angus is probably more accurately called 'oculocutaneous hypopigmentation'. They do have one problem; they are photophobic and prefer to be out of the sun.

A complete albinism in Icelandic **sheep** is manifested by white skin color, pink eyes, and impaired vision in bright light. It is an autosomal recessive. Albinism is also a problem in Karakul sheep.

True albino **horses** rarely if ever occur in nature, but white horses with pigmented eyes do. They are more accurately called pseudoalbinos. A recessive lethal white can also be produced by mating two Overo paint horses (an Overo is a horse with a coat color pattern where white is continuous over the body, but there is pigmented hair in a patch stretching from the ears to the tail). Affected foals develop colic soon after birth, fail to pass meconium, and die at 2-4 days of age. At necropsy there is an irreparable atresia or contraction of the colon associated with a congenital absence of myoenteric ganglia in the terminal portion of the ileum and the cecum and colon. The colon is patent but unable to dilate. Another variety of paint horses, the Tobiano (white markings extend from the dorsal midline ventrally with limbs usually white, and white covering a large part of the horse or very little), are expected to produce lethal whites also but there is no record of it.<sup>1</sup> Both of these varieties of paints have blue or heterochromic irises.

## FELL PONY SYNDROME

This is a familial disease of Fell ponies characterized by immunodeficiency, anemia, opportunistic infection, and death at 2-3 months of age.

### ETIOLOGY

The disease is a putative autosomal recessive genetic defect of the immune system, although the exact nature of the defect has yet to be determined.

### EPIDEMIOLOGY

The disease is restricted to Fell pony foals less than 3 months of age. The disease is

reported in this breed in the United Kingdom, one case is reported in the United States (which has a total population of Fell ponies of <200) and a case is reported in the Czech Republic.<sup>1-3,7</sup> The frequency of the disease is not reported. The case fatality rate is 100%.

### PATHOGENESIS

There is immunodeficiency associated with low concentrations of immunoglobulins in serum and B lymphocytes in blood. T lymphocytes are present in normal concentration and respond appropriately to *in vitro* proliferation tests. Death is coincident with declines in concentrations of antibodies derived from colostrum. Immunodeficiency results in development of opportunistic infections including glossitis, adenoviral pneumonia, and cryptosporidial diarrhea. Aplastic anemia develops and can contribute to death. Anemia is associated with aplasia of red cell series in bone marrow and is not due to hemolysis or blood loss.

### CLINICAL FINDINGS

Affected foals are lethargic at birth, are unable to keep up with the herd, and do not establish a strong bond with the dam. Foals develop ill-thrift, exercise intolerance, and diarrhea beginning at approximately 3 weeks of age. Clinical signs are attributable to anemia and opportunistic infections. At the time that foals develop other clinical abnormalities they are pyrexemic and tachypneic. Most foals have bilateral mucopurulent nasal discharge and abnormal lung sounds consistent with pneumonia. The tongue is covered by a pseudomembranous, hyperkeratotic membrane suggestive of *Candida* sp. infection. Foals develop diarrhea and progressive illness with death occurring by 3-4 months of age even in cases treated aggressively.

### CLINICAL PATHOLOGY

The underlying hematology and serum biochemistry is influenced by the opportunistic infections that develop in all foals affected with Fell pony syndrome. Abnormalities consistently associated with the syndrome and likely as a result of the underlying disease, include anemia, B cell lymphopenia, and variable to low concentrations of immunoglobulins in serum.<sup>1,2,4</sup>

Normocytic, normochromic anemia (6-26%, 6-26 L/L) is present in almost all affected foals. There is no evidence of regeneration in the blood and examination of bone marrow reveals an elevated myeloid:erythroid ratio (21:1 to 62:1, reference values 0.5:1 to 1.5:1).<sup>1</sup> There is no evidence of hemolysis.

White blood cell concentration in affected foals is usually below or in the

lower range of the reference range of normal, age-matched foals, and is attributable to a B-cell lymphopenia.<sup>5,6</sup> Concentrations of CD4+ and CD8+ cells in blood are normal in affected foals.<sup>5,6</sup> The concentration of neutrophils is often elevated in affected foals.

Concentrations of immunoglobulins (IgG<sub>a</sub>, IgG<sub>b</sub>, IgG(T), and IgM) in serum are variable and depend on the amount of immunoglobulin ingested in colostrum and the age of the foal. Affected foals are unable to produce immunoglobulins and therefore have declining concentrations of immunoglobulins with age. Serum concentrations of IgM and IgA become

undetectable before does IgG – a consequence of the shorter half-life of the former immunoglobulins in foals. Measurement of low to undetectable concentrations of IgM at >4 weeks of age provides a reasonable means of diagnosing the disease.<sup>6</sup>

**NECROPSY FINDINGS**

Gross lesions include pale bone marrow, small thymus and lymph nodes, pneumonia, and pseudomembranous glossitis. The underlying disease is characterized by lesions in bone marrow and lymphoid tissue. Bone marrow has evidence of abnormal hemopoiesis with an elevated myeloid:erythroid ratio. Lymph nodes

have sparse to moderate numbers of lymphocytes in cortices and paracortices. The thymus has no clear demarcation of cortex and medulla and the thymic lobules are small.<sup>1,2</sup> Germinal centers are not present in the spleen and the red pulp is markedly contracted and contains siderophages. Ganglionopathy reported in foals in the original report of the disease has not been found in subsequent cases.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of immunodeficiency in foals is provided in Table 35.1.

Table 35.1 Defects of acquired immunity causing disease in foals and horses

Disease	Etiology	Epidemiology and clinical signs	Diagnostic confirmation	Treatment and prevention
Failure of transfer of passive immunity	Failure of mare to produce adequate quantities of colostrum with specific gravity >1.060; prepartum loss of colostrums; failure of foal to ingest or absorb colostrum	<i>Epidemiology:</i> Most common immunodeficiency of foals. Affects 5–35% of foals. Rate is reduced by good management. <i>Clinical signs:</i> Bacterial infections including bacteremia, septicemia, pneumonia, diarrhea, or septic arthritis/osteomyelitis develop between 2 days and 4 weeks of age.	Measurement of foal blood or serum concentrations of immunoglobulin >18 hours after birth. Concentration should be >800 mg/dL (8 g/L).	<i>Treatment:</i> Administration of plasma (20–40 mL/kg) IV. <i>Prevention:</i> Check colostrum specific gravity at foaling. Ensure foal nurses mare within 3 hours of birth. Supplement with banked colostrum. Routinely measure foal serum IgG at 18–24 hours of age.
Severe combined immunodeficiency of Arabians	Failure of V(D)J recombination secondary to a defect of the catalytic subunit of DNA-protein kinase coded for by the DNA-PKcs gene.	<i>Epidemiology:</i> Restricted to Arabians. Autosomal inheritance <i>Clinical signs:</i> Adenoviral pneumonia or diarrhea develop after ~ 4 weeks of age.	Severe lymphopenia (<1 × 10 <sup>9</sup> cells/L); no IgM in presuckle serum sample or sample collected at 4–5 weeks of age; histologic demonstration of lack of lymphoid tissue. Confirmation by demonstration of homozygosity for the abnormal DNA-PKcs gene.	<i>Treatment:</i> None. <i>Prevention:</i> Identification and removal of carrier animals from the breeding population.
IgM deficiency	Unknown.	<i>Epidemiology:</i> Arabian or Quarter horse foals 2–8 months of age. <i>Clinical signs:</i> Pneumonia, septic arthritis, or enteritis.	Low to undetectable serum IgM concentrations with normal to elevated concentrations of other immunoglobulins.	<i>Treatment:</i> None specific. Symptomatic treatment. Rare foal reported to recover. <i>Prevention:</i> None
Fell pony syndrome	Unknown, likely heritable genetic defect.	<i>Epidemiology:</i> Fell Pony foals <4 months of age. <i>Clinical signs:</i> Depression, fever, diarrhea, anemia, and pneumonia in foals <4 months of age.	No single confirmatory test. Presence of disease refractory to treatment in a Fell pony foal with anemia, lymphopenia and, after 4 weeks of age, low IgM concentration, is strongly suggestive. Histologic examination of bone marrow and lymphoid tissues.	<i>Treatment:</i> None effective. <i>Control:</i> Unknown pending elucidation of transmission.
Agammaglobulinemia	Unknown. Suspect sex-linked heritable defect	<i>Epidemiology:</i> Male foals. Sporadic. <i>Clinical signs:</i> Chronic infections develop at >2 months of age (corresponds with declining colostrum immunity).	Low to absent concentrations of all immunoglobulin classes in serum. No B lymphocytes detectable in blood. Normal concentrations of T lymphocytes.	<i>Treatment:</i> None specific. Supportive and symptomatic but all affected foals die. <i>Prevention:</i> None.
Common variable immunodeficiency <sup>8,9</sup>	Unknown in horses	<i>Epidemiology:</i> Adult horses. Sporadic. Either sex. <i>Clinical signs:</i> Chronic or recurrent infections unresponsive to medical treatment. Meningitis. Liver disease can occur in combination with CVI.	Low to undetectable concentrations of IgG, IgG(T), IgM, and IgA in serum. No or few B lymphocytes in blood or lymph nodes. Elevations in serum markers of liver disease.	<i>Treatment:</i> None specific. Affected animals die because of the opportunistic infections. <i>Prevention:</i> Prolonged antimicrobial administration of affected horses.

### CONFIRMATION OF DIAGNOSIS

The disease is confirmed by presence of characteristic lesions at necropsy. Antemortem diagnosis is confounded by the presence of opportunistic infections, but should be suspected in any Fell pony foal with anemia, ill-thrift, and declining serum concentrations of immunoglobulin.

### TREATMENT

There is no effective treatment. Supportive treatment of transfusions of blood or plasma, and administration of antibiotics does not affect the eventual outcome of the disease.

### CONTROL

There are no control measures for the disease pending determination of the nature of its genetic transmission. Should the presumed autosomal recessive inheritance be demonstrated, then identification of carriers and elimination of these animals from the breeding population will permit control of the disease.

## Inherited defects of the alimentary tract

### INHERITED DEFECTS OF THE MOUTH AND JAW

Harelip in cattle often has a distinct familial tendency but little work appears to have been done on the mode of inheritance. An apparently inherited harelip combined with poor growth and accompanying cryptorchidism is recorded in Holstein-Friesian cattle. Bilateral cleavage of the lip which also involves the maxilla is recorded in Texel sheep as being conditioned by a single recessive autosomal gene.

Cleft palate is inherited as a simple recessive character in Hereford and Charolais cattle, concurrent with arthrogryposis in the latter, and is commonly thought to be inherited in sheep and pigs. The progeny of a commercial swine herd (Landrace x Duroc) and Large White Boar contained a number of piglets with cleft palates.<sup>1</sup> Chromosomal analysis of affected piglets found all had identical unbalanced karyotype with partial monosomy of

chromosomes 16 and partial trisomy of chromosome 3, compared to normal piglets in the litters with balanced karyotypes.

Jaw deformity. Shortness of the maxilla is thought to be inherited in Jersey cattle and Large White pigs, sometimes in association with chondrodysplasia. Shortness of the mandible is also inherited in cattle, in Angus in combination with cerebellar hypoplasia and osteopetrosis.

Smooth tongue (epitheliogenesis imperfecta linguae bovis). A defect of Holstein-Friesian and Brown Swiss cattle, this condition is inherited as an autosomal recessive factor. The filiform papillae on the tongue are small, there is hypersalivation and poor hair coat, and the calves do not fare well. The heterozygote is normal.

Tongue aplasia. Congenital absence of the median part of the tip of the tongue occurs rarely in piglets, often in association with cleft palate and/or harelip.

Rectal prolapse may be inherited in piglets as a result of agenesis of the anal sphincter (see below).

### INHERITED RECTOVAGINAL CONSTRICTION

The defect is inherited in Jersey cattle and is manifested as stenosis of the rectum in either sex and stenosis of the vaginal vestibule in females. The tone of both rectal and vaginal sphincters is increased but attempts to detect heterozygotes by electromyographic measurement of these tones have been unsuccessful.<sup>2</sup> The defect is regulated by an autosomal recessive gene. Affected cows are difficult to inseminate and have difficulty in calving. Their udders are small and hard and productivity is low. The condition is due to the presence of bands of non-elastic fibrous tissue. Edema of the udder is also a common complication. Some assistance in the identification of affected animals is available by the detection of collagen type II in muscle biopsies. 50% of heterozygotes also test positively, and so do a small percentage of normals.<sup>3</sup>

### HEPATIC LIPODYSTROPHY IN GALLOWAY CALVES

Hepatic lipodystrophy has been reported occurring in Galloway calves on 5 farms in the UK over a 10-year period.<sup>4</sup> Calves appear normal after birth but die by 5 months of age. Clinically there is tremor, opisthotonus, and dyspnea before affected calves become recumbent and die. At necropsy the liver is enlarged, pale and mottled. Histologically there is evidence of hepatic encephalopathy. The cause is unknown, but limited evidence suggests a storage disease is possible.

### INHERITED ATRESIA OF ALIMENTARY TRACT SEGMENTS

**Anal sphincter atresia** occurs rarely in piglets, causing rectal prolapse.

**Atresia ani** occurs quite commonly in pigs, sheep, and, to a less extent, in cattle. Affected animals may survive for up to 10 days and are identified by their depression, anorexia, colic, marked abdominal distension and lack of feces, feces being replaced by thick white mucus.<sup>1</sup> Abdominal distension in utero occasionally causes dystocia.<sup>2</sup> Surgical repair is possible in some cases but in others a large segment of rectum is missing and creation of a colonic fistula in the inguinal region is necessary. The condition is thought to be inherited in pigs and calves but supporting evidence is slim: the evidence is less clear still in sheep. A suggestion that the defect may be also associated with the manipulation of the fetus during pregnancy examination has not been supported.<sup>2</sup> A calf with atresia ani and diphallus and separate scrota has been described.

Inherited **atresia coli**, with complete closure of the ascending colon at the pelvic flexure, has been recorded in Percheron horses. A clinically similar defect in Overo horses, described in the section on pseudo-albinism, is in fact an aganglionosis. Death occurs during the first few days of life. The defect appears to be inherited as a simple recessive character.

Inherited **atresia ilei** has been recorded in Swedish Highland cattle. Affected calves manifest marked abdominal distension causing fetal dystocia. The distension is caused by accumulation of intestinal contents. Inheritance of a single recessive gene conditions the occurrence of the defect in some species and breeds but the prevalence may be higher than would be expected with that form of inheritance, especially in Jersey cattle with atresia coli.

## Inherited defects of the circulatory system

### BOVINE HEREDITARY DILATED CARDIOMYOPATHY

Bovine hereditary dilated cardiomyopathy is a group of progressive degenerative diseases of the myocardium causing conges-

tive heart failure.<sup>1</sup> At least three different types have been reported: dilatated cardiomyopathy in cattle of Canadian Holstein origin; cardiomyopathy in Japanese Black cattle; and, cardiomyopathy in Hereford cattle.

Pedigree analysis of 75 animals in three age classes and five diagnostic classes based on clinical and pathological findings using the Pedigree Analysis Package provided strong evidence for autosomal recessive inheritance of a single major gene responsible for the disease.<sup>2</sup> Pedigree analyses of affected animals in Canada, Japan, and Switzerland, revealed that the Holstein bull 'ABC Reflection Sovereign', the son of Canadian Holstein sire Montwick Red Apple Sovereign, as the common ancestor.<sup>2</sup> The disease in cattle is being used as a research model of human dilated cardiomyopathy.<sup>3</sup> Using proteomic analysis, the examination of tissue from younger that are genetically diseased but have not yet developed clinical disease, a number of proteins have been identified whose abundance is altered significantly to suggest a possible pathogenetic mechanism for the onset of the disease.<sup>3</sup>

The disease has now been reported in Denmark in the Red Danish Dairy breed, Holsteins, and Red Holsteins.<sup>1,4</sup> Pedigree analysis of 12 cases found both maternal and paternal relationship to the Canadian sire Monwick Red Apple Sovereign, and several sires were identified as carriers of the disease. These sires originated from breeding lines used to upgrade Danish cattle populations and pose a potential animal health problem. The introduction of the defect into the Danish cattle population is an example of how widespread a genetic disease can become in a short period of time. During their active life, two sires used for artificial insemination obtained a total of approximately 62 000 living progeny.

There can be a high incidence in certain herds, possibly associated with some unrecognized environmental precipitating factor but probably caused by autosomal recessive trait concentrated by a high coefficient of inbreeding.

There are three types recorded in cattle:

#### **Type 1 calf – acute heart failure**

Sudden death of Poll Hereford and horned Hereford<sup>5</sup> calves up to 3 months of age may be due to inherited cardiomyopathy. The calves are often identifiable before death by their very rapid growth rate, short curly coat, and moderate bilateral exophthalmos. Death is usually precipitated by stress or exercise and is characterized by dyspnea, the passage of bloody froth from the nose, and a course of a few minutes to a few hours. Less acute cases have a syndrome

of congestive heart failure for several days before death. Life expectancy is less than 6 months. At necropsy there is an obvious patchiness of the myocardium, reminiscent of a bad case of white muscle disease. The disease appears to be conditioned by a single autosomal recessive gene.

#### **Type 2 calf – pulmonary edema**

A second form of inherited cardiomyopathy is recorded in Japanese Black cattle. Death is preceded by a brief period (a few minutes to a few hours) of agonizing dyspnea in calves aged 30 up to 120 days. At necropsy there is edema, ascites, hydrothorax, and marked dilatation of the left ventricle. This is matched by acute myocardial necrosis. A new autosomal recessive gene is credited with initiating the disease.

#### **Type 3 – young adult congestive heart failure**

This occurs in young adult cattle and has been reported in Holstein-Friesian cattle in Japan, Canada, the UK,<sup>6,7</sup> and Australia,<sup>8</sup> and in Simmental-Red Holstein crossbred<sup>9</sup> cattle and Black Spotted Friesian cattle in Switzerland. Similar family lines in Holstein breed have been identified in affected cattle in all three countries and it has been suggested that there is an inherited predisposition to cardiomyopathy in the Holstein breed.<sup>8</sup> Pedigree analysis of hereditary dilatated cardiomyopathy in Holstein-Friesian cattle in Japan suggests an association with hereditary myopathy of the diaphragmatic muscles.<sup>10</sup> The disease is endemic in Switzerland, occurring mainly in the Simmentaler x Red Holstein crossbreed of cattle.<sup>3</sup>

The disease occurs in cattle from 1.5 to 6 years of age with the peak prevalence in 3- and 4-year-old cattle. The stress of pregnancy and lactation may precipitate clinical disease and the majority of cases occur in late pregnancy or early lactation. The onset is sudden and the majority of cases have signs of congestive right heart failure. Edema of the submandibular area, brisket, ventral abdomen, and udder is prominent and there is venous engorgement, hepatomegaly, interstitial nephritis, pleural and pericardial effusion, and ascites. Muffling of the heart sounds, tachycardia, and a gallop rhythm are evident on auscultation of the heart. There is no characteristic biochemical or hematological change.<sup>7</sup>

Necropsy findings include congestive heart failure and histological findings compatible with congestive cardiomyopathy. There is dilation of the chambers of the heart, thickening or thinning of the ventricular wall, subcutaneous, mesenteric and pulmonary edema, hydrothorax, hepatomegaly, and ascites. Histologically there is fibrosis, myocardial degeneration, and vacuolation of cardiomyocytes and infil-

tration of mononuclear cells into the myocardium. In some cases, interstitial non-suppurative nephritis is present.<sup>7</sup> Electron microscopically, the sarcoplasm of the hypertrophic fibers is filled with fine structures of low electron-density, together with thin filamentous material, suggesting myofibrillar lysis.<sup>10</sup>

Following introduction of an eradication program based on culling of carriers in the sire population, the incidence in Switzerland has decreased.<sup>1</sup>

#### **INHERITED LYMPHATIC OBSTRUCTION**

This defect has been recorded in Ayrshire and Hereford<sup>1</sup> calves. Males are more often affected than females; it has been suggested that some affected females may not be detected. The defect is inherited as a single, autosomal recessive character, with variable expressivity and incomplete penetrance.

The outstanding clinical feature is edema, the degree varying from slight to severe; severe cases causing dystocia to the point where embryotomy or cesarean sections is necessary. Some mortality occurs among the dams. Many calves are dead at birth and those born alive may be reared but the edema persists. Before parturition the cow may show evidence of hydrops amnii and have difficulty in rising. In calves the edema may be generalized or, more commonly, be localized to the head, neck, ears, legs, and tail. Drooping of the ears caused by increased weight is characteristic, and accessory lobes are commonly situated behind and at the base of the ears.

The edema is caused by a developmental abnormality of the lymphatic system. The lymph nodes are small and contain cystic dilatations and the lymphatic vessels are enlarged, tortuous, and dilated. Edema of the subcutaneous tissues and body cavities varies in degree; the skin is usually thickened and there is edema of the stomach wall.

## INHERITED VENTRICULAR SEPTAL DEFECT

Ventricular septal defects are common in food animals; reports of their occurrence in lambs and Hereford cattle suggest that the condition can be inherited.

## INHERITED AORTIC ANEURYSM

An inherited defect of the abdominal aorta, resulting in a high mortality from intra-abdominal hemorrhage, has been observed in an unidentified breed of cattle in Holland, and is an important feature in Marfan syndrome of humans.

## BOVINE MARFAN SYNDROME

A model of human Marfan syndrome, this disease of cattle is an autosomal dominant disorder caused by mutations in the fibrillin-1-gene.<sup>1</sup> It is manifested primarily by cardiovascular lesions and signs, but lacks the skeletal abnormalities of the human disease.<sup>2</sup> Necropsy lesions include aortic and pulmonary artery aneurysm, with consequent cardiac tamponade in some cases. Fragmentation of elastic laminae in the vessels is also characteristic.<sup>3</sup>

## INHERITED CONGENITAL PORPHYRIA

### Synopsis

A congenital defect of porphyrin metabolism in cattle and swine characterized by excessive excretion of porphyrins in urine and feces and deposition of porphyrins in tissues, especially bones and teeth. Photosensitization occurs in affected cattle.

## ETIOLOGY

Congenital porphyria is similar to erythropoietic or Gunther's porphyria of humans. Most cases in cattle are due to the inheritance of a single recessive factor, heterozygotes being clinically normal. A deficiency of uroporphyrinogen III co-synthetase results in the accumulation of porphyrin type I isomers. Although there is no strict sex linkage in the mode of inheritance, the incidence is higher in females than in males. In pigs the pattern of inheritance is uncertain but may be due to one or more dominant genes.

## EPIDEMIOLOGY

**Porphyria** is recorded only in cattle and pigs. Shorthorn, Holstein, Black and White Danish, Jamaica Red and Black cattle, and Ayrshires carry the defect.

There are no serious losses except that affected cattle suffer from incapacitating photosensitization when exposed to sunlight and must be kept indoors. In countries where sunlight hours are limited the disease may go unnoticed. Affected pigs appear to suffer little harm. Porphyria is of little economic importance because of its rarity.

## PATHOGENESIS

The porphyrins are natural pigments but in these diseases they are present in larger than normal concentrations in the blood, urine, and feces. In porphyria the metabolic defect is one of abnormal synthesis of heme due to an enzymatic insufficiency at the stage of conversion of pyrrol groups to series 3 porphyrins. Excess series 1 porphyrins, physiologically inactive substances are produced as a result, and there is flooding of the tissues with these coloring and photosensitizing substances. The high tissue levels of porphyrins sensitize the skin to light and photosensitive dermatitis follows.

## CLINICAL FINDINGS

In **cattle** the passage of amber to port wine colored urine, a pink to brown discoloration of the teeth and bones, and severe photosensitization are characteristic. Additional signs include pallor of the mucosae and retardation of growth.

Affected **pigs** are usually normal and photosensitivity does not occur, but the disease can be recognized by the red-brown discoloration of the bones and teeth, which is present even in the newborn.

## CLINICAL PATHOLOGY

In porphyria the urine is amber to port wine in color when voided, due to the high content of porphyrins. The urine of affected cattle may contain 500–1000 µg/dL of uroporphyrins and 356–1530 µg/dL of coproporphyrins. The urine of normal cattle contains 1.84 µg/dL of coproporphyrins and no significant quantity of uroporphyrins. The color of the urine darkens to brown on exposure to light. Spectroscopic examination is necessary to identify the pigment as porphyrin. Erythrocyte survival time is reduced considerably. A macrocytic, normochromic anemia occurs and its severity appears to be related to the level of uroporphyrins in the erythrocytes, and there is evidence of a hemolytic anemia. Cattle with the highest erythrocyte uroporphyrin levels are also the most sensitive to sunlight.

## NECROPSY FINDINGS

In porphyric animals the teeth and bones are stained brown or reddish purple, the pigment occurring chiefly in the dentine in teeth and often in concentric layers in the bones. Affected bones and teeth show a red fluorescence under illumination with

ultraviolet light. The histological findings are unique to this disease.

## DIFFERENTIAL DIAGNOSIS

Confirmation of the diagnosis depends on identification of greatly increased levels of porphyrins in the blood and urine. Presumed affected cattle and pigs can be detected at birth by the discoloration of the teeth. Breeding trials are necessary to detect heterozygous, normal carrier animals.

Differential diagnosis list. Other causes of photosensitive dermatitis.

## TREATMENT

Non-specific treatment for photosensitization may be necessary. Affected cattle should be reared indoors.

## CONTROL

Elimination of affected carrier animals from the breeding program is the only measure available. Periodic examination of the urine and feces for excessive quantities of coproporphyrin is carried out on bulls used for artificial insemination in breeds in which the disease occurs.

Franco DA et al. Bovine congenital erythropoietic porphyria. Comp Cont Educ 1992; 14:822–825.

## INHERITED ERYTHROCYTIC PROTOPORPHYRIA

Inherited erythrocytic protoporphyria is an autosomal recessive disease which occurs in Limousin<sup>1</sup> and Blonde d'Aquitaine<sup>2</sup> cattle. It is similar to the same disease in humans and to porphyria but is milder. There is deficient activity of the enzyme ferrochelatase, resulting in excessive photosensitizing protoporphyrin accumulation with high levels appearing in the erythrocytes and feces. The total amount of the enzyme is normal but up to 96% of it is non-functional.<sup>3</sup>

Protoporphyria is clinically differentiated from porphyria by the absence of anemia and discoloration of the teeth and urine. The major clinical abnormality is photosensitive dermatitis affecting particularly the tips of the ears and the edges of the nostrils. There may be intense pruritus and exudative dermatitis involving the head and upper aspect of the thorax.<sup>4</sup> The hematocrit values are within normal ranges, the teeth are normochromic, and there is no fluorescence of urine; however, whole blood fluoresces under ultraviolet light.<sup>4</sup> Protoporphyrin binds to proteins that are not excreted by the kidney and thus protoporphyrin will not be detected in the urine. In a Limousin calf, the disease was characterized by ataxia, and intermittent seizures.<sup>5</sup> At necropsy

there is hepatic portal fibrosis, bile ductule hyperplasia, and swelling of parenchyma cells. Phagocytic cells in the dermis contain large heterogeneous lysosomes.<sup>6</sup> Histologically, in some cases, the earliest lesions are moderate to severe acanthosis, hyperkeratosis, and parakeratosis with dermal angiofibroplasia. There may be intercellular edema, and intraepithelial vesicles and pustules.<sup>4</sup> Elimination of affected carrier animals from the breeding program is the only control measure available.

#### HEMOCHROMATOSIS

Hemochromatosis is rare in domestic animals.<sup>1</sup> This inherited defect of iron metabolism in humans has also been observed in yearling Salers cattle in circumstances in which an inherited etiology is suggested.<sup>1,2</sup> The pattern of inheritance is uncertain because of the small number of pedigrees available from affected cattle.<sup>1</sup> Hemochromatosis occurs when inappropriately large amounts of iron are absorbed from the intestine over an extended period. The excessive accumulation of iron causes iron-induced lysosomal injury and peroxidation by free radicals, which are the two major mechanisms responsible for hepatocellular necrosis and for sequelae such as fibrosis, bile duct hyperplasia, veno-occlusive disease, and hepatic neoplasia. Unlike hemosiderosis, hemochromatosis is associated with high transferrin saturation values in serum (>60%). Clinical disease develops between 9 and 22 months of age. Animals are normal until weaning but then lose weight, develop rough hair coats, and lose incisor teeth. The skeletal changes in hemochromatosis are due to abnormal bone development.<sup>3</sup> Bone analysis reveals iron levels in affected animals may be 30 to 50 times greater than normal and decreased percent ash in the outer cortex. Periosteal dysplasia and osteopenia are responsible for the pathologic fractures and tooth loss.<sup>3</sup>

At necropsy, there is emaciation, firm dark brown livers and lymph nodes, soft bones, and brown-colored small intestine.<sup>1</sup> The major histological changes are hepatocellular siderosis and periportal bridging, and perivenular fibrosis. Heavy deposits of iron in the liver, and deposits of hemosiderin are visible in liver tissue obtained by biopsy. Hepatic iron concentrations in clinically affected cattle range

from 1500 to 10 500 wet weight (reference range for cattle = <300 g/g. Ultrastructurally, the heaviest intrahepatic deposition is in the hepatocyte. Iron in bone is associated with osteopenia.

#### FAMILIAL POLYCYTHEMIA

This inherited defect has been observed only in Jersey cattle. Attention is drawn to the presence of the disease by early calthood deaths and a clinical syndrome including congestion of mucosae, dyspnea, and poor growth. Hematologically there is marked elevation of erythrocyte count, hemoglobin concentration, and packed cell volume. The disease appears to be a primary polycythemia inherited as a simple autosomal recessive.

#### INHERITED BLEEDING DISORDERS

##### Hemophilia

**Hemophilia A** (deficiency of factor VIII, or classic hemophilia) occurs in Thoroughbred, Standardbred, Arab, and Quarter horses,<sup>1,2</sup> causing uncontrollable bleeding after injury or surgery, or spontaneously. This may be manifested by the sudden appearance of swellings over joints or the upper cervical region causing dyspnea, or into joints or body cavities causing acute hemorrhagic anemia, and blood can be aspirated from them. The platelet-dependent bleeding time is normal but the fibrin-dependent bleeding time is markedly prolonged. The defect is genetically transmitted as a sex-linked recessive trait, appearing clinically only in males.

**von Willebrand's disease** has been identified in a Quarter horse which experienced bleeding episodes and a low blood level of vWF, after a normal platelet count and negative coagulation screening tests.<sup>3</sup>

##### Bovine factor XI deficiency

Factor XI (partial thromboplastin antecedent) is involved in coagulation but animals afflicted by a deficiency of it may be clinically normal even though their whole blood clotting time is very prolonged. Others may have a severe bleeding tendency but the frequency of hemorrhagic episodes with factor XI deficiency is very low.<sup>4</sup> Heterozygotes experience minor episodes, homozygotes may have serious ones, especially neonates, which may die at birth and be classified as uncomplicated neonatal mortality. Affected cows also experience

an increase in repeat breeder problems, apparently associated with a slower luteolysis and the development of small graafian follicles.<sup>5</sup> Both males and females transmit the trait<sup>6</sup> which is inherited as an autosomal recessive.

##### Prekallikrein deficiency

Prekallikrein is necessary to activate factor XII in the coagulation process. An inherited deficiency of it is recorded in a family of Belgian horses,<sup>7</sup> as a cause of a bleeding tendency in the presence of the conventional coagulation factors. The deficiency is of the order of <1% of normal levels of 63–150%. The activated partial thromboplastin time is markedly prolonged.

##### Inherited thrombopathia

Thrombopathia causes uncontrolled bleeding in Simmental cattle.<sup>8,9</sup> Collected blood undergoes good clot retraction but platelet aggregation in response to adenosine diphosphate and collagen in a whole blood aggregation system is badly impaired. Clinical findings include epistaxis, hematuria, the sudden development of subcutaneous swellings, hemorrhagic anemia due to internal bleeding, or bleeding after external lacerations or surgery. Restriction of the problem to the Simmental breed suggests inheritance of a recessive trait. A study of the inheritance of the abnormality using embryo transfer technology and superovulating a donor cow which previously had a calf with platelet aggregation disorder found a very low incidence of the abnormality.<sup>10</sup> This suggests inheritance of the defect is not simple Mendelian recessive.

##### Afibrinogenemia (related diseases are hypofibrinogenemia, dysfibrinogenemia)

Afibrinogenemia is a rare cause of bleeding diathesis recorded in cattle, sheep, and goats, especially the newborn. Confirmation of the diagnosis and differentiation from the related diseases (above) requires sophisticated laboratory technology.<sup>11</sup>

## INHERITED ANEMIAS

### Inherited dyserythropoiesis and dyskeratosis (bovine congenital anemia, dyskeratosis, and progressive alopecia)

This disease occurs in 1–16-month old calves in some Poll Hereford families.<sup>1</sup> It is thought to be inherited as a simple autosomal recessive character.<sup>2</sup> Clinical signs commence at about 2 months of age and include skin lesions which commence on the face and neck, especially around the muzzle and along the edges of the ears, then extend in the midline down the back, then down the sides, and onto the limbs; the long hairs on the tail tip are shed.<sup>3</sup> The hyperkeratotic muzzle accumulates dust. The skin lesions comprise alopecia, with surviving hairs wiry, kinked or tightly curled, accumulations of sebum, and hyperkeratosis and marked wrinkling. The alopecia and hyperkeratotic dermatitis extend and the calves do not thrive, becoming small in stature, intolerant of exercise, susceptible to heat stress, and eventually pining away until they die or are euthanized. Histologically the skin is affected by dyskeratosis, hyperkeratosis, and orthokeratosis, and there are morphological abnormalities of the nucleus in erythroid precursors; anemia results from ineffective erythropoiesis. There is a persistent, non-regenerative anemia due to a failure of maturation of erythrocytes; the blood contains many nucleated erythrocytes, and bone marrow aspirates contain increased numbers of erythroid precursors.<sup>1</sup>

2. Steffen DJ et al. *J Hered* 1993; 84:263.
3. Vestweber JG et al. *J Am Vet Med Assoc* 1993; 203:223.

### Inherited glucose-6-phosphate dehydrogenase enzyme deficiency

A single case of this persistent hemolytic disease has been recorded in a yearling American Saddlebred colt.<sup>1</sup> The disease in humans is well recognized as an inherited defect. A similar clinical disease is recorded in Murray Grey calves in Australia.<sup>2</sup> Signs are observed first when affected calves are 3–8 weeks old. Both sexes are affected. Signs include poor growth, exercise intolerance, progressive weakness, severe jaundice, and death. There is a severe regenerative anemia, hemoglobin levels of 25–30 g/L, and an absolute nucleated erythrocyte count of  $9-18 \times 10^9/L$ .

Necropsy lesions include jaundice, a grossly enlarged, in some cases miss-hapen, greenish liver, and brown urine. Histological lesions are suggestive of a

persistent intravascular hemolysis. A series of cases of hemolytic anemia of undetermined origin, recorded in a familial pattern in horses, was characterized by high blood levels of methemoglobin.<sup>3</sup>

## Inherited defects of the urinary tract

### INHERITED NEPHROSIS (MESANGIOCAPILLARY GLOMERULONEPHRITIS)

An apparently inherited mesangiocapillary glomerulonephritis occurs in Finnish Landrace lambs less than 4 months old,<sup>1</sup> and in newborn Yorkshire pigs.<sup>2</sup> The lambs absorb an agent from the colostrum which causes an immunological response in the lamb and the deposition of immune complexes within the glomerular capillary walls. Many affected lambs are asymptomatic before being found dead. Some have tachycardia, conjunctival edema, nystagmus, walking in circles, and convulsions. Enlarged, tender kidneys are palpable, and there is severe proteinuria, low plasma albumin, hyperphosphatemia, hypocalcemia, and BUN levels greater than 100  $\mu\text{g}/100 \text{ mL}$ . Necropsy findings include pale swollen kidneys and severe vascular lesions in the choroid plexuses and the lateral ventricles of the brain. Uremia supervenes in 75% of lambs by 27 days of age. Cases also occur in crossbred lambs.

### CHRONIC INTERSTITIAL NEPHRITIS

Chronic interstitial nephritis with diffuse zonal fibrosis (CINF) occurs in Japanese Black cattle (Wagyu) as an autosomal recessive disorder leading to death prior to puberty.<sup>3</sup> Clinically there is growth retardation between 3 and 5 months of age. A genome-wide scan using micro-satellite markers in a Wagyu pedigree segregated for CINF, mapped the CINF locus to bovine chromosome 1.

### INHERITED CYSTIC RENAL DYSPLASIA

Inherited, possibly conditioned by an autosomal dominant gene, this disease occurs in lambs sired by carrier Suffolk rams out of mixed ewes. Signs include recumbency and coma by days 2–3. Abortions and stillbirths occur in the same flocks at the same time. The kidneys are enlarged and cystic.<sup>4</sup>

## INHERITED BILATERAL RENAL HYPOPLASIA

This usually lethal condition is inherited as an autosomal recessive character in Large White pigs.

## INHERITED RENAL TUBULAR DYSPLASIA

This occurs in Japanese Black cattle.<sup>5</sup> Affected calves have intermittent diarrhea at 2 months of age, are unthrifty, behave sluggishly, have a rough hair coat, and overgrown hooves from 2 to 5 months of age. There is progressive renal failure, and a high level blood urea nitrogen and serum creatinine. However, appetites are almost normal or only slightly depressed. All affected calves have been sired by the same bull and the defect is due to an autosomal recessive trait.

At necropsy there are no gross lesions of the kidneys. Histologically, there are streaky masses of renal tubules without lumens. In calves over 3 months of age, there is interstitial fibrosis surrounding the abnormal tubules. It is suggested that the genes associated with the adhesion of epithelial cells, such as adhesion molecules, extracellular matrix components, and growth factors are abnormal in animals with renal tubular dysplasia. The causative gene (*rttd*) has been mapped to chromosome 1 by linkage analysis. A part of the *paracellin-1* gene, which encodes the renal epithelial tight junction protein is contained in the deletion and this deletion can be considered to be the cause of renal tubular dysplasia.<sup>6,7</sup> A DNA specific test for this mutation has been developed.<sup>8</sup>

## INHERITED RENAL LIPOFUSCINOSIS IN DANISH SLAUGHTER CATTLE

Dark brown or black discolored kidneys ('black kidneys') have been reported as incidental findings in slaughter cattle for more than 100 years.<sup>9</sup> A pigment with characteristics similar to those lipofuscin is present in secondary liposomes in epithelial cells of the proximal tubules. Cases occurred only in Holstein cattle or the Red Danish Dairy Breed and mainly in animals aged 3 years or older. The prevalences of the abnormality were 0.44% and 2.51%, respectively. Epidemiological and genealogical analyses strongly indicate an autosomal recessive inheritance.

## Inherited defects of the nervous system

### INHERITED LYSOSOMAL STORAGE DISEASES

These are diseases in which there is a genetically determined deficiency of a specific lysosomal hydrolase enzyme causing a defective glycoprotein metabolism. As a result of the deficiency, metabolic substrates accumulate in the lysosomes. The lysosomes themselves are concerned with hydrolyzing polymeric material, which enters the vacuolar system, and converting it to monomeric units, such as amino acids, monosaccharides, and nucleotides, which can be dealt with by the better known metabolic processes.

There are other lysosomal storage diseases caused by poisonings and these are dealt with elsewhere. The best known ones are caused by poisoning with *Swainsona*, *Astragalus*, *Oxytropis*, and *Phalaris* spp. (the chronic form of that disease).

The diseases included in this section are not strictly diseases of the nervous system because the lysosomes in both **neuronal** and **visceral** sites are affected, but the effects of the disease are most obvious in terms of nervous system function.

### MANNOSIDOSIS

Mannosidosis is the best known group of the inherited lysosomal storage diseases in agricultural animals.

#### $\alpha$ -Mannosidosis

This is a lysosomal storage disease in which a deficiency of the enzyme  $\alpha$ -mannosidase results in the accumulation of a metabolite rich in mannose and glucosamine in secondary lysosomes in neurons, macrophages, and reticulo-endothelial cells of lymph nodes, causing apparent vacuolations in them. Similar vacuoles are found in exocrine cells in pancreas, abomasum, and lacrimal and salivary glands. Storage appears to be cumulative in the fetus, but after birth stored material is lost from the kidney into the urine via desquamated tubular epithelium. On the other hand, postnatal storage continues in the brain, pancreas, and lymph nodes. The disease occurs in Angus, Murray Grey, and Galloway cattle, is inherited as a simple recessive, and is recorded as occurring in the United States, Australia, and New Zealand.

**Clinically** it is characterized by ataxia, fine lateral head tremor, slow vertical nodding of the head, intention tremor, an aggressive tendency, failure to thrive, and

death or the necessity of euthanasia at about 6 months of age. These signs appear almost immediately after birth up to several months later and worsen over a period of up to 3–4 months. The signs are bad enough to require euthanasia during the first week of life in many cases.<sup>1</sup> The first sign observed is a swaying of the hindquarters, especially after exercise or with excitement. The stance becomes wide based and the gait jerky, stilted and high stepping, with slight overflexion of the hindquarters so that the animal appears to be squatting as it moves.

The nervous signs are exacerbated by excitement, diarrhea is common, and the calves are usually stunted and unthrifty. They are also aggressive and attempt to charge but are usually impeded by their incoordination. Many calves die after having shown general ill thrift and with minimal nervous signs. Death may occur due to paralysis and starvation, or to misadventure, and some calves appear to die during a 'fit' following a period of excitement. Many others are euthanized because of persistent recumbency. The nervous syndrome of mannosidosis is well known; affected calves will die. An  $\alpha$ -mannosidosis is recorded in Galloway cattle and is manifested by stillbirth, moderate hydrocephalus, enlargement of the liver and kidneys, and arthrogryposis.

### CLINICAL PATHOLOGY

Normal heterozygotes carrying genes for mannosidosis are identifiable because of their reduced tissue or plasma levels of  $\alpha$ -mannosidase. The mannosidase test for  $\alpha$ -mannosidase in goats is specific and does not cross-react with  $\alpha$ -mannosidase.

Advances in molecular biology have now led to the development of a more accurate test based on DNA technology.<sup>2</sup> DNA tests based on the PCR have been developed for the detection of two breed-specific mutations responsible for  $\alpha$ -mannosidosis.<sup>3</sup> One of the mutations is responsible for  $\alpha$ -mannosidosis in Galloway cattle. The other mutation is uniquely associated with  $\alpha$ -mannosidosis in Angus, Murray Grey, and Brangus cattle from Australia. The latter mutation was also detected in ion Red Angus cattle exported from Canada to Australia as embryos. The two breed-specific mutations may have arisen in Scotland and by the export of animals and germplasm disseminated to North America, New Zealand, and Australia.<sup>3</sup>

### CONTROL

A control program can be based on the identification of heterozygotes using the PCR based assays for detection of breed-specific mutations.<sup>3</sup> A program of screening cattle in herds which produce bulls for

sale to commercial herds should stop the spread of the disease very quickly because the number of heterozygous females in the population will be irrelevant to the continuation of the disease in the absence of affected sires.

The  $\alpha$ -mannosidosis gene prevalence is now insignificant and disease incidence has been reduced from an estimated 3000 cases/year to negligible levels.<sup>2</sup>

#### $\beta$ -Mannosidosis

$\beta$ -mannosidosis occurs in Salers cattle<sup>4</sup> and Anglo-Nubian goats<sup>5</sup> and has been recorded in a sheep. In the **cattle** some affected calves are stillborn. The remainder is euthanized forthwith because of the severity of the congenital defects.

### CLINICAL FINDINGS

All cases are affected at birth with craniofacial deformity and inability to stand. The cranium is domed and there is mild prognathism, narrow palpebral fissures, and a tough, hidebound skin. When in sternal recumbency the head is moved in a combined motion of circling and bobbing, eventually converting the calf to lateral recumbency, in which it remains until passively returned to the sternal position, where nystagmus and tremor become evident. There is no suck reflex at any time. In lateral recumbency there is opisthotonos and paddling convulsions.

### CLINICAL PATHOLOGY

The diagnosis is confirmed by a reduced level of  $\beta$ -mannosidase in the blood.

### NECROPSY FINDINGS

Include a deficiency of cerebral cortical and cerebellar substance, distended lateral ventricles, and bilateral renomegaly. The biochemical defect is one of acidic  $\beta$ -mannosidase,<sup>6</sup> and is conditioned by an autosomal recessive character. The carrier rate of the causative gene is very high in the Saler breed.<sup>7</sup>

### DIFFERENTIAL DIAGNOSIS

By the biochemical examination of ultrasound-guided fetal fluid aspiration at between 59 and 65 days of pregnancy in ewes and goat does is accurate but not without the risk of causing abortion.<sup>8</sup>

In the goats the condition is present at birth and characterized clinically by tetraplegia, tremor, deafness, and nystagmus, and an inexorably fatal termination. Additional signs include bilateral Horner's syndrome, carpal contractures, pastern joint hyperextension, thickened skin, and a dome-shaped skull. Although retinal ganglion cells are obviously badly affected, there appears to be no defect of vision.<sup>5</sup> It is an autosomal recessive defect, very similar to  $\alpha$ -mannosidosis.

## GANGLIOSIDOSES

At least five types of gangliosidosis are known to occur in humans and animals. Two have so far been identified in agricultural animals.

### GM<sub>1</sub> gangliosidosis

GM<sub>1</sub> gangliosidosis occurs in cattle and sheep. In Friesian cattle it is inherited as an lysosomal storage disease in which the activity of an enzyme,  $\beta$ -galactosidase, in nervous tissue is greatly reduced. As a result there is an accumulation of the ganglioside (GM<sub>1</sub>) in the tissue. Clinical signs of progressive neuromotor dysfunction and a reduction in growth rate appear at about 3 months of age. The growth rate is reduced, and the animal is in poor condition, blind, and has a staring coat. The neuromotor signs include lack of response to external stimuli, sluggish mastication and swallowing, hindquarter sway while walking, a wide stance, a tendency to fall, reluctance to move, stiff high-stepping gait, aimless walking, head-pressing, and convulsions. Abnormal ECG tracings are common. The blindness results from lesions in the retina and the optic nerve. Ophthalmoscopic examination of the retina is recommended as an aid to diagnosis. A positive diagnosis is made on the grounds of intraneuronal lipid storage plus reduced  $\beta$ -galactosidase activity plus identification of the stored lipid. The stored ganglioside is visible under the electron microscope as stacks and concentric whorls of lamellae. In the live animal enzyme assays are carried out on leukocytes. The enzymatic defect is also detectable in liver, skin, and leukocytes.

The disease is also present in Suffolk and Suffolk-cross sheep. Visceral and neuronal lysosomal storage are both evident but the neuronal lesion is more severe. Deficiencies of  $\beta$ -galactosidase and  $\alpha$ -neuraminidase are evident. Affected sheep become ataxic at 4-6 months old and worsen to recumbency and death in up to 2 months.

GM<sub>1</sub> gangliosidosis has been reported from England in 'Coopworth Romney' lambs closely related to a ram imported from New Zealand.<sup>1</sup>

### GM<sub>2</sub> gangliosidosis

This has been identified in Yorkshire pigs and also causes decreased growth rate, incoordination appearing after 3 months of age, gray-white spots in the retina and dark blue granules in neutrophils, and azurophilic granules in lymphocytes. A serum enzyme assay is a suitable method of detecting 'carrier' heterozygous pigs. The test is based on the amount of N-acetyl- $\beta$ -D-hexosaminidase in tissues.

## CEROID LIPOFUSCINOSIS

The ceroid-lipofuscinoses are a group of inherited storage diseases, inherited as autosomal recessive traits. They are grouped together because of common clinical and pathological phenomena related to brain and retinal atrophy, premature death, and accumulation of a fluorescent lipopigment in neurons and many other cell types within the body.

The disease is recorded in South Hampshire sheep,<sup>1</sup> Rambouillet sheep,<sup>2,3</sup> Borderdale sheep,<sup>4</sup> Merino sheep,<sup>5</sup> Nubian goats, and Devon cattle.<sup>6</sup> It resembles neuronal ceroid lipofuscinosis of humans and is not strictly a primary lysosomal disorder; it is classified as a proteolipid proteinosis, and provides a good animal model for discussing the similar disease (Batten's disease) of humans. It is inherited as an autosomal recessive trait.<sup>7</sup> Secondary lysosomes fill with subunit C of mitochondrial ATP synthase because of excessive peroxidation of polyunsaturated fatty acids.<sup>8</sup> The mechanism of the accumulation is that protein is formed which is normal for mitochondria but is misdirected so that it accumulates in the lysosome.<sup>9</sup> The brains of affected lambs grow till they are 4 months old, then they commence to atrophy.<sup>10</sup> The disease in Merino sheep is a subunit c-storing abnormality, clinically and pathologically similar to ceroid-lipofuscinosis in South Hampshire sheep.<sup>5</sup> The South Hampshire form of the disease maps to chromosome 7q13-15, which is syntenic with human chromosome 15q21-23, the site of human CLN6.<sup>1</sup>

The occurrence of a neuronal ceroid-lipofuscinosis in Borderdale sheep in New Zealand has been described.<sup>4</sup> The severity of neurodegeneration and minor differences in the ultrastructure of storage material suggests this is a different disease from other forms of ovine ceroid-

lipofuscinosis which accumulate subunit-c of mitochondrial ATP synthase.<sup>4</sup> An autosomal recessive mode of inheritance is considered probable.

**Clinical findings** include slowly progressive ataxia of the hindlimbs, commencing usually at about 4 months but possibly as late as 18 months of age, and lasting for 6 months leading to euthanasia at up to 4 years. Inability to keep up with the flock is noticed first, followed by a sawhorse stance, obvious ataxia, severe depression, and an increasing failure of the menace and pupillary light reflexes. Terminal blindness is a constant sign. Positional nystagmus, circling, and head pressing occur in some. Eating, drinking, and defecation are normal, but there is slight weight loss.<sup>11</sup>

The lesion in lambs and calves<sup>12</sup> is atrophy of the cerebrum, especially the optic cortex, with eosinophilic granulation of neurons and macrophages in the central nervous system followed by progressive retinal atrophy. There is a progressive storage of lipopigment in nervous tissue, especially retinal photoreceptors; its presence can be demonstrated by quantitative autofluorescence using a modified slit lamp microscope.<sup>11</sup> Other clinicopathological aids include lysosomal enzyme assay, organ biopsy, and computed tomography, which reveals the enlargement of the lateral ventricles of the brain resulting from cerebral atrophy.<sup>12</sup>

Neuronal ceroid lipofuscinosis has been described in three horses.<sup>13</sup> Clinically, there was developmental retardation, slow movements and loss of appetite at 6 months of age. Torticollis, ataxia, head tilt, and loss of eyesight were present at 1 year of age. There were abnormalities in posture and movements, decreased spinal reflexes, and some cranial nerve dysfunction, dorsal strabismus, and absence of the menace reflex. At necropsy, there was flattening of the gyri and discoloration of the brain. Histologically, eosinophilic, autofluorescent material in the perikarya of neurons were present throughout the brain, spinal cord, neurons of the retina, submucosa, and myenteric ganglia and in glial cells.

### GLOBOID CELL LEUKODYSTROPHY (GALACTOCEREBROSIDOSIS)

Globoid cell leukodystrophy has been identified in Poll Dorset sheep in Australia<sup>1</sup>. Incoordination in the hindlimbs progresses until the animals are tetraplegic. Only histological changes are evident at necropsy. These include myelin destruction and the accumulation of characteristic globoid cells in nervous tissue. There is greatly decreased galactocerebrosidase activity in affected tissue.

### INHERITED NERVOUS SYSTEM ABIOTROPHIES

These diseases are characterized by premature, progressive loss of nervous function due to spontaneous, late degeneration of nervous tissue. As a result most affected animals are born normal but develop signs of a progressive neurological disease that is either fatal or leads to such a serious neurological deficit that euthanasia is the only reasonable solution. In a few rare diseases the patient is abnormal at birth but worsens, and usually dies, during the neonatal period. Again there are exceptions and rare cases in calves recover completely. The genetic nature of some of the cases included may not be certain; they are included here if the evidence that they are inherited can be reasonably presumed. The lysosomal storage diseases, listed in the preceding section, are a specific group of abiotrophic diseases.

#### REVIEW LITERATURE

- de Lahunta A. Abiotrophy in animals, a review. *Am J Vet Res* 1990; 54:65-76.

### CEREBELLAR ABIOTROPHY

This disease occurs in Holstein and Poll Hereford cross<sup>1</sup> calves, pigs, and Merino sheep.

#### Cattle

In the calves ataxia appears for the first time when they are 3-8 months old. The calves are not blind but they often fail to exhibit a menace reflex. The onset of clinical signs is sudden but progression is slow or inapparent. Some become recumbent. Those that remain standing have a spastic, dysmetric ataxia, and a broad-based stance; they fall easily and have a fine head tremor.

All are strong and have good appetites. Abiotrophy, or premature aging, is evident only microscopically and consists of axonal swellings and segmental degeneration and loss of cerebellar Purkinje cells. The disease appears to be inherited, but recovery of some late cases is recorded.

#### Sheep

The disease in sheep does not appear until about 3 years of age. There is incoordination and dysmetria so that the gait is awkward and disorganized and there is frequent falling. There are also a reduced menace response, an apprehensive manner, and a wide-based stance in the hindlimbs. At necropsy there is diffuse cerebellar degeneration and severe loss of Purkinje cells.

#### Pigs

A congenital progressive cerebellar abiotrophy is also reported in piglets of the offspring of Saddleback sows and an unrelated Large White boar. The disorder behaves epidemiologically like an inherited disease conditioned by a simple autosomal recessive trait. Clinical signs include dysmetria, ataxia, and tremor at standing but not at rest. There is gradual adjustment so that the piglets can walk and stand at 5 weeks of age but by 15 weeks they are no longer able to do so. Affected pigs also have a coarse matted hair coat caused by a disproportionate number of coarse hairs to fine hairs. Histopathological lesions are confined to the cerebellum where there is a significant loss of Purkinje cells.

#### Horses

The disease is recorded principally in Arabs but occurs also in the Australian pony, which was developed from the Arab, and in the Gotland breed from Sweden. A similar clinical syndrome occurs in the Oldenberg breed but the pathological picture is quite different.

The disease may be present at birth but is often not observed until the foal is 6-9 months old. The characteristic signs are vertical head-nodding (some cases show horizontal head tremors), especially when excited, and ataxia which is most noticeable at a fast gait. It may not be evident while the foal is walking. Very badly affected foals are unable to stand or suckle at birth, less severe ones are normal until about 4 months of age when head-nodding becomes obvious. The degree of ataxia varies from slight incoordination to inability to stand. A 'goose-stepping' gait which slams the front feet into the ground occurs in some. All foals can see but there is an absence of the menace reflex in many. Nystagmus is not recorded as occurring in this disease.

Necropsy findings are limited to histopathological lesions in the cerebellum. These include widespread loss of Purkinje cells and the presence of a gliosis. There are no degenerative lesions in the spinal cord. In the similar disease in Oldenberg horses the cerebellum is often reduced in size. The disease is an abiotrophy, a premature aging of tissues.

There have been doubts about the heritability of the disease but analysis of European data confirms that it can be inherited as an autosomal recessive.<sup>2</sup>

**Familial convulsions and ataxia**, especially of Angus cattle, is an abiotrophy and on histopathological criteria belongs in this group, but because it is usually present at birth it is included, for ease of diagnosis, in the section on congenital cerebellar defects.

2. Gerber H et al. *Pferdeheilkunde* 1995; 11:423.

### CAPRINE PROGRESSIVE SPASTICITY

A possibly inherited progressive paresis of Angora goats is recorded in Australia.<sup>1</sup> Signs first appear at about 2 months of age, commencing with lethargy, followed by ataxia, then paresis progressing to sternal recumbency and eventual euthanasia. Tendon reflexes are normal but the kids have difficulty getting to their feet, especially in the hindlimbs. The gait is ataxic with frequent stumbles, and the kids are unwilling to run. At necropsy there are many large, clear vacuoles in many neurons of the spinal cord, posterior brainstem and midbrain, and degeneration of nerve fibers in the same areas and peripheral nerves.

1. Lancaster MJ et al. *Aust Vet J* 1987; 64:123.

### INHERITED NEURODEGENERATION (SHAKER CALF SYNDROME)

This is an inherited, degenerative disorder of horned **Hereford** calves. Newborn calves show severe tremor, difficulty in rising, spastic gait, and aphonia. Terminally there is spastic paraplegia. Histologically there are accumulations of neurofilaments within neurons. A similar disease in **Holstein-Friesians** occurs only in males. There are severe degenerative changes in the spinal cord with spongiform lesions and some cavitation. It has the epidemiological distribution of a sex-linked recessive mutation.<sup>1</sup>

#### REFERENCE

1. Bethlehem M et al. *Vet Q* 1992; 14:54.

### INHERITED PROGRESSIVE DEGENERATIVE MYELOENCEPHALOPATHY (WEAVER SYNDROME)

The defect is inherited in Brown Swiss cattle. It appears first in calves when they are 6 months to 2 years old with a small number more than 2 years, and is manifested by progressive bilateral hindlimb weakness and proprioceptive deficits causing difficulty in rising and a weaving, hypermetric gait, goose stepping with the forelimbs, and dragging the hindlimbs. The limb reflexes are normal. The calves are bright and alert throughout. There is a broad-based stance and finally recumbency<sup>1</sup> and, after a course of 12–18 months, inevitable euthanasia. Necropsy lesions include axonal degeneration, including spheroid formation, and vacuolation of white matter in the cerebellum and at all levels of the spinal cord<sup>2</sup> but especially in the thoracic segment.<sup>3</sup> There is some neurogenic atrophy of muscles but there is no muscular dystrophy.<sup>4</sup> The defect can be identified by examination of chromosomes.<sup>5</sup> The defect appears to be linked chromosomally with high milk yield traits.<sup>6</sup>

### INHERITED SPINAL DYSMYELINATION

Bovine spinal dysmyelination is a congenital neurological disease occurring in several national cattle breeds upgraded with American Brown Swiss cattle.<sup>1</sup> The disease was first described in Red Danish Dairy breed. In Denmark, all cases are genetically related to the ABS bull White Cloud Jason's Elegant. It is inherited as an autosomal recessive trait. Genetic mapping of the gene in cross-bred American Brown Swiss cattle to the bovine Chromosome II has been done.<sup>1</sup>

Clinically, in calves there is lateral recumbency, opisthotonos, limb extension, normal to increased reflexes and mental alertness and by dysmyelination, including axonal degeneration and astrogliosis, in spinal tracts, especially the ascending gracile funiculus and dorso-lateral spinocerebellar tracts and the descending sulcomarginal tract.<sup>2,3</sup> This is probably the same defect as spinal muscular atrophy.

### INHERITED PROGRESSIVE ATAXIA

This well-recognized disease occurs in Charolais cattle.<sup>1</sup> The first onset of signs is at about 12 months of age when the gait is seen to be stiff and stumbling, especially in the hindlimbs, and the hind toes are dragged. The ataxia may be asymmetric, and the animal cannot back up. The ataxia progresses over a period of 1–2 years. Affected animals tend to be down a lot and have difficulty in rising and posturing for urination. Urination is abnormal, being a squirting but continuous flow which soils the tail. Some affected animals nod their heads from side to side when excited. Both males and females are affected. It has been described occurring in 2-year-old Charolais steer in New Zealand.<sup>1</sup> Characteristic necropsy lesions are confined to the central nervous system and are histopathological. The white matter of the cerebellum and internal capsule contains multiple foci of oligodendroglial dysplasia. The somatic lymph nodes contain nodules of hyperplastic lymphoid follicles, some catarrh of the medullae of the nodes, and an accumulation of eosinophils.

### INHERITED SPINAL DYSRAPHISM

This is found as a congenital defect in Charolais calves, and is associated with arthrogryposis and cleft palate.

### INHERITED SPINAL MYELINOPATHY

There is a progressive spinal myelinopathy of Murray Grey cattle, similar to that seen in Charolais cattle. It is possibly genetic in origin. Some calves are affected at birth; others do not become affected until 1 year old. The syndrome is one of a progressing paresis, without significant ataxia leading to paresis and permanent recumbency. There are degenerative lesions in spinal cord, midbrain, and cerebellum. The disease is conditioned by an autosomal recessive gene.<sup>1,2</sup>

2. Edwards JR et al. Aust Vet J 1988; 65:108.

### INHERITED MULTIFOCAL SYMMETRICAL ENCEPHALOPATHY

Two forms of the disease are recorded, in **Simmentals**<sup>1</sup> and in **Limousin** and **Limousin-cross** cattle.<sup>2</sup> The **Limousin** calves are normal at birth but from about 1 month of age develop a progressive forelimb hypermetria, hyperesthesia, blindness,

nystagmus, weight loss, and behavioral abnormalities, especially aggression. The signs gradually worsen for up to 4 months when euthanasia is necessary. Necropsy lesions include brain swelling, optic chiasma necrosis, and multifocal, symmetrical areas of pallor, up to 0.5 cm diameter in the brain. These lesions show partial cavitation and multiple, pathological abnormalities especially myelin lysis and vacuolation and demyelination.<sup>3</sup> The distribution of cases suggests an inherited defect.

The disease in **Simmental** and **Simmental-cross** cattle recorded in Australia and New Zealand<sup>4</sup> also has a distribution suggesting an inherited defect. The disease is clinically similar to that in **Limousin** cattle except that affected animals are not blind and it develops later, 5–8 months; calves may survive longer, up to 12 months and, although the characteristic abnormality of gait is hypermetria, the hindlimbs are affected, not the forelimbs. Other signs observed are dullness, a swaying gait and, terminally, gradually developing opisthotonos and forelimb hypertonia in extension. Necropsy lesions are also similar to those in the **Limousins** but the distribution is in the midbrain and the entire brainstem.<sup>5</sup>

A multifocal symmetrical necrotizing encephalomyelopathy in **Angus** calves has been described.<sup>6</sup> Clinically calves exhibited ataxia, nystagmus, strabismus, muscular tremors, opisthotonos, bruxism, hyperaesthesia, tetanic spasms, and episodic convulsions at 2–6 weeks of age. Death occurred 4–7 days after the onset of clinical signs. Lesions consisted of symmetrical degenerative foci affecting the dorsal vagal motor, lateral cuneate and olivary nuclei in the medulla oblongata and occasionally in the spinal cord, substantia nigra and cerebellar peduncles. While an inherited basis for the disease is suspected, the etiology is unknown.

### INHERITED BOVINE DEGENERATIVE AXONOPATHY

Reported in **Holstein-Friesian** calves in Australia,<sup>1</sup> most affected calves are affected at birth by recumbency, hyperesthesia or depression, rigidity of limbs, tremor, especially of the head, nystagmus, apparent blindness, and the development

of opisthotonos and tetanic spasms when stimulated. At necropsy the consistent lesion is a severe, diffuse, axonal swelling and loss in the spinal cord and brainstem. The cause is unknown but the indicators point to heredity.

### **INHERITED OVINE DEGENERATIVE AXONOPATHY (NEURAXONAL DYSTROPHY)**

A heterogeneous group of diseases of genetic or acquired etiology is characterized by spheroidal swellings of axons, the result of accumulation of axoplasmic organelles including neurofilaments.<sup>1</sup>

This is reported in Suffolk, Merino, and Coopworth<sup>2</sup> sheep. An inherited defect is suspected in all three diseases.

In **Coopworths** the lambs are affected at birth but have a progressive syndrome in which cerebellar and proprioceptive signs predominate. Most die by 6 weeks of age. Large axonal spheroids are present in the spinal cord and midbrain, and there is a severe depletion of Purkinje cells in the cerebellum.

In **Suffolks** the disease does not appear until 1–6 months; signs are a gradual onset of ataxia, followed by recumbency, leading to death or euthanasia. Spheroids in central nervous system axons are characteristic, mostly in the spinal cord and cerebellum.

The disease in **Merinos** is in fine-wool sheep, is probably the same disease as that previously called **Murrurrundi disease**, and does not appear until 4–6 years of age. Most cases require to be euthanized after about 2 months but some mild cases survive for up to 3 years. The clinical signs include a wide-based stance, dysmetria of all limb movements with a pronounced hypermetria of the forelimbs resulting in frequent falling, a fine intention tremor of the head, and a diminished menace reflex. A similar disease of medium-wool Merinos, characterized by progressive posterior ataxia and degeneration of sensory tracts in thoracic segments of spinal cord, commencing after 5 months of age and terminating fatally before 2 years of age, is also recorded in Australia.<sup>3</sup> The probability is that it is also an inherited defect.

### **INHERITED SPONTANEOUS LOWER MOTOR NEURON DISEASE**

This progressive disease of Yorkshire piglets 5–10 weeks of age is presumed to be inherited.<sup>1</sup> Clinical signs include hindlimb tremor, weakness, and ataxia appearing at 2–5 weeks of age. The gait includes fetlock knuckling, short choppy steps, and a tendency to collapse after a few steps. Segmental and postural reflexes are normal. By 10 weeks there is complete hindlimb paralysis, the pig is in sternal recumbency and front limb paralysis has begun. The appetite is good and the pig is bright and alert. On necropsy there is symmetrical degeneration and loss of motor neurons in the spinal cord, in some ventral spinal nerve roots.

A lower motor neuron disease in newborn Romney lambs has been described.<sup>2</sup> Lambs are normal at birth but within 1 week they developed weakness and ataxia, which progressed until they were unable to stand. The principal histological lesions were degeneration and loss of neurons in the ventral horns of the spinal cord and brain stem, Wallerian degeneration of ventral rootlets and motor nerves, and associated denervation atrophy of skeletal muscle fibers. Large fibrillar spheroids were found in white and gray matter including nuclei in the brain stem. A similar, though not identical, disease of newborn lambs has been recorded in a Dorset Down flock affecting about 20% of lambs. They lay with hindlimbs tucked under the body and forelimbs splayed sideways.

### **INHERITED MAPLE SYRUP URINE DISEASE (BRANCHED CHAIN KETOACID DECARBOXYLASE DEFICIENCY – BCKAD)**

Calves affected by this disease may be stillborn. Live calves are normal at birth and develop signs only at 1–3 days of age. It is inherited as an autosomal recessive and occurs principally in Poll Hereford, Hereford, and Poll Shorthorn<sup>1</sup> cattle but probably occurs also in other breeds.<sup>2</sup> There is molecular heterogeneity between the breeds, and tests based on detection of the mutation could be prone to error.<sup>3</sup> Hair roots are good sources of target DNA for genotyping cattle for the mutation. This avoids the errors created by hemopoietic chimerism when blood is

used for the test.<sup>4</sup> The disease is caused by an accumulation of branched chain amino acids – including valine, leucine, and isoleucine – due to an absence of branched chain ketoacid decarboxylase.<sup>5</sup> The mutation responsible for maple syrup urine disease in Poll Shorthorns and genotyping Poll Shorthorns and Poll Herefords for the maple syrup urine disease alleles has been determined.<sup>6</sup> The mutations responsible for maple syrup urine disease and inherited congenital myoclonus are present in the Australian Poll Hereford population.<sup>7</sup>

Clinical signs include dullness, recumbency, tremor, tetanic spasms and opisthotonos, a scruffy coat, blindness, and severe hyperthermia. When held in a standing position some calves have tetanic paralysis, others have flaccid paralysis. Terminal coma is followed by death after a course of 48–72 hours. The urine smells of burnt sugar.

At necropsy there is a characteristic severe spongiform encephalopathy similar to that found in comparable hereditary aminoacidurias in humans. Final identification can be made based on the elevated ratios of branched: straight chain amino acids in nervous tissue.<sup>8</sup>

### **INHERITED CITRULLINEMIA**

This autosomal recessive disease is inherited in Australian Holstein-Friesians, USA Holsteins,<sup>1</sup> and Red Holsteins in Europe.<sup>2</sup> A previous report of a high incidence of the disease in a German Holstein herd has been refuted by a negative result in the breed in a wide-ranging survey.<sup>3</sup>

Affected calves are normal at birth but develop signs in the first week of life and die 6–12 hours after the onset of illness. The signs are depression, compulsive walking, blindness, head-pressing, tremor, hyperthermia, recumbency, opisthotonos, and convulsions. Arginosuccinate synthetase deficiency is the likely cause. Blood citrulline levels are of the order of 40–1200 times normal and the assay can be used to detect heterozygotes.<sup>4</sup> The alternative method of detecting heterozygotes is to use a polymerase chain reaction, a restriction endonuclease test designed to identify the mutation that causes the disease.<sup>5</sup> Prenatal diagnosis has been achieved by examination of cell cultures derived from amniotic fluid.<sup>6</sup>

## EQUINE DEGENERATIVE MYELOENCEPHALOPATHY

Equine degenerative myeloencephalopathy is characterized by **symmetrical, slowly progressive spasticity and ataxia** in foals and horses less than 2 years of age. The disease occurs in most breeds in North America and Europe and is reported in captive zebra and Mongolian Wild Horses in North America.<sup>1,2</sup> Neuronal dystrophy of the cuneate and gracilis nuclei is considered a form of equine degenerative myeloencephalopathy.<sup>3</sup>

The prevalence of the disease varies widely, with up to 40% of susceptible animals on a farm being affected, although the disease is usually sporadic. There is a familial predisposition to the disease apparently involving an increased requirement for vitamin E, although other factors, including housing, are contributory.<sup>4-7</sup>

The pathogenesis of the disease is unknown. Abnormal expression of integral synaptic vesicle, synaptic vesicle-associated presynaptic plasma membrane and cytosolic proteins was observed in two Arabian horses with equine degenerative myeloencephalopathy.<sup>8</sup> These proteins have a role in trafficking, docking, and fusion of neuronal synaptic vesicles, and this finding suggests that there is disruption of axonal transport in equine degenerative myeloencephalopathy.<sup>8</sup> Loss of axons leads to defects in neurological function and consequent gait abnormalities.

The clinical signs are those of a slowing progressive spinal ataxia that stabilizes when the animal is 2-3 years of age. Affected foals and yearlings have symmetrical signs that are most severe in the hind limbs, of ataxia characterized by pivoting, circumduction, truncal sway, and difficulty performing complex movements such as backing or walking with the head elevated. At rest, severely affected horses may have an abnormal posture. The cutaneous trunci reflex may be absent. Spontaneous recovery does not occur, but progression to death is unusual. Radiography and myelography of the cervical spine does not reveal evidence of compression of the spinal cord.

Serum vitamin E concentrations may be normal or low. The hemogram, serum biochemical profile, and cerebrospinal fluid analysis are normal. There are no

gross lesions on necropsy. Histological lesions include neuronal atrophy, accumulation of lipofuscin-like pigment, and glial cell proliferation.

Differential diagnoses are listed in Table 36.1. Diagnosis is achieved by exclusion of other causes, of abnormal gait without fever or disease in other body systems in horses, such as compressive myelopathy and equine protozoal myeloencephalopathy.

No treatment is curative, but vitamin E (6000 IU orally once daily) may prevent progression of signs. Supplementation of at-risk foals and yearlings with vitamin E can prevent the disease.<sup>2</sup>

## INHERITED CONGENITAL HYDROCEPHALUS

### Cattle

Congenital hydrocephalus without abnormality of the frontal bones occurs sporadically but is also known to be an inherited defect in Holstein and Hereford and possibly in Ayrshire and Charolais cattle. Two specific inherited entities have been described. In one there is obstruction to drainage of the cerebrospinal fluid from the lateral ventricles which become distended with fluid and may cause bulging of the forehead, often sufficient to cause fetal dystocia. Hereford calves with this defect have partial occlusion of the supraorbital foramen, a domed skull, and poorly developed teeth; at necropsy the cerebellum is found to be small and there may be micropthalmia and skeletal muscle myopathy. They are usually born a few days prematurely, are small in size and unable to stand or suck. In some cows the amniotic fluid is increased in volume.

Another form of inherited hydrocephalus due to malformation of the cranium and with no enlargement of the cranium has also been observed in Hereford cattle. The ventricular dilatation is not marked, and micropthalmia and cerebellar hypoplasia are not features. Affected calves may be alive at birth but are blind and unable to stand. Some bawl continuously and some are dumb. They do not usually survive for more than a few days. At necropsy there is internal hydrocephalus of the lateral ventricles with marked thinning of the overlying cerebrum. Other lesions include constriction of the optic nerve, detachment of the retina, cataract,

coagulation of the vitreous humor, and a progressive muscular dystrophy. The condition is inherited as a recessive character.

Internal hydrocephalus inherited in combination with multiple eye defects in White Shorthorns is dealt with elsewhere, as are non-inherited forms of the disease.

### Sheep

A defect comparable to the Dandy-Walker syndrome in humans and characterized by internal hydrocephalus caused by obstruction of the foramina of Magendie and Lushka occurs in several breeds of sheep, especially Suffolks,<sup>1</sup> and in cattle. Affected lambs are stillborn or die within a few hours of birth; because of the grossly enlarged cranium many cause dystocia which can only be relieved by a fetotomy.

### Pigs

Congenital hydrocephalus in Yorkshire and European pigs has been recorded. The abnormality varies from a small protrusion of dura (meningocele) to an extensive brain hernia in which the cerebral hemispheres protrude through the frontal suture, apparently forced there by increased fluid pressure in the lateral and third ventricles. The condition is thought to be inherited in a recessive manner, but exacerbated in its manifestation by a coexisting hypovitaminosis-A. An outbreak of congenital meningoencephalocele in Landrace pigs is recorded in circumstances suggesting that it was inherited.

### Horses

A Standardbred stallion sired a number of hydrocephalic foals in a pattern that suggested the inheritance of a dominant mutation in the germ line and in the form of a single locus defect.<sup>2</sup> Affected foals caused dystocia and were all stillborn.

## INHERITED PROSENCEPHALY

Recorded in Border Leicester sheep, this defect takes the form of fusion of the cerebral hemispheres and a single lateral ventricle. It is widespread in the breed in Australia<sup>1</sup> and is inherited as an autosomal recessive character. Most affected lambs are stillborn. Live ones have dyspnea due to gross shortening of the nasomaxillary region creating a severely overshot mandible and interference with sucking. Blindness, nystagmus, and recumbency are constant signs. The cerebrum and the cranial cavity are much smaller than normal.

## REFERENCE

1. Roth IJ et al. *Aust Vet J* 1987; 64:271.

## **INHERITED HYDRANENCEPHALY AND ARTHROGRYPOSIS**

The defect is recorded in Corriedale sheep, and breeding trials indicate that it is inherited as an autosomal recessive character.<sup>1</sup> Most affected lambs are found dead but facial deformity, including shortening of the mandible and distortion of the facial bones will be evident. At necropsy the predominant finding is the fixation and deformity of the joints of the limbs and vertebral column, and the almost complete absence of a cerebral cortex.

## **INHERITED CONGENITAL CEREBELLAR DEFECTS**

Several inherited cerebellar defects occur congenitally in calves, lambs, and foals. Lesions of the cerebellum may or may not be obvious. They all need to be differentiated from similar defects known to be caused by intrauterine viral infections such as swine fever, bovine mucosal disease, and bluetongue.

### **Cerebellar hypoplasia**

This occurs in Herefords, Guernseys, Holsteins, Shorthorns, and Ayrshires and appears to be conditioned by a factor inherited in a recessive manner. Most calves are obviously affected at birth. While lying down there is no marked abnormality, although a moderate lateral tremor of the neck occurs, causing a gentle side-to-side swaying of the head. Severely affected calves are blind; they have widely dilated pupils and their pupils do not react to light. Such calves are unable to stand, even when assisted, because of flaccidity of limb muscles. When less severely affected animals attempt to rise the head is thrown back excessively, the limb movements are exaggerated in force and range and are grossly incoordinated, and many calves are unable to rise without assistance. If they are placed on their feet the calves adopt a straddle-legged stance with the feet wide apart and the legs and neck extended excessively. On attempting to move, limb movements are incoordinated and the calf falls, sometimes backwards because of overextension of the forelimbs. Affected animals drink well but have great difficulty in getting to the teat or pail, attempts usually being wide of the mark. There are no defects of consciousness and no convulsions. Tremor may be evident while standing and there may be postrotational nystagmus after rapid lateral head movements. Sight and hearing are unimpaired and, although com-

plete recovery does not occur, the calf may be able to compensate sufficiently to enable it to be reared to a weaning weight. Diagnosis can be confirmed by magnetic resonance imaging.<sup>1</sup>

At necropsy the most severe defect comprises complete absence of the cerebellum, hypoplasia of the olivary nuclei, the pons and optic nerves and partial or complete absence of the occipital cortex. Less severe defects include a reduction in size of the cerebellum and absence of some neuronal elements in a cerebellum of normal size.

Although the disease is dealt with generally as an inherited one there is no firm evidence to substantiate this view, and there are sporadic, non-inherited cases in other breeds.

### **Cerebellar atrophy of lambs (daft lamb disease 1)**

This has been recorded in many sheep breeds in Britain, Corriedales in Canada and New Zealand, and in Drysdale.<sup>2</sup> Affected lambs are normal at birth but are weak and unable to rise without assistance. At 3 days of age it is obvious that there is severe incoordination of limb movement, opisthotonos, tremor, and a straddle-legged stance. At necropsy the cerebellum may be of normal size but on histological examination there is gross atrophy of cerebellar neurons. The disease appears to be conditioned by a recessive gene but not as a simple homozygous recessive. A clinically similar disease has been observed in Border Leicester lambs. There is no histopathological lesion in the cerebellum, but there are significant lesions in the cervical muscles and the nerve supply to them. The disease is inherited, most likely as an autosomal recessive trait.

### **Star-gazing lambs (daft lamb disease 2)**

An hereditary disease clinically similar to cerebral cortical atrophy has been described in newborn Leicester lambs in the UK but without histological evidence of Purkinje cell loss or reactive changes, considered the hallmark of 'cerebellar cortical atrophy'. Affected lambs exhibit 'dorsal arching of the neck with the head being pressed backwards', which has also been described as 'star-gazing'. Histological lesions are present in neck muscles and nerves but it is uncertain if these are primary or secondary.

### **Inherited ataxia of calves**

This is a true cerebellar ataxia inherited as a recessive character in Jerseys, Shorthorns, and Holsteins. Clinically the condition resembles cerebellar hypoplasia except that signs may not occur until the calves are a few days to several weeks old. At necropsy the cerebellum is normal in size

but histologically aplasia of neurons is evident in the cerebellum and also in the thalamus and cerebral cortex. An inherited condition, manifested by cerebellar ataxia which does not develop until calves are 6 weeks to 5 months old, has also been recorded but the cerebellum is small and macroscopically abnormal. Conspicuous degeneration of cerebellar Purkinje cells is evident on histological examination.

### **Cerebellar abiotrophy**

This fourth disease in this group is described under the heading of abiotrophies.

### **Familial convulsions and ataxia in cattle**

A neurological disease is recorded as being inherited in Aberdeen Angus cattle and their crossbreds and Charolais. In young calves there are intermittent attacks of convulsions, and in older animals these are replaced by a residual ataxia. The first signs appear within a few hours of birth; up to several months later there are single or multiple tetanic convulsions lasting for 3–12 hours. As these episodes disappear a spastic goose-stepping gait becomes apparent in the forelimbs and there is difficulty placing the hindlimbs. The characteristic necropsy lesion is a very selective cerebellar cortical degeneration. A proportion of cases make a complete recovery.<sup>3</sup> The epidemiology of the disease is consistent with the operation of an autosomal dominant gene with incomplete penetrance.

### **Inherited congenital spasms of cattle**

This condition has been recorded only in Jersey cattle and appears to be conditioned by a factor inherited in a recessive manner. Affected calves show intermittent, vertical tremor of the head and neck, and there is a similar tremor of all four limbs which prevents walking and interferes with standing. Although the calves are normal in all other respects, they usually die within the first few weeks of life. No histological examinations have been reported but a cerebellar lesion seems probable.

## **INHERITED SPASTIC PARESIS (ELSO HEEL)**

This disease occurs in the Holstein, Aberdeen Angus, Red Danish, Ayrshire, Beef Shorthorn, Poll Hereford, Murray Grey, and many other breeds of cattle. It has been observed in crossbred Brahman

cattle<sup>1</sup> and in an Ayrshire x Beef Shorthorn crossbred steer. The disease occurs principally in calves, with signs appearing from several weeks to 6 months or more after birth. Occasional cases are reported as developing in adult European cattle and there is one report of the occurrence of the disease in adult Indian cattle.

It has been held for a long time that the disease is inherited, and the principal argument has centered on the mode of inheritance. Attempts to determine this have shown that the rate of occurrence in planned test matings is so low that, if inheritance is involved, it can only be the inheritance of a susceptibility to the disease. It is suggested that different time appearances represent a single disease entity with varying expressivity, the late forms being affected by cumulative environmental factors. A hypothesis proposed is of a gene with increased penetrance in the homozygote, with weak penetrance in the heterozygote, acting on a polygenic basis dependent on external factors.<sup>2,3</sup> Infectious agents causing transmissible sub-acute spongiform encephalopathies interacting with trace elements such as lithium have been suggested as etiological agents but there is no evidence to support the hypothesis.<sup>3</sup>

In all forms of the disease there is excessive tone of the gastrocnemius muscle and straightness of the hock, usually more marked in one hindleg. If only one leg is affected it may be thrust out behind while the calf is walking and advanced with a restricted, swinging motion often without touching the ground. There is no resistance to passive flexion of the limb. The gastrocnemius and perforatus muscles are rigid and in a state of spastic contraction. There is a characteristic elevation of the tail. The lameness becomes progressively worse and affected animals spend much time lying down. Much body weight is lost and the animal is usually destroyed between 1 and 2 years of age.

Minor lesions described as regressive changes in the neurons of the red nucleus, in the reticular substance and the lateral vestibular nucleus are of doubtful significance, as are the observed reduction in inorganic phosphate and ascorbic acid levels in the blood and cerebrospinal fluid of affected calves. A lower CSF concentration than normal of a central neurotransmitter, dopamine, could also be an effect rather than a cause.

There are demonstrable lesions on radiologic examination of the tarsus but exhaustive examinations of muscles and tendons fail to reveal histological abnormalities. The absence of any structural lesion and the variation in intensity of the abnormality suggests that it is a functional one. The hypersensitivity of the myotic

reflex which has been observed could be such a defect.

In Europe affected animals are kept for breeding purposes, especially if they are double-muscling. They are kept for this reason because of the efficacy of the curative surgical operation of partial tibial neurectomy and in view of the high incidence of double muscling in such calves. In the Holstein breed, and several German breeds, bulls which sire affected calves have been observed to have very straight hocks and to suffer from various forms of stifle and hock lameness early in life.

Several surgical techniques including tenectomy, partial tibial neurectomy, and triple tenectomy have been described.<sup>2</sup> Partial tibial neurectomy under caudal epidural anaesthesia was done on 113 Belgian blue calves with spastic paresis.<sup>2</sup> A telephone follow-up of the owners 3 months later revealed good results in 83%; a considerable improvement in 4.4%; and severe hyperflexion of the hock necessitated early culling for slaughter; and in 8% there was little or no improvement.<sup>2</sup>

#### INHERITED PERIODIC SPASTICITY OF CATTLE

This disease has been observed in Holstein and Guernsey cattle and usually does not appear until the animals are adults. A recent report described it in a Canadian Hereford bull with an early onset between 1 and 2 years of age.<sup>1</sup> It is a particular problem in mature bulls maintained in artificial insemination centers. In the early stages the signs are apparent only on rising, the hindlimbs being stretched out behind and the back depressed. Marked tremor of the hind-quarters may be noted. Initially the attacks persist only for a few seconds but are of longer duration as the disease progresses and may eventually last for up to 30 minutes. Movement is usually impossible during the attacks. The tetanic episodes fluctuate in their severity from time to time but there is never any abnormality of consciousness. Lesions of the vertebrae have been recorded but no lesions have been found in the nervous system. Idiopathic muscle cramps have been suggested as a cause. The disease is familial and the mode of inheritance appears to be by inheritance of a single recessive factor with incomplete penetrance.

Administration of the spinal cord depressant, mephenesin (3-4 g/100 kg body weight given orally in 3 divided doses and repeated for 2-3 days) controls the more severe signs. A single course of treatment may be effective for some weeks.

#### INHERITED NEONATAL SPASTICITY

The defect is recorded in Jersey and Hereford cattle. Affected calves are normal at birth but develop signs 2-5 days later. The signs commence with incoordination and bulging of the eyes and a tendency to deviation of the neck causing the head to be held on one side. Subsequently, the calves are unable to stand and on stimulation develop a tetanic convulsion in which the neck, trunk, and limbs are rigidly extended and show marked tremor. Each convulsion is of several minutes' duration. Affected calves may survive for as long as a month if nursed carefully. There are no gross or histological lesions at necropsy. Inheritance of the defect is conditioned by a single, recessive character.

#### INHERITED CONGENITAL MYOCLONUS (HEREDITARY NEURAXIAL EDEMA)

This congenital defect of the nervous system has been reported only in Poll Hereford cattle or their crossbreds and appears to be transmitted by inheritance in an autosomal recessive pattern. A similar disease has been tentatively recorded in Peruvian Pasos horses.<sup>2</sup> At birth affected calves are unable to sit up or rise and are very sensitive to external stimuli, manifested by extreme extensor spasm, including fixation of thoracic muscles and apnea, especially if lifted and held upright. The response is one of hyperesthesia with myoclonic jerks of skeletal muscles in response to external stimuli or spontaneously.<sup>3</sup> The intellect of the calves seems unaffected, vision is normal, they drink well, and can be reared but at a great cost in time. Intercurrent disease is common and calves usually die of pneumonia or enteritis before they are 1 month old.

All affected calves have subluxations of the hip joints or epiphyseal fractures of the femoral head caused by muscle spasms in the fetus. Their gestation length is shorter than that of normal calves by 9 days.

There are no microscopic lesions in the central nervous system, but there is a biochemical defect, severe alterations in spinal cord glycine-mediated neurotransmission.<sup>4</sup> The specific and marked defect in glycine receptors and the increase in neuronal

uptake of glycine are accompanied by a change in the major inhibitory system in the cerebral cortex. It has also been shown that there is a specific and marked deficit of [<sup>3</sup>H] strychnine-binding sites in the spinal cord. The disease needs to be differentiated from two other congenital, presumed hereditary, diseases of newborn Herefords – maple syrup urine disease and 'congenital brain edema' – in which spongy degeneration of the CNS is accompanied by severe edema of the gray and white matter. These two diseases are assumed to represent those cases of congenital disease, originally bracketed with inherited congenital myoclonus, in which there was vacuolation of nervous tissue in the central nervous system.

#### INHERITED CONGENITAL POSTERIOR PARALYSIS

Two inherited forms of congenital posterior paralysis are recorded in cattle. In Norwegian Red Poll cattle posterior paralysis is apparent in affected calves at birth. Opisthotonos and muscle tremor are also present. No histological lesions have been found. The disease is conditioned by an inherited recessive factor. In Red Danish and Bulgarian Red cattle a similar condition occurs but there is spastic extension of the limbs, particularly the hindlimbs, and tendon reflexes are exaggerated. Histological examination has revealed degenerative changes in midbrain motor nuclei. Both defects are lethal because of prolonged recumbency.

An inherited posterior paralysis has been recorded in several breeds of swine in Europe. Affected pigs are able to move their hindlimbs but are unable to stand on them. They are normal in other respects. Degeneration of neurons is evident in cerebral cortex, midbrain, cerebellum, medulla, and spinal cord. The disease is conditioned by the inheritance of a recessive character. An inherited progressive ataxia is also recorded in Yorkshire pigs.

#### INHERITED CONGENITAL MYOTONIA

This disease has been observed in goats and possibly in a horse. Because of its great similarity to Thomsen's disease (myotonia congenita) of humans, affected goats have been used in experimental studies to determine the nature of the disease. There is no apparent defect of the nervous system and the condition is thought to be due to abnormality of the muscle fibers. The specific defect is thought

to be one of generalized cell membrane abnormality including muscle fibers. Affected animals run when startled but quickly develop extreme rigidity of all four limbs and are unable to move. Relaxation occurs in a few seconds and the animal can then move again. Signs are not usually present until some time after birth and may vary from day to day for no apparent reason. They tend to diminish immediately before and after parturition. Clinical signs disappear when water is withheld from affected goats for 2–3 days but reappear when drinking is permitted. The disease is inherited but the mode of inheritance is unknown.

#### INHERITED HYPOMYELINOGENESIS (CONGENITAL TREMOR OF PIGS)

Congenital tremor of pigs has a multiple etiology and some of the causes are not yet identified. For this reason the disease as a whole is dealt with in Chapter 36. The inherited diseases are noted here. There are two of them, congenital tremor type A-IV of British Saddleback pigs, and congenital tremor type A-III, a sex-linked inherited form of cerebrospinal hypomyelination of Landrace pigs. The A-IV disease is characterized by the presence of poorly myelinated axons in all parts of the central nervous system. The specific defect in A-IV is one of fatty acid metabolism. The structural abnormalities in the A-III disease have been identified; splayleg is a common accompaniment.

Both diseases are characterized by muscle tremor, incoordination, difficulty in standing, and some squealing. The A-III disease occurs only in males. Both are inherited as recessive characters.

#### EXOPHTHALMOS WITH STRABISMUS

This disease has been recorded in Shorthorn, in which it is not manifested until the first pregnancy or lactation, in Jerseys, in which it may appear at 6–12 months of age, and in German Brown Swiss.<sup>1</sup> Defective vision is the first sign and is followed by severe protrusion and anteromedial deviation of both eyeballs. The defects may get worse over a long period and appear to be inherited in a recessive manner, with relative absence of neurons in the abducens nerve.

#### REFERENCE

1. Distl O. *J Ani Breeding* 1993; 110:393.

#### FAMILIAL UNDULATORY NYSTAGMUS

This is an inherited defect of Finnish Ayrshire cattle characterized by a tremor-like, synchronous movement of the eye-

balls. The tremor has small amplitude (1–2 mm) and fast (200/min) rate and is usually vertical. It is present at all times, there is no sign of impaired vision, and the eye reflexes are normal. The condition is a blemish rather than a disease because there is no functional deficiency.

#### INHERITED IDIOPATHIC EPILEPSY OF CATTLE

Idiopathic epilepsy has been reported as an inherited condition in Brown Swiss cattle and appears to be inherited as a dominant character. Typical epileptiform convulsions occur, especially when the animals become excited or are exercised. Attacks do not usually commence until the calves are several months old and disappear entirely between the ages of 1 and 2 years.

#### FAMILIAL NARCOLEPSY

Affected horses, including Shetlands, Miniature Horses,<sup>1</sup> and Suffolks, suffer recurrent episodes of several minutes duration during which they fall and lie motionless, without voluntary or involuntary movements except respiratory and eye movements. Between episodes there is no clinical abnormality. Handling or the excitement of feeding may precipitate an attack, and a sharp blow may terminate one.

#### DODDLER CALVES

This is an inherited congenital defect in Hereford cattle produced by intensive breeding of half-siblings. It is no longer recorded. It was characterized by continuous clonic convulsions, nystagmus, and pupillary dilatation. Stimulation by touch or sound exacerbated the convulsions.

### Inherited defects of the musculoskeletal system

#### INHERITED DISEASES OF BONES

##### INHERITED OSTEOARTHRITIS

There are strong indications from field evidence that both **degenerative arthropathy**, in which the hip joint is principally involved, and **degenerative osteoarthritis**, affecting particularly the stifle joint, are inherited in cattle. In both diseases other factors, particularly nutritional deficiency and the stress of lactation, exert an

important influence on the appearance of the clinical disease, and in **degenerative arthropathy**, described in the chapter on nutritional deficiency diseases, there is no clear evidence that it is in fact inherited. On the other hand there is good evidence that osteoarthritis can be inherited, at least in Holstein-Friesian and in Jersey cattle.

In **inherited degenerative osteoarthritis**, in which the stifle joints are most severely affected, there is usually a gradual onset of lameness in both hindlimbs in aged animals of both sexes. Occasionally only one limb appears to be involved. Progression of the disease takes place over a period of 1–2 years and is evidenced by failure to flex the limb, resulting in the foot not being lifted high from the ground. Crepitation in the stifle joint can be heard and felt, the muscles of the limb atrophy, and the joints are enlarged. Movement is slow, the hindlimbs at rest are placed further forward than normal, the stifles are abducted and the feet held together. Joint fluid can be aspirated and is clear and straw-colored. Appetite and milk yield remain normal until the late stages, except in cattle running at pasture.

At necropsy there is severe osteoarthritis involving particularly the stifle, with extensive erosion of the articular cartilages, great increase in synovial fluid, and the development of many osteophytes around the edges of the articular surfaces. Less severe changes are evident in other joints. It is suggested that the disease is conditioned by the inheritance of a single autosomal recessive character.

### **INHERITED OSTEOGENESIS IMPERFECTA**

The term osteogenesis imperfecta covers a heterogeneous group of connective tissue diseases caused by quantitative or qualitative defects in Type 1 collagen.<sup>2</sup>

The disease is recorded as being inherited in Holstein-Friesian cattle and New Zealand Romney sheep.<sup>1</sup>

#### **Cattle**

It is transmitted as an autosomal dominant trait. Calves are clinically abnormal at birth with the main presenting signs being bright pink teeth and slackness of the flexor tendons on all four feet so that they are unable to stand. The calves become progressively worse to the point where they cannot walk. The full list of abnormalities in this syndrome includes smaller than normal body size at birth, a dome-shaped cranial vault, and fragility of bones, manifested by multiple fractures occurring during birth. The defect is one of connective tissue cells so that there is a faulty production of collagen and inter-

cellular cement. Radiological examination demonstrates growth-arrest lines and multiple fractures in the long bones, and thin dentine and enamel layers on the teeth which are pink because of the exposed condition of the enlarged pulp. The excessive mobility of the joints results from the small bulk of the ligaments and tendons.

A syndrome of simple bone fragility occurs in Charolais cattle and is called osteogenesis imperfecta.

#### **Sheep**

The disease in New Zealand Romney sheep<sup>2</sup> is similar to that in Holstein-Friesian cattle with additional lesions of thickness of the diaphyses and reduction in size of the medullary cavity, moderate brachygnathia inferior, subcutaneous edema, skin fragility, and a dark blue color of the sclera. It is inherited as an autosomal dominant trait, and was thought to have developed as a new mutation in the testicular cell line of the parent ram.<sup>2</sup>

### **INHERITED DWARFISM**

Most inherited food animal dwarfs are chondrodysplastic; they occur commonly only in cattle and are of two kinds, snorter dwarfs and Dexter bulldog calves.

#### **Snorter dwarfs**

Snorter dwarfs are no longer important because of successful efforts in eliminating carriers of the gene. These calves are short-legged with short, wide heads and protruding lower jaws. The mandibular teeth may protrude 2–4 cm beyond the dental pad, preventing effective grazing and necessitating hand-feeding if the animal is to survive. There is protrusion of the forehead and distortion of the maxillae, and obstruction of the respiratory passages results in stertorous respiration and dyspnea. The tip of the tongue usually protrudes from the mouth and the eyes bulge. There is some variation between affected animals in their appearance at birth. In most cases the defects are as described above but they become more exaggerated as the calf grows. In addition abdominal enlargement and persistent bloat develop. The head is disproportionately large. The calves fail to grow normally and are about half the weight of normal calves of the same age.

The predominant form of the condition appears to be inherited as a simple recessive character, although the relationship of

the 'comprest' types to the total syndrome is more complex. Heterozygotes vary widely in conformation but some of them show minor defects which may be attractive to cattle breeders who were seeking a chunkier, short-legged type of animal. For this reason, indiscriminate selection towards the heterozygote undoubtedly occurred, resulting in widespread dissemination of the character. Herefords and Aberdeen Angus are the breeds most commonly affected but similar dwarfs occur also in Holstein and Shorthorn cattle, and typical dwarf animals have been produced by mating heterozygous Aberdeen Angus and Herefords. Besides the shortness of limbs there is also a looseness of attachment of limbs and abnormal mobility of joints.

Bovine chondrodysplastic dwarfism in Japanese brown cattle is an autosomal recessive defect with the phenotype of short limbs, joint abnormality, and ateliosis.<sup>1</sup> Long bones of affected animals have insufficient endochondrial ossification with irregularly arranged chondrocyte, abnormal formation of cartilaginous matrix, and partial disappearance of the epiphyseal growth plates. The gene *LBN* is the causative gene for bovine chondrodysplastic dwarfism.<sup>1</sup> The bovine fibroblast growth factor receptor 3 (*FGFR3*) gene is not the locus responsible for the defect.<sup>2</sup>

Inherited congenital achondroplasia with hydrocephalus

First recorded as **bulldog calves** in Dexter cattle, this inherited defect has since been observed in a variety of forms in other breeds, including Jerseys, Guernseys, Holsteins, and Japanese Brown cattle.<sup>3</sup> Chondrodysplasia in the Holstein-Friesian breed sharing morphological features with the Dexter bulldog calves have been reported from the United States, the Netherlands, Great Britain, and recently in Denmark.<sup>4</sup> Dexter bulldog type calves have occurred in French and Danish Holstein calves in a familial pattern related to the sire Igale Masc, and it is likely that the genetic disorder is present in the Holstein breed worldwide.<sup>4</sup>

Characteristic features of lethal chondrodysplasia (Dexter bulldog) calves in Australian Dexter cattle include abortion, disproportionate dwarfism, a short vertebral column, marked micromelia, a relatively large head with retruded muzzle, cleft palate and protruding tongue and a large abdominal hernia.<sup>5</sup> Histological changes in limb bones are consistent with failure of endochondral ossification. Dexter chondrodysplasia is considered to be inherited in an incompletely dominant manner with the homozygous form producing the congenital lethal condition. Based on analysis of the contribution of

three obligate heterozygotes whose semen has been widely used in artificial insemination in Australia, it is estimated that the heterozygote frequency is 19% within the registered Australian Dexter herd.<sup>5</sup>

Affected calves are often aborted but some reach full term and cause fetal dystocia because of the extreme hydrocephalus. The forehead bulges over a foreshortened face with a depressed, short nose. The tongue protrudes, the palate is cleft or absent, the neck is short and thick, and the limbs are shortened. Accompanying defects are fetal anasarca and hydrops amnii in the dam.

The defect is primarily chondrodystrophy rather than achondroplasia; the nasal bones and maxillae do not grow. Hydrocephalus develops because of the deformed cranium. In most breeds the condition is inherited as a simple recessive character but a dominant form has occurred in Jerseys. The heterozygous form in Dexters is easily recognized by the shortness of the limbs. The heterozygote in other breeds is normal in appearance.

#### Miscellaneous dwarfs

Other types of dwarfs have been described and include 'comprest' and 'compact' cattle in Herefords and Short-horns and various other forms of **proportional dwarfs**. For example, in Charolais, miniature calves that are exact replicas of normal calves but weigh only 5–16 kg at birth and are born 2 or more weeks prematurely, have been recorded. Most are dead at birth or die soon after so that the condition is effectively lethal. Proportional dwarfs occur also in Simmentals.

Other forms of chondrodystrophy, including 'bulldog calves' and one which causes fatal nasal obstruction in the German Black Spotted breed of cattle, have also been recorded. In the latter there are multiple deformities of limb bones and the condition appears to be inherited due to the influence of a single recessive gene.

**Dwarf lambs** occur sporadically. The best known is the mutant **Ancon** which has appeared and disappeared three times, with one incidence in New Zealand and one in the United Kingdom. The defect is chondrodysplasia and the lambs are not viable.

### CONGENITAL OSTEOPETROSIS

This inherited defect is recorded in Aberdeen Angus calves which are still-born and undersized. The major manifestations are shortening of the mandible with protrusion of the tongue, impaction of the lower molars, a patent fontanelle, and the characteristic lesion of shortness of the long bones and absence of a marrow cavity in them. The absence of the marrow cavity, caused by defective remodeling of the bone, gives it a homogeneous shaft leading to the colloquial name of 'marble bone'. Radiographic examination makes antemortem diagnosis simple. It is considered to be an autosomal recessive trait. It is reported also in foals but there is doubt about its genetic origin in that species.

### INHERITED PROBATOCEPHALY (SHEEPSHEAD)

This defect is inherited in Limousin cattle. The cranial bones are deformed so that the head resembles that of a sheep. The accompanying defects in heart, buccal cavity, tongue, and abomasum increase the chances of an early death.

### INHERITED ATLANTO-OCCIPITAL DEFORMITY

(See Congenital defects of the nervous system).

### INHERITED AGNATHIA

Partial or complete absence of the mandibles with ventral displacement of the ears is common in sheep and is categorized as a lethal recessive because the sheep are unable to graze properly.

### INHERITED DISPLACED MOLAR TEETH

Inherited as a simple recessive character this defect usually results in the death of affected calves within the first week of life. The six premolars of the lower jaw are impacted or erupted in abnormal positions, often at grotesque angles. The mandible is shorter and narrower than normal. There is no abnormality of the incisors or upper jaw.

### INHERITED JAW MALAPPOSITION

Defective apposition of upper and lower incisors, or lower incisors and dental pad in ruminants may result in inefficient grazing and malnutrition. Abnormal protrusion of the mandible (**mandibular prognathism**) is of most importance in ruminants and there is good evidence that abnormal length of the mandible is inherited. Amongst British breeds of **cattle**

the defect is more common in beef than in dairy breeds. In Herefords and Angus the inheritance is thought to be conditioned by a single recessive gene.

**Brachygnathia**, underdevelopment of the mandible, has also been recorded in Dairy Shorthorn, Jersey, Holstein, Ayrshire, and Simmental cattle, with the defect so severe in some cases that the animals are unable to suck. In Angus brachygnathia can occur linked to a generalized degenerative joint disease, in which all joint surfaces are involved. Affected animals, detected at a few days to 4 months of age, are not viable.<sup>1</sup> Inheritance of the defect is probably conditioned by a recessive gene.

A less severe degree of **brachygnathia** has been recorded in Merino and Rambouillet **sheep**. The mode of inheritance is suggested to be by the interaction of several pairs of genes.

**Mandibular prognathism** occurs as a part of other more general defects including achondroplastic dwarfism and inherited displaced molar teeth.

**Brachygnathia** is also seen in **horses**.<sup>2</sup> The defect is present at birth but is often not apparent until much later.

### INHERITED CRANIOSCHISIS (CRANIUM BIFIDUM)

The disease occurs in a number of pig breeds, but has been shown to be inherited only in Poland China pigs and their crossbreds. There is a deficit in the cranial bones and meningoceles or encephalocèles may result. The pigs are not viable. Genetic experiments have shown the inheritance to be of a recessive character with varying penetrance.

Many single cases of cranial and spinal deformity in farm animals have been likened to the human Arnold-Chiari malformation but a specific syndrome of protrusion of the medulla oblongata and the cerebellum through the foramen magnum into the spinal canal has not been identified in a hereditary context in these species.

### INHERITED CRANIOFACIAL DEFORMITY

The defect is incompatible with life. One form in Border Leicester lambs is characterized by a variable degree of nasomaxillary hypoplasia, often associated with incomplete cerebral development with less pronounced sulci and gyri than normal. It appears to be inherited in a simple autosomal recessive mode. A similar lethal defect is recorded in Angus cattle (as brachygnathia superior) in association with generalized degenerative joint disease.<sup>1</sup>

**Cyclops anomaly** occurs sporadically without known cause, but attracts attention when it is part of an inherited, prolonged gestation syndrome when it is often the cause of the investigation being mounted.

### **INHERITED ARACHNOMELIA (INHERITED CHONDRODYSPLASIA)**

#### Cattle

This suspected inherited disease of Simmental, Brown Swiss, Italian Brown calves,<sup>1</sup> and other European breeds of cattle is manifested by excessively long, thin, distal extremities which give the calves a spidery look, hence arachnomelia. The bones are very fragile, there is curvature of the spine, foreshortening of the mandible, and associated cardiac and vascular defects. In Swiss Braunvieh cattle it is combined with arthrogryposis.<sup>2</sup> It is thought to be inherited as a simple recessive.

#### Sheep

##### *Spider lamb syndrome*

A hereditary chondrodysplasia is recorded in Suffolk and Hampshire lambs<sup>3</sup> in which the limbs are thin, disproportionately long, and have abnormal positions of the bones about the joints causing abnormalities of posture. There is also less muscle than normal. In severe cases the deformities are obvious at birth and may be lethal. In less severe cases the deformities do not become apparent until the lambs are several weeks old. The defects are readily visible in X-rays before clinical signs develop, and affected lambs can be detected in this way. The diagnostic lesion is multiple irregular islands of ossification in the upper limb joints.<sup>4</sup> Spinal deformities, especially kyphoscoliosis, and cranial deformities including a roman nose, deviation of the nose poll axis, and shortening of the mandible are observed in some lambs. Inheritance by an autosomal recessive gene with complete penetrance and variable expressivity has been established as the cause in Suffolks.<sup>5</sup> The defect is thought to be one of deficiency of an insulin-like growth factor (IGF) and IGF-binding proteins.<sup>6</sup> Differentiation from arthrogryposis-hydranencephaly is important because of the superficial similarity of the two diseases.

##### *Inherited chondrodysplasia in Texel sheep*

A chondrodysplasia resulting in a dwarfing phenotype has occurred in a Texel sheep flock as a newly recognized recessively inherited genetic disease of the Texel breed.<sup>7</sup> Affected lambs appear normal at

birth but show evidence of dwarfism, wide-based stance and exercise intolerance as early as 1 week of age. Death usually occurs within 3 months, often after developing bilateral varus deformity of the forelimbs. Some severely affected lambs die with respiratory distress, probably due to tracheal collapse. Gross and microscopic lesions of variable severity were present in the tracheal, articular, epiphyseal, and physeal cartilage. In severe cases, articular cartilage in major joints was eroded from weight-bearing surfaces. The trachea was flaccid, abnormally kinked, and had thickened cartilaginous rings and a narrow lumen. Affected sheep which survived to breeding age commonly developed severe degenerative joint disease. Histologically, chondrocyte were disorganized, surrounded by concentric rings of abnormal fibrillar material and the matrix often contained focal to coalescing areas of chondrolysis. The disease has considerable potential as a suitable model for studying various forms of therapy for human chondrodysplasia.

### **COMPLEX VERTEBRAL MALFORMATION IN HOLSTEIN CALVES**

A lethal congenital defect of the axial skeleton of purebred Holstein calves has been reported in Denmark,<sup>1</sup> the United States,<sup>2</sup> and in the UK which are not carriers of the CVM gene.<sup>3,4</sup> It is caused by a mutation in the gene *SLC35A3* coding an uridine-diphosphate-*N*-acetylglucosamine transporter. A single-base transversion of guanine to thymine has been located in the abnormal allele at position 559.<sup>5</sup> It is present in both copies of the allele and the mutation is lethal. It is a simple recessive genetic defect which requires that both the sire and the dam of an affected calf are carriers.

Most affected calves are born between day 250 and 285 of gestation. Approximately 80% of homozygous affected fetuses are aborted before gestation day 260.<sup>6</sup> Birth weights are reduced. Most affected calves are stillborn, but affected calves occasionally are born alive. Euthanasia must be performed for humanitarian reasons.

In premature, stillborn, and neonatal affected calves, the defect is characterized by congenital growth retardation, malformed vertebrae, and tetramelic arthrogryposis.<sup>1,5,7</sup> There is shortening of the cervical and thoracic parts of the vertebral column due to multiple hemivertebrae, fused and misshaped vertebrae, and scoliosis. Growth retardation and vertebral malformation are typical lesions. Malformation of the head, primarily in the form of dysplasia or palatoschisis, also occurs.

Symmetrical flexures of the carpal and joints and the metacarpophalangeal joint in combination with a slight lateral rotation of the phalanges are also present. Similar low-grade arthrogryposis are present in the pelvic limbs. Heart defects were present in 50% of affected calves (interventricular septal defects, dextro-position of the aorta, and eccentric hypertrophy of the right ventricle).<sup>1</sup>

Retrospective genotyping of affected calves according to the mutation in the *SLC35A3* gene, and there were homozygous affected, heterozygotes, and homozygous normal.<sup>5</sup> The morphological expression of the malformation is wide but certain aspects such as growth retardation, vertebral malformation, and symmetrical arthrogryposis are almost constant findings. A presumptive diagnosis of the malformation can be made in most cases based on necropsy findings combined with pedigree analysis and genotyping.<sup>5</sup> Breeding studies were carried out in Denmark using selected cows that were progeny of sires with a heterozygous genotype for the malformation, and were pregnant after insemination with semen from another sire with heterozygous malformation genotype. The number of calves born with the malformation was less than expected suggesting increased intrauterine mortality.<sup>7</sup> Fertility traits in Holsteins are severely affected by the malformation phenotype of the fetus.<sup>6</sup> If the fetus is homozygous for the malformation, 29% of the cows will abort before gestation day 100 increasing to 45% at day 150, and 77% at day 260. Non-return to service rates, frequency of calvings after the first insemination, and interval from insemination to next calving were significantly reduced by a fetal malformation phenotype.

Pedigree analysis and DNA analyses of semen from sires used for insemination have found a widely branched familial occurrence of the malformation in the Holstein breed.<sup>5</sup> The mutation in the *SCL35A3* gene has been traced to the US sire Penstate Ivanhoe Star born in 1963 and his widely used son Carlin-M Invanhoe Bell born in 1974. The malformation mutation is not restricted to

descendants of the American Holstein Friesian bull-Carlin-M Ivanhoe Bell. Through these sires and elite sires genetically related to them, the defect has been disseminated in the Holstein breed worldwide. Using a hair root sample from the dam of the calf, a DNA test is available. Testing is available on registered or registerable Holstein animals only through the Holstein Association (Holstein USA) or through one of the National Association of Animal Breeders' member AI organizations or at the Van Haeringen Laboratory, Wageningen, The Netherlands. A PCR test is being developed.<sup>8</sup>

#### INHERITED ACROTERRIASIS (AMPUTATES)

Patients affected by this deformity, e.g. 'mole' calves of the Danish Black and White breed, are characterized by shortened and malformed limbs, especially the extremities which are sometimes missing altogether. In male calves there is also hydrocephalus, hypoplasia of the mandible, and absence of part of the face. The body is edematous. Many are aborted during the latter part of pregnancy. The deformity is conditioned by a single recessive gene.

#### INHERITED REDUCED PHALANGES (AMPUTATES, ACROTERRIASIS, ECTROMELIA)

This defect has been recorded in cattle and appears to be inherited as a single recessive character. The limbs are normal down to the metacarpal and metatarsal bones, which are shorter than usual, but the first two phalanges are missing and the normal hooves and third phalanges are connected to the rest of the limb by soft tissues only. The calves are unable to stand but can crawl about on their knees and hocks.

Hereditary hemimelia. Bilateral absence of the distal half of the limb, e.g. the patella, and shortening or absence of the tibia, often accompanied by hydrocephalus, meningoceles, ventral abdominal hernia, and cryptorchidism, comprise the syndrome known as **tibial hemimelia**. It is inherited in the Galloway breed of cattle. An autosomal recessive mode of inheritance is assumed. A concerted program of eradicating the defect has been undertaken,

based on test matings and examination for defects of 90-days fetuses obtained by terminating pregnancy with prostaglandin.

Hereditary peromelia of mohair goats. This syndrome includes agenesis of the phalanges and parts of the metacarpus and metatarsus affecting one or more limbs, and an autosomal recessive mode of inheritance.<sup>1,2</sup>

Amputates. An even more serious defect, in which the mandible and all the bones below the humerus and stifle are vestigial or absent, has been reported in British, French, and German Friesians. It appears to be conditioned by the inheritance of a single recessive gene. Similar 'amputates' have been shown not to be inherited.

#### INHERITED CLAW DEFORMITY

Extra claws (**polydactylism**) and fusion of the claws (**syndactylism**) are known hereditary defects of cattle, the former in the Normandy breed and the latter in Holsteins,<sup>1</sup> Angus, Hereford, and Chianina.

**Dactylomegaly** (enlarged dew claws), often associated with syndactyly or deviation of the adjacent major digit and creating a clubfooted appearance, may be inherited in Shorthorn cattle. In most cases they cause no more than inconvenience but an association of syndactyly with susceptibility to hyperthermia is recorded, and some of these animals die of hyperthermia when subjected to high environmental temperatures.

**Adactyly** is a recorded but less well defined defect in cattle and sheep in which the hooves are absent at birth.

There is good field evidence that **corkscrew claw** or **curled toe** is an inherited defect in cattle, especially in beef breeds, but also in Holstein-Friesians. It is almost always the lateral claw which is affected; in some breeds it is more common in the hind feet, and in others it is more common in the front feet. In the affected digit the third phalanx is much smaller than normal and is narrower and longer. The soft tissue and the horn are correspondingly deformed so that the horn grows much longer and narrower and tends to curl over the sole so that the cow walks on the wall of the hoof. The claw also curls over the front of the other digit of the limb. There are often cracks in the front of the claw, originating at the coronet and causing serious lameness. All affected animals suffer gait abnormalities as they get older and heavier. Much of this is due to distortion and wear of the articular

surfaces in the companion claw which has to carry much more weight than is usual. Marked changes in the affected digit are detectable by anteroposterior radiography.<sup>2</sup>

#### INHERITED MULTIPLE EXOSTOSIS

Multiple exostosis affecting both cortical and medullary bone of the limbs and ribs has been described in Quarter horses and Thoroughbreds in the US. The lesions are visible externally but cause little apparent inconvenience. It is inherited as a single dominant autosomal gene. Restriction nuclease analysis is used to diagnose the disease.<sup>1</sup>

#### REFERENCE

1. Leone NC et al. *J Hered* 1987; 78:171.

#### INHERITED CONGENITAL HYPEROSTOSIS (THICK FORELIMBS OF PIGS)

This defect is thought to be caused by the inheritance of a simple recessive character. Affected piglets show obvious lesions at birth and, although many of them die or are destroyed immediately, a proportion of them may survive. The forelimbs are markedly enlarged below the elbows and the skin is tense and may be discolored. There is difficulty in standing and moving about, and starvation and crushing contribute to the mortality rate. There is extensive edema of the subcutaneous tissues, thickening of the bones, and roughness of the periosteum. It is thought that the primary lesion is a separation of the periosteum from the bone.

#### INHERITED RICKETS

This disease of pigs is indistinguishable from rickets due to nutritional inadequacy. The pigs are healthy at birth. Subsequently there is hypocalcemia, hyperphosphatemia, and increased serum alkaline phosphatase. The defect is a failure of active transport of calcium through the wall of the small intestine.

#### INHERITED TAILLESSNESS AND TAIL DEFORMITY

Complete absence of the tail or deformity of the appendage occur relatively commonly as a congenital defect. The condition is thought to be inherited in Holstein cattle and in Landrace and Large White pigs. It is often seen in combination with other deformities of the hind-quarters such as atresia ani and urogenital tract abnormalities.

## INHERITED DISEASES OF JOINTS

### INHERITED ARTHROGRYPOSIS (INHERITED MULTIPLE TENDON CONTRACTURE)

Inherited fixation of limb joints present at birth is recorded in many breeds of cattle especially in the Shorthorn, Charolais, Piedmont, and Swedish Dole. It is thought to be inherited as a single recessive character. There are many environmental causes of the disease, the most common of which is Akabane virus infection of early pregnancy and discussed under that heading.

#### Simple arthrogryposis

The limbs of affected calves are fixed in flexion or extension and cause dystocia due to abnormal positioning and lack of flexibility. There is no involvement of joint surfaces and the joints can be freed by cutting the surrounding tendons or muscles. There is atrophy of limb muscles and those calves which are born alive are unable to stand and usually die or are destroyed within a few days.

#### Arthrogryposis with dental dysplasia

This defect in cattle appears to be inherited in a dominant manner. The teeth are soft, fleshy, and easy to bend. There is no defect of bones or joints other than marked softness and the presence of excess cartilage at the epiphyses. There is abnormal ossification of the cartilage. The calves are of normal size, do not cause dystocia, and, although they are unable to stand because of the excessive flexibility of the limbs, they can suck. Hypostatic pneumonia usually develops and causes death of the calf.

#### Arthrogryposis with palatoschisis (SAP)

This is inherited as a simple recessive with low penetrance in pure French Charolais in France and high penetrance in 7/8 Charolais cattle in Canada, where the gene frequency is high in purebred and crossbred Charolais. Among crossbred Charolais cattle the homozygous condition is almost always markedly expressed and lethal, but a high percentage of purebred homozygous cattle show slight to no visible effect of the gene and survive. Because of the low rate of prevalence in France, attempted eradication does not appear to be economical.

In this syndrome all limbs are usually affected but the front limbs more than the hindlimbs, and the more distal joints are more rigidly fixed than proximal ones. The muscles of affected limbs are atrophic and pale in color. Histological changes in the spinal cord suggest that the muscle atrophy is neurogenic. In affected calves the gestation period may be longer than normal by an average of 2 weeks.

Arthrogryposis with multiple defects In Simmentals a combined set of defects includes arthrogryposis, often with the limbs in a wraparound position around the body, underdevelopment of the mandible, curvature of the spine, and defects of the heart and main vessels.

Arthrogryposis in other species than cattle

Inherited arthrogryposis has also been recorded in Merino and Corriedale **sheep**, and in Norwegian Landrace **pigs** in which it is thought to be inherited as a simple recessive. The Corriedale defect is associated with other lesions including brachygnathia inferior, hydranencephaly, and thoracic scoliosis. Inherited arthrogryposis in pedigree Suffolk lambs has been described.<sup>1</sup> Breeding studies using superovulation and embryo transfer were used to increase the numbers of offspring from females which were carrying the gene or genes responsible for the defect which was inherited as an autosomal recessive trait.

An inherited arthrogryposis also occurs in Norwegian Fjord **horses**. The arthrogryposis affects the hindlimbs and there are accompanying defects of polydactyly, palatoschisis, and brachygnathia in some. Most foals are unable to stand and the defect must be considered to be a lethal one.

### INHERITED MULTIPLE ANKYLOSIS

Multiple ankylosis affecting all limb joints has been recorded as an inherited congenital defect of Holstein calves. The abdomen of the dam shows marked enlargement at the 6th to 7th month of pregnancy and this may occasion some respiratory distress. Excessive fetal fluids are present and insertion of the hand per rectum is impeded by the distended uterus. Abortion during the last month of pregnancy is a common occurrence. Affected fetuses have a very short neck, ankylosed intervertebral joints, and varying degrees of ankylosis of all limb joints. The limbs are fixed in flexion and there is some curvature of the spine. Fetal dystocia always occurs and embryotomy or cesarean section is necessary to deliver the calf.

Ankylosis of limb joints combined with **cleft palate** occurs occasionally in Charolais cattle and is suspected of being inherited. **Ankylosis of the coffin joint**, developing at several weeks of age, has been reported in Simmental calves. The etiology of the condition is not clear.

### INHERITED PATELLAR SUBLUXATION

Unilateral or bilateral subluxation occurs as an inherited defect in *Bos indicus* cattle

and in water buffalo (*Bubalus bubalis*). Shetland ponies also have a predisposition and a monogenic autosomal recessive transmission is suspected.<sup>1,2</sup> There is periodic lameness with the affected limb held in rigid extension; the patella is displaced medially. If the animal shakes the limb the patella may go back into its normal position and the problem is relieved.

### INHERITED HYPERMOBILITY (LAXITY) OF JOINTS

This inherited disease is recorded only in Jersey cattle. It has assumed great importance because of the great popularity of a sire which carried the gene. There is abnormal flexure and extension of all joints but especially the hock, stifle, hip, knee, elbow, and shoulder joints. The muscles are much atrophied and the joints look very enlarged as a result. It is impossible for the calves to stand but they are bright, alert, and eat well. The limbs are so flexible that they can be bent into extraordinary positions, and almost tied in knots. A drawer sign, a displacement of the articular surfaces laterally, and produced by manual pressure, can be elicited easily and with a displacement of up to 2 cm. There are no detectable lesions in the nervous or musculoskeletal systems. Although the disease is known to be inherited as a simple autosomal recessive, it has also been seen in circumstances which preclude inheritance being the cause.

### INHERITED HIP DYSPLASIA

An inherited defective development of the acetabulum occurs in Dole horses. There is no clinical evidence of the disease at birth but osteoarthritis of the joint and disruption of the round ligament develop subsequently. For this disease in cattle see 'Degenerative joint disease'.

## INHERITED DISEASES OF MUSCLES

### GENERALIZED GLYCOGENOSIS (GLYCOGEN STORAGE DISEASE TYPE II)

Generalized glycogenosis is a glycogen storage disease of Corriedale sheep,<sup>1</sup> Shorthorn, and Brahman beef cattle which resembles Pompe's disease in humans.<sup>2,3</sup> Glycogenosis type II in Shorthorn and Brahman cattle is a lysosomal storage disease in which acidic

$\alpha$ -glucosidase is the defective enzyme. In Shorthorn cattle, glycogenosis type II is caused by a single mutation, but the initial DNA/PCR restriction enzyme test of amplicons, was occasionally compromised by inhibition of the restriction enzyme by undefined factors. This was overcome by introduction of wild and mutant allele-specific amplifications and the use of two restriction enzymes, which clarified the anomalies and provided a more accurate testing system.<sup>2</sup>

In Brahman cattle, glycogenosis type II is associated with loss-of-function alleles affecting the  $\alpha$ -glucosidase gene that differ from that in Shorthorns. There is a common mutation affecting many Australian Brahmans and a less common one affecting descendants of one imported bull. In addition, a third mutation was associated with significantly reduced  $\alpha$ -glucosidase activity, but not sufficient to cause clinical disease in the homozygous state.<sup>3</sup>

Clinical signs include poor growth, muscle weakness, incoordination of gait, and difficulty in rising. The animals become permanently recumbent. The disease is identified as a lysosomal storage disease with lesions present in skeletal and cardiac muscle, and central nervous tissue. During the course of the disease there is progressive muscular damage and acute degeneration of muscle fibers in the terminal stage. Affected Brahman calves die at 8–9 months of age and British breed cattle at over 1 year. Only histopathological lesions are evident and include extensive vacuolation and accumulations of granular material in affected tissues. Amongst the biochemical lesions are greatly diminished  $\alpha$ -glucosidase activity in liver and muscle, and a correspondingly high level of glycogen. Animals in affected herds are divisible into normal heterozygotes and homozygotes on the basis of  $\alpha$ -1,4-glucosidase activity in lymphocytes or in muscle, especially the semitendinosus muscle.

Genotyping methods using hair root and blood samples to test Shorthorn cattle for generalized glycogenosis are available,<sup>2</sup> and PCR assays have been developed to genotype Brahman cattle for loss-of-function alleles within the acidic  $\alpha$ -glucosidase gene.<sup>3</sup>

### GLYCOGEN STORAGE DISEASE TYPE V (MUSCLE GLYCOGEN PHOSPHORYLASE DEFICIENCY)

Glycogen storage disease Type V is one of a number of inherited diseases affecting glycogen metabolism and resulting in abnormal accumulation of glycogen in cells. Glycogen storage disease Type V has been recorded in Charolais cattle in North America.<sup>1</sup> As in Type II glycogenosis, Type V is inherited as an autosomal recessive trait  $\alpha$ -glucosidase. There is a deficiency of myophosphorylase, mildly elevated muscle glycogen and elevated serum creatine and aspartate aminotransferase. Severely affected animals may develop rhabdomyolysis which may be accompanied by myoglobinuria.<sup>2</sup>

In Charolais cattle, glycogen storage disease Type V is usually seen in calves at several weeks or months of age and is associated with exercise. Calves lag behind their dam or herd and may become temporarily recumbent for several minutes; with continuous exercise there are further periods of collapse and recumbency which may become prolonged. Not all homozygous animals are clinically affected if they are allowed to 'pace their exercise' and some animals have been known to breed despite muscle weakness.

A polymerase chain reaction-restriction fragment length polymorphism test has been used to identify heterozygous individuals in a Charolais herd in New Zealand that were otherwise normal.<sup>2</sup> Using a similar test, a Blonde d'Acquitaine cross-bred calf with a double-muscled phenotype and suspected of having myophosphorylase deficiency based on clinical findings of brown-colored transparent urine after exercise, pain, and an elevated creatine kinase was considered negative.<sup>3</sup>

### FAMILIAL POLYSACCHARIDE STORAGE MYOPATHY (EQUINE RHABDOMYOLYSIS SYNDROME)

This myopathy is associated with exertional rhabdomyolysis and occurs with a high incidence in some Quarter Horse, American Paint, Appaloosa, and Quarter Horse cross-bred families. An autosomal recessive pattern of inheritance is proposed.<sup>4</sup> Recurrent episodes occur at intervals of about 2 weeks. Clinical signs include exercise intolerance with prolonged recumbency in some. Discomfort varies between stiffness and pain suggestive of colic. Myoglobinuria is common during episodes of clinical illness. Serum activity of creatine kinase are elevated. Biopsy of gluteal or semitendinosus muscles reveals polysaccharide inclusion bodies in some muscle fibers and widespread sarcolemmal vacuoles. The defect is basically an error of glycolysis.

### INHERITED DIAPHRAGMATIC MUSCLE DYSTROPHY

This is an inherited defect in diaphragmatic muscle of Meuse-Rhine-Yssel and Holstein-Friesian cattle<sup>1</sup> appearing in adults and characterized by anorexia, decreased rumination, and eructation leading to recurrent bloat, dyspnea, abdominal respiration, nostril dilation, and death from asphyxia after a course of several weeks. Necropsy lesions comprise degenerative changes in diaphragmatic and thoracic muscles. The immunohistochemical evaluation of some cytoskeletal proteins of affected muscles found an increase in the amount of desmin and vimentin immunoreactivities and similar amounts of actin and  $\alpha$ -actinin compared with controls.<sup>2</sup>

### CONGENITAL MYASTHENIA GRAVIS

Congenital myasthenic syndrome has been reported in Brahman cattle in South Africa.<sup>1</sup> Affected calves develop progressive muscular weakness, beginning at birth and up to 3–4 weeks of age. Within 1 week they are unable to stand without assistance. Some calves are able to stand and walk for 30 to 45 minutes before collapsing, but are still able to suck their dams. The calves remain alert and continue sucking but may collapse after 20 to 60 seconds. The weakness becomes progressively worse and affected calves are usually euthanized. Hematology and serum biochemistry are normal, and muscle biopsies do not reveal any abnormalities.

The underlying defect is a homozygous 20-base pair (bp) deletion in the gene, muscular acetylcholine receptor (*bovCHRNE*), coding for the  $\epsilon$ -subunit of the nAChR at the neuromuscular junction.<sup>2</sup> A PCR-based DNA test, using blood or semen has been developed and validated.<sup>3</sup> The test makes it possible to differentiate rapidly and accurately between homozygous wild-type, heterozygous and homozygous affected animals. Preliminary testing of Brahman cattle in South Africa revealed several carrier animals, some of them influential in the breeding population.

## BOVINE FAMILIAL DEGENERATIVE NEUROMUSCULAR DISEASE

This disease has been reported occurring in Gelbveih cattle in several separate beef herds in the United States.<sup>1</sup> Affected animals are 4 to 20 months of age, and the mortality rate is 100%. Clinical findings include ataxia, weakness, and terminal recumbency. Gross and histological muscle lesions were indicative of nutritional muscular dystrophy with no myocardial lesions. Acute to chronic lesions in most large skeletal muscle groups consist of degeneration, necrosis, regeneration, fibrosis, and atrophy. Fibrinoid necrosis of arterioles is a common feature in multiple tissues. Lesions in the spinal cord white matter and peripheral nerves consisted of degeneration of the dorsal columns and axons, respectively. Chronic interstitial nephritis with fibrosis, hyaline droplet change, and tubular epithelial vacuolar change were most severe in older calves. Vitamin E levels were deficient in most affected calves. Pedigree analysis found a common ancestry for all but one of the affected calves. It is hypothesized that a hereditary metabolic defect, possibly involving anti-oxidant metabolism may be the causative factor.

## INHERITED UMBILICAL AND SCROTAL HERNIAS, CRYPTORCHIDISM, AND HERMAPHRODITISM

Umbilical hernias in cattle and scrotal hernias and cryptorchidism in pigs have been considered to be inherited defects for many years but the evidence is uncertain.

### Umbilical hernias

Umbilical hernias are commonly identified in dairy heifers. In 18 commercial dairy herds in New York, 15% of heifer calves had umbilical hernias during the first 3 months of age.<sup>1</sup> The economic costs of umbilical hernias include the cost of medical and surgical treatment and the loss in value for breeding animals.

It has been generally accepted that umbilical hernias may be inherited in a dominant or recessive mode. Some studies have found the risk of hernias was higher in some breeds: the incidence being much higher in Holstein cattle than other breeds such as Angus, Ayrshire, Brown Swiss, Charolais, Guernsey, Hereford, Jersey, and Shorthorn. However, factors other than genetic may be important. For example, many veterinarians have observed that umbilical infections commonly lead to umbilical hernia by slowing closure of

the umbilicus. It is unlikely that the responsible genes are sex-linked, in spite of the apparent greater incidence in females. Umbilical hernias in Holstein-Friesian cattle can also be conditioned by a dominant character with incomplete penetrance, or be due to environmental factors. In a case control study to determine risk factors associated with identification of an umbilical hernia during the first 2 months after birth in Holstein heifers, the sire and umbilical infection were associated with risk of a hernia.<sup>2</sup> Heifers born to sires with = 3 progeny with an umbilical hernia were 2.31 times as likely to develop a hernia as were heifers born to sires with = 2 progeny with an umbilical hernia. Heifers with umbilical infection were 5.65 times as likely to develop a hernia as were heifers without umbilical infection. Attributable proportion analysis found that the frequency of umbilical hernias in Holstein heifers with umbilical infection would have been reduced by 82% if umbilical infection had been prevented.<sup>3</sup>

The risk factors for congenital umbilical hernias in German Fleckvieh calves offered for sale at livestock markets were examined.<sup>4,5</sup> An umbilical hernia was defined as a palpable opening in the abdominal wall of the umbilical region >1.5 cm, even if no hernia had developed. Inflammation, abscesses or fistulae were excluded. Data from 53 105 calves were collected from 77 livestock markets over a 2-year period. The overall incidence of congenital hernia was 1.8%. The analyses found significant effects for sex of calf, birth type, age of calf at examination, market place and date, sire line, sire, and frequency of affected herdmate calves in male calves, the incidence was 2.2%, in females 1.5%. The calves varied from 3 to 8 weeks of age. The diameter of hernial openings was between 1.5 and 9 cm with 47% of affected calves with a hernia measuring greater than 3 cm. A significantly higher incidence occurred in twin or triplet calves. Shorter gestation periods increased the risk of hernias linearly by a factor of 1.3% for 10 days. There were differences in the incidence of hernias according to sire lines but the heritability estimates were low varying from  $h^2 = 0.04$  (>100 progeny) or  $h^2 = 0.05$  (>25 or 50 progeny). However, analysis of the data found no evidence for an autosomal monogenic recessive inheritance. The analyses indicated that the incidence of congenital umbilical hernia observed could not be explained by one autosomal recessive gene locus, but it seemed much more likely that more than one gene locus is involved or a mixed multifactorial monogenic mode of inheritance may be the

underlying genetic mechanism. It is suggested that the incidence of congenital umbilical hernias could be reduced if all breeding bulls are examined as calves and a veterinary certificate confirms a closed umbilical ring.

Breeders should be aware of the implications of congenital hernias and thus, congenital hernia should get more attention in the selection process of young sires.

Breeding studies and genotyping using the Canadian Holstein bull 'Glenhpton Enhancer', have provided evidence that Enhancer is the carrier of major dominant or codominant gene with partial penetrance for umbilical hernia.<sup>3</sup> Five sons of Enhancer produced progeny with >10% frequency of umbilical hernia, whereas the progeny of 3 sons had <3% umbilical hernia. Genotyping of grand-progeny found significant differences in paternal allele frequencies between the affected and unaffected progeny groups for a marker BMS1591 on bovine chromosome 8(BTA8). The umbilical hernia-associated paternal allele originated from Enhancer.

### Scrotal hernias

Scrotal hernias of pigs have also been shown to be inherited in some breeds, e.g. Duroc and Landrace, but not in others, e.g. Yorkshires.<sup>6</sup>

### Cryptorchidism

Evidence suggesting the inheritance of cryptorchidism in swine, sheep, horses, and Hereford cattle and hermaphroditism in swine is also available. Cryptorchidism in horses appears to be inherited with a polygenic pattern of transmission.

## MYOFIBER HYPERPLASIA (DOUBLE MUSCLING, DOPPELENDER, CULARD)

### EPIDEMIOLOGY

This is an inherited condition, characterized by an increased bulk of skeletal muscles due to the presence of a greater than normal number of muscle fibers; it is well known in many breeds of cattle but appears to be most common in the Charolais, Belgian Blue, Piedmont, and South Devon breeds. The condition is recorded only rarely in sheep. The mode of inheritance has not been established but heterozygotes usually show some degree of muscle hypertrophy. Many of

the muscle changes are in the direction of the current demand for lean, meaty carcasses, and there is interest, especially in Europe, in the exploitation of this anomaly for meat production. Pietrain pigs (see below) exhibit many of the characteristics of double-muscling cattle, including large muscle mass and susceptibility to stress.

### CLINICAL FINDINGS

Severely affected cattle show a marked increase in muscle mass most readily observed in the hindquarters, loin, and shoulder, an increase in the muscle:bone ratio and a decrease in body fat. Affected calves demonstrate above-average weight gains during the first year of life if well fed and managed, although mature size is somewhat reduced. Well-marked grooves along the intramuscular septa in the hindquarters are a distinguishing feature as is an apparent forward positioning of the tail head. Macroglossia, prognathism, and a tendency toward muscular dystrophy and rickets have been observed in affected calves. Electrocardiographic abnormalities have been reported.<sup>1</sup> The condition often gives rise to dystocia, possibly due to increased gestation length, and affected females are said to be less fertile than normal.<sup>2</sup> There is also a very high incidence of Elso heel in affected cattle and this interferes greatly with their economic value. Other associated defects are brachygnathia and deviation of the incisor arch and, in Belgian Blue and White cattle, greater susceptibility than normal to laryngitis and bronchopneumonia.<sup>3</sup>

### CLINICAL PATHOLOGY

Blood lactate is increased, as is susceptibility to stress. These findings are interpreted as being indicators of cell membrane fragility, which is also manifested by fragility of the erythrocytes.

### NECROPSY FINDINGS

The skin is thinner than normal, and the muscle mass is characterized by a disproportionate number of glycolytic, anaerobic fibers.

### PIETRAIN CREEPER PIGS

A progressive muscular weakness is found in stress-susceptible Pietrain pigs. The syndrome commences with muscle tremor at 2–4 weeks of age, leading to complete recumbency by 12 weeks of age. At this stage the pigs move with a creeping gait with the limbs flexed. There are no neuropathological lesions but there are myopathic changes, especially in the forelimbs.

### INHERITED PROGRESSIVE MUSCULAR DYSTROPHY

This is a primary skeletal muscle disease of sheep with a strong probability of having a genetic mode of transmission.<sup>1</sup> It is recorded in Merino flocks in Australia and is characterized by a gradually progressive failure to flex the joints of the hindlimbs commencing at 3–4 weeks of age. Eventually the limbs are rigid at all times, and running becomes impossible. The forelimbs and the head and neck are normal. Affected sheep are easily detected when they are 1 year old and will have mobility problems by the time they are 2–3 years old. At necropsy there are pale areas in skeletal muscle and sometimes the muscles of the diaphragm in those sheep which have a tendency to bloat. The histopathology and histochemistry of the muscle lesions is comparable with that of inherited muscle atrophies in humans.<sup>1,2</sup>

### INHERITED SPINAL MUSCULAR ATROPHY

A progressive ataxia, weakness, muscle atrophy, and recumbency develops in young calves, mostly during the first 2 weeks of life. Sensory functions are unimpaired. Some are already affected at birth and some may be stillborn. No new cases occur after 3 months of age. Conditioned by an autosomal recessive gene the defect occurs in Red Danish cattle which originated from Brown Swiss, and from German Braunvieh and American Brown Swiss. The primary lesion is degeneration of ventral horn cells of the spinal cord, without involvement of the brainstem or cerebellum. The visible lesion is the secondary atrophy of the denervated muscles.<sup>1,2</sup>

1. Nielsen JJ et al. *Acta Vet Scand* 1990; 31:253.
2. Dahme VB. *Neuropathol Appl Neurobiol* 1991; 17:517.

### INHERITED SPLAYED DIGITS

Recorded only in Jersey cattle, this defect appears to be conditioned by an inherited gene; probably a monogenic autosomal recessive. Lameness becomes apparent at 2–4 months of age, the toes becoming increasingly widely spread and the toes themselves misshapen. Walking and standing are painful, especially on the front feet so that some animals graze and walk on their knees. Affected animals either lie down increasingly or stay standing for very

long periods. The apparent abnormality is a defect of the muscles and ligaments holding the phalanges together.

### EQUINE HYPERKALEMIC PERIODIC PARALYSIS

#### Synopsis

**Etiology** Defect in sodium channel of skeletal muscle.

**Epidemiology** Disease of Quarter Horses and crossbreds. Inherited as an autosomal dominant trait with variable penetrance.

**Clinical signs** Episodes of muscle fasciculation, stridor, muscle weakness, and flaccid paralysis.

**Clinical pathology** Hyperkalemia during episodes. Gene probe to detect mutated gene.

**Lesions** None.

**Treatment** Palliative. Potassium-free intravenous fluids. Acetazolamide.

**Control** Selective breeding. Low potassium diet.

### ETIOLOGY

The disease is caused by a heritable defect in the sodium channel of skeletal muscle.<sup>1</sup> The mutation, of which only one form has been identified, results in substitution of a cytosine for guanine, with consequent replacement of phenylalanine by leucine in a transmembrane protein regulating sodium flux across the cell membrane and T-tubule. The disease is transmitted as an autosomal codominant with the result that homozygotes are more severely affected than heterozygotes, and phenotypic expression (disease severity) differs among heterozygotes.

### EPIDEMIOLOGY

The disease is familial and affects Quarter Horse and crossbred descendants of a single Quarter Horse sire, Impressive.<sup>2,3</sup> More than 50 000 registered Quarter Horses are related to known carriers of the disease.<sup>4</sup> Quarter Horses with the disease are presumably selected because they outperform unaffected animals in the halter classes in which they compete at horse shows,<sup>5</sup> although recent rule changes have changed this practice. The disease is occurs in breeds derived from or crossed with Quarter horses including Appaloosas, American Paint horses, and crossbreds.

The disease is inherited in an **autosomal codominant** manner.<sup>1</sup> Therefore, 50% of the offspring of the breeding of a heterozygote and a normal animal will carry the trait, as will 75% of the offspring of the breeding of two heterozygotes. Of the breeding of 2 heterozygotes, 50% of progeny will be heterozygotes, 25% homozygotes for the mutated gene, and 25% homozygotes for the normal gene.

Animals homozygous for the abnormal gene are uncommon, representing only 0.9% of animals tested for the disease.<sup>6</sup> The low prevalence of the homozygote genotype is likely a reflection of severity of disease and the reduced likelihood that homozygotic animals will reach sexual maturity.

The risk of a **heterozygous** animal being affected with periodic paralysis is variable. Most heterozygous horses appear normal and never experience an attack, while others have severe episodes starting at a young age. **Homozygous** horses are much more likely to have severe manifestations of the disease at a young age.

### PATHOGENESIS

The abnormality in the sodium channel coded for by the mutated gene predisposes the horse to episodes of complete depolarization of the muscle membrane and flaccid paralysis. The mutation in the sodium channel increases the probability that any one channel is open, with the result that the resting membrane potential in affected horses is higher (less negative and closer to the depolarization threshold) than that of normal horses.<sup>7</sup> This results in frequent depolarizations of individual muscle fibers causing muscle fasciculations. The weakness associated with severe episodes of the disease results from failure of sodium channels to close after depolarizations. Opening of potassium channels when the muscle is depolarized results in movement of potassium out of the muscle cell, and the development of hyperkalemia.

### CLINICAL SIGNS

The disease in **heterozygous** animals is characterized by periods of muscle fasciculation and tremor that progress to weakness, paralysis, and recumbency. Such episodes may last minutes to hours, and most resolve spontaneously. Horses often sweat, have prolapse of the third eyelid, and contraction of facial and locomotor muscles during episodes. Episodes may be mistaken for colic. Inspiratory stertor commonly noted during episodes is probably due to laryngeal and pharyngeal dysfunction.

Episodes are more frequent and severe in **homozygous** animals and signs of **laryngeal and pharyngeal dysfunction**, such as stridor and dysphagia, occur in almost all of these animals.<sup>6,8</sup> Endoscopic examination of homozygotes reveals pharyngeal collapse, laryngopalatal dislocation, and laryngeal paralysis.<sup>6,8</sup> The disease can manifest in foals as young as 7 days of age. The severity of signs in some homozygotes diminishes with age.

**Electromyographic** demonstration of myotonic discharges, prolonged insertional activity, and doublets and triplets is a sensitive and specific indicator of the disease.<sup>9</sup>

Horses with HYPP have reduced exercise tolerance compared to normal horses.<sup>10</sup> Homozygotic horses have laryngospasm, airway obstruction, hypoxia, hypercapnia, and ventricular depolarizations during intense exercise, which is not recommended for these horses.<sup>11</sup>

### CLINICAL PATHOLOGY

**Hyperkalemia** (>5.5 mEq/L, 5.5 mmol/L) during or immediately after episodes is characteristic of the disease, although the existence of a normokalemic variant has been suggested.<sup>12</sup>

**Diagnostic confirmation** has in the past been achieved by provocative testing by administering potassium chloride (88–166 mg/kg, orally) to suspect horses.<sup>13</sup> However, the development of genotyping has rendered provocative testing obsolete and, for humane reasons and because of the risk of death, its use is not recommended. The **test of choice** for demonstrating the presence of the mutated gene is a specific **gene probe**.<sup>4</sup> The probe can be applied to various tissues, but blood or hair, with attached root (a plucked hair), are preferred for diagnostic testing of live animals. This test classifies horses as normal, heterozygous, or homozygous but does not indicate the propensity of heterozygotes to exhibit the disease. Samples can be analyzed in the United States at the Veterinary Genetics Laboratory, University of California ([www.vgl.ucdavis.edu](http://www.vgl.ucdavis.edu)).

### DIFFERENTIAL DIAGNOSIS

- Colic
- Laminitis
- Hypocalcemia
- Botulism
- Exertional rhabdomyolysis
- Upper airway obstruction.

### NECROPSY FINDINGS

There are no characteristic findings on necropsy examination.

### TREATMENT

#### Acute episodes

Most acute episodes resolve spontaneously or with only minor treatment. The aim in treating more severe or prolonged episodes is to **reduce the plasma potassium concentration** by intravenous infusion of isotonic, potassium free fluids such as sodium chloride, sodium bicarbonate, or dextrose. Some authors recommend infusion of calcium gluconate but others caution against its use. A practical approach is the slow intravenous administration of 0.25 to 0.5 mL of 23% calcium gluconate per kg of body weight (125–250 mL for a 500 kg horse) diluted in isotonic sodium chloride or, preferably, 5% dextrose.

Administration of NaHCO<sub>3</sub> at 1 mL/kg intravenously has been suggested.

### Prevention of episodes

Maintaining affected horses on a **low potassium diet** reduces the frequency with which episodes occur. Alfalfa (lucerne), some oils including soyabean, molasses, lite salt (a mixture of KCl and NaCl), and many sweet feeds are potassium rich and should be avoided. Grass hay (timothy) and straw and oats, corn, and barley are low in potassium. There are commercial feeds that have a guaranteed low concentration of potassium. Alternatively, diets can be formulated using feed of known potassium concentration, as determined by feed analysis. Care should be taken that diets are nutritious and contain appropriate concentrations and ratios of calcium and phosphorus.

Acetazolamide (2–4 g/kg, every 12 hours) reduces the severity and frequency of episodes and is widely used to control the disease. The drug is poorly absorbed in horses but the concentration required in plasma of horses to achieve a pharmacodynamic effect is lower than that of humans.<sup>14</sup>

### CONTROL

The disease is heritable and carriers are readily identified so a breeding program to eliminate the disease is feasible.

### RECURRENT EXERTIONAL RHABDOMYOLYSIS IN THOROUGHbred HORSES (AZOTURIA, TYING UP, CHRONIC INTERMITTENT RHABDOMYOLYSIS)

Recurrent exertional rhabdomyolysis of Thoroughbred horses is a common dis-

ease characterized by repeated episodes of muscle disease. A similar disease occurs in Standardbred horses but its etiology and epidemiology are not well documented.

### ETIOLOGY

Recurrent exertional rhabdomyolysis in Thoroughbred race horses is inherited as an autosomal dominant trait with variable expression influenced by temperament, diet, and sex.<sup>1,2</sup> Horses with recurrent exertional rhabdomyolysis have abnormal muscle contraction and a defect in myoplasmic calcium regulation.<sup>3,4</sup> These abnormalities are evident after caffeine or halothane challenge of muscle fibers from affected horses examined *in vitro*.<sup>2,4</sup> Myotubules from affected horses have higher concentrations of calcium after caffeine stimulation and muscle fibers from affected horses are more likely to contract when exposed to low concentrations of caffeine.<sup>3</sup> The defect does not resemble that found in the ryanodine receptor in animals with malignant hyperthermia, and there is no defect in calcium-ATPase activity or its affinity for calcium in the sarcoplasmic reticulum of Thoroughbred horses with recurrent exertional rhabdomyolysis.<sup>5</sup>

A genetic basis to a similar disease in Standardbreds is suspected, based on analysis of pedigree information of trotters in Sweden.<sup>6</sup>

### EPIDEMIOLOGY

Interpretation of reports of prevalence and risk factors for exertional rhabdomyolysis is difficult because studies to date have mostly not differentiated between the recurrent exertional rhabdomyolysis of Thoroughbreds, polysaccharide storage myopathy of Quarterhorses and related breeds, and the sporadic disease in other breeds.

The **incidence** or 1-year-period prevalence of exertional rhabdomyolysis in Thoroughbreds is 4.9–6.7% in Thoroughbred racehorses in the United States, Australia, and Great Britain, and 6.1% in National Hunt Thoroughbreds in Great Britain.<sup>7–10</sup> The disease occurs repeatedly in 74% of affected Thoroughbred race horses in Great Britain.<sup>10</sup>

**Risk factors** for exertional rhabdomyolysis in Thoroughbred horses, not all of which have the familial disease, include exercise, diet, use, and sex. Horses used for racing are more likely to have episodes of the disease than are horses used for pleasure riding or 'other' uses,<sup>7</sup> although racing and breed (Thoroughbred or Standardbred) are confounding factors. Female race horses are three times more likely to have episodes of exertional rhabdomyolysis than are male (intact or castrated) race horses,<sup>7–10</sup> and young, female Thoroughbreds are at greatest

risk.<sup>7–10</sup> Among National Hunt horses in Great Britain, females are 24 times as likely to have an episode of the disease as are males.<sup>9</sup> Female polo ponies are not more likely to develop the disease.<sup>11</sup> Thoroughbred racehorses and polo ponies, but not National Hunt horses, with a nervous or 'flighty' temperament are more likely to experience episodes of the disease.<sup>8,12,13</sup> Other apparent risk factors include a rest day before hard exercise,<sup>8</sup> feeding >4.5 kg of grain per day,<sup>8</sup> lameness,<sup>8</sup> and training gallops of shorter distance.<sup>9</sup> Susceptible horses consuming a high calorie diet (>30 mCal/day) with a large proportion of the calories provided by readily digestible carbohydrate, such as starch, are at increased risk of the disease.<sup>14,15</sup>

The disease is of considerable **economic impact** because of its frequent occurrence in athletic horses, recurrent nature, and need to rest affected horses. On average, affected Thoroughbred race horses cannot train for 6 days after an episode, and approximately two-thirds of affected horses are unable to race because of the disease.<sup>9,10</sup> The effect of the loss of training days for each episode is magnified because of the recurrent nature of the disease in a large proportion of affected horses. Approximately 6% of the wastage of Thoroughbred race horses in Australia is attributable to exertional rhabdomyolysis,<sup>16</sup> though it is not known if all of these horses are affected by recurrent exertional rhabdomyolysis.

### PATHOGENESIS

The underlying cause is described above under 'Etiology'. The disease is due to dysfunction and death of myocytes with subsequent release of cellular constituents, including the enzymes creatine kinase, aspartate aminotransferase and carbonic anhydrase, and myoglobin. Cell death is likely linked to abnormal accumulation of calcium in intracellular fluids secondary to deranged energy and/or membrane function.<sup>17</sup> Necrosis of myocytes caused pain and inflammation in the muscle, with infiltration of inflammatory cells. Healing and regeneration of myocytes occurs over a period of weeks in the absence of further episodes of myonecrosis.

The release of cellular constituents results in electrolyte abnormalities, primarily hypochloremic metabolic alkalosis, systemic inflammatory response, and pigmenturia. Severely affected horses can have a metabolic acidosis. Myoglobin and, possibly, other cell constituents are nephrotoxic and acute renal failure can develop as a result of myoglobinuric nephrosis. Pain and loss of muscle function are associated with stilted, short stepping gait.

### CLINICAL FINDINGS

The cardinal feature of the disease is the occurrence of multiple episodes of rhabdomyolysis following exercise of Thoroughbred horses. Clinical findings are **variable** and range from poor performance to recumbency and death. Signs are usually mild and resolve spontaneously within 1–6 days.

The **usual presentation** is a young (2–5-year-old) female racehorse with recurrent episodes of stiff gait after exercise. The horse does not perform to expectation and displays a **short stepping gait** that may be mistaken for lower leg lameness. The horse may be reluctant to move when placed in its stall, be apprehensive and anorexic, and frequently shift their weight. More severely affected horses may be unable to continue to exercise, have **hard and painful muscles** (usually gluteal muscles), sweat excessively, be apprehensive, refuse to walk, and be tachycardic and tachypneic. Affected horses may be hyperthermic. Signs consistent with abdominal pain are present in many severely affected horses. Deep red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses may be recumbent.

### CLINICAL PATHOLOGY

Mildly or inapparently affected horses have moderate increases in **serum creatine kinase (CK)** (20 000–50 000 iu/L), **aspartate aminotransferase (AST)** and **lactate dehydrogenase (LDH)** activity. Severely affected horses have large increases in CK (>100 000 iu/L) and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5–6 and 24 hours after exercise, respectively<sup>11,18</sup> and in the absence of further muscle damage serum AST might not return to normal levels for 7–10 days. The half-life of CK activity in serum is approximately 12 hours and in the absence of continuing muscle damage serum CK declines rapidly.<sup>11</sup> The persistence of increased AST activity, compared to CK, is useful in identifying affected horses days or weeks after the episode.<sup>18</sup>

**Serum myoglobin** concentrations increase markedly during exercise in affected horses, and decline within 24–48 hours.<sup>18</sup> Serum carbonic anhydrase III activity is increased in horses with exertional rhabdomyolysis.<sup>12</sup>

Severely affected horses are often **hyponatremic** (<130 mEq/L), **hyperkalemic** (>5.5 mEq/L), **hypochloremic** (<90 mEq/L), azotemic (increased serum urea nitrogen and creatinine concentrations) and **acidotic** or **alkalotic**. Hematocrit (>50%, 0.5 L/L) and increased serum total protein concentration (>80 g/L) indicative of dehydration

are common. Serum bicarbonate concentration can be falsely markedly elevated in animals with severe rhabdomyolysis because of cellular constituents released from damaged muscle that interfere with the analytical method when automated clinical chemistry analyzers are used.<sup>13</sup> Measurement of urinary excretion or fractional excretion of electrolytes is not useful in detecting horses susceptible to recurrent exertional rhabdomyolysis.<sup>19</sup>

**Myoglobinuria** is detectable either grossly or on chemical analysis and should be differentiated from hemoglobinuria or hematuria. Measurement of urinary excretion of electrolytes, although popular in the past, is of no use in diagnosing, treating, or preventing exertional rhabdomyolysis.

**Muscle biopsy** during the acute or convalescent stages reveals myonecrosis of Type II (fast twitch, oxidative) fibers, mild myositis, and fibrosis.

### NECROPSY FINDINGS

Horses dying of exertional rhabdomyolysis have widespread degeneration of striated muscle; principally, the muscles of exertion, but often involving the diaphragm and heart. Affected muscles tend to be dark and swollen, but may have a pale, streaked appearance. The kidneys are swollen and have dark brown medullary streaks. Dark brown urine is present in the bladder. Histologic examination reveals widespread necrosis and hyaline degeneration of predominantly Type II (fast twitch, oxidative) fibers. In horses with recurrent disease there may be evidence of myofiber regeneration. Myoglobinuric nephrosis is present in severely affected horses.

Samples for postmortem diagnostic confirmation

Formalin-fixed kidney and affected muscle for light microscopic examination.

### DIAGNOSTIC CONFIRMATION

Biochemical confirmation of muscle damage by demonstration of increased serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

### DIFFERENTIAL DIAGNOSIS

- Ear tick (*Otobius megnini*) induced muscle cramping<sup>20</sup>
- Polysaccharide storage myopathy of Quarter horses
- *Casia occidentalis* toxicosis
- Hyperkalemic periodic paralysis
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis.

### TREATMENT

The treatment chosen depends on the severity of the disease. The **general principles** are rest, correction of dehydration and electrolyte abnormalities, prevention of complications including nephrosis and laminitis, and provision of analgesia.<sup>21</sup>

**Mildly affected horses** (heart rate <60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (2.2 mg/kg, orally or IV every 12 hours for 2–4 days). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate >60 bpm, rectal temperature >39°C (102°F), 8–10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to their stable, unless it is unavoidable. Isotonic, polyionic fluids, such as lactated Ringer's solution, should be administered IV to severely affected horses to correct any dehydration and to insure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4–6 L every 2–3 hours). Affected horses should not be given diuretics.

**Analgesia** can be achieved by administration of phenylbutazone (2.2–4.4 mg/kg, IV or orally, every 12–24 hours), flunixin meglumine (1 mg/kg IV every 8 hours) or ketoprofen (2.2 mg/kg IV every 12 hours). **Mild sedation** (acepromazine or acetylpromazine 0.02–0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01–0.02 mg/kg) may decrease muscle pain and anxiety. Tranquillizers with vasodilatory activity, such as acetylpromazine, should only be given to horses that are well hydrated. Muscle relaxants, such as methocarbamol, are often used but have no demonstrated efficacy.

Recumbent horses should be deeply bedded and repositioned by rolling every 2–4 hours. Severely affected horses should not be forced to stand.

### CONTROL

Prevention centers on insuring that horses are fed a balanced ration with adequate levels of vitamin E, selenium and electrolytes, and have a regular and consistent program of exercise.

Thoroughbred race horses in training consume diets providing over 30 Mcal/day. The high energy intake is associated with increased risk of exertional rhabdomyolysis, especially if the diet provides a large (40%) of calories as readily digested carbohydrate (starch). **Diets** in which fat provides 20% of digestible energy calories and 7%

as starch are associated with lower serum creatine kinase activities after exercise on a treadmill.<sup>14</sup> These findings have been extrapolated to provide the recommendation that race horses in training receive no more than 20% of daily digestible energy from hydrolysable carbohydrate (starch) and at least 20% of DE from fat.<sup>22</sup> Fat can be incorporated into the diet as rice bran, soy bean hulls, and vegetable (but not animal) fats and oils. High fat, high fiber commercial diets that are formulated for treatment of horses with polysaccharide storage myopathy or recurrent exertional myopathy are available.

Despite lack of clear evidence for a widespread role for **vitamin E or selenium** deficiency in exertional rhabdomyolysis, horses are often supplemented with 1 IU/kg of vitamin E and 2.5 µg/kg of selenium daily in the feed. Care should be taken not to induce selenium toxicosis. **Sodium bicarbonate** and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented and is suspect.<sup>14</sup>

**Phenytoin** has proven useful in the treatment of recurrent rhabdomyolysis. It is administered at a dose rate of 6–8 mg/kg, orally, every 12 hours, and the dose adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months. Dantrolene (800 mg, approximately 2 mg/kg, orally 60 minutes before exercise) was demonstrated in a controlled, cross-over field trial of 77 horses, to be effective in reducing exercise-induced increases in CK and incidence of episodes of recurrent exertional rhabdomyolysis in Thoroughbred race horses.<sup>23</sup> Similar results were obtained in 4 horses with recurrent exertional rhabdomyolysis administered 4 mg/kg orally 90 minutes before exercise on a treadmill.<sup>24</sup>

**Dimethylglycine, dantrolene, altrenogest and progesterone** are all used on occasion in horses with recurrent rhabdomyolysis, but again without demonstrated efficacy.

## PORCINE STRESS SYNDROME (PSS; MALIGNANT HYPERTHERMIA)

### Synopsis

**Etiology** Inherited defect caused by an autosomal recessive gene at a single locus with incomplete penetrance. Also known as the halothane sensitivity gene, or PSS mutation, which is a single point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum.

**Epidemiology** Worldwide in major breeds of swine: Landrace, Yorkshire, Duroc, Pietrain, and Poland China. Market weight pigs, and adult sows and boars. Prevalence of defective gene varies between breeds and countries. Syndromes precipitated by stress of transportation, high environmental temperatures and humidity, exhaustive exercise, and by halothane anesthesia. Major economic importance because of deaths and poor quality pork.

### Signs

- *Porcine stress syndrome*: death during transportation
- *Malignant hyperthermia*: induced by halothane anesthesia resulting in muscular rigidity and death
- *Pale, soft, exudative pork*: rapid rigor mortis after slaughter followed by excessive dripping of carcass and pale watery pork. Dark, firm, and dry pork is variation
- *Back muscle necrosis*: reluctance to move, acute swelling and pain over back and some may die; subacute form too.

**Clinical pathology** Halothane test. Blood creatine kinase test. Blood typing. DNA-based test for PSS mutation gene.

**Lesions** Pale skeletal muscles in PSS deaths. Pale muscles in back muscle necrosis.

**Diagnostic confirmation** Necropsy findings. Identification of homozygous animals with tests.

### Differential diagnosis list

- Mulberry heart disease
- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Intestinal volvulus
- Heat exhaustion
- Suffocation during transportation.

**Treatment** None.

**Control** Genetic selection. Reduction of environmental and management stressors.

### ETIOLOGY

Three closely related stress syndromes occur in pigs. The **porcine stress syndrome (PSS)** is characterized by acute death induced by stressors such as transport, high ambient temperature, exercise and fighting, which results in progressive dyspnea, hyperthermia, disseminated vasoconstriction and the rapid onset of rigor mortis. **Pale, soft and exudative pork (PSE)** occurs post mortem in some pigs slaughtered by conventional methods. **Malignant hyperthermia (MH)** is a drug-induced stress syndrome characterized by muscle rigidity and hyperthermia occurring in susceptible pigs following the use of halothane or the muscle-relaxant suxamethonium. **Back muscle necrosis** of pigs is a special manifestation of the PSS.

Malignant hyperthermia also occurs in humans.<sup>1</sup>

PSS is caused by an inherited defect due to an autosomal recessive gene at a single locus with incomplete penetrance. It is also known as the halothane sensitivity gene, or PSS mutation, which is single point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum. The PSS defect renders muscle hypersensitive to stimulation by various stressors. In stress-susceptible pigs there is a rapid onset of anaerobic glycolysis and loss of control of skeletal muscle metabolism in response to stress and anoxia.

The gene is commonly known as the *halothane-sensitivity gene* (HAL gene) because pigs with the homozygous genotype can be identified with the halothane test which results in malignant hyperthermia. The halothane gene is located within a group of blood type genes on the same chromosome allowing identification of affected pigs by blood typing. A single point mutation in the porcine gene for the skeletal muscle ryanodine receptor is associated with malignant hyperthermia in five major breeds of heavily muscled swine.<sup>2,3</sup> Comparison of the sequences of the HAL genes of porcine stress syndrome and normal pigs revealed a single mutation at nucleotide 1843 in the cDNA derived from the HAL gene.<sup>2</sup> The litera-

ture on the causative mutation for the porcine stress syndrome has been reviewed.<sup>4</sup>

### EPIDEMIOLOGY

#### Prevalence and occurrence

This subject needs to be kept in perspective. It has recently been suggested that only 4% of inferior quality meat is due to genetics (halothane positive) with the remainder being due to pre-slaughter and post-slaughter treatment.<sup>5</sup>

PSS occurs worldwide, but there is considerable breed and area variation in its prevalence. In some European countries the prevalence is a major problem in pig production because of the inadvertent selection for this trait in genetic improvement programs. This underlies the problems of selection based purely on performance and production characteristics.

The prevalence of PSS in the swine population can be determined by the use of screening tests applied on the farm or when pigs enter swine performance test stations. The halothane test and the creatine kinase (CK) test are useful for this purpose. A DNA-based test with 99% accuracy is also available.<sup>6</sup> Surveys in the UK found that the prevalence in the British Landrace varies from 0 to 23% of herds with an average of 11%. In European breeds, the prevalence varies from 0 to 88% with up to 100% in the Pietrain breed. None is present in the Large White breed although one isolated report describes malignant hyperthermia in a single Large White pig. The prevalence of halothane susceptibility is low in the Danish Landrace breed in Denmark.<sup>7</sup> Based on the halothane test, 1.5% of young boars entering a Record of Performance Test Station in Canada were positive reactors. The reactors originated from 7.5% of 107 herds. The halothane succinylcholine test was a more sensitive test because 18% of the same pigs were identified as reactors.

Using a DNA-based test, in a survey of 10 245 breeding swine of various breeds from 129 farms in the US, Canada, and England, approximately 1 of 5 pigs was a heterozygous carrier of the PSS mutation, and 1% were homozygous.<sup>6</sup> The prevalence of the PSS mutation was 97% for 58 Pietrain, 35% for 1962 Landrace, 15% for 718 Duroc, 19% for 720 Large White, 14% for 496 Hampshire, 19% for 1727 Yorkshire, and 16% for 3446 crossbred swine. The PSS gene frequencies for these breeds were 0.72, 0.19, 0.08, 0.10, 0.07, 0.10, and 0.09, respectively. The PSS mutation has also been identified in Poland China and Berkshire breeds. These gene frequencies were 30–75% lower in Canadian swine than in US swine, with the exception of Yorkshires, for which the

gene frequency is threefold in Canadian swine.<sup>6</sup>

### Risk factors

#### Animal risk factors

Susceptibility to the PSS is inherited and the biochemical events leading to PSE, transport death, or malignant hyperthermia are triggered by several external influences or stressors in the living animal. PSS probably occurs in all breeds of pigs, but the incidence is highest in pigs selected for heavy muscling, and stress-susceptible pigs are leaner and more meaty. These include the Pietrain and Poland China breeds and also some European strains of Landrace where a score for muscling as well as growth rate, feed conversion, and back fat has been included in the selection index. A recent study has shown that there are considerable breed differences in that halothane stress susceptible pigs and Hampshires suffer more severely from heat stress than Yorkshires, Danish Landrace, and Duroc boars.<sup>8</sup>

#### There is a correlation between halothane susceptibility and carcass traits.

Halothane status is the most important factor influencing pork quality, although pre-slaughter handling and stunning method also influence the carcass quality.<sup>9,10</sup>

Halothane-positive animals usually score higher for visual conformation of the loin and ham than pigs which are halothane-negative. The progeny of reactor boars are also more susceptible than the progeny of non-reactors. Until recently it was thought that the major limitation of the halothane test was that it identified only those pigs which are stress-susceptible to the syndrome. It is now known that the halothane-sensitivity gene is expressed in heterozygous pigs where it is likely to cause poor carcass quality.

The **gene for the porcine calcium channel** has been sequenced and the site of the causative mutation located.<sup>2</sup> The mutation was found in 5 major breeds of swine: Landrace, Yorkshire, Duroc, Pietrain, and Poland China. The prevalence of the gene in certain breeds in North America and England is given above.

Landrace pigs can be divided into those which are sensitive to halothane and develop pale, soft, exudative pork post mortem, those which are resistant to halothane but develop pale, soft, exudative pork, and those resistant to halothane and pale, soft, exudative pork (the normal pig). Muscle from pigs susceptible to malignant hyperthermia and pale, soft, exudative pork has significantly higher glucose-6-phosphate levels and lower phosphocreatine under thiopentone anesthesia than muscle from pigs susceptible to PSE and normal pigs. Altered

muscle fiber type is not the primary basis of the disease complex.

#### Environmental and management risk factors

The most important precipitating factors are **transportation at high environmental temperatures and humidity, exhaustive exercise**, and under experimental conditions, the more specific reaction towards the **anesthetic halothane**. Response of pigs to transport is dependent on genotype particularly at high temperatures such as 36°C.<sup>11</sup> Experimentally, psychological mechanisms can precipitate the PSS. The effects of mixing, transportation, and duration of lairage can have profound effects on carcass characteristics of susceptible pigs. Death during transportation and PSE are associated with fear, defensive or aggressive reactions in unfamiliar social environments, or conflict with other strange pigs or man. Other activities which may trigger malignant hyperthermia include restraint, mating, farrowing, fighting, and vigorous exercising.

#### Economic importance

The economic losses associated with the PSS are due to mortality from transport death and inferior meat quality due to pale, soft, exudative pork. As a result of the excessive rates of production of lactic acid and heat, sarcoplasmic proteins denature, thereby causing a deterioration of the water-binding capacity of muscle. The increased osmotic activity due to end-products of hypermetabolism causes an influx of water from the extracellular space resulting in hemoconcentration and increased intramyofiber water content. The muscle becomes pale, soft, and exudative, sour-smelling and loose-textured. The shrinkage due to water loss during storage, transport and processing of the carcass is the major cause of wholesale losses at pork packing plants. PSE carcasses yield less bacon and the drip loss from fresh PSE meat is more than doubled compared to normal carcasses. Another cause of lost revenue with malignant hyperthermia susceptible swine is their decreased average daily weight gains, conception rates, litter sizes, and boar breeding performance.

#### Pathogenesis

The molecular basis for susceptibility to the PSS is a hypersensitive triggering mechanism of the calcium-release channel of skeletal muscle sarcoplasmic reticulum.<sup>6</sup> The calcium channel, also known as the ryanodine receptor, plays a critical role in the initiation of muscle contraction. The PSS defect renders muscle hypersensitive to stimulation by various stressors. Stress-susceptible pigs cannot tolerate stress and lose control of skeletal muscle metabolism.

The stress may be from external influences such as transportation, fear and excitement, or halothane anesthesia. There is excessive catecholamine release and the sudden onset of anaerobic glycolysis of skeletal muscle, excessive production of lactate and excessive heat production which, in conjunction with peripheral vasoconstriction, leads to hyperthermia. Following exertional or thermal stress, susceptible pigs undergo more extensive physiological change than do resistant pigs. Halothane sensitive pigs are more susceptible to becoming non-ambulatory and when subjected to multiple stressors and may be more prone to producing inferior pork products.<sup>10</sup> The blood glucose concentrations are dependent on the malignant hyperthermia genotype; the homozygous positive animals having the highest levels and the homozygous negative animals having the lowest.<sup>12</sup> The changes in carbohydrate metabolism at rest in malignant hyperthermia positive animals are caused by latent increases of intracellular Ca<sup>2+</sup> concentrations. Under physical load conditions there is higher lipolysis which may be the result of an indirect activation of the lipolytic system via catecholamine induced cAMP turn-over.

Depending upon the nature, severity, and duration of the stress, the syndrome may manifest in different ways:

- The **porcine stress syndrome** causes rapid death following severe stress.
- The **pale, soft, and exudative (PSE) pork** and **dark, firm, dry (DFD) pork** are seen after slaughter which may have been preceded by mild stressors during lairage
- The **malignant hyperthermia** is drug-induced.

**Pale, soft, exudative pork** is attributed to increased glycolysis after slaughter. In muscles which develop **dark, firm, dry pork**, the muscle glycogen is already depleted before slaughter.<sup>13</sup> When PSE develops in a muscle, pH drops to values lower than 5.8 at 45 minutes after death. In normal muscles, the pH decreases from approximately 7 in living muscles to 5.3 to 5.8 at 24 hours after death. The lower pH in PSE muscles, combined with a high carcass temperature within the first hour after death, causes the proteins in the muscles to denature. This contributes to the pale color of PSE meat and to its reduced water-holding capacity. Development of muscles with PSE characteristics seems to be initiated by a combination of lower muscle pH already at exsanguination and a faster pH decrease.<sup>13</sup>

**Malignant hyperthermia** is the drug-induced, often fatal, stress syndrome occurring in susceptible pigs within 3 minutes following the inhalation of a

mixture of halothane and oxygen.<sup>14</sup> Susceptible pigs develop limb rigidity and a hyperthermia which are not easily reversed and may result in death. There is an increased rate of intracellular ATP hydrolysis leading to a progressive failure of ATP-dependent  $\text{Ca}^{2+}$  accumulation by sarcoplasmic reticulum and/or the mitochondria with a rise in myoplasmic concentration of  $\text{Ca}^{2+}$  and consequent contraction of muscle. The same molecular defect occurs in lymphocytes from affected susceptible pigs. There is no histomorphometric evidence of cardiac abnormalities in malignant hyperthermia susceptible pigs.<sup>15</sup> The mitochondria from predominantly red muscle fibers have a greater calcium binding capacity than those from predominantly white muscle fiber areas. There is extreme rigidity of skeletal muscles, hyperthermia, tachycardia, cardiac arrhythmia, an increase in oxygen consumption, lactate formation and high-energy phosphate hydrolysis in muscle, respiratory and metabolic acidosis and a rise in the creatine kinase activity and concentration of potassium, lactate, glucose, free fatty acids and catecholamines in blood. There is a large release of glucose and potassium from the liver which contributes to the hyperglycemia and hyperkalemia. There is a marked  $\alpha$ -adrenergic stimulation which is responsible for the heat production in malignant hyperthermia susceptible pigs. However, the  $\beta$ -adrenergic response in stress-sensitive and stress-resistant pigs is inconsistent.<sup>16</sup> The lactic acidemia is severe due to the overproduction of lactate peripherally and failure of normal lactate uptake.

Malignant hyperthermia can also be induced using methoxyflurane, isoflurane and enflurane, and succinylcholine.

Exposing stress-susceptible pigs to halothane or exercise induces glycolysis but the mechanisms are different. There are no histochemical differences between muscles of susceptible and normal swine. There is some indication that halothane causes a transient but significant vasoconstrictive action which could be a contributing factor in initiating the severe reactions in malignant hyperthermia. Electron microscopy of platelets from stress-susceptible pigs reveals a defect characterized by dilatation of the open canalicular system.

## CLINICAL FINDINGS

### Porcine stress syndrome (transport death)

Death during or following transport to market may be significant and is more prevalent when overcrowding occurs and during the hot summer period.<sup>17</sup> If seen alive, affected pigs initially show a rapid

tremor of the tail, general stiffness associated with increased muscular rigidity, and dyspnea to the extent of mouth-breathing. The body temperature is elevated, often beyond the limits of the clinical thermometer, and there are irregularly shaped areas of skin blanching and erythema. At this stage the affected pig is frequently attacked by other pigs within the group. The pig collapses and dies shortly afterwards and the total time course of the syndrome is generally of the order of 4–6 minutes.

### Malignant hyperthermia

Malignant hyperthermia is also a manifestation of the PSS. It may be induced in stress-susceptible pigs by anesthesia with potent volatile anesthetics such as halothane or by the administration of succinylcholine. It is characterized by the development during anesthesia of increased muscle metabolism with muscular rigidity, lactic acidosis, and a marked increase in basal metabolic rate, increased oxygen consumption, carbon dioxide production and severe hyperthermia and tachycardia, tachyarrhythmia and death. Once fully developed the syndrome is irreversible. The syndrome poses a hazard in swine anesthesia which can be averted by prior medication with dantrolene and has received considerable study as a model for an analogous syndrome in man. It has also been used as a method for determining stress susceptibility for genetic selection programs.

### Pale, soft, and exudative pork (PSE)

In stress-susceptible pigs, after slaughter, the inferior quality of the meat with its pale, soft, exudative characteristics is obvious. This is due to excessive post-mortem glycolysis with lactic acid production and a rapid fall in muscle pH with depigmentation and reduced water binding as a consequence. In affected muscle, rigor mortis occurs rapidly after slaughter, but then decreases so that affected carcasses have been 'set' and postmortem drip is excessive. Affected pork has a pH of less than 6 and generally a temperature of 41°C (106°F) or greater 45 minutes after slaughter, compared to the normal pork with a pH above 6 and a temperature less than 40°C (104°F). This causes denaturation of muscle proteins leading to affected meat which has inferior taste, cooking and processing qualities, and does not accept curing as readily. The occurrence of this syndrome is considerably influenced by the stress of transport and handling prior to and during slaughter, and this aspect of the syndrome is of major economic importance.<sup>9,18,19</sup> Rapid chilling helps prevent PSE but chill type has no effect.<sup>20</sup>

### Dark, firm, and dry pork (DFD)

Dark, firm, dry pork has darker color and higher ultimate pH than normal meat. In muscles which develop DFD the muscle glycogen is already depleted before slaughter, which may be related to prolonged transport with fasting.

### Back muscle necrosis

Acute necrosis of the longissimus dorsi occurs in German Landrace pigs and other breeds. The acute syndrome lasts approximately 2 weeks and is characterized by swelling and pain over the back muscles with arching or lateral flexion of the spine and reluctance to move. The swelling and pain then subside, but there is atrophy of the affected muscle and development of a prominent spinal ridge. Some regeneration may occur after several months. Acute cases may die. The syndrome occurs in young adults weighing from 75 to 100 kg. The mild form may be undetectable except for pigs lying down near the feed trough. In the severe form, affected pigs may assume the dog-sitting position with a hunched-up back.

## CLINICAL PATHOLOGY

Several testing methods are available for predicting susceptibility.

### Halothane test

The halothane test is highly reliable for the identification of pigs which are homozygous for the single recessive gene responsible for susceptibility to the PSS. However, the test is not 100% accurate because of the incomplete penetrance of the halothane sensitivity trait (not all homozygous malignant hyperthermic susceptible pigs react by developing limb rigidity). Penetrance of the halothane sensitivity trait is estimated to vary from 50 to 100% depending on the breed, herd, and investigators. The test detects the worst clinical outcomes, and will not identify all the pigs which will develop PSE. There is now evidence that it will detect the heterozygote.<sup>21</sup> Stress-susceptible pigs are sensitive to halothane at 8 weeks of age and if the anesthetic challenge is removed immediately after obvious signs of limb rigidity develop and before the development of fulminant hyperthermia, the mortality from the procedure is negligible. Pigs that remain unreactive for a challenge period of 5 minutes are considered normal.

A halothane-sensitive muscle defect can be present in certain individuals which do not develop rigid malignant hyperthermic episodes on brief exposure to halothane. A longer halothane exposure combined with succinylcholine is required if these false negatives are to be identified. The halothane test has good predictive value for the occurrence of PSE.

However, there may be breed variations as mentioned above.

A decrease in the amplitude of the phosphocreatine (PCr) signal in the *in vivo*  $^{31}\text{P}$  nuclear magnetic resonance spectrum of skeletal pigs is an early and 100% predictive measurement for the detection of malignant hyperthermia in anesthetized piglets.<sup>22</sup> Nuclear magnetic resonance techniques such as magnetic resonance imaging and magnetic resonance spectroscopy are sensitive diagnostic aids for detecting the onset of PSS in young animals and for following the metabolic changes in muscle tissue during the syndrome.<sup>7</sup>

Halothane concentration markedly affects the outcome of halothane testing, and either higher halothane concentrations or longer exposure might be required to identify positive reactors in a heterogeneous population. The ionophore A23187, a lipophilic carboxylic antibiotic which binds and transports divalent cations across both natural and artificial membrane bilayers, allows clear differentiation between the muscles of normal and pathological animals and may be a useful adjunct to the halothane test.

#### Blood creatine kinase levels

The blood creatine kinase (CK) levels are higher in stress-susceptible pigs. Pigs are subjected to a standard exertion test and blood samples taken 8–24 hours later and analyzed for CK. The original work indicated a good correlation between the CK levels and the halothane test. There is also an increase in CK levels in pigs as they are transported from the farm to the abattoir. However, not all pigs which develop PSE have increased serum levels of CK. Increased CK activity is highest in stress-susceptible pigs of a certain phenotype Phi-B, and their total plasma CK levels are higher than non-reactors.<sup>23</sup> The initial test was modified so that blood could be collected as drops on a filter paper and sent to a laboratory for identification by a bioluminescent technique. A recent evaluation of a commercial CK screening test using the method of bioluminescence compared with the halothane challenge test on young boars entering a Record of Performance Test Station revealed that it was an inadequate indicator of susceptibility to the PSS or MH. In a different study the CK levels of piglets 8–10 weeks of age predicted halothane-induced stress syndrome with an accuracy of 87–91%.

**Plasma pyruvate kinase activity** has been compared with CK activity as indicators of the PSS. Both enzymes are increased significantly in homozygous halothane-reacting pigs compared to

non-reacting pigs. Pyruvate kinase activity was less variable within groups than CK activity which may allow more effective discrimination between the two different genotypes. However, age-related effects and the failure to identify heterozygotes may restrict the use of plasma pyruvate activity as a diagnostic test.

#### Blood typing

Blood typing is also used as a method for the identification of susceptible pigs. On one of the chromosomes of the pig, a region with four known loci has been identified. These loci contain the genes responsible for variants of the enzymes 6-phosphogluconate dehydrogenase and phosphoferose isomerase (PHI). The H-blood group system is determined by one of the loci, and halothane sensitivity is also determined by genes at a locus in this region. This region is of special interest because a close connection has been found between this and important carcass traits such as the PSE condition. Thus, blood grouping may be used to detect halothane-sensitive pigs as well as heterozygote carriers.

**A DNA-based blood test** can now be used to detect the HAL gene status.<sup>2,3</sup> It can be adapted for rapid batch analysis of many samples simultaneously, is less invasive, and can be applied to as little as 50  $\mu\text{L}$  of blood. The test is more than 99% accurate, is cost-effective, and can be used to determine the prevalence of the PSS mutation in various breeds of swine in various countries.<sup>6</sup> A recent study showed that 23% of pigs classified as Hal-1843 free based on a DNA test responded abnormally to halothane anesthesia.<sup>24</sup>

#### Pale, soft, and exudative pork

This is evaluated by a meat quality index which combines meat color, pH at 24 hours postmortem, and water-binding capacity. Susceptible lines can be identified by carcass inspection and the results applied to sibling or progeny selection. A recent approach is the measurement of mitochondrial calcium efflux. Mitochondria isolated from Mm longissimus dorsi muscle exhibit a rate of  $\text{Ca}^{2+}$  efflux twice that of normal pigs. Most of the tests readily predict the worst examples of the syndrome but are not sufficiently precise to be able to identify tendencies towards it, which restricts their value in breeding programs.

#### Erythrocyte osmotic fragility

Erythrocyte osmotic fragility may be correlated with malignant hyperthermia and is being examined as a possible aid in the determination of susceptibility.<sup>21</sup>

#### Other tests

Any reliable test which can identify stress-susceptible pigs without using

halothane testing is attractive. Increased peroxidation of the erythrocytes may be an improved diagnostic test for PSS.<sup>25</sup> Differences in the levels of cortisol, creatinine, aspartate aminotransferase, and lactate dehydrogenase are highly significant between halothane-sensitive and halothane-negative lines of pigs.<sup>26</sup>

An allele specific PCR (AS-PCR) technique has been developed.<sup>27</sup> A PCR followed by reduction endonuclease assay has been developed and used<sup>28</sup> on plucked hair as a source of genomic DNA. In a test with this method 9 of 12 Pietrains were tested homozygous or heterozygous. A one-step procedure has been developed called mutagenically separated PCR (MS-PCR).<sup>29</sup>

#### NECROPSY FINDINGS

In the PSS, rigor mortis is present immediately following death, and carcass putrefaction occurs more rapidly than normal. The viscera are congested and there is usually an increased quantity of pericardial fluid as well as pulmonary congestion and edema. The muscles – especially the gluteus medius, biceps femoris, and longissimus dorsi – are pale, wet, and soft. In back muscle necrosis, these changes appear grossly to be confined to the epaxial musculature. Histologically, the lesions in skeletal muscle may be minimal, and are easily obscured by autolysis. In some instances only interstitial edema is visible while in animals which have survived repeated episodes there is obvious phagocytosis of degenerate myofibers, with ongoing regeneration and fibrosis. The most typical microscopic finding is hypercontraction of myofibers, characterized by division of the cell into irregularly-sized segments by transverse and sometimes branching bands. Degenerate sarcoplasm of a floccular or sometimes hyaline character may be present. Degenerative changes may also be detected in myocardial cells.

#### Samples for confirmation of diagnosis

- **Genetic analysis** – 50 g frozen muscle (DNA ANALYSIS) and hair for PCR tests.
- **Histology** – formalin-fixed skeletal muscle (several sections, including longissimus dorsi), heart (LM).
- **Biochemistry** – it has been reported that pigs with PSS develop metabolic acidosis in association with respiratory acidosis<sup>30</sup> which is manifested as lower values of acid-base excess and  $\text{HCO}_3^-$  – with higher  $\text{H}^+$  concentrations and  $\text{pCO}_2$  than resistant pigs.

## DIFFERENTIAL DIAGNOSIS

The acute nature of the PSS and its relation to stress serve to differentiate it from most other syndromes causing sudden death in market and adult sized pigs. The sudden death syndrome must be differentiated from:

- Mulberry heart disease
- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Other causes of sudden death including intestinal volvulus, heat exhaustion, suffocation during transportation
- Hypocalcemic tetany resulting from severe vitamin D deficiency can produce a similar clinical syndrome
- Porcine viral encephalomyelitis may also result in a similar clinical syndrome in postweaned pigs. Pathological and biochemical examinations differentiate these from the PSS.

## TREATMENT

The acute syndromes are usually not treated. Several drugs are available for the protection of pigs against drug-induced malignant hyperthermia. A combination of acepromazine and droperidol will delay the onset or prevent the occurrence of halothane-induced malignant hyperthermia. Dantrolene is also effective for treatment and prevention.<sup>9</sup> The therapeutic dose is 7.5 mg/kg BW. Carazolol is effective for the prevention of transport death when given 3–8 hours before transportation and improves meat quality compared to untreated susceptible animals. Acute back necrosis has been treated successfully with isopyrin and phenylbutazone. Experimentally, the supplementation of the diets of stress-susceptible pigs with vitamin E and C will provide some protective effect on cell membrane integrity.

## CONTROL

The control of this syndrome depends on genetic selection and possible eradication of the PSS mutation and reduction of the severity of stress imposed on pigs.

## Genetic selection

The best strategy for control of this complex is not clear.<sup>6</sup> Several factors must be considered. Swine homozygous for the PSS mutation are at very high risk for developing PSS and severe PSE to make them useful for market pigs. They are used primarily as a source of the PSS mutation for breeding programs and research purposes. Using swine which are heterozygous for the PSS mutation as market pigs may be advantageous. They benefit from the positive effects of the mutation, have minimal risk of developing PSS, and may have acceptable prevalence and severity of PSE, if during marketing and slaughter

the environmental and management risk factors which precipitate PSE are minimized. The mutation is not a prerequisite for leanness and muscularity and it is possible for breeders to eradicate the gene from their breeding stock. The negative effects of the halothane gene on fresh pork quality are well known.<sup>31</sup> However, such a policy may result in the loss of an easily accessible and cost-effective selection criterion for favorable carcass characteristics. The PSS mutation has been used successfully in most swine breeds for increasing leanness and muscling. With the development of the DNA-based test for the PSS mutation, the mutation can be selected for with high precision and accuracy, and its expression finely controlled in a breeding program.

The various testing methods described under clinical pathology are used to identify pigs with the halothane gene. The tests can be applied to breeding stock entering swine performance test stations or on a herd basis. A reliable diagnostic test such as a DNA-based blood test to identify it will provide the basis for elimination of the gene or its controlled inclusion in swine breeding programs.<sup>2</sup>

## Management of stressors

Control through reduction of stress is not easily applied because frequently the syndrome is induced by routine minor procedures within the piggery. The incidence of transport deaths or the necessity for immediate slaughter salvage of severely stressed pigs on arrival at the abattoir and the occurrence of pale, soft, exudative meat characteristics are a significant economic problem in some countries. The necessity to climb an upper deck in the transport poses a significant stress, and the use of single-deck transports or mechanical lifts for multiple-deck transports, and the shipment of pigs in containers has resulted in a decreased incidence. The provision of spacious, well-ventilated transport vehicles and spray-cooling of pigs on arrival at the holding pens is also beneficial. Pigs should not be slaughtered directly after arrival at the abattoir but should be rested for at least 1–2 hours if they have been stressed only by transportation. In cases of severe physical exertion even more time should be allowed for recovery. Where possible transport distance should be kept to a minimum and transport should be avoided on excessively hot days.

## Inherited defects of the skin

### INHERITED SYMMETRICAL ALOPECIA

This is an inherited skin defect of cattle in which animals born with a normal hair coat lose hair from areas distributed symmetrically over the body. It has been observed in Holstein cattle as a rare disease but its appearance among valuable purebred cattle has economic importance. It appears to be inherited as a single autosomal recessive character. Loss of hair commences at 6 weeks to 6 months of age. The alopecia is symmetrical and commences on the head, neck, back, and hind-quarters, and progresses to the root of the tail, down the legs, and over the forelimbs. Affected skin areas become completely bald. Pigmented and unpigmented skin is equally affected; there is no irritation and the animals are normal in other respects. Failure of hair fibers to develop in apparently normal follicles can be detected by skin biopsy.

## INHERITED CONGENITAL HYPOTRICHOSIS

In this congenital disease there is partial or complete absence of the hair coat with or without other defects of development. The main importance of the disease is in cattle, in which there are six syndromes, but it is also inherited in **pigs**, in which it is associated with low birth weights, weakness, and high mortality, and in Poll Dorset **sheep**, in which the face, ears, and lower legs are bald, there are no eyelashes, and the patient lacrimates excessively. The skin is thick, wrinkled, greasy, scaly, and erythematous. Hair fibers are completely absent from the follicles, but wool fibers and follicles are normal.<sup>1</sup>

### Viable hypotrichosis

The condition is recorded in North America in Guernsey and Jersey cattle. Calves are viable provided they are sheltered. They grow normally but are unable to withstand exposure to cold weather or hot sun. In most instances hair is completely absent from most of the body at birth but eyelashes and tactile hair are present about the feet and head. Occasionally hair may be present in varying amounts at birth but is lost soon afterwards. There is no defect of horn or hoof growth. The skin is normal but has a shiny, tanned appearance and on section no hair follicles are present in the skin. The condition is inherited as a single, recessive character.

Congenital hypotrichosis has been reported in a Perheron draught horse.<sup>2</sup> At birth there were circumscribed patchy areas alopecia which was progressive becoming almost complete by 1 year of age. Skin biopsy at 7 months of age revealed severe follicular hypoplasia and the animal was still alive at 6 years of age.

### Non-viable hypotrichosis

This is a complete hypotrichosis in which the thyroid is abnormally small and hypofunctional and the calves die shortly after birth.

### Hypotrichosis with anodontia

Congenital X-linked hypotrichosis with missing teeth in cattle is characterized by abnormal morphogenesis to teeth, hair follicles, and eccrine sweat glands.<sup>3</sup> Two different forms can be distinguished according to the severity of the tooth defects: (1) congenital hypotrichosis with complete or almost complete anodontia; (2) congenital hypotrichosis with completely missing incisors or defective incisors. Impaired body condition and growth of the affected animals result from missing teeth. In addition, animals with sparse hair are more susceptible to cold and more prone to skin lesions.

The phenotype and inheritance of hypotrichosis with nearly complete anodontia has been recorded in pedigreed German Holstein calves.<sup>3</sup> The phenotype is inherited as a monogenic X-linked recessive trait. A reverse transcription-PCR assay was used to identify the causative large genomic deletion in the bovine *EDI* gene. The *EDI* gene for the hypotrichosis and anodontia phenotype appears to have pleiotropic effects on hair follicles, eccrine nasolabial glands, apocrine sweat glands, individually expressed contours of the muzzle, and on development of incisor and premolar/molar teeth. A molecular genetic test for the pathological mutation allows the unequivocal classification of animals with congenital hypotrichosis and anodontia and identification of heterozygous carriers and their exclusion from further breeding.<sup>3</sup>

### Streaked hairlessness

A sex-linked semidominant gene causes development of a streaked hairlessness in which irregular narrow streaks of hypotrichosis occur in female Holsteins.

### Partial hypotrichosis

Recorded in polled and horned Hereford cattle. At birth there is a fine coat of short, curly hair which later is added to by the appearance of some very coarse, wiry hair. The calves survive but do not grow well. The character is inherited as a simple recessive. The disease in Poll Herefords has the same short curly coat but there is also a deficiency of hair in the switch, and over the poll, brisket, neck, and legs in some cattle. Some have a much lighter hair coat color. Histologically there is a characteristic accumulation of large trichohyaline granules in the hair follicles.

### Rat tail syndrome in calves

The 'rat tail' occurred following the importation of continental European breeds of cattle into the United States when those breeds were crossed with Angus or Holsteins.<sup>4</sup> The abnormality is characterized by short, curly, malformed, sometimes sparse hair and lack of normal tail switch development. Histologically, there are enlarged, irregularly distribute, and clumped melanin granules in the hair shafts, which are asymmetrical, short, curled, and small. The scale surface is rough and pitted, and scale fails to form in some areas. A study of the inheritance of the abnormality found that all rat-tail calves were sired by Simmental bulls and were from cows with various percentages of Angus breeding.<sup>4</sup> The abnormality had no effect on birth weight, weaning weight, or gain from birth to weaning. However, rat-tail calves had significantly lower rates of gain during the winter months from weaning to yearling than non-rat-tail calves. The syndrome is controlled by

interacting genes at 2 loci. Cattle which express the syndrome must have at least one dominant gene for black color and be heterozygous at the other locus I

## INHERITED HAIR COAT-COLOR-LINKED FOLLICLE DYSPLASIA

Some 'buckskin'-colored follicular dysplasia occurs in so-called 'Portugese' Holstein cattle, a grade variant of Red Holsteins with a tan color instead of the red. This defect consists of a coat-color-linked hair follicle dysplasia, in which the colored hairs are shorter and less lustrous than the white hair, making the coat much finer and smoother. Test matings seem to confirm an autosomal dominant inheritance.<sup>1</sup>

A black hair colored follicular dysplasia is also recorded in Holstein cattle.<sup>2</sup> Patches of hair loss varying from hypotrichosis to complete alopecia occur in a random fashion but only on black areas. Follicular dysplasia is evident in biopsy samples. The abnormality persists for the life of the animal and is of cosmetic importance only. An inherited etiology is assumed.

A follicular dysplasia in a mature Brangus-cross cow and a mature Angus cow has been described.<sup>3</sup> Adult onset alopecia occurred and skin biopsy revealed follicular distortion and atrophy, with melanin clumping in follicular epithelium, hair bulb matrix cells, hair shafts, and infundibular keratin.

## INHERITED BIRTHCOAT RETENTION

This is recorded in Merino and Welsh mountain sheep and characterized by a coat of hairy medullated fibers in contrast with the non-medullated wool fibers of the normal sheep fleece.

## INHERITED LEUKODERMA

The Arab fading syndrome commences in young horses in particular families of Arab horses as round, unpigmented patches of skin around the lips, eyes, perineum, preputial orifice. Some cases recover spontaneously but the blemish is usually permanent.

## INHERITED ALBINISM AND LETHAL WHITE FOAL SYNDROMES

Albinism is a congenital lack of melanin pigment in the skin, hair, and other normally pigmented structures such as the uveal tract. Albinism is classified as generalized or localized and as complete or partial or incomplete. The affected skin in albinism is characterized microscopically as melanopenic rather than melanocytopenic, which distinguishes partial albinism from piebaldism. Most of the normal, inherited white markings which occur on horses are localized forms of piebaldism. Generalized and complete albino animals (oculocutaneous albinism) have white hair, white skin, pink irides and usually exhibit photophobia.<sup>2</sup> Generalized albinism in the horse is inherited as autosomal dominant trait which is only viable in the heterozygous states. These horses have incomplete albinism as there is some coloration to the iris. Matings of heterozygous albino horses produce a nonviable embryo 25% of the time which is resorbed in gestation. This is one form of lethal white foal syndrome. A second form of lethal white foal syndrome is an autosomal recessive defect which occurs by mating of overo paint horses. Lethal white foals from such breedings are characterized by albinism and congenital defects of the intestinal tract.

## INHERITED EPIDERMAL DYSPLASIA (BALDY CALVES)

This is a lethal defect of Holstein-Friesian calves inherited as an autosomal recessive character. The calves, most commonly heifers, are normal at birth but at 1–2 months of age begin to lose condition in spite of good appetites. The skin over most of the body is slightly thickened, scaly, and relatively hairless. There are also patches of scaly, thickened, and foiled skin especially over the neck and shoulders, and hairless, scaly, and often raw areas in the axillae and flanks and over the knees, hocks, and elbow joints. The skin over the joints is immovable. There is usually alopecia about the base of the ears and eyes. The tips of the ears are curled backwards. The horns fail to develop and there is persistent slobbering, although there are no mouth lesions. The hooves are long, narrow, and pointed because of gross overgrowth of the walls; these and stiffness of joints cause a shuffling, restricted gait. Calves assume a recumbent posture for most of the time. Severe emaciation leads to destruction at about 6 months of age.

Histological changes in the skin include acanthosis, hyperkeratosis, and patchy neutrophil invasion. The similarity of this

condition to inherited parakeratosis and to experimental zinc deficiency suggests an error in zinc metabolism, but treatment with zinc had no effect on the course of the disease.<sup>1</sup>

## INHERITED PARAKERATOSIS (LETHAL TRAIT A46, ADEMA DISEASE)

See 'Lymphocyte maturation deficiency'.

## INHERITED DYSERYTHROPOIESIS-DYSKERATOSIS

See 'Inherited blood diseases'.

## INHERITED CONGENITAL ABSENCE OF THE SKIN

### Classical epitheliogenesis imperfecta

Absence of mucous membrane, or more commonly, absence of skin over an area of the body surface has been recorded at birth in pigs, calves, lambs,<sup>1</sup> and foals. There is complete absence of all layers of the skin in patches of varying size and distribution. In **cattle** the defect is usually on the lower parts of the limbs and sometimes on the muzzle and extending onto the buccal mucosa. The disease is best known in Holstein-Friesians, but is also recorded in Japanese Black, Shorthorn, Sahiwal,<sup>2</sup> and Angus cattle. In **pigs** the skinless areas are seen on the flanks, sides, back, and other parts of the body. The defect is usually incompatible with life and most affected animals die within a few days. Inheritance of the defect in cattle is conditioned by a single recessive gene. Tissue-cultured fibroblasts from affected animals produce subnormal amounts of collagen and lipids.<sup>3</sup>

### Familial acantholysis

Suspected of being inherited, this defect in Angus calves is characterized by defective collagen bridges in the basal and prickle layers of the epidermis so that skin, normal at birth, is subsequently shed at carpal and metacarpophalangeal joints and coronet, and there is separation of horn at the coronet.

### Epidermolysis bullosa

This congenital disease of Suffolk and South Dorset Down sheep<sup>4</sup> and Simmental<sup>5</sup> and Brangus calves is characterized by the formation of epidermal bullae in the mouth and on exposed areas of skin, such as the extremities of the limbs, the muzzles and ears, leading to shedding of the covering surface and separation of the horn from the coronet. Lesions may be present at birth. Simmental calves grow poorly, have hypotrichosis, and suffer

repeated breaks in the skin, apparently due to an abnormal susceptibility to trauma. Most calves die but some survive and the lesions subside. In Simmentals the disease is inherited as an autosomal dominant trait. The disease in Brangus calves is very similar to familial acantholysis in Angus cattle.

The severe form of Herlitz junctional epidermolysis bullosa, which occurs in humans has been recorded in foals of the French draft horse breeds.<sup>6</sup> A mutation in the *LAMC2* gene is responsible for the defect. Affected foals were born with skin blistering, skin and buccal ulceration followed by loss of hooves. In the affected skin there was disjunction of the epidermis from the underlying dermis at the dermal-epidermal junction. Genomic DNA testing is used to determine the presence of the mutation in carrier animals.

### Hereditary junctional mechanobullous disease

This defect is inherited in Belgian foals, Angus and Simmental calves, and Suffolk and South Dorset Down lambs.<sup>7,8</sup> It is usually recorded under the heading of epidermolysis bullosa. There may be no shedding of skin but the initial bullous lesions at the coronet, considered to be initiated by abrasions, lead to sloughing of the hooves.

### Red foot disease of sheep

This is similar to both of the above diseases. It is recorded in Scottish Blackface and Welsh mountain<sup>9</sup> sheep. The lesions are not present at birth but become apparent at 2–4 days of age when there is sloughing of skin of the limbs, the accessory digits, the ear pinna, and of the epidermal layers of the cornea and buccal mucosa, especially the dorsum of the tongue. There is also an absence of head horn and a separation of hoof horn from the coronet. Pieces of horn become completely detached exposing the red corium below, hence 'red foot'. The cutaneous and mucosal lesions often commence as blood-filled or fluid-filled blisters. The corneal lesions are similarly the result of sloughing of epidermal layers. Although the cause is unknown there are indications that it is inherited.

## INHERITED CROP EARS

Inherited as a single autosomal, incomplete dominant character in Bavarian Highland cattle, this anomaly affects both ears, appears at birth, and varies from a minor trimming up to a complete deformity and reduction in size.<sup>1</sup>

## INHERITED HYPERBILIRUBINEMIA AND PHOTOSENSITIZATION

An inherited photosensitization with hyperbilirubinemia has been observed in Southdown sheep in New Zealand and the United States, and in Corriedales in California.<sup>1</sup> It is inherited as an autosomal recessive trait.

Liver insufficiency is present but the liver is histologically normal. Phylloerythrin and bilirubin excretion by the liver is impeded and the accumulation of phylloerythrin in the bloodstream causes the photosensitization. There is also a significant deficiency in renal function. Symptomatic treatment of photosensitization and confining the animals indoors may enable the lambs to fatten to market weight. The persistent hyperbilirubinemia is accompanied by an inability of the kidneys of these sheep to concentrate urine and the eventual death of the sheep from renal insufficiency.

Affected sheep live for several years if they are protected from sunlight and tend to die from renal failure associated with progressive fibrosis of the kidney.

A similar disease in Corriedale sheep in California is inherited as an autosomal recessive trait.<sup>1</sup> The functional defect is not in the uptake of unconjugated bilirubin and phylloerythrin, but rather its excretion from liver into bile. It affects lambs as they begin to eat pasture. Lambs live until 6 months of age if provided with some shade. There is also marked melanin-like pigmentation of the liver.

These two diseases are examples of the involvement of external environmental disease factors with a genetic disease: a diet of green forage (chlorophyll) and sunlight, working in concert with the inborn error of metabolism to induce photosensitization.<sup>1</sup>

## INHERITED CONGENITAL ICHTHYOSIS (FISH-SCALE DISEASE)

Congenital ichthyosis is a disease characterized by alopecia and the presence of plates of horny epidermis covering the entire skin surface. It has been recorded only in Holstein and Norwegian Red Poll

and probably in Brown Swiss calves among the domestic animals, although it occurs also in humans.

The newborn calf appears to be either partly or completely hairless and the skin is covered with thick, horny scales separated by fissures which follow the wrinkle lines of the skin.<sup>2</sup> These may penetrate deeply and become ulcerated. There are plenty of normal hair follicles and normal hairs but these are lost in the areas covered by the growth of scales. A skin biopsy section will show a thick, tightly adherent layer of keratinized cells. The disease is incurable and, although it may be compatible with life, most affected animals are disposed of for esthetic reasons. The defect has been shown to be hereditary and to result from the influence of a single recessive gene.

## INHERITED DERMATOSIS VEGETANS

This disease appears to be conditioned by the inheritance of a recessive, semilethal factor. Affected pigs may show defects at birth but in most instances lesions appear after birth and up to 3 weeks of age. The lesions occur at the coronets and on the skin.<sup>3</sup> Those on the coronets consist of erythema and edema with a thickened, brittle, uneven hoof wall. Lesions on the belly and inner surface of the thigh commence as areas of erythema and become wart-like and covered with gray-brown crusts.

Many affected pigs die but some appear to recover completely. Many of the deaths appear to be due to the giant-cell pneumonitis which is an essential part of the disease. The pathology of the disease indicates that it is the result of a genetic defect which selectively affects mesodermal tissue. It is known to have originated in the Danish Landrace breed.

## DERMATOSPARAXIS (HYPERELASTOSIS CUTIS)

This is an extraordinary fragility of skin and connective tissue in general, with or without edema. It is probably inherited as a recessive character. It occurs in cattle, horses, in Finnish and White Dorper<sup>1</sup> sheep, and a mild form is seen in Merino sheep. The latter is inherited as a simple autosomal recessive. The skin is hyperelastic, as are the articular ligaments; marked cutaneous fragility, delayed healing of skin wounds, and the development of papyraceous scars are also characteristic. Pieces of skin may be ripped off when affected sheep are being handled.

In horses the skin in some parts of the body is thinner than elsewhere, e.g. the skin of the ventral abdomen and the collagen bundles in the area are more loosely packed and are curved rather than straight. The proportion of acid-soluble collagen is also much higher in this abnormal skin. The disease involves a molecular defect of a collagen-binding protein,<sup>2</sup> and is related to a recognized problem in dogs and cats identified as 'dominant collagen packing defect'.<sup>3</sup>

Hereditary equine regional dermal asthenia has been recorded in related Quarter horses in Brazil similar to that reported in the United States.<sup>4</sup> Reported cases of horses with hyperextensible skin have involved Quarter Horses.<sup>5</sup> Clinically there were bilateral asymmetrical lesions of the trunk and lumbar regions, where the skin was hyperextensible. Handling of the skin elicited a painful response and superficial trauma led to skin wounds. The skin was thinner than normal in affected areas, with thickened borders and harder fibrotic masses. Histologically, the collagen fibrils were thinner and smaller, which created a loose arrangement of collagen fibers within the deep dermis. The deep dermis contains a distinctive horizontal linear zone in which separation of collagen bundles results in formation of large empty cleft-like spaces between the upper and lower regions of the deep dermis: 'zonal dermal separation'.<sup>5</sup> Pedigree analysis indicates an autosomal recessive type of inheritance.

The Ehlers-Danlos syndrome, recorded in Charolais and Simmental cattle, and Ripposlea sheep,<sup>6</sup> is also characterized by extreme fragility of skin and laxness of joints in the newborn. There is a defect in collagen synthesis, and histopathological findings include fragmentation and disorganization of collagen fibers.

The syndrome has also been recorded in lambs.<sup>7</sup> The skin was loose and present in excessive amounts, with folds over the carpal joints and lower regions of the legs. In some lambs, there may be separation of epidermis from dermis with blood-filled cavitations and intact skin which can be easily torn.

## INHERITED MELANOMA

Inherited cutaneous malignant melanoma are found in National Institute for Health (NIH miniature) and Sinclair miniature swine. Its expression is associated with two genetic loci, one of them associated with the swine major histocompatibility complex.<sup>1</sup> Familial melanoma have also been recorded in members of successive litters from an individual Duroc x Slovak White sow.<sup>2</sup>

## INHERITED HYPERHIDROSIS

A condition characterized by excessive sweating, and thought to be inherited, is recorded in beef Shorthorn calves. The syndrome includes conjunctivitis, some cases progressing to complete opacity of the cornea, heavy dandruff, and persistent wetness of the hair coat.

## Miscellaneous inherited defects

### INHERITED EYE DEFECTS

An inherited, congenital **corneal opacity** occurs in Holstein cattle. The cornea is a cloudy blue color at birth and both eyes are equally affected. Although the sight of affected animals is restricted they are not completely blind, and there are no other abnormalities of the orbit or the eyelids. Histologically there is edema and disruption of the corneal lamellae.

With **lens dystrophy** Brown Swiss cattle are affected by an inherited congenital blindness with a cloudy shrunken lens as the cause. Japanese Black cattle also suffer from an inherited blindness caused by defects in the pupil, retina, and optic disk.

Bilateral **cataract** has been observed to be an inherited defect in Romney sheep. It is inherited as an autosomal dominant and can be eradicated easily by culling.

Complete **absence of the iris** (aniridia) in both eyes is also recorded as an inherited defect in Belgian horses. Affected foals develop secondary cataract at about 2 months of age. Total **absence of the retina** in foals has also been recorded as being inherited in a recessive manner.

**Microphthalmia** is reported to be an inherited defect in Texel sheep, but the incidence is low. It is a well-recognized genetic defect of Texel sheep in Europe.<sup>1,2</sup> Following importation and 'breeding up'

of the breed in New Zealand in the 1990s, animals were released from quarantine for further expansion of the breed. The abnormality has occurred in a number of flocks in New Zealand and an experimental breeding flock is maintained to study the molecular genetics.<sup>3</sup> It is inherited as an autosomal recessive trait. An outbreak in Texel sheep in New Zealand has been recorded.<sup>1</sup> The optic globes are approximately one half normal size and the optic nerves at the chiasma are approximately one half normal size. No other lesions are present in any organs. The retina is composed of an irregular mass attached to and continuous with the ciliary apparatus at one pole, and connected to the optic nerve posteriorly by a short stalk.<sup>1</sup> The morphology and morphogenesis of the defect has been followed in embryos at different ages from ewes known to be carriers of the microphthalmia factor.<sup>2</sup> The primary event was abnormal development of the lens vesicle, with disintegration of the lens and subsequent overgrowth of mesenchymal tissue. The mesenchymal tissue later differentiated in various directions, whereas the epithelial structures found in the microphthalmic eyes at days 56 and 132 of gestation and in newborn lambs appeared to be remnants of the epithelial lens vesicle.

**Typical colobomata**, ophthalmoscopically visible defects of one or more structures of the eye, caused by an absence of tissue, have assumed a more prominent position than previously because of their high level of occurrence in Charolais cattle. The lesions are present at birth and do not progress beyond that stage. They affect vision very little, if at all. However, because they are defects they should be named in certificates of health but they are not usually considered as being a reason for disqualification from breeding programs. In Charolais cattle the inheritance of the defect is via an autosomal dominant gene with complete penetrance in males and partial (52%) penetrance in females. The prevalence may be as high as 6% and in most cases both eyes are affected. The defect is due to incomplete closure of one of the ocular structures at or near the line of the embryonic choroidal fissure. Failure of the fissure to close represents the beginnings of the coloboma. The retina, choroid, and sclera are usually all involved.

**Entropion** is inherited in a number of sheep breeds including Oxfords, Hampshires, and Suffolks. Affected lambs are not observed until about 3 weeks of age when attention is drawn to the eyelids of the apparent conjunctivitis. A temporary blindness results but even without treatment there is a marked improvement

in the eyelids and the lambs do not appear to suffer any permanent harm.

**Ocular dermoids** are recorded as genetically transmitted in Hereford cattle. They occur as multiple small masses of dystrophic skin complete with hair on the conjunctiva of both eyes of affected cattle. They can be anywhere on the cornea, on the third eyelid, or the eyelid and may completely replace the cornea; there may be a resulting marked dysplasia of the internal ocular structures.

### Combined ocular defects

Although the vision appears unaffected a large number of congenital defects of the eye have been observed in cattle, including Herefords, affected by partial albinism. The defects include iridal heterochromia, tapetum fibrosum, and colobomas. Congenital blindness is also seen in cattle with white coat color, especially Shorthorns. The lesions are multiple and include retinal detachment, cataract, microphthalmia, persistent pupillary membrane, and vitreous hemorrhage. Internal hydrocephalus is present in some, and hypoplasia of optic nerves also occurs.

A combination of **iridal hypoplasia, limbic dermoids and cataracts** was recorded in the eyes of progeny of a Quarter Horse stallion, presumably as a result of a mutation in the stallion and transmission to the foals via an autosomal, dominant gene.<sup>4</sup> The inheritance is a simple autosomal recessive.

**Iridiremia** (total or partial absence of iris), **microphakia** (smallness of the lens), ectopia lentis and cataract have been reported to occur together in Jersey calves. The mode of inheritance of the characters is as a simple recessive. The calves are almost completely blind but are normal in other respects and can be reared satisfactorily if they are hand-fed. Although the condition has been recorded only in Jerseys, similar defects, possibly inherited, have also been seen in Holsteins and Shorthorns.

**Inherited night blindness** occurs in Appaloosa horses which have otherwise normal sight. No defect has been described in the eyes.

## INHERITED PROLONGED GESTATION (ADENOHYPOPHYSEAL HYPOPLASIA)

Prolonged gestation occurs in cattle and sheep in several forms and is usually, although not always, inherited. The two recorded forms of the disease are prolonged gestation with fetal giantism and prolonged gestation with deformed or normal or small size fetuses.

### Prolonged gestation with fetal giantism

The inherited disease is recorded in Holstein, Ayrshire, and Swedish cattle with prolongation of pregnancy from 3 weeks to 5 months. The cows may show marked abdominal distension but in most cases the abdomens are smaller than one would expect. Parturition, when it commences, is without preparation. Udder enlargement, relaxation of the pelvic ligaments, and loosening and swelling of the vulva do not occur and there is also poor relaxation of the cervix and a deficiency of cervical mucus.<sup>1</sup> Dystocia is usual and cesarean section is advisable in Holstein cattle but the Ayrshire calves have all been reported as having been born without assistance. The calves are very large (48–80 kg body weight) and show other evidence of post-term growth, with a luxuriant hair coat and large, well-erupted teeth which are loose in their alveoli, but the birth weight is not directly related to the length of the gestation period.

The calves exhibit a labored respiration with diaphragmatic movements more evident than movements of the chest wall. They invariably die within a few hours in a hypoglycemic coma. At necropsy there is adeno-hypophyseal hypoplasia and hypoplasia of the adrenal cortex and the thyroid gland. The progesterone level in the peripheral blood of cows bearing affected calves does not fall before term as it does in normal cows.

### Prolonged gestation with craniofacial deformity

This form of the disease has been observed in Guernsey, Jersey, and Ayrshire cattle. It differs from the previous form in that the fetuses are dead on delivery, show gross deformity of the head, and are smaller than the normal calves of these breeds born at term. In Guernseys the defect has been shown to be inherited as a single recessive character and it is probable that the same is true in Jerseys. The gestation period varies widely with a mean of 401 days.

**Clinical examination** of the dams carrying defective calves suggests that no development of the calf or placenta

occurs after the seventh month of pregnancy. Death of the fetus is followed in 1–2 weeks by parturition unaccompanied by relaxation of the pelvic ligaments or vulva or by external signs of labor. The calf can usually be removed by forced traction because of its small size. Mammary gland enlargement does not occur until after parturition.

The calves are small and suffer varying degrees of hypotrichosis. There is hydrocephalus and in some cases distension of the gut and abdomen due to atresia of the jejunum. The bones are immature and the limbs are short. Abnormalities of the face include cyclopic eyes, microphthalmia, absence of the maxilla, and the presence of only one nostril. At **necropsy** there is partial or complete aplasia of the adeno-hypophysis. The neural stalk is present and extends to below the diaphragm sellae. Brain abnormalities vary from fusion of the cerebral hemispheres to moderate hydrocephalus. The other endocrine glands are also small and hypoplastic.

The disease has been produced experimentally in ewes by severe ablation of the pituitary gland, or destruction of the hypothalamus, or section of the pituitary stalk in the fetus and by adrenalectomy of the lamb or kid. Infusion of ACTH into ewes with prolonged gestation due to pituitary damage produces parturition but not if the ewes have been adrenalectomized beforehand.

### Prolonged gestation with arthrogryposis

A form of prolonged gestation, which occurs in Hereford cattle and is thought to be inherited, is accompanied by arthrogryposis, scoliosis, torticollis, kyphosis, and cleft palate.

## INHERITED COMBINED IMMUNODEFICIENCY (CID) IN FOALS OF ARABIAN BREEDING

### Synopsis

**Etiology** Inherited immunodeficiency in foals of Arabian parentage caused by a mutation in the gene coding for DNA-protein kinase catalytic subunit.

**Epidemiology** Familial pattern of occurrence with autosomal recessive inheritance. Approximately 8% of Arabian horses are heterozygous for the mutation (carriers). Random mating results in approximately 1 in 600 foals being affected, but not all matings are random and the incidence of the disease is less than this number.

**Clinical findings** Foals normal at birth but succumb to systemic infection soon after birth and die before 3 months of age.

Death from acute septicemia, or recurrent or chronic continuous infection, usually of respiratory tract. Poor response to normally effective antibiotic therapy.

**Clinical pathology** Lymphopenia, hypogammaglobulinemia. PCR test detects animals heterozygous (carriers, parents of affected foals) or homozygous (affected foals) for the mutated gene.

**Necropsy findings** Thymic, lymph node, and splenic hypoplasia and a marked reduction in the numbers of splenic and lymph node lymphocytes.

**Diagnostic confirmation.** PCR detection of mutated gene (homozygous in affected foals). Lymphopenia and agammaglobulinemia in a foal of Arabian breeding.

**Treatment** Nil.

**Control** Ideally, elimination of the mutated gene by not breeding carrier animals. The disease can be prevented by not breeding a carrier animal to another carrier.

### ETIOLOGY

The fundamental defect is a 5 base-pair deletion in the specific gene that codes for DNA-dependent protein kinase.<sup>1–3</sup> The gene is located on chromosome ECA9.<sup>4</sup> This mutation causes a lack of activity of the catalytic subunit of DNA-dependent protein kinase.<sup>1,2,3</sup> The deficiency of protein kinase activity, which is absolute in affected foals, results in the inability to join DNA strands that have been broken as part of the normal process of creation of V (variable) regions of T cell and B cell antigen receptors on lymphocytes. Without these receptors the lymphocytes are unable to respond to antigens and thus the foal is not capable of mounting adaptive, either cellular or humoral (antibody), immune responses.<sup>1</sup>

### EPIDEMIOLOGY

The immunodeficiency is inherited as an autosomal recessive defect. The disease occurs in purebred and part-Arabian horses. It has also occurred in an Appaloosa foal that had an Arab stallion in the fifth past generation of its mother's pedigree. In one survey of Arabian foals in the United States, the prevalence rate of affected foals was 2.3% of 257 foals of Arabian breeding, and 25.7% of the parents of affected foals were estimated to be carriers of the genetic defect.<sup>5</sup> However, this likely represents an over-estimation of the incidence of the disease and prevalence of the mutation in the population of Arabian horses because of selective testing.<sup>6</sup> The frequency of carriers of the mutation for severe combined immunodeficiency is approximately 8%, with an estimated 0.2% (1 in 600) of foals of random matings between Arabian horses affected with the disease, based on

a survey of 250 horses.<sup>6</sup> Approximately 17% of Arabian horses are heterozygous for the mutation and 0.3% of foals are homozygous among > 6000 horses tested by a commercial laboratory.<sup>7</sup>

Affected foals usually appear normal at birth, but are highly susceptible to infections from 2 to 65 days after birth and usually die from one or more infections by 3 months of age. The sires and dams of affected foals are clinically normal and have normal lymphocyte counts and serum immunoglobulin concentrations.

#### **PATHOGENESIS**

Affected foals are born with a combined immunodeficiency associated with a deficiency in both B-lymphocytes (which produce immunoglobulins) and T-lymphocytes (which provide cellular immunity). There is a marked lymphopenia and failure of immunoglobulin (Ig) synthesis and absence of delayed hypersensitivity of skin responses. Foals that receive immunoglobulins from the dam's colostrum derive passive immunity and can survive for as long as 4 months. Foals that do not receive colostrum die much earlier. The cause of death is infectious disease.

Affected foals are susceptible to infections of all kinds, but mostly of the respiratory tract. Adenoviral pneumonia is considered to be the most common secondary complication, probably because adenovirus infection is so widespread in the horse population. Affected foals may also die from hepatitis, enteritis, or infection of other organs without pulmonary involvement. While adenoviral pneumonia is the most common complication, infections with bacteria and *Pneumocystis carinii* also occur. *Cryptosporidium* sp. has also been recorded in a number of foals with diarrhea, which is also a common complication.

#### **CLINICAL FINDINGS**

Affected foals usually become ill from 10 to 35 days of age. Commonly there is a history suggesting a mild disease of the respiratory tract, especially the appearance of a bilateral nasal discharge, which often becomes sufficiently thick to interfere with sucking. The foal is unthrifty, lethargic, and tires easily but still nurses and eats solid feed. A deep dry cough and a serous to mucopurulent ocular and nasal discharge are common when pneumonia is present. There is moderate fever (39.5°C, 103°F) and an increase in the heart and respiratory rates. The depth of respirations is increased and a double expiratory effort is common. On auscultation, loud bronchial tones and moist and dry crackles are common over the anterior ventral aspects of both lungs. A chronic diarrhea is present in some

foals, and alopecia and dermatitis, commonly associated with an infection by *Dermatophilus congolensis*, also occur. An important clinical feature is that affected foals do not respond favorably to treatment with antimicrobial agents. The course of the illness will vary from a few days to a few weeks and probably depends on the degree of immunodeficiency and the nature of the infection. Most affected foals become progressively worse over a period of 2–4 weeks, and death by 3 months of age is the usual outcome.

#### **CLINICAL PATHOLOGY**

Lymphopenia is a constant finding with counts often less than 1000/mL and there is a concurrent hypogammaglobulinemia in foals that have not received colostrum. There is no IgM in precolostral serum of the foal. Following ingestion of colostrum, all subclasses of immunoglobulin will be present but in affected foals the level of IgM will steadily decrease weekly until at about 36 days when IgM is detectable. The lack of IgM is because of lack of synthesis and the shorter half life of this isotype of immunoglobulin in foals – serum IgG concentrations decline more slowly. Until the development of the PCR test for detection of homozygous foals and confirmation of the disease, the measurement of serum Ig concentrations was considered essential for a definitive diagnosis. Additional tests include enumeration of B-lymphocyte and T-lymphocyte responses to phytolectin stimulation and other tests of lymphocytic immunological function, but these tests are no longer required for diagnostic confirmation of the disease.

#### **NECROPSY FINDINGS**

The lymph nodes are small and splenic follicles are not visible. A viral interstitial pneumonia and a secondary bacterial bronchopneumonia are common. The thymus gland is usually hypoplastic. Histologically the lymph nodes and spleen are depleted of lymphocytes, and germinal centers are absent. In some foals there are foci of necrosis of the intestinal epithelium but with minimal infiltration of inflammatory cells. Inclusion bodies of adenovirus may be present in the cells of several different body systems. In Australian foals *Rhodococcus equi* can be commonly isolated from pulmonary abscesses. Additional histological findings include a severe adenoviral pancreatitis and adenitis of the salivary glands.

#### **DIFFERENTIAL DIAGNOSIS**

Diagnostic confirmation in an apparently chronic case of pneumonia in a young foal depends on the identification of the characteristic lymphopenia.

The differential diagnosis list includes:

- Septicemia and pneumonia of foals, caused by *Rhodococcus equi*
- Agammaglobulinemia due to failure of transfer of maternal immunoglobulins from colostrum. In many foal populations as many as 20% of foals are immunodeficient for this reason
- Other immunodeficiencies (Table 35.1). Foals with these deficits are very susceptible to a variety of infectious diseases and are usually chronically ill, most often with respiratory infections. However, because they have partial protection, they survive and their life span is much longer than that of foals with CID, usually over 1 year and often 18 months. Hematologically the foal is normal unless an infection is in process, but electrophoretic examination usually reveals a marked deficiency of beta globulins. Further tests are needed to identify the exact deficiency. A radioimmunoassay is used to quantitate serum immunoglobulins – IgA and IgM levels are usually at negligible levels, but IgG levels are discernible, although diminished. An intradermal test by injection of phytohemagglutinin determines T-lymphocyte status – a normal response is migration of mononuclear cells
- An isoimmune neonatal leukopenia can cause immune deficiency in foals; antibodies to the sire's lymphocytes are detectable in the mare's serum
- Neonatal septicemias.

#### **TREATMENT**

There is no satisfactory treatment for CID in foals. Hyperimmune serum, whole blood transfusions, and broad-spectrum antibiotics are all used without more than a temporary response. Affected foals may be kept alive by twice-weekly injections of hyperimmune serum and a constant antibiotic cover. Immunotherapy using a transplant of bone marrow and a fetal thymus transplant has been attempted without success. Corticosteroids are contraindicated.

#### **CONTROL**

Horses heterozygous for the mutation can be detected using a commercial PCR assay.<sup>6,7</sup> These horses have normal serum immunoglobulin concentrations and lymphocyte counts. Detection of heterozygous animals, which is required by some national breed organizations, is

useful for several reasons. Firstly, it should, ideally, permit elimination of the disease from the population by breeding of only homozygous normal animals. However, this approach has not met with success because of the financial and emotional value of some heterozygous animals. Secondly, identification of the status of an animal permits controlled breeding such that the risk of producing homozygous affected foals is eliminated. This is achieved by mating only pairs of homozygous normal animals, in which case none of the off-spring will carry the

mutated gene, or by mating a heterozygous animal with a homozygous normal animal. In this instance 1 in 4 of the progeny will carry the mutated gene, but none of the progeny will be homozygous for the mutated gene and, therefore, afflicted with the disease. This second approach, if applied consistently, should almost eliminate the disease.

**Introduction**

It was anticipated that, with time, this chapter would shrink in succeeding editions and, eventually, disappear. As the causes of individual diseases are demonstrated they are removed to other chapters but in the past newly identified diseases have been added at almost the same rate so that the net effect on the chapter has been small. The process could have been hastened by moving diseases when the consensus of opinion, short of proof, was that the cause had been identified. We have thought it preferable to leave those diseases here, together with those in

which the combination of causes is complex, such as 'weaner illthrift'.

**Diseases characterized by systemic involvement****UNTHRIFTINESS IN WEANER SHEEP (WEANER ILLTHRIFT)****ETIOLOGY**

A number of different diseases have been associated with this syndrome in both lambs and calves. In many cases an association has been established by a response trial but in others the association has not been established as causal. These include

**Synopsis**

**Etiology** Several causes including parasitism, trace element deficiencies, pasture palatability and fungal infestations of pasture.

**Epidemiology** Loss of weight at weaning and failure to make satisfactory weights subsequently, in spite of the presence of ample feed and when adult sheep are faring well.

**Clinical findings** Poor body condition and failure to thrive.

**Lesions** Inanition

**Diagnostic confirmation** Laboratory testing for specific cause. Correction-response trial.

**Treatment** Correction

**Control**

intestinal parasitism, coccidiosis, infection with hemoplasma (eperythrozoosis), deficiencies of copper, cobalt, selenium, zinc, thiamin, vitamin A, and vitamin D. A combination of these deficiencies has also been suspected.

Palatability of pasture appears a cause of illthrift in some instances, or at least associated with it, and moving the animals to a different pasture will sometimes alleviate the condition. This has been observed with perennial rye-grass (*Lolium perenne*), setaria grass (*Setaria sphacelata*), tall fescue (*Festuca arundinaceae*), and turnips (*Brassica repens*). Infestation of grass species with endophyte fungi may prove an important cause of illthrift and poor growth rates occur in calves with the 'summer syndrome' associated with the endophyte *Acremonium coenophialum* in tall fescue pastures. Infection of pasture species with toxigenic *Fusarium* spp. has been associated with illthrift in lambs in South Africa, New Zealand, and Australia. Pasture and soil fungi have also been suspected of being associated with illthrift in sheep in eastern Canada.

#### EPIDEMIOLOGY

- The problem has seemed to be most severe in the **southern hemisphere** but this may be because sheep are so prevalent there
- It may also be due partly to the predominance of **Merino** and Merino-type sheep; the disease is most common in these breeds which have their own particular timorous nature which makes weaning and the need to shift for themselves more traumatic than in most other breeds
- This trait is particularly noticeable if there is **overcrowding** on pasture
- Lambs that are **weaned at light weights** are more prone to illthrift following weaning and ideally they should be 45% of mature weight when weaned
- Merino ewes have a low persistency of milk production and consequently management of the flock and the pastures is critical for effective weaning weights
- **Other management** factors likely to lead to low weaning weights and subsequent unthriftiness are multibirth lambs, small ewes, ewes with little milk, and lambs born late in the season.

Weaner illthrift does occur in breeds other than Merino and is also reported from several countries in the **northern hemisphere**. Weaner illthrift has been reported on a variety of different pastures and under a variety of different management systems.

In bad years there may be many **deaths**; in any circumstance there is a gross **delay in maturation** so that maiden lambing

may be delayed to as late as 3 years of age. The economic effects can be disastrous. Illthrift syndromes are also recorded in calves although with less frequency.

#### CLINICAL AND NECROPSY FINDINGS

As the name indicates the disease in weaned sheep is manifest primarily by **poor body condition and failure to thrive**. Within an affected group not all lambs are equally affected and there will be a range of conditions. Those lambs in very poor condition are usually anemic, frequently have diarrhea, and there is a sporadic but continuing death loss amongst them. Commonly the sheep have been treated with anthelmintics with no response. There are usually no abnormal findings at post-mortem other than those associated with emaciation but villous atrophy is often found on histological examination of the small intestine.

This lack of significant findings is probably the **defining factor** for placing a problem in this disease category.

#### DIFFERENTIAL DIAGNOSIS

When faced with this problem the initial approach should be to examine for the most likely cause which is a deficiency in energy or protein intake.

An examination of the **teeth** to insure that there is no excessive attrition of the teeth, or even breaking of the incisors if the sheep are being fed roots, is also a logical preliminary step in any investigation of an illthrift problem.

**The Parasite Status** of the group should be examined by techniques appropriate to their detection as outlined in previous chapters. Clinical or subclinical infestations with nematodes are common occurrences at this time in the sheep's life, before immunity is properly developed and when pasture contamination can be high.

Infections with coccidia, cryptosporidia, or *Mycoplasma (Eperythrozoon)* should be significant causes of illthrift and ought to be examined as outlined in previous chapters.

**The Trace Element Status** of the group should be examined if the cause cannot be found with the above examinations. Many trace element deficiencies are area deficiencies or in an area are strongly associated with certain soil types. If trace element deficiency is a cause it is likely that there will be some prior history of this problem in the area. Diagnosis by response to supplementation is a common approach and the diagnostic aspects of the trace element deficiencies are outlined under their specific headings in this text.

Examination of the above-mentioned possible causes is time-absorbing and costly and, if there is a residuum of unsolved cases, they are likely to remain undiagnosed.

**Infectious Agents** can produce enteric lesions and illthrift (e.g. coronavirus and yersiniosis) and the malabsorption which results may be manifested by weight loss and by chronic diarrhea. They are differentiated on the initial postmortem examinations.

## BULLER STEER SYNDROME

#### Synopsis

**Etiology** Unknown. Behavioral problem of steers in feedlots

**Epidemiology** Prevalence varies and increases with increasing age and weight at entry.

**Clinical findings and lesions** Areas of denuded hair, subcutaneous hematomas, other traumatic injuries

**Treatment** Symptomatic

**Control** Removal from pen.

#### ETIOLOGY

The buller steer syndrome is a **behavioral** problem in cattle confined in feedlots<sup>1</sup> of unknown etiology. Within a pen of cattle, one or more cattle persistently ride a particular individual or individuals of the group. The ridden animals are referred to as bullers. There have been several suspect etiologies. Improper placement of hormonal growth implants has been suspected as being associated.

#### EPIDEMIOLOGY

##### Occurrence

The syndrome occurs only in cattle in feedlots. The prevalence varies, but in one study ranged from 0 to 11% with a mean of 2.7%.<sup>1,2</sup> The prevalence increases with increasing weight and age.<sup>1,2</sup> The case fatality has been estimated at 1%.<sup>3</sup> The incidence of occurrence is higher in the summer and the fall and during the first 30 days of the feeding period.<sup>4</sup>

Epidemiological studies indicate that bullers occur as a point source epidemic with the cause occurring soon after cattle arrive in the feedlot and mingle into pen groups.<sup>1</sup> The peak incidence of bullers occurs much sooner after arrival and declines much quicker in older cattle. Bullers occur significantly sooner after mixing in older cattle than in younger cattle. The pen prevalence also increases as cattle become older on arrival at the feedlot and are more aggressive. As the prevalence of intact bulls increases in pens of cattle, so does the prevalence of bullers, presumably due to more aggressiveness in the bulls.

##### Risk factors

Postulated causative and risk factors include the incorrect timing and administration of hormonal growth implants, reimplantation and double dosing, estrogenic substances in feeds, pheromones in the urine of certain cattle, improper or late castration of young cattle, daily feedlot management, weather and seasonal factors, disease, group size, and dominance behaviour. However, these factors have not been well substantiated and controlled studies have found little influence of

implant type and implant timing on buller incidence.<sup>5</sup>

The mixing and confinement of **unfamiliar cattle** into pen groups, with subsequent agonistic interactions as these cattle established a social hierarchy, are considered as important risk factors. Both riding behavior and antagonistic behavior cease once cattle establish a stable social hierarchy. This suggests that riding behavior and subsequent identification of bullers is associated with this dominance behavior. It is possible that when a dominant animal becomes ill in a pen, other more subordinate animals in the pen that were previously subdued in dominance contests may want to fight the sick animal to achieve higher social status

### Economic importance

The syndrome has been ranked along with acute undifferentiated bovine respiratory disease and footrot as **one of the three most important disease syndromes** in beef feedlots in North America. In addition to the economic loss from decreased weight gain, injury, treatment, death, and carcass condemnation, there is economic losses associated with extra handling necessary to accommodate affected cattle, the disruption of uniform marketing of cattle, especially in custom feedlots, and the need for extra pens in which to house the bullers. The importance of the syndrome includes the animal welfare aspects.

Bullers may be at significantly greater risk of illness and mortality (from bacterial pleuropneumonia) than other steers.<sup>2</sup> The association between illness, mortality, and bullers among individuals was greatest among the oldest yearling steers.<sup>2</sup>

### CLINICAL FINDINGS

Two types of bullers are identified.<sup>3</sup>

**Type 1 or true bullers** stand as if they were a heifer in estrus and do not move away or show agonistic behaviour when being mounted by rider cattle. There can be several rider cattle in a pen and type 1 bullers are rapidly damaged.

**Type 2 bullers** are animals that appear low in social dominance. They use aggression to discourage riders and will lie down to avoid being ridden.

Affected animals show areas of denuded hair and have extensive subcutaneous hemorrhage. The hematomas may become infected and develop to subcutaneous pockets of pus and gas. Other traumatic injuries, such as limb fractures, also occur.

### CONTROL

Management of the syndrome has usually involved identification and removal from the pen to prevent injury and even death from riding-related injuries.

The high rate of risk of illness and mortality in bullers relative to other feedlot

steers suggests that bullers should always be checked for evidence of illness in addition to their removal from their designated pen to prevent severe riding-related injuries. Treating sick bullers may improve the chance of settling them back into their designated pen by allowing them to resume their original position in the social hierarchy.

## STILLBIRTH/PERINATAL WEAK CALF SYNDROME

### Synopsis

**Etiology** Multifactorial

**Epidemiology** Most commonly multiple cases on a farm. Several farms affected in a geographic region in a single season. Problem may not occur for several years and then occur as 'epidemic' in a region.

**Clinical findings** Calves may be born weak and unable to stand. More commonly are born apparently normal and stand but subsequently collapse with hypothermia and die within a few hours of birth.

**Lesions** Petechial hemorrhages, subcutaneous edema, and hemorrhage commonly in the subcutaneous tissue of the carpal and tarsal joints.

**Diagnostic confirmation** Specific to cause

**Treatment** Heat and supportive.

**Control** Correction of underlying nutritional deficiency.

### HISTORICAL ASPECTS

A disease of newborn calves called the 'weak calf syndrome' was first recognized in Montana in 1964.<sup>1</sup> It has been recognized throughout the US and other countries since then, and is considered a major economic loss in beef cattle herds. In the earlier descriptions of the syndrome, calves were affected by 10 days of age, and approximately 20% were affected at birth.<sup>2</sup> Morbidity ranged from 6 to 15%. In some herds, sporadic abortions occurred before calving season of the herd began. In some cases, affected calves died within minutes after being born with varying degrees of obstetrical assistance.<sup>3</sup>

In calves which survived for a few days, clinical findings included lassitude, depression, weakness, variable body tem-

perature, a reddened and crusty muzzle, lameness, and reluctance to stand, enlargement of the carpal and tarsal joint capsules along with periarticular subcutaneous swellings, and a hunched-up back if they stood. Diarrhea occurred in some calves after a few days of illness but was not a major clinical finding. Treatment was ineffective and the case fatality rates ranged from 60 to 80%.

At necropsy, the prominent lesions were hemorrhage and edema of the subcutaneous tissues over the tarsal and carpal joint regions and extending distally. Polysynovitis with hemorrhagic synovial fluid often containing fibrin was also common. Erosive and hemorrhagic lesions of the forestomachs and abomasum also occurred. Several different pathogens were isolated from these calves but no consistent relationship between the pathogens and the lesions was ever determined.<sup>1</sup>

In retrospect, the **case definitions** were not well described and it is possible that several different diseases of newborn calves were lumped into the enigma of the weak calf syndrome. As more detailed clinical and laboratory examinations of sick newborn calves have been done over the years, some of the causes of the original syndrome have been identified as certain diseases of newborn calves which are characterized by such non-specific signs as lack of desire to suck, weakness, and failure to respond to therapy.

A wide spectrum of clinical and pathological findings has been associated with the weak calf syndrome. In the most common situation, which is a major diagnostic challenge, calves are born weak and die within 10–20 minutes after birth; sometimes they live for up to a few days. At necropsy there are no obvious or only few lesions to account for the illness. Calves which are weak after birth due to traumatic injuries associated with dystocia or other significant lesions can be accounted for according to the nature and severity of the lesions. Reports from Northern Ireland in recent years indicate that in dairy herds the incidence of the weak calf syndrome has ranged from 10 to 20% of all calves born.<sup>4</sup> Field observations in problem herds found that the gestation period is of normal duration but parturition is usually prolonged with the first and second stages of labor lasting 24 hours.<sup>5</sup> Affected calves usually are born alive but are unable to sustain breathing following birth. Despite resuscitation efforts, they commonly die within 10 minutes often accompanied by prominent incoordinated movements of the limbs.<sup>4</sup> Some calves are stillborn and whether or not this is a variation of the syndrome is uncertain. In a report from the UK, the syndrome occurred in calves born from heifers and was characterized

by failure to breathe at birth, or breathing with difficulty, and/or failing to move after birth, and failure to suck.<sup>6</sup> The term still-birth/perinatal weak calf syndrome has been suggested as more appropriate.

#### Dummy calf syndrome

A variation of the weak calf syndrome is the dummy calf syndrome reported from the southern US.<sup>7</sup> Affected calves appear normal at birth, are generally alert, but lack the instinct or the desire to seek the teat or suck after birth and for up to several hours later. The syndrome may occur in calves of any birth weight. The incidence has been highest in purebred Brahman females but it has also occurred in Aberdeen Angus, Hereford, Chianina, and Brown Swiss breeds of cattle. Field observations indicate that affected calves did not stand for up to 1–2 hours after birth to initiate teat-seeking.<sup>7</sup> Dummy calves appear to lack the sensitivity to teat-see and if they fail to locate a teat by about 4–5 hours after birth they commonly lose the sucking reflex and then require intensive nursing care by bottle feeding to initiate sucking. In calves which fail to suck and ingest colostrum, hypothermia, hypoglycemia, and neonatal infections are common complications. Concurrently, the dam loses interest in the calf and may abandon it. The cause is unknown but is thought to be a behavioral disorder inherent in some breeds; this has not been supported with any scientific evidence.

#### ETIOLOGY AND EPIDEMIOLOGY

The etiology of the weak calf syndrome is unclear, but several epidemiological observations have suggested some possible causes.<sup>8</sup> These include:

- Fetal infection near term
- Underdevelopment because of nutritional inadequacy of the maternal diet during pregnancy
- Placental insufficiency
- Maternal dietary deficiencies of selenium and vitamin E
- Hypothyroidism
- Traumatic injuries associated with dystocia and excessive force during obstetrical assistance
- Fetal hypoxia from prolonged parturition.

#### Fetal infections

Fetal infections in the last few days before term can result in stillbirth or weak calves which may die within hours or days after birth. In one series of 293 weak calves in Northern Ireland, leptospiral infection was present in 25% of them.<sup>8</sup> Calves in which leptospiral antigen was detected in the placenta were significantly lighter by an average of 6 to 10 kg than calves with no antigen in the placenta.<sup>9</sup> Calves infected with *Leptospira* in the uterus were more

likely to be infected by *Arcanobacterium pyogenes* or *Bacillus* species, and infection of the placenta is associated with a lower bodyweight. The adrenal gland, lung, and placenta are most useful tissues to examine for leptospiral antigen.<sup>9</sup>

There is some evidence that an immune inadequacy based on T lymphocyte function may be associated with the weak calf syndrome in Japanese Black calves but the data are not compelling.<sup>10</sup>

An unidentified type of adenovirus has been associated with the weak calf syndrome on a large dairy farm in Israel.<sup>11</sup> At birth the calves were reluctant to suck or drink colostrum and were force fed colostrum with a gastric tube. Affected calves were weak at birth, unable to rise without assistance and when forced to move, walked stiffly, suggestive of polyarthritis. An adenovirus was detected in the feces, synovial fluid, and aqueous humor of affected calves.

#### Maternal nutritional deficiency causing fetal underdevelopment

**Hypothyroidism due to iodine deficiency** in the pregnant dam has been considered on the basis of thyroid hyperplasia in some calves.<sup>12</sup> Analysis of the laboratory data from 365 calves which died from the stillbirth/perinatal weak calf syndrome in Ireland, found some differences between calves with an abnormal and normal thyroid gland.<sup>13</sup> Glands weighing more than 30 g were probably abnormal. Abnormal glands were heavier, constituted a greater percentage of the calves bodyweight and had a lower iodine concentration. A higher proportion of calves with an abnormal thyroid gland had uninflated lungs and pneumonia. Abnormal thyroid glands had a lower selenium concentration in the kidneys.

However, the experimental reproduction of iodine deficiency in pregnant heifers by feeding an iodine deficient diet over the last 4 to 5 months of pregnancy resulted in clinicopathological changes and pathological changes in the thyroid glands of both the heifers and their calves, but all calves in the iodine deficient group were born clinically normal.<sup>8</sup>

**A maternal dietary deficiency of selenium** in pregnant cattle has also been examined but field trials have failed to show any protective effect from the parenteral administration of pregnant cattle with selenium.<sup>4,5</sup> The parenteral administration of both selenium and iodine to pregnant cattle did not have any effect on the incidence of the syndrome between treated and untreated herds where the incidences were 7.9% and 7.4%, respectively.<sup>14</sup> A general nutritional inadequacy in the maternal diet can result in underdevelopment of the fetus and the birth of smaller than normal calves

but the deficiency usually must be grossly inadequate. Radiographic examination of affected calves found that intrauterine growth retardation is not a common feature in calves dying with the syndrome.<sup>15</sup>

#### Placental insufficiency

Intrauterine growth retardation associated with fetoplacental dysfunction has been described in Japanese Black beef calves.<sup>16</sup> Affected calves were weak when born at term and were underweight compared to normal calves. Anemia due to bone marrow dysfunction was present in affected calves and presumably was associated with intrauterine growth retardation. Dams delivering weak calves had lower serum concentrations of estrone sulfate during late pregnancy than those of normal calves suggesting a fetoplacental dysfunction. The dysfunction was influenced by sires and maternal families.

#### Fetal hypoxemia

Fetal hypoxemia due to a prolonged parturition or dystocia may be a cause of the weak calf syndrome.<sup>17</sup> While asphyxia is not an integral part of normal delivery, it is still an important cause of fetal death during abnormal parturitions. Various predisposing factors can cause prolonged interference with fetal blood or oxygen supply, which results in death during delivery or shortly after.<sup>18</sup>

In newborn mammals subjected to anoxia, initially there is a period of struggling and rapid gasping during which blood pressure rises and bradycardia becomes profound. A relatively short period of primary apnea follows, after which there is a period of more regular and deeper gasping, which may become more frequent terminally. This is followed by a period of secondary apnea, the heart rate continues to beat at a slowly declining rate, and blood pressure falls slowly. The brain lesions begin in lower brainstem nuclei and, as asphyxia becomes prolonged, progress to involve the cerebellar and thalamic nuclei and the cerebral cortex. Examination of blood gas values on newborn calves has shown that a prolonged parturition or delivery terminated by forced extraction may result in a severe acidosis due to oxygen deprivation. As blood pH drops, first vitality is reduced, subsequently vital organs like the brain are damaged and ultimately the fetus dies.<sup>19</sup>

The bovine fetus appears relatively susceptible to anoxia which has been studied experimentally by clamping the umbilical cords of fetuses for 4–8 minutes, at 24–48 hours before expected birth, followed by a cesarean section 30–40 minutes later. Calves born following this procedure may die in 10–15 minutes after birth or survive for only up to 2 days. Under these experimental conditions, fetuses can survive anoxia for 4 minutes

but most will die following 6 or 8 minutes of anoxia.<sup>17</sup> During the clamping of the umbilical cord, there is a decline in the blood pH,  $PO_2$  and standard bicarbonate levels and an increase in the  $PCO_2$  and lactate levels.<sup>17</sup> Hypoxia in neonatal calves can result in high plasma lactate concentrations, which contributes to a progressive primary metabolic acidosis.<sup>20</sup>

During the clamping there is also increased fetal movement and a release of meconium which stains the calf and the amniotic fluid. Those which survive for a few hours or days are dull, depressed, cannot stand, have poor sucking and swallowing reflexes, and their temperatures are usually subnormal. They respond poorly to supportive therapy.

Some calves whose umbilical cords were clamped for 4 minutes were born weak, and made repeated efforts to raise their heads and move onto their sternum but were unable to maintain an upright position for long. These calves become hypothermic, dull, and their sucking and swallowing reflexes are present but weak. These calves are usually too weak to suck the cow even when assisted, and commonly develop diarrhea and other complications.

#### *Dystocia and traumatic injuries at birth*

Dystocia is a major cause of neonatal mortality in range beef cattle and may be a cause of the weak calf syndrome because of fetal hypoxia or traumatic injuries associated with obstetrical assistance.<sup>21,22</sup> In a study of 13 296 calvings over a period of 15 years in two research herds in Montana, calf mortality due to dystocia accounted for the single largest loss category through the first 96 hours postpartum.<sup>21</sup> Dystocia accounted for 51% of calf deaths and 53% of dystocia deaths occurred in calves which were born without assistance. Calf deaths from primiparous 2- and 3-year-old dams accounted for 41% of total mortality. Necropsies done on 798 of 893 calves found that 77.7% were anatomically normal and 22.3% abnormal. At necropsy of the calves which died associated with dystocia the findings included a froth-filled trachea, non-functional lungs, bruises, contusions, hemorrhages, bone fractures, and joint dislocations. It was concluded that the provision of adequate obstetrical assistance at the right time could have reduced the mortality associated with dystocia.

Similar reports of weakness following dystocia have been reported; in some cases a collapsed trachea is present.<sup>23</sup> In a study of parturient calf mortality in Australia, death rates as high as 44% from heifer groups have been reported.<sup>24</sup> The death rate was significantly higher in male calves than female calves. Pathological changes in many of the dystocia-related deaths were

minimal but a congested swollen tongue was a definitive lesion.

**Traumatic injuries of calves at birth** are caused primarily by the mechanical influence of traction during delivery and can result in asphyxia and a high perinatal mortality rate.<sup>25</sup> Excessive traction is the most important cause of rib and vertebral fractures in the calf during dystocia. A series of 235 calves which died perinatally were examined by necropsy to determine the possible causes of death related to dystocia. Most of the parturitions were protracted and needed veterinary assistance, and 58% of the calves had pathological evidence of asphyxia. Calves delivered by extraction had pathological evidence of asphyxia more often than those born unassisted or delivered by cesarean section. Intrapulmonary amniotic material may be present in the lungs<sup>26</sup> and represent evidence of perinatal respiratory distress.<sup>27</sup> The aspiration of small amounts of amniotic fluid with or without meconium is common in calves and is not associated with hypoxemia, respiratory acidosis, or failure of passive transfer.<sup>28</sup>

#### *Premature expulsion of placenta*

Premature expulsion of the placenta has been associated with perinatal calf mortality.<sup>29</sup> Field observations indicate that the majority of affected fetuses die from fetal hypoxia during stage two of calving. The most significant risk factor associated with premature expulsion of the placenta was fetal malpresentation and malposture. Prolongation of the second stage of parturition allows for sufficient detachment of the placenta for it to occupy the posterior part of the genital tract. The placenta is frequently expelled together with the calf.<sup>30</sup> In one series of cases, there was no significant relationship between the occurrence of premature expulsion of the placenta and parity, calving difficulty, previous calving history, or sex of the calf.<sup>29</sup>

#### **NECROPSY FINDINGS**

All calves which die should be examined by necropsy to identify possible causes. It is important to establish if there is one disease complex or several different diseases of newborn calves.

In the weak calf syndrome described in Northern Ireland, at necropsy, many calves had petechial hemorrhages in the thymus gland, on the ventricular epicardium and the parietal pleura and endocardium.<sup>8</sup> These lesions were similar to those present in animals which died of acute terminal asphyxiation.<sup>18</sup> The gasps made in response to asphyxia in utero result in amniotic fluid being inhaled into the respiratory tract. In one study, 84% of stillborn calves had these lesions of asphyxia. It is well established that asphyxiation during birth is a major factor in intrapartum stillbirth in piglets and contributes to early post-

natal mortality.<sup>18</sup> Froth may be present in the caudal trachea of some calves which die within 10–20 minutes after birth.

Varying degrees of subcutaneous edema of the head and/or bruising of the rib cage are also common. Fractures of the ribs are common, accompanied by intrathoracic hemorrhage. Vertebral body fractures occur commonly at the thoracolumbar region and may be accompanied by intra-abdominal hemorrhage. The lungs may be inflated normally, partially inflated, or not inflated. Severe bruising and hemorrhage occur around the costochondral junctions, the sternal extremities of the costal cartilages, and over the sternum and shoulder regions. In some cases, the traumatic lesions are severe and may involve primarily the right side of the rib cage.<sup>6</sup> Severe subcutaneous hemorrhage and edema may be present over the carpal and fetlock joints due to the pressure applied by the obstetrical chains or ropes.

In the syndrome described in the US, the lesions either appeared at birth or developed in the first few weeks of life.<sup>1</sup> At necropsy the prominent lesions are marked edema and hemorrhages of the subcutaneous tissues over the carpal and tarsal joints and extending distally down the limbs. The synovial fluid may be blood-tinged and contain fibrinous deposits. Erosions or ulceration of the gastrointestinal tract, petechial hemorrhage of internal organs, involution of the thymus gland, and hemorrhages in skeletal muscle have also been present.

Samples for confirmation of diagnosis

- Bacteriology – fetal liver, lung, stomach content, adrenal gland; placenta (CULT). Special detection techniques for *Leptospira* antigens.
- Histology – fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (LM, IHC)

#### **DIFFERENTIAL DIAGNOSIS**

Determination of the cause of the weak calf syndrome in a herd is often difficult because the limits of the case definition cannot be determined. Several risk factors may interact to contribute to the disease. The most common definition is a calf that is alive at birth, appears normal otherwise, but either fails to breathe or breathes for less than about 10 minutes and then dies. If they survive for several hours or a few days, affected calves are usually in sternal recumbency, depressed, reluctant to stand unassisted, reluctant to walk, and not interested in sucking. They may not respond favorably to supportive therapy.

#### **Case definition**

When an epidemic of the disease is encountered, an epidemiological investigation of the herd is necessary in an attempt to identify possible risk factors.

The patterns of occurrence should be determined:

- Is the problem more common in calves born to heifers than cows? In some situations, the owner may provide more surveillance for the calving heifers and less for the mature cows with a consequent greater incidence of weak calves born from the cows
- Is there any evidence that parturition is prolonged in the heifers or the cows and what are the possible reasons?
- How long are heifers and cows in the herd allowed to calve unassisted before obstetrical assistance is provided?
- Is it possible that some nutritional, management or environmental factor is interfering with normal parturition?
- Is the condition more common in male or female calves and what are the relative birth weights?
- How soon after birth are the calves affected?
- What is the course of the illness after the first clinical abnormalities are noted?
- What level of calving surveillance and assistance is being provided by the attendants?
- The veterinarian should make every effort to clinically examine a representative number of affected calves.

## TREATMENT

Calves born weak, unable to stand, lacking the instinct to seek the teat or lacking a suck reflex, need intensive care including force-feeding of colostrum and the provision of warm surroundings to prevent hypothermia and other complications. Affected calves must be assisted to suck the dam normally. Bottle feeding for a few days may be necessary until the calf becomes strong enough to suck the dam on its own.

## CONTROL AND PREVENTION

Control and prevention of the weak calf syndrome is based on empirical observations beginning with insuring **adequate nutrition of the dam** to avoid any possible nutritional factors affecting neonatal calf vitality. The provision of **adequate surveillance at calving time** and competent obstetrical assistance when necessary is also crucial to avoid prolonged parturition and fetal hypoxia in calves.

When epidemics of the disease are occurring, the surveillance of calving must be intensified, and it may be necessary to intervene with obstetrical assistance earlier than usual. Determination of the cause may require that the veterinarian attend several calvings, make detailed clinical examinations of the length of parturition and observe the parturition process and the health of the calves at birth.

## WATERY MOUTH OF LAMBS (RATTLE BELLY, SLAVERS)

### Synopsis

**Etiology** Non-enteropathogenic *E. coli* endotoxemia predisposed by failure of passive transfer

**Epidemiology** Higher risk with intensive housing with poor hygiene

**Clinical findings** Loss of sucking reflex, retention of meconium or feces, excessive mucoid saliva, abomasal distension.

**Lesions** None specific

**Diagnostic confirmation** Nothing pathognomonic.

**Treatment** Fluids and energy via stomach tube. Antimicrobials.

**Control** Antimicrobials at birth, pen hygiene, ensure adequate colostrum transfer

## ETIOLOGY

This disease is believed to be the result of **endotoxemia** in young lambs. It is postulated that the neutral pH of the abomasum in newborn lambs, coupled with

low concentrations of colostral immunoglobulin in the gut, allow rapid multiplication of non-enteropathogenic strains of *Escherichia coli* in the gut, and to some extent systemically, to result in endotoxemia.<sup>1</sup>

## EPIDEMIOLOGY

### Occurrence

The syndrome is primarily reported in **lambs in Great Britain** but has also been reported in New Zealand and in goat kids in Spain and North America.<sup>1,2</sup>

### Animal and environmental risk factors

Lambs 12 to 72 hours of age are affected. The disease is seen under all management systems but is rare in pastured flocks and occurs most commonly in lambs kept in **intensive housing** where there is **poor hygiene** of the lambing environment. Lambs from prolific ewes are at risk and the disease is more common in triplets than twins or singles.

Delayed or **poor colostrum intake** is a major risk factor and situations that predispose this may lead to outbreaks. A high prevalence has occurred in ram lambs castrated by the use of an elastic band at a very young age and the resulting pain may have dissuaded them from feeding.

Other risk factors, all of which reduce sucking by the lamb, are inclement weather, mismothering, maternal agalactia, competition between twins or triplets, low vitality, and ewes in poor condition.

### Experimental reproduction

An equivalent clinical syndrome is reproducible by administering non-enterotoxigenic strains of *E. coli* by mouth to colostrum-deprived lambs, all of whom died within 24 hours.<sup>3</sup>

### Economic importance

Watery mouth disease is a major cause of mortality of housed newborn lambs in Great Britain and is reported to be the cause of approximately 25% of all deaths of lambs in indoor intensive lambing systems.<sup>1</sup> Where conditions allow morbidity rates may approach 24% and without early treatment case fatality rates are high.<sup>4</sup>

## PATHOGENESIS

Gram-negative bacteria, non-enterotoxigenic and non-enteropathogenic *E. coli* in the environment, are ingested as a result of a contaminated environment, or from a contaminated fleece, and survive passage through the neutral pH of the abomasum to be absorbed into the systemic circulation by the natural pinocytosis that occurs in the intestinal epithelium of newborn ruminants, to produce an endotoxemia.

## CLINICAL FINDINGS

Affected lambs are normal at birth but become sick at 24–48 hours and up to 72 hours old. The disease is characterized by dullness, a complete failure to suck, and excessive mucoid saliva around and drooling from the mouth. As the disease progresses there is hypothermia, failure to pass feces, cold extremities, depression to the point of coma, anorexia and, in the late stages, abdominal distension and recumbency, but rarely diarrhea. The alimentary tract is full of fluid and the lamb rattles when it is shaken. Some lambs are hypothermic but the temperature is normal at the onset of the condition and falls to subnormal as the disease progresses. Progress is rapid with death 6–24 hours after the first signs of illness.

## CLINICAL PATHOLOGY

Total protein concentrations and base excess values are significantly elevated compared to normal lambs.<sup>5</sup> Blood glucose concentrations are normal but may be low in the terminal phase of the disease.

## NECROPSY FINDINGS

There are no findings specific to the syndrome. The abomasal contents are fluid and mucoid, and contain small milk curds and the intestine is gas filled.

## TREATMENT

Treatment with intramuscular amoxicillin and clavulanic acid, intravenous flunixin meglumine, and oral rehydration fluid, when administered early in the clinical course, has resulted in a high recovery rate in field cases.<sup>5</sup> Dextrose solution should also be given to those lambs that are hypoglycaemic and external warming should be provided. Other recommended treatments include emptying the alimentary tract by purgation or enema.

## DIFFERENTIAL DIAGNOSIS

Most neonatal disease of lambs is manifest with diarrhea which is not present in watery mouth. The early stages of Colisepticemia and *Clostridium perfringens* type B or C present with similar clinical signs but are easily differentiated later in the clinical course or at post mortem examination. Hypothermia/starvation/cold stress can present with similar clinical findings but the history and environmental circumstances of occurrence differ.

## CONTROL

In outbreaks the administration of antibiotics to all newborn lambs within 15 minutes to 2 hours of birth dramatically reduces the occurrence of further cases.<sup>4,6</sup> Fresh or frozen sheep or cow colostrum should be supplemented to lambs at risk. The provision of ewe colostrum at 50 mL/kg body

weight within 6 hours of birth prevents the disease.

Lambing areas and associated pens and yards should be kept clean and fresh bedded. Contaminated fleece should be removed from around the udder of the ewe prior to lambing and every effort should be made to insure early and adequate colostrum intake by newborn lambs, especially for twins and triplets.

## COLD COW SYNDROME

This is a herd disease problem reported from the UK in cows freshly turned out onto lush pasture with a high (27–43%) soluble carbohydrate content.<sup>1</sup> There is a high morbidity (up to 80%) and a large number of outbreaks in an area. The syndrome includes hypothermia, dullness, inappetence, agalactia, and profuse diarrhea. Affected cows feel cold to the touch. Some have perineal edema, some collapse. The herd milk yield falls disastrously but there is a quick return to normal if the cows are moved to a different field. The problem may occur on the same pasture each year and recur if the cows are returned to the same pasture. There is no obvious clinicopathological abnormality. It is postulated that the syndrome might be due to zearalenone or related metabolites produced by field micro fungi in the pasture.<sup>2</sup>

## THIN SOW SYNDROME

### Synopsis

**Etiology** The syndrome is the result of inadequate nutrition and unbalanced nutrition in pregnancy and lactation but can also result from parasitic or chronic infectious disease.

**Epidemiology** Loss of weight to the point of inanition particularly in first and second litter gilts.

**Clinical findings** Inanition

**Control** Recognition of the relation between voluntary feed intake in pregnancy and lactation, feeding based on condition scores.

## ETIOLOGY

The 'thin sow syndrome' is discussed in this chapter because of its multiple etiology. Regardless of etiology the effects of this syndrome on fertility and overall farm productivity can be formidable. There are a number of causes of wasting and the occurrence of thin sows:

- The major cause of sow abnormality under this heading results from **errors in feeding** and management, which are likely to be exaggerated and multiplied on farms where intensive management is practiced. The most common errors are incorrect feeding in pregnancy and lactation. These can be exacerbated by cold or drafty housing, fluctuating temperatures, too high a temperature in the farrowing house, low-level feeding to avoid obesity, wet bedding, and lack of drinking water. Early weaning increases the risk for the thin sow syndrome, especially if nutrition is inadequate.
- Parasitic disease**, particularly associated with infestation with *Oesophagostomum* spp. and *Hyostromylus* spp. Is a cause of wasting in sows and the occurrence of the thin sow syndrome and is discussed under those headings (Ch. 27)
- Thin sows can be a component of the syndrome of **infectious diseases** such as cystitis and pyelonephritis.

## EPIDEMIOLOGY AND PATHOGENESIS.

The syndrome is most common in first and second litter gilts but can affect all parities when nutrition is inadequate. It emerged as a problem in the 1970s as a result of poor understanding of the **inter-relation between feed intake in pregnancy and that in lactation**, combined with the move to intensive indoor housing of pregnant sows. Penning of sows exacerbated social dominance/submissive relationships. The voluntary intake of food by sows during lactation is inversely related to the intake in pregnancy. Consequently sows that are fed at high levels during pregnancy will gain excessive weight during pregnancy but will voluntarily restrict feed intake during lactation and lose excessive weight during lactation. In contrast sows that are fed what is basically a maintenance ration 2.0–2.5 kg (4.5–5.5 lbs) of a balanced sow ration during pregnancy will gain adequate weight for conceptus and body growth and during lactation will consume adequate feed for lactation requirements and lose minimal weight in this period. Knowledge of sow nutrition has improved such that major problems with this syndrome should not occur but there is still a risk of

inadequately feeding sows selected for lean genotype and high litter size and weaning weights. First and second litter gilts may require more feed to provide for body growth.

#### CLINICAL FINDINGS

Within a herd the thin sow syndrome develops over a period of months and often one or two pregnancy cycles, with a gradually declining of body condition of the group until 20% to 30% of sows have a low body condition score. No abnormalities are evident on clinical examination but the sow fails to regain weight after weaning, particularly sows after their first litter. The most critical period for weight loss is the first 2 weeks after weaning. Affected sows have a poor appetite but often show pica and excessive water intake and may be anemic.

#### CONTROL

##### Feeding during pregnancy

Currently the risk for the thin sow syndrome exists where it is assumed that all pregnant sows can be fed a standard amount of ration. Problems are likely to occur when sows are run in groups and fed as a group where timid sows are likely to be bullied out of their required share of food.

Individual feeders or stall feeding will prevent this.

##### Feeding during lactation

The critical issue is to ensure adequate feed and energy intake during lactation. This can be achieved by:

- not feeding to excess during pregnancy restricting the feed intake of sows in the first few days after farrowing to encourage better feed intake in later lactation
- ensuring an adequate and constant supply of water
- ad lib feeding during lactation
- a high-energy-density lactation diet
- enclosing the creep with heat for the piglets so that the farrowing house can be kept at a lower temperature 65°F (65°C) for the sow
- control of parasitic disease.

**Condition scoring** is a valuable guide to the feeding of individual sows and for a judgement of feeding practices in the herd as a whole. On a score of 1 to 5 it should be very rare to find sows with condition scores of 1 or 5. The optimum is to have sows entering the farrowing house between condition score 3 and 4 and not less than 2.5 at weaning. First and second parity sows in poor condition at weaning are best 'skipped' at the first heat and mated on the second heat.

Methods for condition scoring and guidelines can be found at [http://www.](http://www.defra.gov.uk/animalh/welfare/farmed/pigs/pb3480/pigscotc.htm)

[defra.gov.uk/animalh/welfare/farmed/pigs/pb3480/pigscotc.htm](http://defra.gov.uk/animalh/welfare/farmed/pigs/pb3480/pigscotc.htm)

### ACUTE HEPATITIS (POSTVACCINAL HEPATITIS) OF HORSES (THEILER'S DISEASE, SERUM HEPATITIS)

An acute hepatopathy of horses often associated with administration of equine biological products such as tetanus antitoxin.

#### ETIOLOGY

Etiology is unknown, although an infectious agent is suspected.

#### EPIDEMIOLOGY

The disease occurs in horses administered equine serum or tissue products. The first reports of the disease were in horses in South Africa administered equine serum as prophylaxis for Africa Horse Sickness. Outbreaks of the disease have occurred in horses in Africa, Europe, and North America administered equine serum as prophylaxis for a variety of diseases including African horse sickness, encephalomyelitis, botulism, *Strep. equi* infection, tetanus, and influenza and in mares given pregnant mare serum.<sup>1</sup> Most sporadic cases of the disease appear to be associated with administration of tetanus antitoxin.

The disease is reported only from adult horses (>1 year of age) and most cases are reported in the summer and autumn.<sup>2</sup> There is a suspicion that pregnant mares are at increased risk.

The **morbidity rate** in outbreaks among horses administered equine serum ranges between 2 and 18%,<sup>3</sup> although the rate among horses administered tetanus antitoxin as prophylaxis following injuries is clearly much lower. Acute hepatitis developed in 4 (0.4%) of 1260 horses >1 year of age administered commercial equine plasma at one institution in the United States over a 6-year period.<sup>4</sup> The disease can occur after intrauterine infusion of equine serum to mares.

The **case fatality rate** is between 50 and 90%.

The disease occurs sporadically in horses that have not been administered equine biological products. There are reports of in-contact, non-treated horses developing the disease.

#### PATHOGENESIS

Destruction of hepatocytes results in hepatic dysfunction. Hepatoencephalopathy develops in severely affected horses.

#### CLINICAL FINDINGS

The disease usually occurs after an **incubation period** of 40–70 days (range 27–165 days). Depression, anorexia, and

icterus are evident in mildly affected cases. There may be mild to moderate colic. Body temperature and heart rate are usually normal. Acutely affected, or horses observed infrequently, can die unexpectedly. Signs of **hepatoencephalopathy** include restlessness, excitement, compulsive walking and head pressing, abnormal head position, seizures, apparent blindness, muscle tremors, and ataxia. Affected horses often injure themselves by walking into fences and troughs.

#### CLINICAL PATHOLOGY

Leukocytosis with neutrophilia and mild lymphocytopenia is common. The hematocrit and plasma total protein concentrations may be mildly increased. Hyperbilirubinemia and an increase in direct (conjugated) bilirubin concentration are present and serum bile acid concentration is increased, as is serum activity of liver specific enzymes aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), and sorbitol dehydrogenase (SDH). Increases in serum GGT activity is often less than expected for the increases in serum AST, SDH, and bile acid concentrations, likely reflecting the primary insult to hepatocytes.

Hypoglycemia (<2 mmol/L, 40 mg/dL) and hyperammonemia (>150 μmol/L) may be severe. Clotting time, especially the one stage prothrombin time, may be prolonged.

#### NECROPSY FINDINGS

The liver may be enlarged, normal or shrunken and discolored slightly yellow to green. There is severe centrilobular necrosis of hepatocytes with mild infiltration of lymphocytes and plasma cells. Alzheimer type II astrocytes are present in the brains of horses with encephalopathy.

#### DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation antemortem is achieved by examination of a liver biopsy, although this should not be performed in animals with coagulation abnormalities.

##### Differential diagnosis list:

- Acute aflatoxicosis
- Rubratotoxicosis (Penicillin rubrum)
- Pyrrolizidine alkaloid intoxication
- Dioxin intoxication
- Idiopathic hyperammonemia.<sup>5</sup>

#### TREATMENT

Treatment is essentially supportive and consists of correction of metabolic and acid–base abnormalities, reduction of plasma ammonia concentration, and preventing horses with hepatoencephalopathy from injuring themselves.

Hypoglycemia and dehydration can be corrected by intravenous administration of

5% dextrose and isotonic electrolyte solutions. Metabolic acidosis can be corrected by infusion of sodium bicarbonate. Plasma transfusions may be necessary to correct coagulation abnormalities.

Hyperammonemia can be treated by giving neomycin (20 mg/kg, orally, every 6 hours for 4 doses) or lactulose (0.25 mL/kg, orally every 8 hours) to decrease absorption of ammonia from the gastrointestinal tract.

**Sedation** with xylazine or similar compounds may be necessary to prevent the animal injuring itself. The affected horse should be housed in an area where it has the least opportunity to injure itself, and may need to be fitted with a padded helmet.

### CONTROL

Minimal use of biologics, including plasma, of equine origin is prudent.

## GRANULOCYTOPENIC DISEASE OF CALVES

A fairly widespread disease of recent origin, granulocytopenic disease of calves is commonly ascribed to poisoning with furazolidone. Affected calves are those being reared on milk replacer and sometimes, but not always, receiving prophylactic antibiotics.<sup>1,2</sup>

Affected calves show persistent fever, and increased salivation and nasal discharge, and there are hemorrhages and necrotic lesions in the mouth and lower alimentary tract. The disease is characterized by decreased myelopoiesis in bone marrow, neutropenia, and thrombocytopenia. The course varies from 2 to 5 days, and the mortality rate is high, apparently from bacterial invasion. Pneumonia, peritonitis, and enteritis are common accompaniments. *Fusobacterium necrophorum* can be isolated from necrotic lesions.<sup>1</sup> These clinical, pathological, and hematological findings resemble those of radiation sickness, and poisoning by bracken fern.

The disease has been related to long-term feeding of furazolidone (2 mg/kg BW daily), either in the milk replacer or as specific therapy, and the disease can be reproduced by this means. At higher dose rates (20–30 mg/kg BW) nervous signs, including convulsions, and death follow within a few days; both syndromes may occur at the same time in a group of calves.<sup>3</sup>

## SWEATING SICKNESS (TICK TOXICOSIS)

### Synopsis

**Etiology** Unknown, associated with bites of *Hyalomma truncatum*.

**Epidemiology** Reported in Africa, India, and Sri Lanka affecting calves 2 to 6 months of age.

**Clinical findings** Fever, salivation, lacrimation, hyperemia of mucosae, epistaxis, and extensive and severe dermatitis, necrosis of oral epithelium

**Lesions** Dermatitis and necrotic stomatitis, disseminated intravascular coagulopathy.

**Treatment** Symptomatic and use of hyperimmune serum

**Control** Tick control

### ETIOLOGY

The cause has not been identified, but it behaves as though it were an epitheliotropic toxin produced by the salivary glands of certain strains of the tick *Hyalomma truncatum*. Not all strains of *H. truncatum* have the ability to produce the disease and antigens unique to sweating sickness-inducing strains are described.<sup>1,2</sup>

### EPIDEMIOLOGY

Attempts to transmit the disease between animals by mediate or immediate contact and by injections of tissue or blood are unsuccessful. The disease occurs in Central, East and South Africa, Sri Lanka, and probably southern India. Only calves 2–6 months of age are affected as a rule but rare cases occur in adults. Sheep, pigs, and goats are susceptible, although the disease does not naturally occur in them, and the disease has been produced experimentally in dogs. Sweating sickness occurs at all times of the year but is most prevalent during the wet season when ticks are more plentiful. The morbidity rate varies with the size of the tick population but is usually 10–30%. The case fatality rate is up to 30%.

### PATHOGENESIS

The clinical signs begin 4–7 days after the ticks attach, probably 3 days in experimental infestations. The effects are dose-specific; if the ticks are removed very early there is no clinical response and the animal remains susceptible; with a longer exposure before the ticks are removed the animal becomes immune but shows no clinical signs. With longer exposure of more than 5 days the subject develops the

full-blown clinical disease and may die. If it recovers it has a solid and durable immunity.

### CLINICAL FINDINGS

There is a sudden onset of fever up to 41°C (106°F), anorexia, hyperemia of the mucosae, and hyperesthesia. The animal is lethargic, depressed, dehydrated, and has a serous then mucopurulent oculonasal discharge, an arched back, and a rough coat. There is an extensive, moist dermatitis commencing in the axilla, groin, perineum, and at the base of the ears which extends to cover the entire body in bad cases. 'Sweating' refers to this moist dermatitis. The hair is matted together by exudate and moisture collects in the form of beads on the surface. The eyelids may be stuck together. Subsequently patches of the skin and hair are rubbed off or can be pulled off to leave raw, red areas of subcutaneous tissue exposed. The tips of the ears and tail may slough.

Affected calves seek shade and their skin is very sensitive to touch. Later it becomes dry and hard, and cracks develop. Secondary bacterial infection and infestation with blowflies or screw-worm larvae are common sequelae. The oral mucosa is hyperemic at first and then becomes necrotic with the formation of ulcers and diphtheritic membranes. The calf salivates profusely, cannot eat or drink, and becomes emaciated and rapidly dehydrated. There are similar mucosal lesions in the vagina and nasal cavities, the latter causing dyspnea. The severity of the mucosal lesions appears to vary with different 'strains' of the toxin.<sup>3</sup> There may be abdominal pain and diarrhea in some calves.

The course may be as short as 2 days but is usually 4 or 5 days. In recovered animals the skin may heal and the hair may regrow, but there may be permanent, patchy alopecia and the calves may remain stunted and unthrifty.

### CLINICAL PATHOLOGY

There is a severe neutropenia and eosinopenia and a degenerative left shift.  $\alpha$ -globulin and beta-globulin levels are raised. Urinalysis indicates the existence of nephrosis but serum creatinine levels are normal.<sup>4</sup> Dermatological examination fails to reveal the presence of any of the usual infectious causes of dermatitis.

### NECROPSY FINDINGS

The lesions are essentially those seen clinically. There is also evidence of severe toxemia, dehydration, emaciation, and hyperemia of all internal organs and disseminated intravascular coagulation. The necrosis of the oral epithelium extends into the esophagus and may reach the forestomachs.

**DIFFERENTIAL DIAGNOSIS**

The combination of extensive dermatitis and mucosal necrosis is unusual. Mucosal disease and bovine malignant catarrh may bear some resemblance and there could be difficulty in differentiation in areas where the tick *Hyalomma truncatum* occurs.

**TREATMENT**

There is no specific treatment; efforts should be directed at relieving the severity of the dermatitis and mucosal loss. Non-steroidal anti-inflammatory drugs (NSAIDs) and broad-spectrum antibiotic cover is a logical regimen. Hyperimmune serum, produced in sheep and cattle by infesting them with *Hyalomma truncatum* at 6-week intervals for 2–5 occasions, is an effective treatment in pigs, sheep, and to a less extent calves.<sup>2,5</sup>

**CONTROL**

Control is limited to control of the causative tick. No vaccine is available.

## Diseases characterized by alimentary tract involvement

### EQUINE GRASS SICKNESS (EQUINE DYSAUTONOMIA, GRASS DISEASE, MAL SECO)

**Synopsis**

**Etiology** Unknown

**Epidemiology** Horses of all breeds and both sexes in the UK, Western Europe, Scandinavia, and southern South America. Greatest incidence in early summer.

**Clinical signs**

**Acute grass sickness:** Colic, nasogastric reflux, absent gut sounds, depression, dysphagia, and small intestinal distension of <2 days duration at time of death.

**Subacute grass sickness:** Tachycardia with or without signs of colic, reduced intestinal sounds, impaction of the colon, and clinical course of 2–7 days.

**Chronic grass sickness:** Insidious onset weight loss, intermittent colic, decreased appetite, rhinitis sicca, patchy sweating, and mild dysphagia.

**Clinical pathology** None is specific or diagnostic.

**Lesions** Both forms of the disease have degeneration of neurons of the autonomic nervous system, especially of the myenteric and submucosal plexuses.

**Diagnostic confirmation** Examination of ileal biopsy.

**Treatment**

**Acute grass sickness/subacute grass sickness:** Supportive. None effective.

**Chronic grass sickness:** Nursing care. Cisapride.

**Control** None

**ETIOLOGY**

The cause is unknown but is suspected to be a neurotoxin, possibly *Clostridium botulinum* toxin, based on epidemiologic data.<sup>1,2</sup> Evidence supporting a role for *Cl. botulinum* in the etiology of the disease included the isolation of toxin (BoNT/c) producing strains of *Cl. botulinum* type C from the ileum of 45% of horses with grass sickness and 4% of clinically normal control horses.<sup>2</sup> In addition to preventing the release of acetylcholine at cholinergic nerve terminals and thereby causing paralysis, a function that it shares with other botulinum toxins, BoNT/C is neurotoxic. Other studies have demonstrated increased numbers of bacterial organisms, including anaerobes, and number of species of clostridia in feces of horses with grass sickness compared with normal horses.<sup>3</sup> Whether these findings represent a causative role of *Cl. botulinum* in grass sickness, or an effect of the modified gastrointestinal motility and on intestinal flora remains to be determined. Further evidence to support a role for *Cl. botulinum* in the etiology of grass sickness include the observations that low serum concentrations of antibodies to *Cl. botulinum* are associated with increased risk of the disease.<sup>1,4</sup> However, the hypothesis of a role for toxicoinfectious botulism in grass sickness of horses does not explain the geographic distribution of the disease given that botulism occurs worldwide in horses and grass sickness does not.

**EPIDEMIOLOGY****Occurrence**

Grass sickness is not common and appears to be restricted in its distribution to all parts of Great Britain (including possibly Ireland), Sweden, and the northern and western coasts of Europe. A clinically and histologically indistinguishable disease, *mal seco* occurs in the Patagonia region of Argentina, southern Chile, and in the Falkland (Malvinas) Islands.<sup>5,6</sup>

Horses, ponies, donkeys, zebra, Przewalski's horses, rabbits, and hares are the predominant species affected.<sup>7</sup> The morbidity and mortality rates are not reported, but the incidence on farms with a history of the disease ranges between 0.4 and 16% per year<sup>8</sup> or 2.1 grass sickness cases per 100 horses per year.<sup>9</sup>

The case fatality rate for acute grass sickness is 100%, while that for the chronic form of the disease in horses treated at a referral hospital is 60–70%.<sup>10,11</sup> Horses that survive the chronic form of the disease are often destroyed because of weakness and emaciation, although make complete recoveries.<sup>12</sup> However, given the difficulty in establishing an antemortem diagnosis, it is unclear whether horses that fully recovered actually had chronic grass sickness.

**Risk factors****Animal risk factors**

The risk of disease is greatest in 4–5 year old horses (adjusted odds ratio of 1.9 compared with 0–3 year olds) and then declines such that the risk of disease is lowest in horses >12 years old (odds ratio 0.02 compared to that of 0–3 year olds).<sup>1</sup> Cases in horses 10 months to 20 years of age have been encountered. Foals born of affected mares are clinically normal.<sup>13</sup> There is no apparent breed predilection.<sup>8</sup>

Horses at pasture are at increased risk (hence the colloquial name of the disease), although the disease does occur rarely in stabled horses. A recent (<14 day) change of pasture carries an increased risk (odds ratio 24) of development of the disease.<sup>14</sup> Horses that have been on the farm for less than 2 months are at increased risk of developing the disease.<sup>8</sup> Horses on farms with previous cases of the disease are at increased risk (odds ratio 2.2–45) of the disease,<sup>14,15</sup> although horses that have been in contact with animals with the disease are at reduced risk (odds ratio 0.1) of developing the disease.<sup>14</sup>

**Environmental risk factors**

There is a marked seasonal distribution of cases, with the peak incidence occurring in early summer in the British Isles.<sup>8,9,16</sup> Outbreaks of the disease are associated with the occurrence of cooler and drier weather than normal during the 2 weeks preceding the outbreak,<sup>9,17</sup> although this is not consistently reported.<sup>15</sup>

**Farm or premise risk factors**

As mentioned, farms with a history of horses with the disease are at increased risk of having further cases. For premises with previous cases of grass sickness there is an increased risk of the disease developing as the number of horses on the farm increases, with the presence of young horses, on stud farms and livery/riding schools, on farms having sandy or loamy

soil, and those rearing of domestic birds and using mechanical fecal removal.<sup>9</sup> The risk of recurrence of disease on a farm decreased with presence of chalk soil, cograzing ruminants, grass cutting of pastures, and manual removal of feces.<sup>9</sup> There is no association between the disease and the type of pasture, nor with provision of supplementary feeds.<sup>8</sup> Feeding hay or haylage is associated with a decreased risk of the disease.<sup>1</sup> Any disturbance of the soil, such as by ploughing, increases the risk of disease.

#### Transmission

The disease is not contagious. Injection of normal horses with serum of affected horses causes lesions, but not clinical signs, consistent with the disease.

#### PATHOGENESIS

The clinical signs are attributable to widespread damage to the autonomic nervous system, resulting in sympathetic and parasympathetic dysautonomia that is most clinically evident in the gastrointestinal tract. Coincident with damage to the autonomic nervous system are increases in plasma concentrations of dihydroxyphenylalanine, epinephrine, norepinephrine, and dopamine,<sup>18</sup> possibly because of increased secretion of these compounds from affected sympathetic ganglia and neurons.<sup>19</sup> Lesions in the cranial nerves and brain stem are probably responsible for dysphagia and drooling evident in most cases. Rhinitis is associated with diminished nonadrenergic, noncholinergic (NANC) innervation, greatest in neurons positive for substance P or calcitonin gene-related peptide, of the nasal mucosa in subacute and chronic cases.<sup>20</sup>

Electrocardiographic examination of affected horses reveals evidence of loss of parasympathetic innervation of the heart, which is consistent with lesions in the terminal cardiac ganglia.<sup>21</sup> Splanchnic lesions are most severe in the myenteric and submucosal plexuses of the ileum, with less severe changes in the large colon and celiaco-mesenteric ganglion.<sup>22</sup> There is also a reduction in interstitial cells of Cajal (cells involved in pacemaker activity and autonomic transmission within the gut).<sup>23</sup> These neuronal changes are associated with a marked impairment of cholinergic activity in ileal tissue of affected horses.<sup>24</sup> Because of the altered autonomic activity, peristalsis decreases (in chronic cases) or ceases (in acute cases) with subsequent accumulation of ingesta in the small intestine, stomach, and large colon. Death is due to emaciation in chronic cases or rupture of the stomach or intestine in acute cases.

#### CLINICAL FINDINGS

The clinical signs of grass sickness are varied, and accurate diagnosis on clinical

signs alone is very difficult. The incubation period of the disease is approximately 10–14 days<sup>17</sup>. **Acute, subacute, and chronic** forms of the disease are recognized,<sup>25</sup> although some authorities use a designation of acute and chronic.<sup>26</sup> In all cases, there is some dysphagia, resulting in drooling of saliva and trickling of ingesta from the nose. Dried food is impacted between the cheeks and the teeth and the animal plays at drinking. These signs are attributable to lesions in the cranial nerves. Most animals are depressed.

**Acute cases** the onset is sudden and the course of the disease is 1–4 days. Abdominal pain may be severe but also may be absent even in the presence of severe tachycardia. There is tachycardia (80–90/min may be >100), decreased to absent gut sounds, lack of defecation, and abdominal distension. On rectal examination, there are hard, dry pellets of feces, the large colon contains firm ingesta which has a corrugated feel that is quite distinct to the smooth surface of a primary colonic impaction. The small intestine is distended with fluid and readily palpable in the caudal abdomen. Nasogastric intubation yields a large (20 L) quantity of fluid. Urination is frequent and may be accompanied by tenesmus. Affected horses may wander about in a restless manner and a fine muscle tremor occurs constantly, especially in the upper forelimb. Periodic attacks of patchy sweating occur commonly. There is noticeable salivation. Esophageal endoscopy reveals linear ulcerations resulting from reflux esophagitis.

**Subacute** cases have signs of mild colic, or may not have any signs of colic, in the presence of tachycardia, depression, reduced gastrointestinal sounds, and impaction of the large colon with characteristic corrugated appearance.<sup>25</sup> The clinical course is 2 to 7 days and death is inevitable. Esophageal endoscopy reveals the presence of linear erosions in many affected horses.

**Chronic cases** the course is usually >7 days and is characterized by weight loss, patchy sweating, and intermittent colic. Horses stand with all four feet close together under them ('elephant on a tub stance') and have a tucked up abdomen. Dysphagia is evident and the gut is empty except for the colon and rectum which contain dry, hard feces. In the late stages the patient snores, the penis droops, and attempts are made to eat abnormal materials. Most cases of the chronic form have rhinitis, characterized by crusting of mucopurulent material on the turbinates and this is considered, in the presence of appropriate history and other clinical signs, almost pathognomonic for grass sickness.

Application of phenylephrine (0.5 mL of a 0.5% solution) into one eye causes a dorsal deviation of the eyelashes of the upper eyelid in horses with grass sickness, but not in normal horses.<sup>27</sup>

There is a radiological discernible defect in esophageal motility in horses with grass sickness.<sup>28</sup>

Recurrence of the disease in a horse is exceedingly rare.

#### CLINICAL PATHOLOGY

Serum biochemical profiles and hematological examinations do not demonstrate pathognomonic changes.<sup>29</sup> Signs of dehydration, electrolyte imbalances, hyperbilirubinemia, and elevations of serum activity of liver derived enzymes are all secondary to the disease.<sup>30</sup> Urine from horses with grass sickness has higher specific gravity, protein and creatinine concentrations, and lower pH than that from unaffected horses,<sup>31</sup> consistent with dehydration and electrolyte imbalances that occur with the disease. Peritoneal fluid is often abnormal, having an increased protein concentration and leukocyte count but, because of the considerable overlap with values in horses with lesions of the gastrointestinal tract requiring surgery, is of limited diagnostic value.<sup>32</sup>

Antemortem diagnostic confirmation can only be achieved by examination of biopsy specimens of the ileum,<sup>33</sup> although biopsy of nasal mucosa has been suggested as an alternative.<sup>18</sup> Examination of rectal biopsy is specific, but not sensitive, for the disease.

#### NECROPSY FINDINGS

In cases of short duration, the stomach and small intestines are distended with an excess of fluid and gas, and the colon is often impacted with corrugated ingesta coated with black material. In chronic cases, the alimentary tract is empty.

Histologically there is extensive degeneration of neurons of the autonomic nervous system without evidence of inflammation.<sup>33</sup> These neurons include those of the ganglia (cranial cervical, stellate, coeliaco-mesenteric, etc.) and those of the myenteric and submucosal plexi of the intestines. Degenerative neuronal changes may also be observed in the central nervous system, including the oculomotor, facial, lateral vestibular, hypoglossal and vagal nuclei, the ventral horns of spinal cord and the dorsal root ganglia. This neuropathy is difficult to confirm unless fresh, well-fixed samples are submitted for histological examination. Immunohistochemical staining for synaptophysin aids in the differentiation between autolytic tissue and tissue from horses with grass sickness.<sup>34</sup>

Samples for post-mortem confirmation of diagnosis

Samples for light microscopic examination: formalin-fixed sympathetic ganglia, brain stem, spinal cord with dorsal root ganglia, gastric fundus, duodenum, jejunum, distal ileum, ventral colon, and dorsal colon.

### DIFFERENTIAL DIAGNOSIS

#### Differential diagnosis list:

##### Acute grass sickness

- Small intestinal strangulation or volvulus
- Large colon torsion
- Anterior enteritis
- Peritonitis
- Terminal ileal impaction
- Ileocecal intussusception.

##### Subacute or chronic grass sickness

- Impaction of the large or small colon
- Helminthiasis
- Mesenteric abscessation or other chronic inflammatory disease
- Gastric squamous cell carcinoma
- Alimentary lymphosarcoma or other neoplasia
- Inadequate diet
- Poor dentition
- Equine motor neuron disease.

### TREATMENT

Acute cases respond transiently to gastric decompression and intravenous fluid administration, but death is inevitable. Selected chronic cases may benefit from careful nursing care and the administration of the promotility, indirect acting cholinergic agent, cisapride (0.5–0.8 mg/kg orally every 8 hours for 7 days).<sup>35</sup> Administration of brotizolam (a putative appetite stimulant), acetylcysteine (antioxidant and neuroprotectant), and aloe vera gel (antioxidant, anti-inflammatory and laxative) was without beneficial effect in 29 cases.<sup>36</sup>

### CONTROL

Successful measures have not been satisfactorily established and no definitive recommendation can be made. However, consideration should be given to the factors identified as increasing the risk of disease, such as pasturing, movement to new properties and especially those on which previous cases of this disease have occurred, and the disturbance of soil. Feeding of hay and haylage is associated with a reduced risk of developing the disease. Although administration of ivermectin is associated with an increased risk of the disease, appropriate parasite control should not be ignored in horses in areas in which grass sickness is endemic.

### IDIOPATHIC CHRONIC INFLAMMATORY BOWEL DISEASES OF HORSES

A syndrome of combinations of weight loss, ill thrift, diarrhea, intestinal malabsorption, and hypoproteinemia attributable to chronic inflammatory disease of the small and/or large intestine of horses is well described. The syndrome has been subdivided into granulomatous enteritis, eosinophilic enteritis, lymphocytic-plasmacytic enterocolitis, basophilic enterocolitis, and multisystemic eosinophilic epitheliotropic disease.<sup>1</sup> Other causes of chronic inflammatory bowel disease in horses include alimentary lymphosarcoma, tuberculosis, pithyosis, and histoplasmosis.<sup>2</sup>

### GRANULOMATOUS ENTERITIS OF HORSES

The etiology of granulomatous enteritis is unknown. Infection with *Mycobacterium* spp. is suggested as a cause but demonstration of acid fast bacteria in tissue sections or by culture of gut or mesenteric

lymph nodes of affected horses is rare and inconsistent. The disease occurs with greatest incidence in Standardbred horses between 1 and 6 years of age, although it does affect other breeds of horses. The disease is usually sporadic, although it has been recorded in siblings raised on the same farm.<sup>1</sup> Estimates of incidence are not available. The disease has an almost 100% case fatality rate.

Accumulation of lymphocytes and multinucleated giant cells in the lamina propria is associated with villous blunting in the small intestine. There is malabsorption of carbohydrates and fats and excessive loss of protein in feces<sup>2</sup> with subsequent hypoalbuminemia, edema, and weight loss. Weight loss and anorexia are the most common presenting signs. Fever is uncommon. Approximately one-third of horses have diarrhea or a history of abdominal pain. Affected horses may have a diffuse, scaling alopecia and excoriations especially of the coronary band. Rectal examination may reveal enlarged, soft mesenteric lymph nodes. Exploratory laparotomy in horses with signs of colic attributable to inflammatory bowel disease often reveals constricting circumferential bands in the large or small intestine.<sup>3</sup>

**Hematological and serum** biochemical examination reveals:

- A mild, macrocytic anemia (hemoglobin <100 g/L, hematocrit <30%) with a normal leukogram
- Hypoalbuminemia is a consistent finding (<25 g/L, <2.5 g/dL) while the globulin concentration may be normal, low or, more commonly, high (>50 g/L, >5.0 g/dL)
- Plasma fibrinogen concentration is usually increased (>4 g/L, 400 mg/dL)
- There are no characteristic changes on serum biochemical analysis
- Peritoneal fluid is normal.

**Absorption tests** using (D(+)-xylose, glucose, or starch) may indicate diminished absorption of carbohydrate by the small intestine. The **D(+)-xylose absorption test** is performed by administering D(+)-xylose at a dose of 0.5 or 1 g/kg as a 10% solution by nasogastric intubation after an overnight fast. The concentration of D(+)-xylose in blood samples collected at 0, 1, 2, 3, 4, and 5 hours after dosing is determined. An abnormal test is one in which there is not an obvious peak in the D(+)-xylose curve and in which the peak concentration is lower than expected for a normal horse on a similar diet. Administration of a 10% glucose solution orally at a dose of 1 g/kg body weight results in an increase in plasma glucose concentration of >85% the baseline values in horses with normal small intestine. An increase of <15% over baseline is found in horses with small intestinal disease that impairs

glucose absorption. Intermediate values are found in both normal and diseased horses.<sup>4</sup>

**Diagnostic confirmation** is achieved by histological examination of biopsy of rectum or small intestine. **Rectal biopsy** has a low sensitivity (less than 50%) but high specificity for diagnosis of granulomatous enteritis.<sup>5</sup> **Biopsy of small intestine** and mesenteric lymph nodes has a much higher sensitivity than rectal biopsy and is the recommended test.

#### NECROPSY FINDINGS

**Necropsy examination** reveals that the intestinal wall is thickened uniformly especially in the jejunum and ileum. Mesenteric lymph nodes may be enlarged. There is villous atrophy with a diffuse and patchy granulomatous infiltration of the lamina propria of the small intestine. Crypt abscesses are common. Granulomas are also present in the liver, spleen, kidney, and bone marrow of many cases. The predominant cell types are macrophages and epithelioid cells with occasional giant cells. The disease may be difficult to distinguish from alimentary lymphosarcoma.

#### DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes:

- Parasitism
- Poor nutrition or dentition
- Alimentary lymphosarcoma
- Basophilic enterocolitis
- Eosinophilic enteritis
- Intrabdominal abscessation
- Gastric squamous cell carcinoma
- Small intestinal adenomatous polyposis.<sup>6</sup>

#### TREATMENT

Attempts at treatment with a variety of anti-inflammatory and antimicrobial drugs, including prednisone and sulfasalazine, have been almost universally unsuccessful.<sup>7</sup> Resolution of the disease occurred for up to 7 months while a horse was treated with a decreasing dose of dexamethasone, beginning at 40 mg (0.1 mg/kg) intramuscularly every 4 days for 4 weeks, and then slowly decreasing.<sup>7</sup> Surgical resection of defined, solitary lesions is reported but this is an unusual manifestation of the disease.

#### CONTROL

There are no effective control measures.

#### LYMPHOCYTIC-PLASMACYTIC ENTEROCOLITIS

This is an uncommon disease of horses, in contrast to dogs, affecting horses of any age and without discernible breed or sex predilection.<sup>1,2</sup> The etiology is unknown. Presenting signs include weight loss, diarrhea, and lethargy. Clinicopathologic abnormalities include hypoproteinemia and hypoalbuminemia in approximately one-half and three-quarters of cases, respectively.<sup>2</sup> Results of an oral glucose tolerance test are abnormal in approximately 75% of cases. Histologic examination of a rectal mucosal biopsy reveals abnormal tissue suggestive of the disease in about one-half of cases. The diagnosis is confirmed by biopsy of ileum or necropsy examination. Differential diagnoses are similar to those for granulomatous enteritis. There is marked infiltration of the lamina propria with lymphocytes and plasma cells. Effective treatment has not been described. Control measures are not available.

#### CHRONIC EOSINOPHILIC GASTROENTERITIS OF HORSES

Eosinophilic enterocolitis occurs either as part of the multisystemic, eosinophilic, epitheliotropic disease complex or as a lone entity. Multisystemic, eosinophilic, epitheliotropic disease is characterized by eosinophilic infiltrates in the gastrointestinal tract and other organs, while horses with eosinophilic enterocolitis have no evidence of extraintestinal disease.

**Multisystemic, eosinophilic, epitheliotropic disease** occurs in adult horses of any age and without apparent breed or sex predilection. The etiology is unknown, but some cases are associated with lymphosarcoma, suggesting that the disease in these horses is due to clonal expansion of a T-lymphocyte population that secretes interleukin-5.<sup>1</sup> The disease is idiopathic in most horses. Clinical signs include weight loss in all cases and diarrhea or dermatitis in approximately two-thirds of cases.<sup>2</sup> The dermatitis occurs mainly on the face, limbs, and ventral abdomen and is exudative with alopecia, hyperkeratosis, and lichenification.<sup>3</sup> Lesions of the coronary band and mouth are common. Urticaria occurs in some horses. Most affected horses have low serum protein and albumin concentrations. Hypereosinophilia is not a consistent feature of the disease and blood leukocyte concentrations are usually within the reference range. There are often elevations in serum activity of gammaglutamyl transpeptidase (GGT) and alkaline phosphatase, consistent with lesions in the

biliary tree. This can be useful in differentiating horses with this disease from horses with granulomatous enteritis.<sup>2</sup> Histologic examination of tissues reveals eosinophilic infiltration of skin, liver, and gastrointestinal tract. Rectal biopsy can reveal the presence of eosinophilic granulomas, but these must be differentiated from the more common eosinophilic infiltrate secondary to parasitism. Treatment is usually ineffective and the prognosis for recovery is very poor. Affected horses should be administered an anthelmintic in case the disease is due to nematodiasis. Administration of corticosteroids (dexamethasone, prednisolone) is the usual treatment but is only transiently effective in most cases. Hydroxyurea, which is used to treat a similar syndrome in people, was only transiently effective in one horse.<sup>4</sup> There are no recognized control measures.

**Idiopathic eosinophilic enteritis** is a sporadic disease of horses of any age. Affected horses rarely have weight loss or diarrhea.<sup>2</sup> The common form of the disease is one in which the infiltration is segmental and associated with acute colic due to obstruction of the small intestine or large colon by mural lesions.<sup>5,6</sup> The D(+)-xylose absorption curve is usually normal in affected horses.<sup>7</sup> Histologically, the disease is characterized by the presence of eosinophilic infiltrates in a chronic inflammatory reaction affecting the small or large intestines. The infiltrates are restricted to the intestinal tract. The cause has not been identified but the lesion suggests a continuing hypersensitivity reaction to an ingested allergen. Antemortem diagnostic confirmation is achieved by rectal or small intestinal biopsy. Successful treatment is usually surgical. Control measures are not reported.

#### OVINE MOUTH AND GUM OBSCURE DISEASE (OMAGOD)

During the outbreak of foot-and-mouth disease (FMD) in the UK in 2001, field investigations reported the appearance of oral lesions, initially in sheep and then in cattle which complicated the diagnostic process.<sup>1,2</sup> While the lesions appeared to have a common, though obscure, etiology, prior to that they had not been identified as a differential diagnosis for FMD. The lesions were usually singular, located predominantly (but not exclusively) in the gingival mucosa ventral to the incisors, often in the midline; circular to nearly circular in shape and usually ranging in

diameter from 4 to 10 mm; never vesicular but always erosive with a raised edge, giving the ulcer a crater-like appearance; and were more prevalent in adult sheep than in lambs.<sup>2</sup>

Experienced sheep veterinarians in the UK have reported ulceration of the gums of sheep as a regular occurrence in late winter and spring.<sup>1</sup> It has been suggested that grazing sparse rough or short pasture, the provision of feed or salt blocks, and the use of feeding troughs with sharp edges, could be predisposing causes.

An abattoir survey of sheep in New Zealand examined the lesions of the anterior lips and gums of the animals after slaughter.<sup>3</sup>

Lesions of the midline of the lips and gums of traumatic or irritant etiology were common, and the prevalence was higher in adult sheep than in lambs. The lesions probably arose from the fright/flight response behaviour of sheep, resulting in the mouth impacting against wire fences or yard railings while being handled. A smaller percentage of lesions may have been due to abrasive or irritant feed or soil. The presence of plant material and bacteria in lesions delayed healing and contributed to the formation of ulcers.

## ULCERATION OF THE PARS ESOPHAGEA OF THE STOMACH OF SWINE (GASTRIC ULCER, HYPERKERATOSIS)

Naturally occurring ulcers of the stomach in swine occur in the *pars esophagea* (non-glandular part) of the stomach. They are single or multiple bleeding ulcers often associated with hyperkeratosis. Experimental lesions in the stomach are usually produced in the glandular part of the stomach as a model for the condition in humans. The condition was first reported in Illinois in 1897.

### Synopsis

**Etiology** Fine particle and pelleted feed. Certain bacterial species may contribute.

**Epidemiology** Highly variable incidence but has increased with greater intensification of swine industry, emphasis on improving digestibility and feed efficiency and use of fine particle and pelleted feed. Growing and finishing pigs, adult sows, and boars.

**Signs** Sudden death from peracute gastric hemorrhage. Subacute form causes anemia, pallor, unthriftiness, black tarry feces.

**Clinical pathology** Hemorrhagic anemia.

**Lesions** Hyperkeratosis, erosions, ulcers of *pars esophagea*, gastric hemorrhage, anemia.

**Diagnostic confirmation** Lesions at necropsy.

### Differential diagnosis list

- Proliferative enteritis of swine
- Enteric salmonellosis
- Swine dysentery.

**Treatment** None.

**Control** Use of diets prepared through hammer mill screen of at least 6 mm. Incorporate 5-methylmethionine-sulphonium chloride in diet.

## ETIOLOGY

The etiology is multifactorial. Finely ground and pelleted feed are important causes. *Helicobacter heilmannii*<sup>1</sup> and *Gastropillium suis*,<sup>2</sup> have been found in gastric ulcers, but not ulcers of the *pars esophagea* of pigs and are unlikely to be the primary cause of the lesion.<sup>3</sup> Certain environmental stressors may also be contributing factors.

## EPIDEMIOLOGY

### Occurrence

The disease is most common in pigs of 45–90 kg BW<sup>4</sup> but the disease may also occur in pigs after weaning and in adult sows and boars. All breeds are susceptible. Prevalence in groups of pigs may vary anywhere in the world from 5 to 90%. In some countries the rate is 1% and in others 87%.<sup>5</sup>

Most gastric ulcers of pigs are localized in the *pars esophagea* and are referred to as esophagogastric ulceration. Examination of the stomachs of pigs at abattoirs in various countries has revealed a high proportion of pigs with varying degrees of hyperkeratosis, erosions, and ulcers of the *pars esophagea*. Extensive erosions of the *pars esophagea* may be present in up to 63% of sows and 36% of finishing pigs.<sup>6</sup>

The incidence is variable between countries which may reflect differences in feeding or husbandry methods. In the Netherlands 11% of the pigs may be affected.<sup>7</sup> The incidence of ulceration may be increasing in pigs in the UK compared to earlier studies.<sup>8</sup> An abattoir survey of the stomachs of pigs in the UK found ulceration of the *pars esophagea* in 23% with a range from 4 to 57%.<sup>8</sup> The ulcers were mild in 9.5% and severe in 13.4%.

The disease has assumed increased economic importance with increased intensification of the swine industry.<sup>9</sup> The feed manufacturing industry is faced with the dilemma of finely ground pelleted feed providing high digestibility and feed efficiency in growing and finishing pigs but with a high incidence of lesions of the *pars esophagea* which may affect performance. Pelleting swine feed is also advan-

tageous because it flows more easily and effectively in automated distribution systems in swine farms compared to finely ground meal which may bridge and clog in distribution systems, decrease dustiness and segregation of ingredients and increase bulk density. Meal is less damaging than pellets.

The incidence of clinical disease is low but the case fatality rate is high when severe hemorrhage occurs. The effects of the lesions on performance may vary considerably. In one study, pigs with extensive lesions gained 50–75 g/day less than pigs with no lesions<sup>10</sup> while in another the presence of ulcers as determined at the abattoir did not influence growth rate.<sup>8</sup> The disease has increased in significance with the occurrence of PMWS and PDNS associated with porcine circovirus 2. There is also an increased occurrence where there is a problem with porcine respiratory disease complex (PRDC) particularly during summer months.

### Risk factors

Anything that causes an empty stomach which potentially increases the acidity in the *pars esophagea* region of the stomach is a risk factor.<sup>7</sup> Back in the 1960s all that was needed to produce an esophageal ulcer in a pig was to keep the pig restricted in a feeding or farrowing crate and deprive it of water for 24 hours and it would have an ulcer. This would therefore include intermittent feeding and watering, respiratory disease and hot weather.

### Dietary risk factors

The disease occurs primarily in penned pigs receiving a grain diet and growing rapidly. It has also occurred in pigs fed large quantities of cheese whey or skimmed milk. Too much copper and not enough zinc may also be a factor. The incidence is highest in pigs receiving diets containing a higher proportion of corn (maize) than other grains. The incidence is even greater if the corn is finely ground or is gelatinized or expanded. Ulceration in some pigs may be associated with *Ascaris suis* infection, but in other studies there is no significant association between the parasite and ulcers.

### Finely ground feed

This is the most important risk factor.<sup>11</sup> One of the explanations of this may be the rapid emptying of the stomach when fine particles are used.<sup>12</sup> There is normally a gradation of ascending pH from the cardia to the oesophagus but with rapid emptying there is the possibility of the low pH reaching the esophageal region.<sup>11,12</sup>

Feeding a diet based on finely ground barley to pigs beginning at 10–11 weeks results in lesions as early as 1 month later, and the incidence and severity of lesions increased progressively over the next

2 months. Diets high in wheat or corn starch may be worse than diets based on barley. The incidence and severity of hyperkeratosis may be greater in some breeds compared to others, but the effects of previous diets and environmental factors may have influenced the results.

The particle size and the physical form of the feed are important risk factors. Finely ground diets and pelleting have detrimental effects on the gastric mucosa of finishing pigs.<sup>13</sup> A pelleted diet uses grain that is finely ground before it is compressed into a pellet but on reaching the stomach it reverts to the fine particles. A diet finely ground through a 3 mm screen in a hammer mill and then pelleted will be associated with a 75% incidence of pigs with hyperkeratosis of the *pars esophagea* and 11% of the pigs may have severe erosions and ulceration of the *pars esophagea*.<sup>10</sup> The incidence of lesions decreases when the diet is ground through a 6 mm screen.<sup>14</sup> Finely ground barley or wheat is associated with a marked increase in gastric abnormalities compared to the use of coarsely ground grains. The size of particles in feed is significant whatever feed is used, even straw; coarsely ground barley straw at 5–10% of the ration gives almost complete protection. In growing pigs, dietary fiber rich in structural polysaccharides has been shown to be important in preventing the development of parakeratotic lesions in the *pars esophagea*.<sup>15</sup> But an increase in the crude fiber content of a diet which is finely ground does not affect the occurrence of severe erosions and/or ulcers of the *pars esophagea*.

Grinding barley through a 1.56 mm screen results in finely ground feed, which is associated with an increased incidence and severity of gastric ulcers in pigs. Grinding through a 4.68 mm screen approximates the screen size used most frequently for grinding barley for pigs in practice and is associated with a low incidence of ulcers.<sup>15</sup>

Reducing particle size and pelleting improves growth performance of finishing pigs.<sup>16</sup> For every 100 microns of decrease in size of the particle size there is an approximately 1.3% increase in gain efficiency but each time the level of ulcers increases.<sup>17</sup> The processes have additive effects on digestibilities of dry matter, nitrogen, and energy, with maximum nutrient digestibility in pelleted diets with corn milled to a particle diameter size of 400  $\mu\text{m}$ . Reducing the particle size to below 400  $\mu\text{m}$  causes practical problems with milling and an increased incidence of gastric lesions and it is suggested that a particle size of 600  $\mu\text{m}$ , or slightly less, is optimal for corn in either meal or pelleted diets for finishing pigs.

Using endoscopic examination of the stomachs of pigs fed a fine particle diet (geometric mean size of 578  $\mu\text{m}$ ) it was found that as ulcer severity increases, the growth performance of individually fed pigs decreases. Feeding a coarse particle diet (geometric mean size of 937  $\mu\text{m}$ ) for 3 weeks resulted in a decrease in the severity of the ulcers.<sup>18</sup>

High levels of unsaturated dietary fat are not helpful especially if they are accompanied by low levels of vitamin E. Similarly pigs fed waste food had more severe gastric lesions.<sup>19</sup>

#### Environmental and management risk factors

It has been suggested that confinement, crowding, transportation, changes in environment, and exposure to other pigs, were important in the etiopathogenesis of gastric ulcers of pigs. All of these stresses and many others including anxiety, fear, pain, fatigue, fasting, etc., will be associated with an increase of ulcers. There is an even greater occurrence in summer when water demands are higher. Males are always more affected in prevalence and severity but that may be that they are more easily stressed. One of the most important factors is time in the lairage. Pre-mortem handling is extremely important.<sup>20</sup> Pigs kept overnight in the lairage have more ulcers than pigs killed on the day of arrival.<sup>21</sup> Similarly there is no difference in the prevalence of lesions in small and medium farms but there is a considerable increase in the prevalence in these two groups compared to the larger producer.<sup>22</sup> Larger herds always show more of the problem<sup>23</sup> and it is probably a reflection of the different diets that they use (based on wheat and pelleted). The larger farms also have more infection pressure, more selection pressure, and more feed-related factors.

Pigs that receive porcine somatotrophin may have an increased level of ulcers possibly due to the elevated circulating gastrin.<sup>24</sup>

There are a variety of foreign bodies reported from the pigs' stomach including stones, which outside sows chew all the time, and also sand. The majority of stones is probably passed in the feces, but may accumulate in and stretch the stomach. The stomach capacity is normally about 3–6 L. This may lead to reduced appetite and gastritis but is not believed to be a contributor to esophageal ulceration. Similarly, hairballs are a common finding, reaching 10–15 cm in size in the stomach. The occurrence of rubbish indicates pica or a depraved appetite which is often an indicator of inadequate feeding. One of the other substances found in outdoor pigs stomachs is the flakes of bitumen that remain from clay pigeon shooting, which are toxic.

Increased frequencies of any of four combinations of behavioral indicators of stress, recorded 4 weeks after weaning, were weakly associated with increased risk of acute fundic ulcers in slaughter pigs from a conventional farrow-to-finish herd.<sup>25</sup>

#### Pathogen risk factors

##### *Gastric bacteria*

The spiral-shaped *Gastrospirillum suis* has been found in 84% of the stomach of pigs with frank gastric ulcers of the *pars esophagea*. The organisms were mainly in the mucus layer and in gastric foveolas of the antral and oxyntic mucosa and only occasionally in the cardiac-*pars esophagea* region.<sup>2</sup> The presence of the organism has been associated with lesions of the pyloric mucosa in pigs.<sup>26</sup>

There is no known cause and effect relationship but the gastric environment associated with gastric ulcer may favor colonization of the organism. The oral inoculation of *Gastrillum*-like bacteria into laboratory animals is capable of inducing gastric ulceration.<sup>27</sup> *Helicobacter heilmannii* type 1<sup>28</sup> has been found more frequently in the stomachs of pigs with ulcers (100%) and in those with pre-ulcer lesions (90%) than in stomachs with macroscopically normal *pars esophagea* (35%).<sup>1</sup> It has been suggested that *Helicobacter heilmannii* may play a role in the pathogenesis of gastric ulcers in swine by causing increased acid secretion. *H. pylori* can colonise the pig stomach. Experimental reproduction of *Helicobacter suis* infection has recently been described.<sup>29</sup> The pigs had no ulcers and infection was only accompanied by a mild superficial gastritis.

#### **PATHOGENESIS**

In pigs, nearly all naturally occurring gastroduodenal ulcers are localized in the *pars esophagea* of the stomach. Excessive gastric acid production, depletion of the gastric buffering system resulting in prolonged activation of pepsinogens, and changes in mucus composition are suggested as important factors related to gastric ulceration in swine. The physical texture of the feed can influence pepsin and acid secretion, and the fluidity of the stomach contents induced by ulcerogenic diets may alter the normal pH gradient within the stomach. This allows greater pepsin and acid contact to the esophago-gastric area.

The concentrations of short chain fatty acids are high in the proximal gastric contents of pigs and associated with intakes high in readily fermentable carbohydrates, like ground corn. These products of bacterial metabolism, principally acetate and lactate, reach high concentrations within 4 hours after feeding because of high pH

in the proximal gastric contents which may allow some types of bacteria to proliferate. These weak acids are lipid soluble in their undissociated form and could penetrate and acidify underlying tissue more readily than free hydrogen ions. In this way, rapid production of short chain fatty acids, followed by their absorption and tissue acidification, may be similar to ruminal acidosis and rumenitis in ruminants following the ingestion of large quantities of readily fermentable carbohydrates.<sup>30</sup>

The rumen epithelium, also a stratified squamous mucosa, is easily injured by short chain fatty acids at pH  $\leq$  5.0. The breaking of the barrier by short chain fatty acids could result in underlying inflammation and widespread tissue destruction. Experimentally, exposing undissociated short chain fatty acids to swine gastric mucosa results in rapid penetration of the outer barrier and acidification of the underlying viable tissue.<sup>30</sup> This results in cell swelling and vesicle formation, followed by sloughing of the outer barrier, erosion into deeper zones, and finally, ulceration.<sup>30</sup>

Weak organic acids, at pH  $\leq$  2.5 induce a greater degree of functional and histological injury in 3 stomach zones (squamous, cardiac, and oxyntic) than does hydrochloric acid. The predilection for the squamous mucosa in naturally occurring ulcers may be attributed to the lack of defense or repair mechanisms that are present in the cardiac and oxyntic mucosa, which are capable of HCO<sub>3</sub><sup>-</sup> and mucus secretion, which may raise the pH adjacent to these epithelial layers.<sup>30</sup> Thus the increased digestibility associated with decreased particle size of the diet may promote rapid fermentation following eating resulting in the production of increased concentrations of short chain fatty acids. Any increase in fluid content will also contribute to the changes in pH gradient that exist in the stomach. Excessive gastrin is then stimulated and more acid secretion follows.

Normally, the *pars esophagea* is white, smooth, and glistening and may be bile stained. The first stage in ulceration is hyperkeratosis. This is followed by erosions, ulcerations, and hemorrhage. The erosions may heal, resulting in a fibrous contraction. Chronic ulceration may occur with the development of several ulcers in combination with fibrous tissue involving all of the squamous mucosa. Advanced hyperkeratosis may cause partial stenosis of the terminal esophagus.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, affected pigs being

found dead from acute hemorrhage into the stomach.

The regurgitation of bile into the stomach and the intensity of bile staining of esophagogastric tissue have been linked to the pathogenesis of esophagogastric ulcers in pigs. Almost all stomachs of pigs contain bile and bile staining of the *pars esophagea*; there is no evidence for the hypothesis that the regurgitation of bile into the stomach is associated with esophagogastric lesions in finishing pigs.<sup>31</sup> There is no evidence of an association between gastritis and ulcer.<sup>32</sup>

### CLINICAL FINDINGS

Most cases are sub-clinical but sows will die from blood loss. Pigs frequently die from ulcers during concurrent disease such as respiratory disease<sup>33</sup> and in this case anorexia may disturb the gastric contents and allow material of high acidity to reach the cardia. Similarly where there is a reduced consumption of water the integrity of the mucus may be broken by the desiccation that results on mucosal surfaces.

Gastric ulceration is most common in pigs over 6 weeks of age and occurs in adult sows and boars; the clinical findings are dependent on the severity of the ulcers. The effects of ulceration on production may be highly variable. Most pigs with esophagogastric ulcers are clinically normal, and growth rate and feed intake appear unaffected. Some observations suggest that there is no effect of ulceration on growth rate, while others indicate that the presence of esophagogastric ulcers results in a marked decrease in growth rate and an increase in the length of time required for the pig to reach market weight. Some affected pigs also eat slowly and regurgitate frequently. Endoscopic monitoring of the stomachs of pigs fed ulcerogenic diets found that as the severity of the ulcer increased growth performance was decreased.<sup>18</sup> The greatest economic losses were associated with sudden deaths due to hemorrhage and marked decreases in performance associated with fine particle size.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, affected pigs being found dead from acute hemorrhage into the stomach. When pigs are found dead from peracute hemorrhage, inspection of the in-contact pigs may reveal other animals with pallor and black tarry feces which represent those with subacute hemorrhage.

Cases with subacute gastric hemorrhage may survive for a few days and there is

evidence of marked pallor, weakness, anorexia, and black-pasty feces changing to mucus-covered pellets in small amounts. The weakness may be sufficient to cause recumbency. Vomiting frothy bile-stained fluid and grinding of the teeth may occur. Abdominal pain may be elicited by deep palpation over the xiphisternum and there may be a reluctance to walk along with a rigid back indicative of pain.<sup>6</sup> Animals that survive are often unthrifty, usually due to anemia from chronic blood loss with a few cases affected by chronic peritonitis. When the disease is occurring careful observation may detect early cases. Suggestive signs are a darkening of the feces and the development of pallor.

### CLINICAL PATHOLOGY

Laboratory testing is not indicated. Animals with gastric ulceration generally have lower hematocrit values, haemoglobin concentrations, and erythrocyte counts than normal. The black tarry feces can be examined for the presence of blood.

### NECROPSY FINDINGS

Ascarids have been found in the stomach but these are not a factor in the field.<sup>34</sup>

At necropsy, the ulcers are confined to the esophageal region of the stomach. Affected stomachs consistently have more fluid contents than unaffected ones. If severe blood loss from the ulcer has been the cause of death then the carcass is pale and fresh blood is usually present in the stomach (there may be large blood clots) and intestines. The colonic contents may also appear melanic. Early lesions in clinically unaffected animals include hyperkeratinization of the mucosa (usually pale raised areas without bile staining initially) which progresses to epithelial erosion without actual ulceration. Ulcers usually initially occur along the junction of the *pars esophagea* with the glandular stomach but may enlarge to efface the entire squamous portion of the stomach. These more diffuse ulcers are easily missed on cursory examination due to their uniform appearance. Chronic gastric ulcers develop thickened, raised edges due to ongoing fibrosis, occasionally resulting in a gastroesophageal stricture. The histological appearance varies with the stage of lesion development but in fatalities there is typically complete loss of the epithelial layer, with exudation of neutrophils from a bed of mature granulation tissue. Recent studies have demonstrated *Helicobacter*-like bacteria in porcine stomachs but further research is required to determine if this infection plays a significant role in ulcer formation. Small clusters of *H. hellmanii* have been seen in the gastric crypts,<sup>35</sup> but are not associated with histological changes.<sup>36</sup> A recent survey suggested no correlation between infection

in the cardiac mucosa and the severity of the lesions shown by the esophagogastric region.<sup>37</sup> The macroscopic findings are usually sufficient for the confirmation of a diagnosis of esophagogastric ulceration. The initial lesion of hyperkeratosis leads to parakeratosis with fissures and the lamina propria is then exposed. The epithelium sloughs off and then ulcers of the epithelium develop with haemorrhage from the vessels.

#### Severity and extent of esophagogastric lesions can be graded according to the following scheme<sup>6</sup>:

- 0: intact epithelium
- 1: small degree of hyperkeratosis (< 50% of total surface)
- 2: distinct hyperkeratosis (= 50% of the total surface)
- 3: hyperkeratosis and less than 5 erosions smaller than 2.5 cm in size
- 4: hyperkeratosis and more than 5 erosions or erosions larger than 2.5 cm in size
- 5: hyperkeratosis and more than 10 erosions or erosions larger than 5 cm in size, and/or an ulcer (with or without bleeding) or stenosis of the esophagus towards the stomach.

No difference in lesion score was found between Duroc, Landrace, and Iberian pigs.<sup>38</sup>

#### DIFFERENTIAL DIAGNOSIS

The occurrence of sudden death with a carcass that shows extreme pallor and a marble-white skin suggests the possibility of peracute hemorrhage from an esophagogastric ulcer. The disease must be differentiated at necropsy from proliferative hemorrhagic enteropathy, swine dysentery, and salmonellosis. Black tarry feces in growing and finishing pigs are characteristically due to subacute hemorrhage associated with esophagogastric ulceration.

It is possible to detect stomachs with *Helicobacters* by covering the stomach with urea gel containing an indicator sensitive to pH change. If there are large numbers of urease-positive bacteria then the pH changes.<sup>39</sup>

Severe infestation with whipworms is a differential. The clinical diagnosis can be confirmed by endoscopy<sup>40</sup> which requires an empty stomach (may cause ulceration in itself) and anesthesia.

#### TREATMENT

Vitamin K and hematinics have been tried with little success. Bovine serum concentrate given as a 1% solution is supposed to have reduced the extent and severity of signs associated with ulcers in growing pigs but in general medication does not help.<sup>41</sup> If a diagnosis is made euthanasia is advised.

#### CONTROL

Control of esophagogastric lesions of growing and finishing pigs is dependent on using diets with a particle size and physical form which will provide the most economical performance in terms of digestibility and feed efficiency and minimize the incidence of lesions.

The most desirable particle size or physical form of diet, meal, or pelleted form, has not been determined. The use of a diet ground through a 6 mm screen instead of 3 mm screen is recommended. However, screen size is not the only factor affecting particle size. Other factors include the condition of the screen and hammer, the type and variety of grain and its moisture content, the speed of the mill, the pelleting process and the flow rate in the distribution of the feed to the pigs. A particle size of 600 µm, or slightly less is suggested as optimal for corn in either meal or pelleted diets for finishing pigs.<sup>16</sup>

The incorporation of S-methyl-methionine-sulphonium chloride (MMS), a nutritional component of many vegetables such as cabbage and carrots, has anti-gastric ulcer properties. Its addition to the diet, ground through a 3 mm screen, and fed to grower pigs from 45 to 107 kg liveweight, at 400 ppm decreased the incidence of severe erosions or ulcers by about 50%.<sup>14</sup> The addition of lucerne meal to increase the crude fiber content of one of the experimental diets did not have an effect on the incidence or severity of the lesions.

The diet should contain adequate amounts of vitamin E and selenium. Where applicable a reduction of the amount of corn in the ration and the feeding of meal rather than pellets may also be of value. The reduction of environmental and managerial stressors with attention to stocking rates may be of value.

#### CHRONIC INFLAMMATORY BOWEL DISEASE OF SHEEP

This syndrome of unknown etiology is manifest with wasting, ill thrift and mortality, or culling for poor production, and is reported in England and Canada.<sup>1,2</sup> It affects both housed and pastured sheep predominantly in their first year of life, but cases up to 3 years of age have been seen. Affected sheep are dull and anorectic with pale mucous membranes and have fecal staining of the perineum. The rumen fill is reduced and the feces are soft and malodorous. Blood examination shows hypoalbuminemia, an elevated blood urea nitrogen, and leukocytosis with neutrophilia. On post mortem there is lymphocytic enteritis with gross thickening of segments or the entire or distal part of the small intestine. There is no evidence for Johne's disease or parasitic gastroenteritis and the syndrome has similarities to the proliferative enteropathies of swine and horses.

## Diseases characterized by respiratory tract involvement

### INTERSTITIAL PNEUMONIA OF CATTLE

Interstitial pneumonia of cattle has been known for many years under many different terms including: atypical interstitial pneumonia, acute pulmonary emphysema and edema, bovine pulmonary emphysema, 'panthers', 'lungers', bovine asthma, pneumoconiosis, and 'fog fever'.

Diffuse or patchy damage to alveolar septa is the essential feature of interstitial pneumonia which may be acute or chronic and can be caused by many forms of pulmonary injury. There is an obvious lack of lesions of the small airways which differentiates interstitial pneumonia from bronchopneumonia. Traditionally it was thought that interstitial pneumonias were characterized by chronic inflammation in which there is a predominantly proliferative response involving the alveolar walls and supporting stroma. However, acute diffuse damage of the alveolar walls accompanied by an early intra-alveolar exudative phase, which can be followed by proliferation of type 2 alveolar epithelial cells and fibroblasts, is now commonly recognized.

The recognition that interstitial pneumonia can have an acute exudative phase was the reason for the designation of acute interstitial pneumonia in cattle as 'atypical' interstitial pneumonia. The use of the word 'atypical' may create some confusion in the interpretation and diagnosis of lesions and in the conveying of information. It may be more appropriate to use the term interstitial pneumonia and specify where possible, clinically, epidemiologically, and pathologically the various forms of interstitial pulmonary disease in cattle.

The diseases in which interstitial pneumonia is the essential lesion are listed in Table 36.1. Pulmonary congestion and edema, alveolar exudation, hyaline membrane formation, interstitial emphysema, and alveolar epithelial cell hyperplasia and fibrosis of the supporting stroma without lesions of the smaller airways are the characteristic lesions, with their presence and extent varying according to the stage of the disease process.

The term atypical interstitial pneumonia as originally proposed is still useful in describing some of the diseases clinically and sets them apart from the common acute infectious diseases, especially the viral diseases of the respiratory tract of cattle. Clinically, they are atypical with regard to most clinical signs, especially when compared to the bacterial pneumonias:

Some are acute, like fog fever, while others are chronic as in 'bovine farmer's lung'

- There is usually acute or chronic respiratory distress and a relative absence of toxemia
- Most are progressive and non-responsive to treatment
- Pathology consists of varying degrees of pulmonary emphysema, edema, hyaline membrane formation, and alveolar epithelial cell and interstitial tissue hyperplasia.

While there are obvious clinical, and particularly epidemiological, differences between the various diseases, there are fewer differences between the pathological findings which tend to merge from one to another.

#### Synopsis

**Etiology** D, L-tryptophan in forage. Inhalation of certain gases. Hypersensitivity to molds. Mycotoxicosis and plant poisonings. Viral and bacterial infections.

**Epidemiology** Primarily in adult cattle moved from dry to lush pasture.

Outbreaks of acute pulmonary emphysema and edema occur primarily in adult cattle moved from dry to lush pasture in autumn in North America. In UK and Europe other interstitial pneumonias due to hypersensitivity to molds occur.

**Signs** Outbreaks of acute respiratory distress in pasture form of disease; severe dyspnea, mouth breathing, expiratory grunt, subcutaneous emphysema, and rapid death. Subacute form less severe and may survive but develop cor pulmonale later. Individual cases of interstitial pneumonia in UK and Europe are subacute and chronic.

**Clinical pathology** None clinically applicable.

**Lesions** Enlarged firm lungs which do not collapse, diffuse congestion and edema, interstitial and bullous emphysema, cranioventral consolidation, hyaline membrane formation, alveolar epithelial hyperplasia, fibrosis.

**Diagnostic confirmation** Lesions at necropsy.

#### Differential diagnosis list

- Pneumonic pasteurellosis
- Organophosphatic insecticide poisoning
- Nitrate poisoning
- Other interstitial pneumonias
- Bovine farmer's lung or extrinsic allergic alveolitis
- Lungworm pneumonia
- Verminous pneumonia caused by aberrant migration of *Ascaris suis* larvae
- Feedlot interstitial pneumonia
- Enzootic pneumonia of calves

**Treatment** None.

**Control** Grazing management. Use of antimicrobials to control conversion of tryptophan to 3-methylindole. Adequate housing and ventilation to control hypersensitivity pneumonias.

Table 36.1 Diseases of the lungs of cattle in which the essential lesion is interstitial pneumonia

#### A. Diseases of uncertain etiology

1. Acute bovine pulmonary emphysema and edema (ABPEE) also known as 'fog fever', in cattle moved from dry to lush pasture (may be due to D,L-tryptophan). Usually occurs in outbreak form
2. Diffuse fibrosing alveolitis. Chronic disease which occurs sporadically in mature cows
3. Sporadic cases of acute interstitial pneumonia of young cattle (6–18 months of age). May be due to bovine respiratory syncytial virus or sequel to pneumonic pasteurellosis

#### B. Hypersensitivity diseases

1. Extrinsic allergic alveolitis (bovine farmer's lung). Epidemiologically associated with moldy feeds in housed cattle. May be sudden in onset in individual animals or develop insidiously as a chronic disease in several cows
2. Milk allergy. Occurs sporadically and is sudden in onset

#### C. Plant poisoning

1. *Ipomoea batatas* (sweet potatoes infested with the mold *Fusarium solani*)<sup>3</sup>
2. *Ziera aborescens* (stinkweed)
3. *Perilla frutescens* (purple mint)
4. *Brassica* spp.

#### D. Parasitic diseases

1. *Dictyocaulus viviparus* (including the hypersensitivity aspect)
2. *Ascaris suum*

#### E. Exposure to irritant gases and fumes

1. Nitrogen dioxide
2. Zinc dioxide

#### F. Endotoxic or metabolic

Shock lung due to endotoxemia such as in peracute coliform

## ETIOLOGY

There are several different possible causes.

Acute bovine pulmonary emphysema and edema (ABPEE) or fog fever

This is an acute atypical interstitial pneumonia also known as acute respiratory distress syndrome of cattle. The cause in adult cattle which have been moved from a dry to a lush pasture in the autumn season is related to the ingestion of a toxic level of D,L-tryptophan in the forage.<sup>1</sup> The experimental oral administration of toxic amounts of D,L-tryptophan to cattle causes clinical and pathological findings similar, if not identical, to those of the naturally occurring disease. D,L-tryptophan is converted in the rumen to 3-methylindole which, when given orally or intravenously, also produces the characteristic lesions in cattle and goats. The 3-methylindole exerts a direct effect upon cells and cell membranes of bronchioles and alveolar walls, perhaps as a result of strong lipophilic properties.

Specific forages have not been implicated, but affected cattle have often been consuming alfalfa, kale, rape, turnip tops, rapidly growing pasture grass, and several other feeds. However, pasture levels of tryptophan are not necessarily higher in those associated with the disease compared to normal pastures. In some naturally occurring cases of fog fever in beef cows changed from a dry summer range to a lush green pasture, there is a marked increase in the ruminal levels of 3-methylindole while in other cases the levels are not abnormal. Failure to detect abnormally high levels in the rumen and plasma of naturally occurring cases may be related to the rapid metabolism and elimination of 3-methylindole.

The levels of tryptophan in lush pasture are sufficient to yield toxic doses of 3-methylindole. A 450 kg cow eating grass at an equivalent DM intake of 3.5% of BW/day with a tryptophan concentration of 0.3% of DM would ingest 0.11 g tryptophan/kg BW/day. The total amount ingested over a 3-day period would approximate the single oral dose of 0.35 g/kg BW needed to reproduce the disease experimentally.

Diffuse fibrosing alveolitis

This is a chronic interstitial pneumonia of cattle which occurs sporadically and is suspected of being caused by repeated subclinical incidents of ABPEE or from recovered cases of the disease. Experimentally, repeated oral doses of 3-methylindole can result in diffuse pulmonary fibrosis and alveolitis in cattle.

Parasitic infestation

For many years it was thought that massive infestation of the lungs by large numbers of lungworm larvae in a lungworm-

sensitized animal could cause an allergic reaction resulting in the development of acute bovine pulmonary emphysema. The possibility of such hypersensitivity as being associated cannot be totally ignored but at the present time there is no evidence to support such a theory. Such hypersensitivity may occur when the level of larval infestation of pasture is extremely high but it is not involved in the great majority of cases. In most cases of naturally occurring fog fever there is no laboratory evidence of lungworms in the lungs or feces of affected and in-contact animals. Reinfection of cattle with lungworm will occur 2-3 weeks following introduction to an infected pasture and cause acute respiratory distress which is indistinguishable clinically from fog fever. The migration of abnormal parasites, particularly *Ascaris suum*, has been observed to cause an acute interstitial pneumonia in cattle which were allowed access to areas previously occupied by swine.<sup>1</sup>

Inhalation of irritant gases

The experimental inhalation of nitrogen dioxide gas is capable of causing acute interstitial pneumonia in cattle<sup>1</sup> and severe alveolar edema and emphysema in pigs but it seems unlikely that animals of either species would be exposed naturally to a significant concentration of the gas for a sufficiently long period to produce such lesions.

Pigs which survived experimental exposure to silo gas did not have the lesions seen in silo-fillers' disease in man, and experimental exposure of cattle to nitrogen dioxide gas produces lesions which do not occur in naturally occurring fog fever. Acute pulmonary emphysema and deaths have occurred in cattle exposed to zinc oxide fumes produced by the welding of galvanized metal in an enclosed barn housing cattle.

Hypersensitivity to molds

The ingestion or inhalation of molds may be a cause of the disease in cattle.<sup>1</sup> The disease has been associated with hypersensitivity to moldy hay based on the presence of serum precipitins of the thermophilic antigens of *Thermopolyspora polyspora*, *Micropolyspora faeni*, and *Thermoactinomyces vulgaris* in cattle affected with extrinsic allergic alveolitis or bovine farmer's lung.

In Switzerland, a high incidence of serum precipitins against *Micropolyspora faeni* (60%) and moldy hay antigen (80%) was demonstrated in exposed but apparently healthy cattle from an area where 'allergic pneumonia' is common. The precipitins decreased during the pasture season and increased during winter housing.

Outbreaks of acute respiratory disease in adult cattle due to acute allergic pneu-

monitis can occur 15 hours after the introduction of severely moldy hay. Serological investigation and provocative challenge may reveal a hypersensitivity pneumonitis due to allergens of *Micropolyspora faeni*. A hypersensitivity pneumonitis has been produced experimentally in calves by exposure to aerosols of *Micropolyspora faeni* with or without prior sensitization by subcutaneous injection of the antigen.

In some Canadian cattle barns the disease occurred in cattle located near the hay chute from which hay and bedding are thrown down from the hay storage above the floor where the animals are kept. It has been suggested that the degree of exposure to dusty hay was greater in these cattle but that has not been substantiated. Similarly, it has been proposed that feeding finely ground feed may be associated with interstitial pneumonia in feedlot cattle but there is little evidence to support the observation.

The high incidence of ABPEE in the autumn when many legumes and other pasture plants are flowering, and the common occurrence at this time of allergic rhinitis in cattle, suggest that the inhalation of pollen may cause an allergic response of the alveolar epithelium. However, many outbreaks of the disease have occurred in cattle solely on grass pasture with no flowers; intradermal tests of sensitivity to many pasture plants and to the ruminal contents of affected animals have been negative, and blood histamine levels are within the normal range.

Mycotoxicosis and plant poisonings

In North America, the ingestion of sweet potatoes infested with the mold *Fusarium solani* has been incriminated as a cause of acute interstitial pneumonia in cattle. Growth of the mold on the potatoes produces the toxins ipomeamarone and ipomeamaranol, and a lung edema factor. The latter is a collective term for a group of substances capable of causing death associated with severe edema and a proliferative alveolitis of the lungs of laboratory animals. It produces a respiratory syndrome which is clinically and pathologically indistinguishable from ABPEE.

The fungus *Fusarium semitectum* growing on moldy garden beans, *Phaseolus vulgaris*, which were discarded on pasture, was associated with acute pulmonary emphysema in cattle that consumed the beans and their vines. The fungus produces a pulmonary toxin. The pulmonary toxin, 4-ipomeanol (ipomeanol), accumulates in mold-damaged sweet potatoes and induces pulmonary edema, bronchiolar necrosis and interstitial pneumonia in many mammalian species. Outbreaks have occurred in lactating cows following ingestion of sweet potatoes damaged by *Myzus persicae*.<sup>2</sup> Other *Fusarium* spp. have been found in

peanut-vine hay, which has been associated with acute respiratory distress and atypical interstitial pneumonia in adult beef cattle.<sup>3</sup> The population mortality rate due to respiratory disease was about 12% and the case fatality rate 77%. Clinical signs occurred within a few days to 2 months after the animals were fed the peanut-vine hay.

A weed, *Perilla frutescens*, is considered to be a cause of the disease in cattle in the US and wherever the plant is found. High morbidity and high case fatality rates are characteristic, and the plant contains a perilla ketone which can be used to produce the disease experimentally.

Turf-quality perennial ryegrass straw (*Lolium perenne*) infected with the endophyte (*Acremonium lolii*) which yields toxic substances, including lolitrem-B has been associated with atypical pneumonia in weaned beef calves.<sup>4</sup> However, feeding the suspect hay resulted in typical ryegrass staggers but not atypical interstitial pneumonia.

#### Bacterial and *Mycoplasma* spp. infections

There is no evidence that any of the common bacterial pathogens of cattle such as *Mannheimia haemolytica*, *Pasteurella multocida*, *Histophilus (Haemophilus) somni*, or *Mycoplasma* spp. are primarily associated with acute interstitial pneumonia. In a series of feedlot cattle with clinical findings consistent with acute interstitial pneumonia, the pathogens were present in the lung tissues of some animals at necropsy but their presence was not considered as a primary cause of the pneumonia but rather secondary to the initial injury of the lung which was undetermined.<sup>5</sup>

#### Viral infections

Certain viral infections of the lung may result in interstitial pneumonia. In the interstitial pneumonias caused by the bovine respiratory syncytial virus (BRSV) there is a bronchiolitis and alveolitis and these should be termed bronchiointerstitial pneumonias. The BRSV is an important cause of outbreaks of acute interstitial pneumonia in beef calves 2–4 weeks after weaning. Pathologic evaluation of the lung tissues of feedlot cattle which had acute interstitial pneumonia found that BRSV was not a causative agent.<sup>6</sup> In a series of cases of interstitial pneumonia in feedlot cattle in Saskatchewan the presence of the BRSV antigen was demonstrated in only 7% of cases and there was more severe bronchiolar epithelial necrosis than in the other cases which were negative for the virus.<sup>7</sup>

### EPIDEMIOLOGY

**Acute pulmonary emphysema and edema (ABPEE) or fog fever** occurs

almost exclusively in adult cows and bulls, usually 4–10 days after they are moved abruptly from a dry or overgrazed summer pasture to a lush autumn pasture. The new pasture may or may not have been grazed during that summer and the species of grass or plants does not seem to make a difference, but usually there is some lush regrowth of grass, legume or other palatable plants. Merely changing pasture fields in the autumn has precipitated the disease. In the mountainous areas of North America the disease occurs commonly in cattle brought down from high altitude grasslands to the cultivated and perhaps irrigated lush pastures.

ABPEE usually occurs in outbreaks, the morbidity ranging from 10% in some herds up to 50% and higher in others, with a case fatality ranging from 25 to 50%. It is not unusual to observe a mild form of the disease in about one-third of the adults at risk but only 10% of those at risk may be severely affected. Often, a number of cows are found dead without premonitory signs; many others are severely ill and die within 24 hours and the owner believes that the entire herd will die because of the sudden onset and the large number of animals which are affected at once. Calves and young growing cattle up to 1 year of age grazing the same pasture are usually unaffected.

A retrospective analysis and random sample survey of cattle ranches in northern California found that the type of forage management has a significant effect on the occurrence of the disease. The greatest occurrence of the disease was in herds where the cattle were moved from summer ranges to second-growth hay fields or to irrigated pastures, or from one irrigated field to another. The adult morbidity rate was 2.6% and the case fatality rate about 55%. The disease did not occur on ranches with limited or no movement of cattle from summer ranges to lush autumn pastures.

Placing cattle on rape or kale forage fields or in fields where turnips have been pulled and the cattle allowed access to the tops may have the same effect. The disease has also occurred commonly in western Canada when cattle have been placed in a stubble field following harvesting of any of the cereal crops. Veterinarians have noted that the timespan over which the disease occurs during the autumn months is only 2–4 weeks and that, following the first frost in the fall, the incidence of the disease declines rapidly. The disease has also occurred in the same herd on the same pasture in successive years.

**ABPEE in adult cattle in autumn** has been recorded in Canada and the US, Great Britain, Holland, and New Zealand. The disease is rare in Australia. The

chronic form of the disease in housed cattle appears to be the predominant form of the disease in Switzerland, but the acute form in cattle which have been changed from a dry to lush pasture is now reported. The disease has been recognized in France for many years as aftermath disease or aftermath emphysema, especially in the Normandy region. Some reports have suggested a breed incidence, Herefords being more commonly affected than the Jersey, Holstein, Shorthorn, and Angus breeds, but there are few exact epidemiological data to support the observation. One report suggested that the chronic type in housed cattle was more common in the Channel Island breeds.

#### **Acute interstitial pneumonia in feedlot**

**cattle.** Interstitial pneumonia is recognized as important cause of economic loss in feedlot cattle in western Canada and the United States.<sup>8</sup> The disease occurs sporadically and the incidence is about 3.1% of all cattle placed in feedlots.<sup>9</sup> Cases occur most commonly during the summer and fall months and new cases occur in an even distribution across all stages of the finishing period. In southern Alberta, the disease is most common during hot, dry, dusty, spring and summer days, and typically affects animals expected to be ready for slaughter within 15 to 45 days. Some feedlot operators have observed that the disease is more common in cattle exposed to excessive dust from bedding.

In southern Alberta feedlots the disease occurred late in the finishing period, when animals had been on feed an average of 114 days and weighed 475 kg.<sup>10</sup> All confirmed cases were in heifers and plasma concentrations of 3-methylindole metabolites (adducts) were higher in heifers with interstitial pneumonia than in controls. Most of the heifers were receiving melengestrol (MGA) to suppress estrus. The BRSV antigen was not found in lung tissue of confirmed cases. The odds of an animal with acute interstitial pneumonia being a heifer were 3.1 times greater than the odds that an animal with the disease was a steer.<sup>9</sup> In some large feedlots the estimated relative risk was 4.9.

The role of 3-methylindole (3MI) has been examined as a possible cause of interstitial pneumonia in feedlot cattle.<sup>10</sup> Anaerobic ruminal fermentation of large amounts of tryptophan leads to a surge in 3-methylindole concentrations, which is readily absorbed across the ruminal and intestinal wall and disseminated throughout the body. Bioactivation of 3MI by Clara cells leads to profound cellular injury in Clara and type-1 alveolar epithelial cells and, ultimately, acute interstitial pneumonia. It is postulated that the compound

responsible for causing the injury is the electrophilic metabolite of 3MI, 3-methylenedolenine (3MEIN) which forms stable adducts with cellular macromolecules. (Adducts are compounds formed by an addition reaction.)

Concentrations of 3-methyleneindolenine (3MEIN) in lung tissue and blood were higher in feedlot cattle that had died of acute interstitial pneumonia than in healthy feedlot cattle.<sup>9</sup> However, lung tissue concentrations of 3MEIN were similar in samples from cattle with interstitial pneumonia and bronchopneumonia.<sup>9</sup> Time-dependent patterns and magnitudes of plasma concentrations of 3MI and blood concentrations of 3MEIN-adduct in feedlot cattle during the first 8 weeks after arrival have been followed.<sup>11</sup> Mean concentration of 3MEIN-adduct increased to a maximum value on day 33 and then decreased to a minimum on day 54. Plasma 3MI concentrations initially decreased and remained low until after day 54. Neither 3MEIN-adduct concentrations nor plasma 3MI concentrations were associated with deleterious effects on weight gains. A single dose of acetylsalicylic acid (aspirin) to feedlot cattle on arrival did not affect serum or rumen concentrations of 3MI.<sup>12</sup> The combination of aspirin and vitamin E fed daily to feedlot cattle did not decrease the risk of developing respiratory tract disease.<sup>13</sup>

**Sheep.** Acute interstitial pneumonia has been recorded in sheep and there was extensive alveolar epithelialization. In Norway, an acute respiratory distress syndrome has occurred in lambs moved from mountain pastures onto lush aftermath pasture. The lesions were those of acute interstitial pneumonia and alveolar epithelial hypersensitivity to molds in the grass is being explored. The experimental oral administration of 3-methylindole to lambs will result in acute dyspnea and lesions similar to those which occur in cattle and adult sheep following dosing with 3-methylindole. However, the lesions in experimental lambs are different from those which occur in lambs affected with the naturally occurring disease.

The other types of interstitial pneumonia occur sporadically and may affect only a single animal or several over a period of time. There is not necessarily a seasonal incidence except in areas where cattle are housed and fed dusty and moldy hay during the winter months. The disease has occurred in feedlot cattle in open feedlots and in young cattle fed on fattening rations indoors.<sup>6</sup> Acute interstitial pneumonia occurs in weaned beef calves about 4 weeks after weaning. The interstitial pneumonia which may be the result of anaphylaxis also occurs

sporadically and therefore not in outbreaks.

### PATHOGENESIS

Because of the number and variety of circumstances in which acute or chronic interstitial pneumonia occurs, it is difficult to suggest a basic underlying cause, or to explain the mechanisms for the development of the lesions and the variations which occur from one circumstance to another. The reaction which occurs is a non-specific but fundamental reaction of the pulmonary parenchyma to a wide variety of insults which may be ingested, inhaled or produced endogenously. The reaction to sublethal injury is a combination of congestion, edema, an outpouring of protein-rich fluid into the alveolus, hyaline membrane formation, alveolar and interstitial emphysema which is secondary, and proliferation of alveolar septal cells and fibrosis of the interstitial spaces. Unlike the bacterial pneumonias, the emphasis is on edema and proliferation rather than on necrosis. Because mild cases of ABPEE may recover completely, it is suggested that the lesion can be reversible.

### Experimental ABPEE

There has been considerable effort to experimentally induce ABPEE similar to the naturally occurring disease, by the oral administration of D,L-tryptophan or one of its metabolites, 3-methylindole, to cattle, sheep, and goats. The L-isomer of tryptophan is metabolized by ruminal microorganisms to indolacetic acid which is then converted to 3-methylindole. The conversion of L-tryptophan to 3-methylindole is maximal at a ruminal pH near neutrality. When cattle are moved from a relatively dry pasture to a lush green pasture, there is an increase in ruminal ammonia, a decrease in ruminal pH, and a decrease in ruminal buffering capacity. The 3-methylindole is absorbed from the rumen and metabolized by a mixed-function oxidase system to an active intermediate which has pneumotoxic properties.

Pulmonary edema is the first morphological change occurring in ruminants given 3-methylindole, and the severity and extent of the lesion is probably the single most important factor which determines the severity of the clinical response and the likelihood of survival. The edema is preceded by degeneration, necrosis, and exfoliation of type I alveolar septal cells. During the acute phase, there is flooding of the alveoli with serofibrinous exudate, congestion, and edema of alveolar walls, and hyaline membrane formation. Varying degrees of severity of interstitial emphysema also occur. The interstitial emphysema may spread within the lymphatics to the mediastinum and into the subcutaneous tissues over the withers, over the entire

dorsum of the back and, occasionally, over the entire body including the legs. If the acute phase is severe enough there is marked respiratory distress and rapid death from hypoxemia.

In the experimental disease, the typical clinical signs of respiratory disease appear within 24–36 hours after the oral administration of L-tryptophan to adult cattle and within 4 days 50% of the dosed cows will die. The predominant pulmonary lesions include edema, interstitial emphysema, hyaline membranes, and hyperplasia of alveolar lining cells. The L-tryptophan is converted to indolacetic acid, which is decarboxylated to 3-methylindole, which is absorbed and metabolized by a mixed function oxidase system in the lung to produce pneumotoxicity.

The lesions have also been produced in cattle, sheep, and goats following oral or IV administration of 3-methylindole. Calves may be more resistant to experimental toxicity with 3-methylindole than adults, which supports the observation that the naturally occurring disease is uncommon in calves grazing the same pasture in which adults are affected. Young calves, 30–45 days of age, are susceptible to pulmonary injury induced by 3-methylindole characterized by pulmonary edema and damage to type-1 alveolar epithelial cells and non-ciliated bronchiolar epithelial cells. The 3-methylindole injury does not make the bovine lung more susceptible to the bovine respiratory syncytial virus as is the case for the parainfluenza-3 virus.

**Proliferative stage.** If the animal survives the acute phase, proliferation of alveolar type II cells marks the beginning of the shift from the exudative to the proliferative stages of pneumonia. There is alveolar epithelialization and interstitial fibrosis, the latter being progressive and irreversible. The central features of chronic interstitial pneumonia are intra-alveolar accumulation of mononuclear cells, proliferation and persistence of alveolar type 2 cells, and interstitial thickening by accumulation of lymphoid cells and fibrous tissue. Diffuse fibrosing alveolitis is a form of chronic interstitial pneumonia of uncertain etiology, but possibly the chronic form of ABPEE. Repeated oral administration of 3-methylindole in cattle provides a good experimental model for diffuse pulmonary fibrosis.

### Effects of 3-methylindole on pulmonary function

The effects of 3-methylindole on pulmonary function and gas exchange have been examined in cattle, goats, and horses. In cattle there is impairment of sympathetic pulmonary vasoconstriction, and changes in intra-acinar pulmonary arteries which may be related to a sudden elevation in arterial

and venous pressures in the pulmonary system. There are large increases in respiratory rate, minute viscous work,  $PCO_2$  and large decreases in tidal volume dynamic lung compliance, and  $PO_2$ . All of these are compatible with the severe pulmonary edema and alveolar injury.

In goats there is a pronounced decrease in lung compliance, a moderate increase in airway resistance, a concomitant hypoxemia, a progressive decrease in tidal volume and alveolar ventilation and an increase in the dead-space-to-tidal volume ratio. These changes are characteristic of a restrictive type of respiratory tract disease in goats in which pulmonary edema and the pulmonary function changes are similar to those of adult respiratory distress syndrome in man.

### CLINICAL FINDINGS

Acute bovine pulmonary emphysema and edema

This disease, also known as 'fog fever', is usually obvious, because of its characteristic clinical presentation. The onset is sudden. Within 4–10 days after adult cattle have been moved onto a new pasture, they may be found dead without any premonitory signs. Many cattle exhibit labored breathing, often with an expiratory grunt, open-mouthed breathing, frothing at the mouth, and anxiety. Severely affected cattle do not graze, stand apart from the herd, and are reluctant to walk. If forced to walk they may fall and die within a few minutes. Often, removal of the affected herd from the pasture will result in an increased number of deaths. Moderately affected cattle continue to graze but their respirations are increased above normal. Coughing is infrequent regardless of the severity. The temperature is normal to slightly elevated (38.5–39.5°C, 102–103°F) but may be up to 41–42°C (106–108°F) during very warm weather. There is a similar variation in the heart rate (80–120/min) and those with a rate of more than 120/min are usually in the terminal stages of the disease. Bloat and ruminal atony are common in severe cases. Subcutaneous emphysema is common over the withers and may extend to the axillae and ventral aspects of the thorax. The nostrils are flared and the nasal discharge is normal. Diarrhea may occur but is mild and transient.

Loud, clear breath sounds audible over the ventral aspects of the lung, indicating consolidation without bronchial involvement, are the characteristic findings on auscultation in the early stages of the acute disease. The intensity of the breath sounds may be less than normal over the dorsal parts of the lung if involvement is severe, but in animals which survive for several days the loud crackles characteristic of interstitial emphysema are of diagnostic significance. Most severely affected cases

will die within 2 days of onset but less severe cases will live for several days and then die from diffuse pulmonary involvement. Those which survive longer than 1 week will often have chronic emphysema and remain unthrifty. Of those moderately affected cattle which recover in a few days, some will develop congestive heart failure a few months later, due to chronic interstitial pneumonia (cor pulmonale). Calves running with their adult dams will usually not be affected.

### Other interstitial pneumonias

These diseases usually occur sporadically, but several animals may be affected over a period of time. There may or may not be a history of a change of feed or the feeding of moldy or dusty feed. In many cases, a few days elapse after the appearance of signs before the owner is aware of the affected animals. The animal may have been treated with an antimicrobial for a bacterial pneumonia with little or no response. Dyspnea, increased respiratory effort sometimes with a grunt, deep coughing, a fall in milk production, an absence of toxemia, a variable temperature (38.5–40°C, 102–104°F) and a variable appetite are all common. On auscultation there are loud breath sounds over the ventral aspects of the lungs and crackles over both dorsal and ventral aspects. The presence of moist crackles suggests secondary bacterial bronchopneumonia. Subcutaneous emphysema is uncommon in these and most will become progressively worse.

Yearling cattle with acute interstitial pneumonia which may be viral in origin may become much worse and die in a few days in spite of therapy. Mature cattle affected with bovine farmer's lung will survive in an unthrifty state with the chronic disease for several weeks and even months.

The major clinical features of all these other interstitial pneumonias are obvious respiratory disease, lack of toxemia, poor response to treatment, progressive worsening, and abnormal lung sounds distributed over the entire lung fields.

### CLINICAL PATHOLOGY

There are no abnormalities of the hemogram or serum biochemistry which have any diagnostic significance. Examination of feces and forage for lungworm larvae will aid in differentiation from verminous pneumonia if past the prepatent period. The observed high levels of farmer's lung hay' antibodies in serum are not of much value diagnostically because of the similar levels found in many clinically normal cows; many cases of classic fog fever have negative serum precipitin levels.

### NECROPSY FINDINGS

In ABPEE, the lungs are enlarged and firm and do not collapse on cutting. In the early

stages of acute cases they contain much fluid which is more viscid than usual edema fluid. The pleura is pale and opaque and appears to be thickened. In peracute cases, the entire lungs are homogeneously affected in this way. Such cases usually have edema of the larynx.

In the more common acute case, the lung has a marbled appearance. Adjacent lobes may be affected with any one of four abnormalities. Areas of normal, pink lung are restricted to the dorsal part of the caudal lobes. There are areas of pale tissue indicative of alveolar emphysema, areas of a dark pink color affected by early alveolar exudation, yellow areas in which the alveoli are filled with coagulated protein-rich fluid, and dark red areas where epithelialization has occurred. The latter two lesions are firm on palpation and resemble thymus or pancreas. They are more common in the ventral parts of the cranial lobes.

In chronic cases, as a sequel to the acute form described above, the obvious differences in the age of the lesions suggest that the disease progresses in steps by the periodic involvement of fresh areas of tissue. In all cases there is usually a frothy exudate, sometimes containing flecks of pus, in the bronchi and trachea, and the mucosa of these passages is markedly hyperemic.

Histologically, the characteristic findings are an absence of inflammation, except in the case of secondary bacterial invasion, and the presence of an eosinophilic, protein-rich fluid which coagulates in the alveoli, or may subsequently be compressed into a hyaline membrane. This is more apparent in acute cases and, if animals live for a few days, there is evidence of epithelialization of the alveolar walls. In longstanding cases, there is extensive epithelialization and fibrosis.

The pathology of bovine farmer's lung and diffuse fibrosing alveolitis has been described and consists of variations of the lesions of chronic interstitial pneumonia.

Bacteriological examination of the lungs is often negative, although in long-standing cases in which secondary bacterial pneumonia has developed *Pasteurella multocida*, *Mann. haemolytica*, *Streptococcus* spp., and *Arcanobacterium pyogenes* may be found. A careful search should be made for nematode larvae.

### TREATMENT

The treatment of fog fever in cattle is empirical and symptomatic. The lesion is irreversible in severe cases and treatment is unlikely to be effective. When outbreaks of the disease occur on pasture the first reaction is to remove the entire herd from the pasture to avoid the development of new cases. However, almost all new cases will usually occur by the 4th day after the onset of the outbreak and removal from

## DIFFERENTIAL DIAGNOSIS

**Acute bovine pulmonary emphysema and edema****Acute bovine pulmonary emphysema and edema**

is usually obvious when presented with an outbreak of acute respiratory disease in adult cattle which have recently been moved onto a new pasture. The onset is sudden, many cattle are found dead and many are dyspneic. ABPEE must be differentiated from:

**Pneumonic pasteurellosis****Pneumonic pasteurellosis**

is characterized by fever, toxemia, mucopurulent nasal discharge and less dyspnea; young cattle are more commonly affected and there is a beneficial response to therapy within 24 hours.

**Organophosphatic insecticide poisoning****Organophosphatic insecticide poisoning**

may resemble the pasture form of pulmonary emphysema because of the dyspnea but additionally there is pupillary constriction, mucoid diarrhea, muscular tremor and stiffness of the limbs, and no abnormal lung sounds.

**Nitrate poisoning**

may occur in cows moved into a new pasture with high levels of nitrate. Many cows are affected quickly, they are weak, stagger, gasp, fall down, and die rapidly. The chocolate brown coloration of the mucous membranes, the lack of abnormal lung sounds, and the response to treatment are more common in nitrate poisoning.

**Other interstitial pneumonias**

All of the other types of acute interstitial pneumonia in cattle not associated with a change of pasture in the autumn are difficult to diagnose clinically and pathologically, especially when they occur in a single animal. Their epidemiological characteristics summarized on p. 513 will often offer some clues.

The chronic and subacute types of interstitial pneumonia are difficult to differentiate from each other and from other pneumonias of cattle.

**Bovine farmer's lung**

**Bovine farmer's lung** or extrinsic allergic alveolitis occurs in housed cattle exposed to dusty or moldy feeds for a prolonged period and is characterized by a history of chronic coughing, weight loss, poor milk production, occasionally green-colored nasal discharge, and dry crackles over most aspects of the lungs. Not infrequently, acute cases occur and die within a week after the onset of signs.

**Lungworm pneumonia**

**Lungworm pneumonia** occurs in young cattle on pasture in the autumn months and causes subacute or acute disease which may resemble bovine farmer's lung clinically but not epidemiologically. Necropsy is necessary for the diagnosis.

**Verminous pneumonia**

**Verminous pneumonia** caused by aberrant migration of *Ascaris suis* larvae may be indistinguishable from acute interstitial pneumonia, but a history of previous occupation of the area by pigs may provide the clue to the diagnosis which can only be confirmed on histological examination of tissues. It is impossible to differentiate clinically between verminous pneumonia and some of the acute interstitial pneumonias seen in yearling cattle except by identification of the larvae in the feces or tissues of affected animals.

**Feedlot interstitial pneumonia**

**Feedlot interstitial pneumonia** occurring in recently weaned beef calves or feedlot cattle is characterized by the sudden onset of acute respiratory distress, absence of toxemia, lack of abnormal nasal discharge, and a poor response to treatment with antibiotics. It is difficult to differentiate clinically from acute viral interstitial pneumonia or pneumonic pasteurellosis. However, in acute interstitial pneumonia there is marked dyspnea and the abnormal lung sounds are usually distributed over the entire lung fields.

**Enzootic pneumonia of calves**

**Enzootic pneumonia of calves** may resemble acute or chronic interstitial pneumonia but is almost entirely restricted to housed calves less than 6 months of age. They respond to treatment gradually over a few days.

the pasture usually will not prevent new cases. Conversely, leaving the herd on pasture usually will not result in additional cases. Severely affected cattle should be removed from the pasture with extreme care, very slowly and only if necessary, and moved to shelter from the sun. Immediate slaughter for salvage may be indicated in severe cases. Mild or moderately affected cases will commonly recover spontaneously without any treatment if left alone and not stressed, a fact that has not been given due consideration when claims are made for the use of certain drugs.

Several different drugs have been advocated and used routinely for the treatment of ABPEE in cattle. However, none has been properly evaluated and definitive recommendations cannot be made.

Treatment of the chronic interstitial pneumonias is unsatisfactory because the lesion is progressive and irreversible.

**CONTROL**

There are no known reliable methods for the prevention of ABPEE in pastured cattle

but there are some strategies which merit consideration.

**Grazing management**

If lush autumn pasture contains toxic levels of the substance that causes the acute disease it would seem rational to control the introduction of cattle to the new pasture. This can be done by controlling the total grazing time during the first 10 days: allow the cattle to graze for 2 hours on the first day, increasing by increments of 1 hour per day, and leave them on full time at the end of 10–12 days. Such a management procedure is laborious, requires supplementation with other feeds and daily removal of cattle from the pasture, and may not be practical depending on the size and terrain of the pasture and the holding yards which are available.

**Inhibition of 3-methylindole production in rumen**

Controlling the conversion of D,L-tryptophan in forage to 3-methylindole is a plausible control strategy. Experimental tryptophan-induced ABPEE can be prevented by the simultaneous oral administration of chlortetracycline or polyether antibiotics such as monensin. The daily oral administration of 2.5 g/head of chlortetracycline beginning 1 day before and for 4 days following administration of a toxin of L-tryptophan will prevent clinical signs.<sup>14</sup>

The daily oral administration of monensin at the rate of 200 mg/head/day beginning 1 day before and for 7 days after an abrupt change from a poor quality hay diet to a lush pasture reduced the formation of 3-methylindole during the 7 days of treatment, but the effect of the drug was diminished on day 10, 3 days after its withdrawal. Because the effects of monensin on ruminal 3-methylindole are diminished within 48 hours after withdrawal of the drug, effective prevention of acute pulmonary edema and emphysema may require continuous administration of monensin for the critical period of approximately 10 days after the mature animals are exposed to the lush pasture. The daily feeding of monensin in either an energy or protein supplement will effectively reduce ruminal 3-methylindole formation in pasture-fed cattle.

Successful prevention of the disease requires monensin supplementation with organized grazing management to reduce the intake of lush pasture by hungry cows. This may be accomplished in several ways: feed dry, mature hay ad libitum to adult cattle just before and during the transition period of a pasture change, then continue to feed hay for at least 4 days into this grazing period; cut all lush forage and allow to wilt before allowing adult cattle access to the

pasture. Alternatively, over a 7-day period, gradually increase the amount of time cattle spend grazing lush pasture. If possible, this may be accomplished by rotating cattle back and forth, either between the summer and fall pastures, or between the fall pasture and a drylot where ample supply of dry, mature hay is available. Any combination of these management practices while providing monensin at 200 mg/head per day in an energy or protein supplement may reduce 3-methylindole production to a greater extent than just providing monensin or implementing grazing management techniques.<sup>6</sup>

To maximize the effectiveness of monensin in reducing 3-methylindole formation, dry hay plus wilted forage should be fed to pastured cattle for at least 4 days after they are allowed access to lush pasture. Lasalocid at a dose of 200 mg per head once daily in ground grain for 12 days reduced the conversion of tryptophan to 3-methylindole and prevented pulmonary edema.<sup>15</sup>

The daily administration of inhibitors during the critical period immediately before and after the cattle are turned onto the lush pasture may be a practical problem.

Other interstitial pneumonias

The control of non-pasture cases of interstitial pneumonia depends on the suspected cause and removal of it from the environment of the animals. Every attempt must be made to control the concentration of dust and moldy foods to which cattle are exposed. Feed supplies must be harvested, handled, and stored with attention to minimizing dust and molds. In the preparation of mixed ground feed for cattle, the fineness of grind must be controlled to avoid dusty feed particles which may be inhaled. Because of the creation of dust, the grinding and mixing of dry feeds like hay, straw, and grains should not be done in the same enclosed area in which cattle are housed. If dusty feeds must be used they should be wetted to assist in dust control.

**Lungworm control** is essential in endemic areas where the disease occurs. This may necessitate careful monitoring and regular treatment to reduce the level of infestation on pasture.

**Viral interstitial pneumonias.** In countries where cattle are housed, especially during the winter months, the provision of adequate ventilation is necessary to minimize aerosol viral interstitial pneumonias. Vaccination is a consideration.

#### TRACHEAL STENOSIS OF FEEDLOT CATTLE

Tracheal stenosis, also known as 'honker cattle', occurs in feedlot cattle.<sup>1</sup> The etiology is unknown. It is characterized by extensive edema and hemorrhage of the dorsal wall of the trachea, resulting in coughing (honking), dyspnea, and respiratory stertor. Complete occlusion of the trachea may occur. Affected animals may be found dead without any premonitory signs.

In tracheal stenosis of feedlot cattle, there is marked submucosal hemorrhage dorsal and ventral to the tracheal is muscle resulting in ventral displacement of the mucosa and partial to complete occlusion of the tracheal lumen. Diffuse hemorrhage in the peritracheal connective tissue and surrounding muscles of the neck is common in animals dying of asphyxia. Histologically there is hyperemia and hyperplastic tracheal mucosa with focal erosions, squamous metaplasia, and loss of cilia. In acute cases the mucosa is markedly thickened because of hemorrhage and edema. Culture reveals a mixed bacterial flora.

#### INTERSTITIAL PNEUMONIA OF ADULT HORSES

In its most severe form, this is a disease characterized by insidious progression of pulmonary inflammation and fibrosis. Less severe forms, associated with transient viral or bacterial infections of the lungs, resolve when the infection is cleared from the lungs.

#### ETIOLOGY

There are many potential agents but few have been conclusively implicated as

being associated with the disease. In most instances of the disease no causal association is identified.

Interstitial pneumonia is a common finding in horses associated with various infectious agents (Hendra virus infection, *Rhodococcus equi* in foals, *Aspergillus* sp., *Cryptococcus* sp. and *Histoplasma* sp., *Pneumocystis carinii*,<sup>1</sup> *Parascaris equorum*, and *Dictyocaulus arnfeldi*). Intoxication with perilla ketone, derived from *Perilla frutescens*, causes acute restrictive lung disease of horses.<sup>2,3</sup> Similarly, ingestion of *Eupatorium* sp. in Australia and Hawaii causes interstitial pneumonia in horses.<sup>4</sup> Inhalation of silica causes a similar disease in horses in California.<sup>5</sup> Inhalation or ingestion of agricultural chemical or environmental toxins (e.g. paraquat) has the potential to cause interstitial pneumonia in other species, but this has not been demonstrated in horses.

Hypersensitivity reactions may cause severe respiratory disease in horses. Incriminating allergens include fungi (unspecified) and chicken dust.<sup>6,7</sup>

Interstitial pneumonia has also been reported subsequent to administration of an immunostimulant containing mycobacterial cell wall extract.<sup>8</sup>

#### EPIDEMIOLOGY

The disease occurs in adult horses without apparent breed, sex, or age predisposition. In cases in which the cause is infectious, the epidemiology of the disease is characteristic of that of the causal organism.

#### PATHOGENESIS

The initial insult causes injury to parenchymal cells and an acute alveolitis.<sup>9</sup> Alveolitis results from damage to epithelial and endothelial cells by toxic, metabolic (free radicals), or infectious agents. This is followed by a phase of cellular proliferation of type 2 pneumocytes and fibroblasts with connective tissue deposition.<sup>3</sup> At this time there is an influx of inflammatory cells, the exact type depending to some extent on the cause of the disease. Infiltration of neutrophils, lymphocytes, and macrophages is common. Continued injury to the lung results in development of severe interstitial fibrosis and destruction of gas exchange units.

Interstitial pneumonia results in altered pulmonary function including reduced compliance, impaired pulmonary gas exchange, and a reduction in total and vital lung capacity. The work of breathing is increased.<sup>10</sup>

#### CLINICAL SIGNS

Horses with idiopathic interstitial pneumonia have various combinations of: weight loss, recurrent cough, depression,

anorexia, fever, or respiratory distress. Signs of respiratory disease are not readily apparent at initial examination in all affected horses. As the disease progresses respiratory distress develops in most, but not all, cases. The usual history of is a gradual onset of increased respiratory effort, although some horses have a sudden onset of respiratory distress.<sup>11</sup> Heart and respiratory rates may be elevated. Pyrexia is not a constant finding. There may be a nasal discharge. Thoracic auscultation may reveal only increased intensity of normal breath sounds or the presence of occasional crackles and wheezes. Typically, there is tachypnea with an increased respiratory effort.

Thoracic radiography reveals pulmonary disease, usually apparent as severe, diffuse interstitial disease. The interstitial opacity may be diffuse or nodular with multiple well defined opacities against an overall background of increased interstitial density. Ultrasonographic examination may reveal the presence of multiple nodules in the lung parenchyma confluent with the pleural surface. There is no excess pleural fluid.

Intradermal skin testing may be useful to identify the inciting allergen in cases of allergic interstitial pneumonia.<sup>7</sup>

The prognosis is poor in most cases of the idiopathic disease. Should recovery occur, it does so within approximately 2 weeks of diagnosis.

#### CLINICAL PATHOLOGY

Hematologic examination usually reveals a neutrophilic leukocytosis.<sup>11,12</sup> Mild anemia and hyperfibrinogenemia are common. Examination of a tracheal aspirate reveals neutrophil inflammation. In cases of verminous pneumonia, there may be an increased proportion of eosinophils in tracheal aspirate. Bronchoalveolar lavage fluid can reveal a similar neutrophilic leukocytosis or may be normal.<sup>13</sup> Serologic testing for antibodies to fungi or other inciting agents may be useful.<sup>9</sup>

Definitive diagnosis is provided by examination of tissue obtained by lung biopsy.

#### NECROPSY FINDINGS

The lungs do not deflate as anticipated and there may be indentations from the ribs on the surface of the lungs. Multiple pale, yellowish-white nodules 3–4 cm in diameter may be apparent on the surface of the lung and throughout the lung parenchyma. There is histologic evidence of severe, fibrosing alveolitis with minimal airway involvement. The acute phase of the disease is evident as extensive alveolar edema and hemorrhage.<sup>14</sup>

#### TREATMENT

Treatment should be directed toward any cause of the disease that is identified such as administration of anthelmintics. In cases of idiopathic disease, treatment is frequently unrewarding as by the time the animal is examined the disease is often advanced. Treatment includes anti-inflammatory drugs including dexamethasone or prednisolone, antimicrobials, and supportive care. Immunosuppressive drugs, such as vincristine, are not effective. Bronchodilating drugs, such as clenbuterol, may be considered, but bronchoconstriction is not a prominent component of the disease.

#### CONTROL

Prevention of exposure to potential infectious, toxic or environmental causes is prudent.

#### ACUTE BRONCHO-INTERSTITIAL PNEUMONIA IN FOALS

This is a disease of foals less than 7 months of age, and usually <2 months of age, characterized by a rapid onset of respiratory distress. The **etiology** is unclear in many cases, but suggested causes or agents associated with the disease include equine influenza virus infection,<sup>1</sup> *R. equi*, equine herpes virus II, equine arteritis virus,<sup>2</sup> or *Pneumocystis carinii*.<sup>3–6</sup> The disease is likely a result of severe pulmonary injury by any of a number of infectious or toxic agents. The respiratory distress results from loss of pulmonary function because of necrosis of the epithelium of alveoli and terminal bronchioles.

Foals typically present with an acute onset (<4 days) of respiratory distress, pyrexia and tachycardia. Foals are depressed and reluctant to eat. There is a pronounced

respiratory effort with a marked abdominal component in most affected foals. Crackles, wheezes, and increased bronchial breath sounds are auscultable in most foals. Radiographic examination reveals a broncho-interstitial pattern which is always diffuse, although in some foals there is also a focal interstitial pattern. The prognosis is guarded, with approximately 50% of affected foals dying of the disease.

There is a neutrophilic leukocytosis and hyperfibrinogenemia in most cases. Arterial hypoxemia is present in severely affected foals. Tracheal aspirate demonstrates neutrophilic inflammation. Culture of the tracheal aspirate yields *Rhodococcus equi*, *Strep. zooepidemicus*, *Actinobacillus* sp., and other organisms of questionable significance. Serology might demonstrate evidence of infection by equine influenza virus or equine herpes virus II.<sup>1,3,4</sup> Viral isolation can identify equine influenza virus.<sup>1</sup>

#### NECROPSY FINDINGS

**Necropsy** examination reveals the presence of diffusely reddened, wet and firm lungs that fail to collapse.<sup>3,4</sup> The predominant histologic lesion is necrosis of the epithelium of terminal bronchioles and alveoli.

#### TREATMENT

Principles of **treatment** are correction of hypoxemia, reduction of inflammation and removal of inciting causes. Severely affected foals may require nasal insufflation of oxygen to ameliorate or correct hypoxemia. Administration of corticosteroids has been associated with improved survival.<sup>3</sup> Broad spectrum antibiotics are administered to treat concurrent bacterial infections and prevent secondary infection.

#### CONTROL

There are no specific control measures, but reduction of exposure of foals to infectious respiratory disease would be prudent.

#### CHRONIC INTERSTITIAL PNEUMONIA OF FOALS

A sporadic disease of foals less than 10 months of age characterized by respiratory distress of several weeks duration is caused by chronic interstitial pneumonia.<sup>1</sup> The etiology is unknown, but the disease likely represents a common final response to injury caused by any one of a number of infectious or toxic agents (see 'interstitial pneumonia of horses' and 'acute bronchointerstitial pneumonia of foals').

Affected foals are bright and alert and have markedly increased respiratory effort. The respiratory rate is elevated and there is a prominent abdominal component to respiratory effort. Fever is low grade and intermittent. Thoracic auscultation reveals increased intensity of normal breath sounds and the presence of wheezes and crackles in most affected foals. Ultrasonographic examination of the thorax reveals extensive 'comet tail' signs in most cases. Radiography demonstrates the presence of moderate to severe interstitial pneumonia which in some cases can include focal opacities suggestive of alveolar disease. The prognosis with appropriate treatment is excellent.

Affected foals have neutrophilic leukocytosis and hyperfibrinogenemia. Serological examination for antibodies to common respiratory viruses is unrewarding. Culture of tracheal aspirates does not consistently yield growth of known pathogens. Lung biopsy is not warranted because the characteristic changes on radiographic examination, combined with the clinical signs, are diagnostic for the disease. The risk of adverse events associated with lung biopsy outweighs any diagnostic utility given the good prognosis for complete recovery from the disease.

Treatment consists of administration of corticosteroids such as dexamethasone phosphate at an initial dosage of 0.1–0.25 mg/kg intravenously for 3–5 days followed by a declining dose administered orally over 2–3 weeks. Prednisolone can be substituted for dexamethasone. Broad spectrum antibiotics (combination of penicillin and aminoglycoside, trimethoprim-sulfonamide, or doxycycline) should be administered for 1–2 weeks.

There are no recognized control measures, although control of infectious respiratory disease in the herd is prudent.

## Diseases characterized by nervous system involvement

### POLIOENCEPHALOMALACIA (CEREBROCORTICAL NECROSIS) OF RUMINANTS

#### Synopsis

**Etiology** Several different causes including thiamin inadequacy, sulfate toxicity.

**Epidemiology** Sporadic disease in young well-nourished ruminants on high level grain diets and not synthesizing sufficient thiamin. Ingestion of preformed

thiaminase in certain plants or production by ruminal microbes may also cause destruction of thiamin. May also occur in cattle and sheep of all ages ingesting excess amount of sulfates in feed and water.

**Signs** Sudden blindness, ataxia, staggering, head-pressing, tremors of head and neck, ear twitching, champing fits, clonic-tonic convulsions, recumbency, opisthotonos, rumen contractions normal initially, pupils usually normal and responsive, nystagmus, death may occur in 24–48 hours. Hydrogen sulfide odor of ruminal gas in sulfate toxicity.

**Clinical pathology** Erythrocyte transketolase activity decreased and thiamin pyrophosphate effect increased but both measurements difficult to interpret; blood thiamin levels decreased but not reliable.

**Lesions** Diffuse cerebral edema, flattened dorsal gyri, coning of cerebellum, multifocal to linear areas of fluorescence in gray and white matter borders of cortical gyri and sulci.

**Diagnostic confirmation** Fluorescence of gray and white matter of cortical gyri and sulci of brain.

#### Differential diagnosis list Cattle:

- Lead poisoning
- Hypovitaminosis-A
- *Histophilus meningoenephalitis*.

#### Sheep:

- Pregnancy toxemia
- *Clostridium perfringens* Type D Enterotoxemia
- Focal symmetrical encephalomalacia
- Lead poisoning.

#### Goats:

- Caprine leukoencephalomyelitis
- *Listeria meningoenephalitis*
- *Clostridium perfringens* Type D Enterotoxemia
- Lead poisoning.

**Treatment** Thiamin hydrochloride parenterally.

**Control** Thiamin supplementation of diet. Avoid excess feeding or access to sulfate in feed and water supplies.

#### ETIOLOGY

Historically, PEM was considered to be caused by a thiamin inadequacy. It is now known that there are several different causes of the disease.

#### Thiamin inadequacy

The evidence that a thiamin inadequacy can be associated with the disease includes the following<sup>1</sup>:

- Affected animals respond to the parenteral administration of thiamin if given within a few hours after the onset of clinical signs
- Affected animals have biochemical findings consistent with thiamin diphosphate (TDP) inadequacy
- The clinical signs and pathological lesions can be reproduced in sheep

and cattle by the administration of large daily doses of pyrimidine containing structural analogs of thiamin, principally amprolium, given orally or intraperitoneally.<sup>1</sup>

#### Excess dietary sulfur

The ingestion of excessive quantities of sulfur from the diet and water supply can cause the disease in cattle<sup>2</sup> and sheep<sup>3</sup> without any change in the thiamin status of the tissues.

#### EPIDEMIOLOGY

##### Occurrence

PEM occurs sporadically in young cattle, sheep, and goats, and other ruminants. In North America, UK, Australia, and New Zealand, the disease has been most common in cattle and sheep which are being fed concentrate rations under intensified conditions such as in feedlots. An inadequate amount of roughage can result in a net decrease in the synthesis of thiamin. The disease occurs most commonly in well-nourished thrifty cattle 6–18 months of age (peak incidence 9–12 months of age) which have been in the feedlot for several weeks. Feedlot lambs may also be affected only after being on feed for several weeks. The disease also occurs in goats and in antelope and whitetail deer.<sup>4</sup> The disease may affect goats from 2 months to 3 years of age and is commonly associated with milk-replacer diets in kids or concentrate feeding in older goats. The disease occurs only rarely in adult cattle which may be a reflection of the greater quantities of roughage they usually consume. However, there are recent reports of the disease occurring in adult cows on pasture with access to drinking water containing excessive concentrations of sulfates.<sup>2</sup>

In Cuba, the disease occurred in feedlot cattle fed primarily on molasses with a minimal quantity of roughage, and was reproduced by feeding a molasses-urea and roughage diet by gradual removal of the roughage without the use of thiamin analogs.

#### Morbidity and case fatality

Accurate morbidity and case fatality data are not available, but outbreaks can occur suddenly in which up to 25% of groups of feeder cattle may be affected, with case fatality rates from 25 to 50%. Case fatality rates are higher in young cattle (6–9 months) than in the older age group (12–18 months) and mortality increases if treatment with thiamin is delayed for more than a few hours after the onset of signs. In feedlot lambs, it has been suggested that approximately 19% of all deaths are due to polioencephalomalacia.

#### Risk factors

When PEM was first described in 1956, and for about 30 years, it was considered

to be a thiamin deficiency conditioned by dietary factors such as high-level grain feeding and inadequate roughage. PEM occurred most commonly in well nourished young cattle from 6 to 12 months of age which were being fed high-level grain rations. The scientific investigations centered on the effects of dietary factors such as grain diets, and the presence of thiaminases in certain diets on thiamin metabolism in the rumen. In recent years, it has become clear that the disease is not etiologically specific because many different dietary factors have been associated with the occurrence of the disease, and in some instances the thiamin status of the affected animals is within the normal range. Notable examples are the recent observations linking dietary sulfate with the occurrence of the disease.

#### Dietary risk factors

While there has been general agreement that thiamin inadequacy is associated with the cause of PEM, the possible mechanisms by which this occurs are uncertain.<sup>5</sup> Thiamin inadequacy in ruminants could, theoretically, occur in any of the following situations where inadequate net microbial synthesis of thiamin in the rumen may occur:

- Concentrate-fed animals receiving inadequate roughage
- Impaired absorption and/or phosphorylation of thiamin
- The presence of a thiamin inhibitor in the tissues of the host
- Lack of sufficient or appropriate apoenzyme or coenzyme-apoenzyme binding for thiamin dependent systems
- Increased metabolic demands for thiamin in the absence of increased supply
- Increased rate of excretion of thiamin resulting in its net loss from the body.

Thiamin can be destroyed by thiaminases of which significant amounts can be found in the rumen contents and feces of cattle and sheep affected with naturally occurring polioencephalomalacia.

#### Thiamin inadequacy

In cattle under farm conditions, using transketolase activity as a measurement of thiamin status, up to 23% of cattle under 2 years of age and 5% over 2 years may be in a thiamin-low state. Newly weaned beef calves on a hay diet are not subject to a thiamin deficiency but a low and variable proportion of young cattle on barley-based feedlot diets (1.7%) may have some evidence of thiamin deficiency based on a thiamin pyrophosphate activity effect in excess of 15%.<sup>2</sup> The supplementation of the diet of feedlot steers on an all-concentrate barley-based diet with thiamin at 1.9 mg/kg DM resulted in an increase in average

daily gain and final carcass weights. Thus some animals may be marginally deficient in thiamin which may be associated with decreased performance in cattle fed all-concentrate diets. However, thiamin supplementation of cattle on all-concentrate diets does not consistently result in improved animal performance. The experimental disease can be produced in young lambs fed a thiamin-free milk diet and it may be unnecessary to postulate that thiamin analogs produced in the rumen are essential components of the etiology.

#### Thiaminases

A major factor contributing to PEM in cattle and sheep is a progressive state of thiamin deficiency caused by the destruction of thiamin by bacterial thiaminases in the rumen and intestines. Certain species of thiaminase-producing bacteria have been found in the rumen and intestines of animals with PEM. *Bacillus thiaminolyticus* and *Clostridium sporogenes* produce thiaminase type I and *Bacillus aneurinolyticus* produces thiaminase type II. While there is good circumstantial evidence that the thiaminases from these bacteria are the real source of thiaminases associated with the disease, it is not entirely certain. The experimental oral inoculation of large numbers of thiaminase type I producing *Clostridium sporogenes* into lambs did not result in the disease.

Certain species of fungi from moldy feed are also thiaminase producers but the evidence that they destroy thiamin and are associated with PEM is contradictory and uncertain.

The factors which promote the colonization and growth of thiaminase-producing bacteria in the rumen are unknown. Attempts to establish the organism in the rumen of healthy calves or lambs have been unsuccessful. Thiaminases have also been found in the rumen contents and feces of normal animals which may suggest the existence of a subclinical state of thiamin deficiency.<sup>5</sup> Poor growth of unweaned and weaned lambs can be associated with a thiaminase-induced subclinical thiamin deficiency. Weekly testing of young lambs over a period of 10 weeks revealed that 90% of unthrifty lambs were excreting high levels of thiaminase in their feces; low levels of thiaminase activity were present in 20% of clinically normal animals, and there were significant differences in the mean erythrocyte transketolase activity of the unthrifty animals excreting thiaminase compared to the thiaminase-free normal animals.<sup>5</sup>

Field and laboratory investigations have supported an association between inferior growth rate of weaner sheep in Australia and a thiaminase-induced

thiamin deficiency.<sup>5</sup> Thiaminase activity has been detected in the feces of lambs at 2–5 days of age, with the levels increasing for 10 days and then declining over the next 3–4 weeks.<sup>5</sup> Decreased erythrocyte transketolase activity indicated a thiamin insufficiency in lambs with high thiaminase activity and mean growth rates were 17% less than lambs with low thiaminase activity. The oral supplementation with thiamin at 2–3 weeks of age was the most appropriate prevention and treatment for subclinical thiamin deficiency.<sup>5</sup>

The parenteral or oral administration of thiamin to normal calves raised under farm conditions resulted in a marked reduction in the percentage thiamin pyrophosphate effect which is an indirect measurement of thiamin inadequacy. Goats with PEM were found to have elevated ruminal and fecal thiaminase activities, low erythrocyte transketolase activity, elevated thiamin pyrophosphate effect, low liver and brain thiamin levels, and elevated plasma glucose levels compared with goats not affected with the disease. With the increased interest in goat farming, some breeders attempt to improve body condition of breeding stock for sale or show by feeding grain or concentrate, which creates a situation similar to feedlot rearing of sheep and cattle which is conducive to the establishment of thiaminases in the rumen and the occurrence of polioencephalomalacia.

High levels of thiaminase type I are present in the rhizomes of bracken fern (*Pteridium aquilinum*) and horsetail (*Equisetum arvense*). The feeding of the bracken fern rhizomes (*Pteridium esculentum*) to sheep will cause acute thiamin deficiency and lesions similar to those of polioencephalomalacia but neither of these plants is normally involved in the natural disease. The disease has occurred in sheep grazing the Nardoo fern, *Marsilea drummondii*, in flood-prone or low-lying wet areas in Australia. The fern contains a high level of thiaminase type I activity.

*Amaranthus blitoides* (prostrate pigweed) may contain high levels of thiaminase and be associated with polioencephalomalacia in sheep.<sup>6</sup>

#### Sulfates

Polioencephalomalacia has been associated with diets high in sulfur, particularly in the form of sulfate. A high concentrate of sulfates in the diet of cattle has been associated with episodes of the disease in 6–18-month-old cattle. **Inorganic sulfate salts in the form of gypsum (calcium sulfate)** added to feedlot rations to control the total daily intake of the diet may cause PEM.<sup>7</sup> Seasonal outbreaks have occurred in feedlot beef cattle between 15 and 30 days after introduction to a **high-sulfur**

diet and the risk may increase when water is an important source of dietary sulfur, and during hot weather, when the ambient temperatures exceeded 32°C.<sup>8</sup>

Initial outbreaks may follow the use of a **new well of water containing more sulfate** than water used previously from another well, increasing from a monthly incidence of 0.07% to 0.88%. Growing cattle consume 2.4 times more water when the temperature is 32°C than at 4°C and consequently total ingestion of sulfur by consumption of high sulfate water increases during hot weather. The feed contained 2.4 g of SO<sub>4</sub>/kg DM with a total sulfur content of 0.20%. Samples of drinking water contained between 2.2 and 2.8 g of SO<sub>4</sub>/L. During hot weather daily sulfur ingestion from feed and water combined was estimated to be 64 g/animal corresponding to total dietary sulfur of approximately 0.67% of DM. Daily SO<sub>4</sub> ingestion was approximately 160 g/animal.<sup>8</sup> The ruminal sulfide levels were much higher 3 weeks after entering the feedlot, when the incidence of the disease was greatest, than 2 months after entering the feedlot when the risk of the disease was low.

In western Canada, there is an association between PEM and high levels of sodium sulfate in water, and range cows are usually affected when certain waters become concentrated with this salt during the summer months.<sup>2</sup> Water containing high levels of magnesium sulfate, often called '**gyp water**', is common in the western plains and intermountain areas of the United States and Canada.<sup>9</sup> Ideally, water for livestock consumption should contain less than 500 ppm sulfate, and 1000 ppm is considered the maximum safe level in water for cattle exposed to moderate dietary sulfur levels or high environmental temperatures. A level of 2000 ppm of sulfate in drinking water is the taste discrimination threshold for cattle. Performance of feedlot cattle is reduced when offered water with sulfate levels of 2000 ppm or higher. The National Research Council states that the requirement of sulfur in feed to be 1500 to 2000 ppm for both growing and adult beef cattle; 4000 ppm is considered the maximum tolerated dose.<sup>9</sup> Ruminant diets normally contain between 1500 to 2000 ppm (0.15–0.20% sulfur).

Based on National Research Council guidelines, 30 g of sulfur is the calculated maximum tolerated dose of sulfur for a 650 lb (294 kg) steer consuming 16.25 (7.39 kg; 2.5% BW) of feed daily. If the ambient temperature reaches 32°C, a 650 lb steer can drink 14.5 gallons (53.9 L) of water daily. Consumption of 14.5 gallons of water containing 3000 ppm sulfate results in a daily intake of 55 g sulfur. A feed intake of 2.5% BW would also consume 22.2 g of sulfur from feed containing 3000 ppm

sulfur for a total daily intake of 77.2 g of sulfur from both feed and water which is 2.5 times the maximum tolerated dose.

In some surveys, water supplies in western Canada contained contained 8447 ppm of total dissolved solids and 5203 ppm of sulfate. A survey of the sulfate concentrations in water on farms, found that high levels of sulfate can have a detrimental effect on the thiamin status of the cattle on those farms.<sup>10</sup> Cattle exposed to sulfate concentrations >1000 ppm had blood thiamin levels lower than those drinking water with low levels <200 ppm. This raises the possibility that a sub-population of cattle under such circumstances could be marginally deficient in thiamin.

**The total dietary intake of sulfur** by cattle must be considered when investigating sulfur as a cause of PEM. In a study of one farm, water from a 6.1 m well containing 3875 mg/L of total dissolved solids with 3285 mg/L of sodium sulfate was associated with PEM in heifers 6 months of age.<sup>11</sup> However, the water contributed about 20% of the total sulfur content in the diet of the heifers, and 60% of the dietary sulfur intake was supplied by the hay and 20% by the grain supplement. The hay contained 0.4% total sulfur which is at the maximum tolerable level for cattle and at the upper limit for hay.<sup>11</sup> The hay consisted of variable amounts of kochia (*Kochia scorpia*) and Canada thistle (*Cirsium arvense*). *Kochia scorpia* (summer cypress or Mexican fireweed), is high in sulfur content and has been associated with the disease in range cattle.

PEM has occurred in pastured cattle usually 5–10 days after change from a poor to a good pasture, and may occur in range cattle grazing on dry, short, grama grass pasture.<sup>12</sup>

The levels of sulfate in water which have affected feed intake in cattle have varied from 2800 to 3340 mg sulfate per/L while other studies found no reduction in feed intake with levels up to 7000 mg/L.<sup>11</sup> It appears that the different effects of sulfur toxicity for similar sulfur contents in saline water are attributed to the total sulfur intake. Outbreaks of the disease may occur in adult cattle on pasture drinking water containing 7200 ppm of sodium sulfate.<sup>2</sup> Thus established guidelines for saline drinking water are not applicable when cattle are fed feeds grown in saline areas.

A combination of excessive intake of sulfur and a low dietary intake of trace minerals, especially copper, may affect the thiamin status of a cattle herd and contribute to PEM.<sup>13</sup> Sulfur adversely affects both thiamin and copper status in sheep.<sup>14</sup> A nutritionally related PEM has also been reproduced in calves fed a semipurified,

low-roughage diet of variable copper and molybdenum concentrations and it was not related to copper deficiency.<sup>15</sup> The disease has occurred in cattle in New Zealand fed chou moellier (*Brassica oleracea*) which contained sulfur concentrations of 8500 mg/kg DM.<sup>16</sup> The morbidity was 25% and mortality 46% despite rapid conventional therapy.

**Ammonium sulfate** used as a urinary acidifier in the rations of cattle and sheep has been associated with outbreaks of PEM.<sup>3</sup> Morbidity rates ranged from 16 to 48% and mortality rates from 0 to 8%. Affected animals did not respond to treatment with thiamin.

Outbreaks have occurred in sheep exposed to an alfalfa field previously sprayed with 35% **suspension of elemental sulfur**.<sup>17</sup> The disease can be induced experimentally in lambs by the administration of sodium hydrosulfide into the esophagus<sup>18</sup> and has occurred in lambs 3–4 weeks after being fed a concentrate ration containing 0.43% sulfur.<sup>19</sup> Feeding experimental diets containing inorganic sulfur to young lambs was associated with PEM and supplementation of those diets with thiamin decreased the severity of the lesions.<sup>20</sup> Rumen microbes are able to reduce sulfate to sulfides which may be directly toxic to the nervous system. Feeding calves (115–180 kg) a semipurified diet high in readily fermentable carbohydrate, without long fiber, and with added sodium sulfate for a total sulfur content of 0.36% resulted in PEM within 21 days of the introduction of the experimental diet.<sup>21</sup> An odor of hydrogen sulfide was frequently detected upon passage of a stomach tube into the rumen of all calves during the experiment. The total thiamin concentrations in affected and control calves remained within normal limits.

The dietary content of copper, zinc, iron, and molybdenum may also have important modifying influences on sulfur toxicosis. Molybdenum and copper can combine with sulfur to form insoluble copper-thiomolybdate. Copper, zinc, and iron form insoluble salts with sulfide, and their expected effect would be to decrease the bioavailability of sulfide in the rumen. Conversely, low, but not necessarily deficient, dietary contents of these divalent metals could be prerequisites for excess absorption of sulfide to occur. PEM is not associated with copper deficiency but copper and sulfur metabolism are interdependent. An excess of dietary sulfur may result in depression of serum copper, or alternatively, low serum copper may potentiate the actions of toxic levels of sulfur. Chronic copper poisoning in a lamb has been associated with PEM.<sup>22</sup> It is suggested that the copper toxicity may have caused decreased hepatic function resulting in

increased plasma concentration of sulfur containing amino acids which may have predisposed to sulfur toxicity encephalomalacia.

**Molasses toxicity occurs in Cuba in cattle** fed on a liquid molasses-urea feeding system with limited forage. The clinical and necropsy findings are identical to polioencephalomalacia. However, molasses toxicity is not thiamin responsive and can be reversed by feeding forage. Molasses has high inorganic sulfur content and the thiamin concentrations in the brain and liver with PEM which were fed molasses and urea did not differ from those in normal cattle.

Other dietary circumstances

**Deprivation of feed and water.** In some outbreaks there is a history of deprivation of feed and water for 24–28 hours, because of either a managerial error or frozen water supplies. In other cases, a rapid change in diet appears to precipitate an outbreak. Some outbreaks are associated with a temporary deprivation of water for 24–36 hours, followed by sudden access to water and an excessive supply of salt, a situation analogous to salt poisoning in pigs, but these require more documentation to insure that they indeed are not salt poisoning.

In sheep flocks, a drastic change in management, such as occurs at shearing time, will precipitate outbreaks in which only the yearlings are affected. Changing the diet of sheep from hay to corn silage resulted in a decrease in thiamin concentrations in ruminal fluid to about 25% of control values on hay. The cause of the drop in thiamin concentrations is unknown.

**Phalaris aquatica 'polioencephalomalacia-like' sudden death in sheep and cattle.** The Mediterranean perennial grass, *Phalaris aquatica* (formerly *Phalaris tuberosa*) can cause sudden death in sheep and cattle throughout southern Australia.<sup>23</sup> The nervous form of disease is similar clinically to polioencephalomalacia but atypical because of the very rapid onset and the absence of either neuronal necrosis or malacia in cerebral cortical sections from affected animals. The available evidence suggests that this form of phalaris sudden death is more likely to involve a peracute form of ammonia toxicity than a peracute form of polioencephalomalacia.

## PATHOGENESIS

### Thiamin inadequacy polioencephalomalacia

High levels of thiaminases are formed in the rumen, which destroy thiamin that is naturally synthesized.<sup>1</sup> The circumstances in the diet or in the rumen which allow for the development of high levels of

thiaminases are unknown but may be related to the nature of the ruminal microflora in young cattle and sheep fed concentrate rations which results in the development of ruminal acidosis. These rations may also allow for the development and growth of thiaminase-producing bacteria which, combined with a smaller net synthesis of thiamin in the rumens of concentrate-fed ruminants, could explain the higher incidence in feedlot animals. Experimentally PEM has been produced in lambs by continuous intraruminal infusion of a highly fermentable diet. Animals changed very rapidly to high concentrate rations develop increased ruminal thiaminase levels.

The possibility that intraruminal thiaminases may also create thiamin analogs capable of acting as thiamin antimetabolites and accentuating the disease has been studied but the results are inconclusive. The presence of naturally occurring second substrates (cosubstrates) in the rumen could produce, by the thiaminase type I reaction, a potent thiamin antimetabolite capable of accentuating the condition. In vitro studies have shown that thiaminase only caused rapid destruction of thiamin when a second substrate was added, and a large number of drugs commonly used as anthelmintics or tranquilizers may be active as second substrates. Many compounds found in the rumen of cattle are potential cosubstrates.

Amprolium has been used extensively to produce the lesions in the brains of cattle and sheep that are indistinguishable from the naturally occurring disease.<sup>1</sup> However, since amprolium has been found in the brain tissue, the experimental disease should perhaps be known as 'amprolium poisoning encephalopathy'. The administration of other antagonists such as oxythiamin and pyrithiamin does not produce the disease. This suggests that polioencephalomalacia is a particular form of thiamin deficiency in which the supply of thiamin is reduced by the action of intraruminal thiaminase. Thus, the thiamin status of the animal will be dependent on dietary thiamin intake, thiamin synthesis, the presence of thiaminase in the rumen and the effects of possible antimetabolites. Subclinical states of thiamin deficiency probably exist in apparently normal cattle and sheep being fed diets which are conducive to the disease. This suggests that in outbreaks of the disease the unaffected animals of the group should be considered as potential new cases and perhaps treated prophylactically.

Thiamin is an essential component of several enzymes involved in intermediary metabolism and a state of deficiency results in increased blood concentration

of pyruvate, a reduction in the lactate to pyruvate ratio and depression of erythrocyte transketolase. These abnormalities affect carbohydrate metabolism in general, but in view of the specific requirements of the cerebral cortex for oxidative metabolism of glucose, it is possible that a thiamin inadequacy could have a direct metabolic effect on neurons.<sup>1</sup> The brain of the calf has a greater dependence on the pentose pathway for glucose metabolism, in which pathway the transketolase enzyme is a rate-limiting enzyme. Ultrastructural examination of the brain of sheep with the natural disease reveals that the first change which occurs is an edema of the intracellular compartment, principally involving the astrocytes and satellite cells. This is followed by neuronal degeneration which is considered secondary. It has been suggested that the edema may be due to a reduction in ATP production following a defect of carbohydrate metabolism in the astrocyte. There are three basic lesions which are not uniform: compact necrosis, edema necrosis, and edema alone. This may suggest that a uniform etiology such as thiamin deficiency cannot be fully supported.

In the cerebral cortex of affected animals, autofluorescent spots are observed under ultraviolet 365 nm illumination and are a useful diagnostic aid. The distribution of autofluorescence corresponds to that of mitochondria in cerebrocortical neurocytes in affected calves, suggesting that metabolic impairment occurs and the autofluorescent substance is produced in the mitochondria.<sup>24</sup> Mitochondrial swelling and disorganization of cristae are also observable in brain tissue, but are not specific to polioencephalomalacia.

### Sulfate-induced polioencephalomalacia

Diets high in sulfur result in hydrogen sulfide production in the rumen and anaerobic bacteria from rumen samples of cattle fed high-carbohydrate, short fiber diets with added sulfate will generate hydrogen sulfide in rumen fluid broth medium.<sup>18,25</sup> Rumen microflora adapt to higher dietary sulfate content over a period of 10–12 days before they are capable of generating potentially toxic concentrations of sulfide.<sup>26</sup> In experimental sulfate diets which induce PEM, the rumen pH decreases during the transition to the experimental diet and acidic conditions in the rumen favor increased rumen gas cap concentrations of hydrogen sulfide. With a change of pH from 6.8 to 5.2, the percent hydrogen sulfide in the rumen gas cap increased from 47 to 97%.<sup>7</sup>

If ruminants inhale 60% of eructated gases, inhalation of hydrogen sulfide could be a route of systemic sulfide absorption,

in addition to gastrointestinal absorption.<sup>21</sup> Sulfide inhibits cellular respiration leading to hypoxia which may be sufficient to create neuronal necrosis in polioencephalomalacia. The nervous system lesions of sulfur toxicosis are indistinguishable from lesions in the naturally occurring disease.

### Acute cerebral edema and laminar necrosis

Acute cerebral edema and laminar necrosis occur and the clinical signs are usually referable to increased intracranial pressure from the edema, and the widespread focal necrosis. Recovery can occur with early treatment which suggests that the lesions are reversible up to a certain point. ECGs of buffalo calves with amprolium-induced PEM found decreased frequency patterns, occasional spindles and decreased voltage patterns during the onset of clinical signs. In the comatose stage, there was little evidence of electrical activity. EEGs of animals treated with thiamin hydrochloride found normal awake patterns.<sup>27</sup>

### CLINICAL FINDINGS

#### Cattle

Animals may be found dead without premonitory signs especially in beef cattle on pasture.<sup>2</sup> The clinical findings are variable but characteristically, there is a sudden onset of **blindness, walking aimlessly, ataxia, muscle tremors**, particularly of the head with ear twitching, **champing of the jaws** and frothy salivation, **head-pressing**, and the animal is difficult to handle or move. Dysphagia may be present when one attempts to force feed hay by hand. Grinding of the teeth is common. Initially, the involuntary movements may occur in episodes, and convulsions may occur, but within several hours they become continuous. The animal usually then becomes recumbent, and there is marked opisthotonos, nystagmus, clonic-tonic convulsions, particularly when the animal is handled or moved, and tetany of the forelimbs is common. The temperature is usually normal but elevated if there has been excessive muscular activity. The heart rate may be normal, subnormal, or increased and is probably not a reliable diagnostic aid.

Rumen movements remain normal for a few days, which is an important distinguishing feature from lead poisoning in which the rumen is static.

The **menace reflex is always absent** in the acute stage and its slow return to normal following treatment is a good prognostic sign. The **palpebral eye-preservation reflex is usually normal**. The pupils are usually of normal size and responsive to light. In severe cases the pupils may be constricted. Dorsal strabismus due to stretching of the trochlear nerve is common. Nystagmus is common

and may be vertical or horizontal. Optic disc edema is present in some cases but is not a constant finding.

Calves 6–9 months of age may die in 24–48 hours, while older cattle up to 18 months of age may survive for several days. Recovery is more common in the older age group.

In less severe cases, affected animals are blind, head-press into walls and fences, and remain standing for several hours or a few days. In outbreaks, some cattle will be sternally recumbent; others remain standing with obvious blindness, while others are anorexic, mildly depressed, and have only partial impairment of eyesight. Those with some eyesight will commonly return to almost normal. Some survivors are permanently blind to varying degrees but may begin to eat and drink if provided with assistance. Some cases will recover following treatment and may grow and develop normally.<sup>3</sup>

Evidence of recovery within a few hours following treatment with thiamin indicates that the disease is associated with thiamin inadequacy. A failure of response indicates the possibility of sulfur toxicity polioencephalomalacia.

#### Sheep

Sheep usually begin to wander aimlessly, sometimes in circles, or stand motionless and are blind, but within a few hours they become recumbent with opisthotonos, extension of the limbs, hyperesthesia, nystagmus, and periodic tonic-clonic convulsions. Hoggets affected at shearing time may show blindness and head-pressing but, if fed and watered, usually recover within a few days. Occasional animals show unilateral localizing signs, including circling and spasmodic deviation of the head. In goats, early signs may include excitability and elevation of the head. Blindness, extreme opisthotonos, and severe extensor rigidity and nystagmus are common.

In sulfur-induced PEM in sheep introduced to a diet containing 0.43% sulfur, clinical signs occurred 15–32 days later and consisted of depression, central blindness, and head-pressing, but no hyperesthesia, nystagmus, or opisthotonos were observed.<sup>11</sup> In sulfur toxicity in lambs with PEM, the rumen contents may have a strong odor of hydrogen sulfide (rotten egg smell).<sup>17</sup>

There are some reports from Australia of unthriftiness in unweaned and weaned lambs being associated with thiamin deficiency due to the presence of thiaminases in the alimentary tract.<sup>5</sup> In affected flocks the incidence of illthrift in lambs is much higher than the usual incidence and other causes of unthriftiness were ruled out. Affected lambs lose weight, may have chronic diarrhea, and become emaciated

and die from starvation. In some flocks, clinical signs of PEM may occur in a small percentage of animals. The disease occurs most commonly in early July which is the coldest part of the year in Australia for lambs which are born in May and June. In affected lambs the fecal thiaminase levels are high and the blood transketolase level activity is increased above normal. Treatment of affected lambs with thiamin resulted in an increase in growth rate.<sup>5</sup>

### CLINICAL PATHOLOGY

#### Thiamin status and metabolism

The biochemical changes occurring in cattle and sheep with the thiamin-deficiency PEM have not been well-defined diagnostically based on thoroughly investigated naturally occurring clinical cases. However, some estimates are available including the changes which occur in the experimental disease. Interpretation of the values may also be unreliable if the animals have been treated prior to death.

The **erythrocyte transketolase activity** is decreased and the thiamin pyrophosphate (TPP) effect is increased. The erythrocyte transketolase activities in normal sheep will range from 40 to 60  $\mu\text{M}$ /mL red blood cells. A TPP effect of 30–50% is commonly found in normal healthy cattle and sheep and an increase to above 70–80% occurs in animals with polioencephalomalacia.

The **thiamin concentrations** of blood of animals with polioencephalomalacia have varied widely and may be difficult to interpret because of the possibility of thiamin analogs inducing deficiency even when blood thiamin levels are normal. However, this would not apply when blood thiamin levels are below normal. A normal reference range of 75–185 nmol/L is suggested for both cattle and sheep, and levels below 50 nmol/L are considered indicative of deficiency.<sup>28</sup> In normal goats, the mean thiamin content of blood was 108 nmol/L, with a range of 72–178 nmol/L.<sup>12</sup> In goats with polioencephalomalacia, blood thiamin levels were less than 66 nmol/L with a mean of 29 nmol/L. Levels as low as 1.8–3.6  $\mu\text{g}/\text{dL}$  (6–12 nmol/L) have been found in suspected cases of polioencephalomalacia. The thiamin concentrations of liver, heart, and brain of cattle and sheep with polioencephalomalacia are decreased. The levels of blood pyruvate and lactate are also increased and thiamin pyrophosphate-dependent enzymes such as pyruvate kinase are decreased.<sup>3</sup> The thiaminase activity of the feces is increased.<sup>5</sup>

The **hemogram** is usually normal; the total and differential leukocyte counts may indicate a mild stress reaction, a finding which may be useful in differentiation

from encephalopathies due to bacterial infections.

**Cerebrospinal fluid pressure** taken at the cisterna magna is increased from a normal range of 120–160 mm saline to levels of 200–350 mm. The level of protein in the CSF may be normal to slightly or extremely elevated. A range from 15 to 540 mg/dL with a mean value of 90 mg/dL in affected cattle is recorded. There may also be a slight to severe pleocytosis in the CSF in which monocytes or phagocytes predominate.

**Ruminal sulfide measurement.** Changes in rumen gas cap H<sub>2</sub>S concentrations are larger than changes in rumen fluid H<sub>2</sub>S concentrations and estimation of rumen gas H<sub>2</sub>S concentration may be a practical method of detecting pathological increases in ruminal hydrogen sulfide gas.<sup>29,30</sup> A simple, rapid, minimally invasive method may be useful for estimating the H<sub>2</sub>S concentration of ruminal gas under field conditions. A sterile 8.9 cm 18 g needle with stillete is introduced into the gas cap of the rumen by way of the left paralumbar fossa. The needle is then connected to calibrated H<sub>2</sub>S detector tube. In cattle, with sulfate-induced polioencephalomalacia, increases in ruminal gas H<sub>2</sub>S may be as high as 100 times more than control animals.<sup>29</sup>

**Brain function.** The effects of high dietary sulfur on brain function have been examined using evoked potentials techniques.<sup>31</sup> Altered nerve conduction pathways occur in sheep fed high sulfur diets without supplemental thiamin compared to animals which have received thiamin.<sup>31</sup> The visual evoked potentials are abnormal in ruminants with thiamin-responsive polioencephalomalacia.<sup>32</sup>

#### NECROPSY FINDINGS

Diffuse cerebral edema with compression and yellow discoloration of the dorsal cortical gyri is evident and the cerebellum is pushed back into the foramen magnum with distortion of its posterior aspect.

In recovered animals, there is macroscopic decortication about the motor area and over the occipital lobes. The lesion can be identified grossly using ultraviolet illumination which results in a fluorescence that indicates necrosis of brain and engulfment of necrotic tissue by lipophages. In general, there is a good correlation between the presence of characteristic fluorescence and the biochemical changes in cases of polioencephalomalacia. A small percentage of false negatives may occur.

Histologically the lesions are widespread but most common in the cerebral cortex. There is bilateral laminar necrosis and necrosis of deeper cerebral areas. The necrosis is most prominent in the dorsal

occipital and parietal cortex, but bilateral areas of necrosis are also seen less frequently in the thalamus, lateral geniculate bodies, basal ganglia, and mesencephalic nuclei. Lesions of the cerebellum are also present. The severity and distribution of the lesions probably depend on the interrelationships between clinical severity, age of affected animal, and length of illness before death.

Subnormal levels of thiamin are detectable in the liver and brain of calves with the natural disease and low levels are also found in the experimental disease.<sup>21</sup> In the molasses-induced disease in Cuba, the tissue thiamin levels were within the normal range.

In some cases of sulfur-associated polioencephalomalacia, the rumen contents have a strong odor of hydrogen sulfide – the rotten egg smell.

#### DIFFERENTIAL DIAGNOSIS

None of the biochemical tests described under clinical pathology is practical. The diagnosis must be made on the basis of clinical findings and the readily available simple tests which rule out other diseases that resemble polioencephalomalacia. A careful consideration of the epidemiological history often assists in the diagnosis.

#### Cattle

The differential clinical diagnosis for cattle is summarized in Table 32.3. Polioencephalomalacia in cattle occurs primarily in young growing animals 6–9 months of age on concentrate rations and is characterized clinically by a sudden onset of blindness, muscular tremors of the head and neck, head-pressing, nystagmus, and opisthotonos. The disease also occurs in mature beef cattle on pasture containing a high level of sulfate in their water and feed.

In cattle the disease must be differentiated from:

- **Acute lead poisoning** which is most common in calves after spring turnout but occurs in adult cattle too and is characterized by central blindness, tremors, convulsions, uncontrollable activity with bellowing, champing fits, hyperexcitability, rumen stasis, and death in several hours. Early treatment may be successful
- **Subacute lead poisoning** characterized by blindness, stupor, head pressing, rumen stasis, weak palpebral reflexes, and no response to therapy
- **Hypovitaminosis-A** characterized by a history of a vitamin A deficient diet and nyctalopia, peripheral blindness, dilated and fixed pupils, optic disk edema, and transient convulsions followed by recovery
- **Histophilus meningoencephalitis** characterized by sudden onset of ataxia, recumbency, fever, depression with eyes closed, lesions of the fundus, marked changes in hemogram, enlarged joints, and death in several hours if not treated early.

#### Sheep

In sheep polioencephalomalacia must be differentiated from:

- **Enterotoxemia (pulpy kidney disease) due to *Cl. perfringens* type D** in unvaccinated sheep, especially feedlot lambs, in which the clinical findings are almost identical; it occurs under the same management conditions as polioencephalomalacia. Enterotoxemia in lambs usually develops within several days after being placed on a grain ration, whereas polioencephalomalacia occurs after several weeks of grain feeding. Glycosuria in pulpy kidney disease may assist the diagnosis but a necropsy is usually more informative
- **Focal symmetrical encephalomalacia** also resembles polioencephalomalacia but is sporadic, usually involves only a few animals and will not respond to treatment.

#### Goats

In goats the disease must be differentiated from caprine leukoencephalomyelitis, listeriosis, enterotoxemia, pregnancy toxemia, lead poisoning, and meningoencephalitis.

#### TREATMENT

##### Thiamin hydrochloride

The treatment of choice for thiamin deficiency PEM is thiamin hydrochloride at 10 mg/kg BW IV initially and followed by similar doses every 3 hours for a total of 5 treatments. When treatment is given within a few hours of the onset of signs, a beneficial response within 1–6 hours is common and complete clinical recovery can occur in 24 hours. Goats and sheep will commonly respond within 1–2 hours. For those which take longer to recover, the eyesight and mental awareness will gradually improve in a few days and the animal will usually begin to eat and drink by the third day after treatment. Rumen transplants of rumen juice from roughage-fed cattle may improve appetite and rumen function in those responding slowly. In sheep, following treatment with thiamin the blood transketolase activity begins to return to normal in 2–4 hours and is considered normal 24 hours after treatment.

Some cattle improve to a subnormal level within a few days and fail to continue to improve. These are usually affected with diffuse cortical and subcortical necrosis and will usually not improve further in spite of continued treatment. Those which return to a clinically normal state will usually do so by 48 hours or sooner after initial treatment. Those which are still clinically subnormal and anorexic by the end of the third day will usually remain at that level and should be slaughtered for salvage.

Treatment is ineffective in advanced cases, but unless an accurate history is

available on the length of the illness, it is usually difficult to predict the outcome until 6–12 hours following treatment. Thus, it is usual practice to treat most cases with thiamin at least twice and monitor the response. If there is no beneficial response in 6–8 hours, emergency slaughter for salvage should be considered.

The oral administration of thiamin or thiamin derivatives is indicated when thiaminases are thought to be in the alimentary tract. Thiamin hydrochloride at a rate of 1 g for goats and lambs and 5 g for calves, in a drench, is recommended. However, because the action of thiaminase type I on thiamin may result in the production of thiamin analogs which may act as inhibitors of thiamin metabolism, the use of thiamin derivatives which are resistant to thiaminases, lipid soluble and absorbed from the intestine are being explored as therapeutic and prophylactic agents. Thiamin propylsulfide can depress the thiaminase activities in the ruminal fluid of sheep with polioencephalomalacia within 2 hours after oral administration. The blood pyruvate levels and transketolase activities are also restored to normal and treated animals recovered clinically.

#### Outbreak management

In outbreaks, the in-contact unaffected animals on the same diet as the affected animals may be on the brink of clinical disease. The diet should be changed to one containing at least 50% roughage or 1.5 kg of roughage per 100 kg BW. Thiamin may be added to the ration at the rate of 50 mg/kg of feed for 2–3 weeks as a preventive against clinical disease, followed by a level of 20–30 mg/kg of feed (cattle and sheep) if the animals remain on a diet that may predispose them to the disease.

#### Sulfur toxicity polioencephalomalacia

There is no specific treatment for PEM caused by sulfate toxicity. The use of thiamin hydrochloride in doses given above is recommended.<sup>7</sup>

#### CONTROL

##### Thiamin supplementation

A rational approach to the control of PEM associated with thiamin inadequacy is to supplement the rations of concentrate-fed cattle and sheep with thiamin on a continuous basis. The daily requirements for protection have not been determined using controlled feeding trials but a rate of 3 mg/kg DM of feed for cattle and sheep has been recommended. This level may not be protective in all situations and response trials may be necessary to determine protective levels for different situations. Levels up to 20–30 mg/kg of feed may be necessary for protection. Most

natural feedstuffs for ruminants contain thiamin at about 2 mg/kg DM which when combined with the thiamin synthesized in the rumen will meet the requirements. However, the presence of thiaminases in the rumen will necessitate dietary supplementation with thiamin, but the optimal amount that will provide protection under practical conditions is uncertain.

The IM injection of 500 mg thiamin 3 times weekly into 6-month-old calves raised under practical farm conditions will steadily reduce the percentage thiamin pyrophosphate effect to zero in about 6 weeks. The daily oral administration of 100 mg thiamin to young calves fed initially on milk substitutes and then on concentrates and hay results in a decrease in percentage pyrophosphate effect.

For animals which are fed diets associated with thiamin inadequacy, it is recommended that thiamin be added to the diet at the rate of 5–10 mg/kg DM.<sup>12</sup> Cattle and sheep on concentrate-fed rations must also receive supplements containing all necessary vitamins and minerals, especially cobalt, a deficiency of which may be associated with some outbreaks of the disease.

#### Feeding roughage

The minimum amount of roughage which should be fed to feedlot cattle and sheep in order to prevent the disease and still maintain them on high levels of concentrates is unknown. A level of 1.5 kg of roughage per 100 kg BW has been recommended but this may not be economical for the feedlot whose profits are dependent on rapid growth in grain-fed cattle. Supplementation of the diet with thiamin appears to be the only alternative.

The prevention of the disease in sheep which are being moved long distances or gathered together for shearing and other management practices will depend on insuring an ample supply of roughage and water and avoiding drastic changes in management.

#### Sulfate toxicity PEM

The prevention of the disease associated with a high sulfur intake in the feed and water supplies will depend on analysis of the feed and water for sulfate and making appropriate adjustments in the sources of feed and water in order to decrease the intake of sulfur to safe levels.

### EQUINE NEONATAL ENCEPHALOPATHY (NEONATAL MALADJUSTMENT SYNDROME OF FOALS, DUMMY FOAL, BARKERS, AND WANDERERS)

This is a syndrome of foals less than 36 hours of age characterized by a spectrum of changes in mentation ranging from failure to suckle, abnormal behavior, seizures, through coma in otherwise apparently healthy foals.

#### ETIOLOGY

A number of diseases cause the clinical signs consistent with this syndrome. These include antenatal, natal or postnatal hypoxia, congenital and metabolic anomalies, placental abnormalities, intracranial hemorrhage, prematurity, and thoracic trauma.<sup>1</sup> Of these causes, hypoxia before, during or soon after birth is considered the most common cause of neonatal encephalopathy, although hypoxia is rarely documented. It is important to realize the neonatal encephalopathy is one of many manifestations of hypoxia of the fetus or neonate, the other manifestations including gastrointestinal and renal damage.<sup>2,3</sup>

#### EPIDEMIOLOGY

The disease is sporadic and occurs worldwide with an annual **incidence** in foals of approximately 1%.<sup>4</sup> Foals of either sex and of any breed born to mares of any age

Table 36.2 Differential diagnosis of comatose (sleeper) neonatal foals

Disease	Epidemiology	Clinical findings	Clinical pathology	Lesions	Treatment and prognosis
<i>Actinobacillus equuli</i> septicemia	Foals to 3 months but usually <2 weeks. Enzootic to some farms.	Sudden onset recumbency, fever, abdominal pain, diarrhea, joint distension. Death.	<i>A. equuli</i> in blood or joint fluid	Septicemia, septic synovitis/arthritis, nephritis with abscesses in renal cortex.	Penicillin and gentamicin or other broad spectrum antibiotic, supportive care. Fair prognosis if treated early.
Septicemia	<i>E. coli</i> , <i>Klebsiella</i> sp., <i>Streptococcus</i> sp., <i>Salmonella</i> sp., <i>Actinobacillus suis</i> , Equine herpesvirus-1. Failure of transfer of passive immunity.	Abrupt onset of depression, fever, failure to nurse and recumbency. Later diarrhea, pneumonia and joint distension.	Culture of organism from blood or lesions (joints, lungs, feces).	Consistent with septicemia. Pneumonia. Septic synovitis, arthritis, osteomyelitis.	Broad spectrum antibiotics, supportive care (see 'Principles of providing care to the critically ill neonate'). Guarded to poor prognosis.
Isoimmune hemolytic anemia	Incompatible mating of Aa+ or Qa+ stallion with negative mare.	Normal at birth. Subsequent depression, cessation of nursing, exercise intolerance, icterus, anemia. Hemoglobinuria in severe cases.	Positive Coomb's test to demonstrate immunoglobulin on foal's red cells. Dam's colostrum agglutinates or lyses foal red cells.	Anemia, icterus. Death due to anemic hypoxia.	Transfusion of washed dam's red blood cells or of compatible donor (check dam's plasma with donor's red cells). Fair prognosis.
Uroperitoneum	Ruptured bladder, urachus or ureteral defect. Colts 1 to 3 days of age. Foals of either sex with other systemic diseases.	Normal at birth. Onset of abdominal distension, mild colic, depression and recumbency. May urinate small volumes.	Peritoneal fluid has high creatinine concentration. Hyperkalemia, hyponatremia, hypochloremia.	Uroperitoneum. Rupture bladder, urachus or ureter.	Surgical correction AFTER drainage of abdomen and resolution of hyperkalemia with intravenous dextrose or 0.9% NaCl. Good prognosis with appropriate care.
Hypoglycemia	Failure to nurse. Rejection by mare. Mare has no milk (agalactia)	Normal at birth, repeated attempts to nurse. Gradual onset (hours) of weakness and depression.	Low blood glucose concentration (<60 mg/dL, 3 mmol/L).	None. No food in stomach.	Excellent response to feeding or intravenous glucose.
Neonatal maladjustment syndrome	Sporadic	Onset of abnormal behavior, recumbency, failure to nurse or orient to mare. Aimless wandering and vocalization.	None characteristic. Frequently failure of transfer of passive immunity.	Usually none apparent. Occasional intracranial vascular accidents.	Supportive care (see 'Principles of providing care to critically ill neonates'). Good prognosis.
Congenital defects	Sporadic	Depends on nature of cardiac, gastrointestinal or central nervous system defect.	None	Consistent with defect.	Usually no treatment. Poor prognosis depending on defect.

or reproductive history can be affected. The **case fatality rate** is very low for appropriately treated foals without other systemic illness.

### PATHOGENESIS

It is speculated that hypoxia resulting from intracranial vascular accidents,<sup>5</sup> asphyxia at birth or placental insufficiency before birth damages the central nervous system. Neurological abnormalities and a failure to nurse, result in a failure of the transfer of maternal immunoglobulins, which predisposes the foal to septicemia and hypoglycemia.

### CLINICAL SIGNS

**Foals that are abnormal at birth** can display a range of behavioral abnormalities,

from lack of suckle reflex to convulsions with extensor rigidity. The placenta of affected foals is often abnormal or there is a history of prolonged parturition. Affected foals either do not develop or lose the suck reflex, and have no affinity for the mare and are unable to locate the udder or teat. Aimless wandering and a characteristic 'barking' vocalization are sometimes present. Recumbent foals struggle wildly and in an uncoordinated fashion to stand. Convulsing foals usually display opisthotonos with extensor rigidity. Other signs of convulsive activity include facial twitching and grimacing, nystagmus, rapid blinking, sucking, chewing, and drooling.<sup>1</sup> Between episodes foals are usually depressed or somnolent. Affected

foals display little or no interest in the mare. Convulsing foals are tachypneic, tachycardic (>180 bpm), and hyperthermic (>39°C, 102°F) during and immediately after convulsions. It is important to recognize that the severity of clinical signs varies from very mild (foals are often described by owners as being a bit slow or dimwitted) through to grand mal seizures.

**Foals that are normal** at birth may develop signs by 24 hours of age. The signs are similar to those described above, with the exception that the foals are initially able to ambulate. It is important to realize that healthy newborn foals lack a menace reflex, have a hypermetric gait and intention tremor, and become flaccid when restrained.

Affected foals can take days to weeks to recover completely. Blind foals that do not have ocular lesions can take as long as 4–6 weeks to regain vision.

Ancillary testing is not usually indicated unless the foal fails to respond after approximately 7 days. At that time, CT or MRI examination of the brain might be indicated to detect congenital anomalies such as hydrocephalus. Examination of cerebrospinal fluid should be performed in any foal with signs of CNS dysfunction in the presence of fever or other signs of sepsis.

### CLINICAL PATHOLOGY

There are no hematological or serum biochemical abnormalities characteristic of the disease:

- Affected foals usually have **failure of transfer** of maternal immunoglobulins (serum IgG <400 mg/dL)
- They may be **hypoglycemic** (<80 mg/dL, 4 mmol/L)
- **Cerebrospinal** fluid is often normal, although it may contain red blood cells or appear xanthochromic as a result of bleeding.

### DIAGNOSTIC CONFIRMATION

**Definitive diagnosis** of the disease is difficult and is based on exclusion of other diseases that can cause similar signs and, at necropsy, demonstration of intracranial lesions consistent with the disease.

### NECROPSY FINDINGS

Gross changes are typically limited to diffuse pulmonary congestion with a variable degree of atelectasis. In cases in which dystocia has been a contributing factor, fractured ribs, and foci of subcutaneous edema and hemorrhage are sometimes noted. Occasionally, macroscopic cerebral hemorrhages are visible. Histologically, the key findings are hemorrhagic foci within the brain and areas of ischemic necrosis in the cerebral cortex.<sup>6</sup> Meconium and other components of aspirated amniotic fluid accompanied by atelectasis and a mild inflammatory response may be present within the lung. In less affected foals the brain lesions are restricted to hemorrhage, cerebral swelling, and edema. Many affected foals have evidence of intracranial vascular accidents.<sup>7</sup> Affected foals that are euthanased often have no detectable lesions in the brain.

### Samples for post-mortem diagnostic confirmation

Formalin-fixed brain, including cerebral cortex, cerebellum and brain stem, and lung for light microscopic examination.

### DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other diseases that cause neurological or behavioral abnormalities in foals including: sepsis; renal, hepatic, or gastrointestinal disease, which can occur secondary to fetal hypoxia; hydrocephalus; hypoglycemia; meningitis; neonatal isoimmune hemolytic anemia; and prematurity, dysmaturity, or immaturity.

### TREATMENT

The principles of treatment are:

- Control of convulsions
- Treatment of cerebral edema and hemorrhage
- Correction of failure of transfer of passive immunity
- Nutritional support and general nursing care. The management of affected foals is mainly supportive and is time consuming and labor intensive.

Provision of nutritional support, treatment of failure of passive transfer of maternal immunoglobulins, and nursing care is dealt with in detail in the section 'Principles of care of the critically ill neonate'.

For other than emergency treatment of seizures, in which **diazepam** (0.1–0.4 mg/kg, intravenously, as required) or **midazolam** (0.05–0.1 mg/kg IV, as required) are useful, **phenobarbital** (phenobarbitone), **phenytoin** and **primidone** are the drugs of choice for long-term control of seizure activity. Phenobarbital is administered initially at a dose of 1–3 mg/kg intravenously in 30 mL of isotonic saline infused over 15–30 minutes. Maintenance therapy is a similar dose intravenously or orally, every 8 hours, and the dose adjusted to provide control of seizures while minimizing the degree of sedation. Because of the long elimination half life of phenobarbital in foals (~200 hours) and the transient nature of the disease, once seizure control is achieved administration of phenobarbital can be discontinued. Drug concentrations will be at or above the target concentration (5–30 µg/mL) for several days after the final dose. **Phenytoin** (5–10 mg/kg intravenously or orally initially, then 1–5 mg/kg every 4 hours) or **primidone** (20–40 mg/kg orally every 12–24 hours, to effect) are also used to control convulsions.

Definitive demonstration of the presence of cerebral edema or intracranial hemorrhage is impossible without sophisticated imaging devices, such as magnetic resonance imaging or computed tomography (CT).<sup>8</sup> However, treatment is often

initiated on the basis of clinical signs. None of the treatments have demonstrated efficacy, and some are controversial. **Dimethyl sulfoxide** (DMSO) is given intravenously at 0.5–1 mg/kg once or twice daily for 3 days as a 10% solution. **Mannitol** (0.25 g/kg, intravenously as a 20% solution) may be effective in treating cerebral edema but is contraindicated if intracranial hemorrhage is present. **Glucocorticoids** (dexamethasone, 0.2–1 mg/kg or prednisone, 1–2 mg/kg) might reduce intracranial inflammation and swelling. They might be contraindicated in foals with sepsis.

**Magnesium sulfate** (0.05 mg/kg per hour for one hour, then 0.025 mg/kg/h IV for up to 48 hours) is often administered to foals with suspected hypoxic encephalopathy in an attempt to minimize neuronal damage. There is no objective evidence of its efficacy in foals.

Foals with respiratory depression can be administered caffeine (10 mg/kg orally once and then 3.0 mg/kg orally q 24 hours).<sup>3</sup> Adverse effects include agitation, hyperesthesia, tachycardia, and convulsions.

**Good nursing care** is critical in affected foals, and a concerted and persistent effort should be made to encourage the foal to nurse the mare. Encouraging the foal to nurse can be frustrating for the handler and mare, but should be done regularly, about every 4 hours, and preferably when the foal is hungry. Affected foals often begin to nurse quite suddenly.

Affected foals can require up to 4–6 weeks to recover completely, although most do so within 1 week of birth, and hasty decisions regarding euthanasia should not be made without recognition of the sometimes long time required for complete recovery.

### CONTROL

Prevention of hypoxia in neonates by close monitoring of the health of the mare and of parturition may reduce the incidence of the disease.

## CONGENITAL TREMOR SYNDROMES OF PIGLETS

Tremors in pigs are not a common clinical sign. Recently, generalised tremors have been described in grower pigs<sup>1</sup> but until this report the condition has only been described as a neonatal condition. The condition has been known for a long time in Britain.

This group of at least four etiologically distinct congenital diseases of the nervous system has a similar clinical and pathological identity. In particular they all have congenital tremor (*myoclonia congenita*) and these rhythmic tremors are most evident while the piglet is standing, are reduced when it lies down, and disappear when it is asleep. It is therefore not encephalitis but an increased sensitivity of the spinal cord reflexes.

Although the tremor is present at birth it may not be observed until the piglets are 2 or 3 days old and beginning to move about actively. The tremor varies from a very rapid twitch affecting only the head to a slow tremor causing the pig to 'dance'; there may be such a severe tremor that the body and head tremble violently and rock from side to side. There is no muscular weakness and the piglets get up and scamper about, but there may be ataxia and dysmetria so that the gait may be badly affected. Mildly affected piglets are not greatly incapacitated and can survive and eventually recover in 2-8 weeks; the tremor fades gradually, and near the end of the course it may be evident only during exercise. Badly affected piglets may be unable to get to the teat to suck and may die of starvation. Many are fatally crushed or trampled by the sow.

For convenience, entities within the syndrome have been classified into two types.

**Type A** has morphological lesions and there are 5 types AI, AII, AIII, and AIV for which the causes are known.

Type AI (*myoclonia congenita*) results from transplacental infection of the fetus by particular strains of swine fever virus.<sup>2-4</sup> In litters affected by swine fever virus usually about 40% of the litter is affected. The characteristic lesions are cerebellar hypoplasia and cerebrosplinal dysmyelinogenesis. When the disease caused by the unidentified viral infection of the fetus first appears in a piggery all litters are affected. Most pigs in each litter have the disease, but after a period of several months the disease disappears, apparently because of herd immunity. The principal sign as in the swine fever induced disease is myoclonia, and most piglets recover. Spinal dysmyelinogenesis is the characteristic lesion.

Type AII (*myoclonia congenita*) is caused by transplacental infection with an agent presumed to be a virus and it is believed to be the most common type of congenital tremor.

Type AIII (congenital cerebrosplinal hypomyelinogenesis) is a hereditary form so far found only in Landrace and known as Landrace trembles.<sup>5</sup> The inherited sex-linked disease occurs in the progeny of Landrace or Landrace-cross sows. Up to 11% of Landrace piglets may be affected compared to only 0.3-0.8% in the Yorkshire, Hampshire, and Duroc breeds. The mode of transmission is via a monogenic sex-linked recessive character, and half of all male pigs born are affected. Histologically, there is cerebrosplinal myelinogenesis. Most affected pigs die. It is essentially a deficiency of oligodendrocytes.

Type AIV is also a genetically determined condition due to an autosomal recessive condition found in Saddlebacks. It is seen in about 25% of the progeny, and is fatal in most of them. Cerebrosplinal dysmyelinogenesis is the characteristic lesion. It is characterised by a deficiency of myelin throughout the CNS.<sup>6</sup> A type distinct from this has also been reported in Saddleback x Large White sows.<sup>7</sup>

Type AV occurs naturally in Scandinavia<sup>8</sup> and is characterized by cerebellar hypoplasia and has been experimentally produced following dosing of pregnant sows between 45 and 75 days of gestation with trichlorfon.<sup>9</sup>

**Type B** is a form of congenital tremor not yet adequately characterized and without morphological lesions and is of unknown etiology. The differentiation of these diseases is now possible on the basis of histopathological and neurochemical findings and relating these to the epidemiological data. In piglets born from sows inoculated with the Weybridge congenital tremor strain of the swine fever virus in early pregnancy, the severity of the clinical signs was related to the degree of spinal myelin deficiency. Semiautomated planimetry can be used to determine the cross-sectional areas of spinal gray and white matter of affected piglets. The spinal cord cross-sectional area is significantly reduced in piglets affected with Type AI congenital tremor. The reduction is similar to Type AII. The neurochemical findings relate to the presence of particular fatty acid profiles in the cholesterol esters in the lipids of the spinal cord.

Control of the disease depends on its cause. If it is inherited the recommended procedure is to keep none of the affected recovered pigs for breeding. If the cause is one of the maternal infections of early pregnancy it is recommended practice to deliberately expose empty females to affected piglets so that they become

immunized before pregnancy. Failure to identify the cause may necessitate adopting both procedures.

The disease appears to occur sporadically but when it does occur it may assume great importance. As many as 15% of litters born in a piggery may be affected, and of these 72% of the piglets may be affected and the case fatality rate amongst these may be as high as 50%. There is a feeling amongst veterinarians that the condition has increased recently but this may just be an increased awareness. If there is an increase, the specific cause of the increased prevalence has not been identified but it is possibly the unidentified virus referred to above: the virus of congenital tremor Type AII. There is also the possibility that the observed concurrent increase in prevalence of both splayleg and congenital tremor may indicate that they are possibly caused by the same virus. In this context, there is conjecture, that the PCV2 virus which is extremely small and similar in size to the particles that were described in the early electron micrographs of the spinal cord of affected piglets may be responsible. As yet there is no confirmation that splayleg and congenital tremor are PCV2 associated disorders.<sup>10</sup>

## OVINE HUMPYBACK

This is a disease of sheep, mainly Merino wethers, in western Queensland, characterized by stiffness and shortness of steps when forced to walk for about a kilometer. The sheep stops walking and adopts an arched back posture. At this time the body temperature is significantly elevated and the level of lymphocytes in the blood is lowered. The greatest incidence is in summer after rain and when the sheep are in full wool, and the hyperthermia and ataxia disappear when the sheep are shorn. Environmental temperatures at the time of the greatest prevalence of the disease are high,

commonly 40°C. This occurs in spite of the presence of a characteristic degeneration of spinal cord tracts.<sup>1</sup> The obvious explanation of the phenomenon is that it is a form of heat stroke and that the nervous system lesions are incidental.

## EQUINE CERVICAL VERTEBRAL STENOTIC MYELOPATHY, (WOBLER, 'WOBBLES', EQUINE SENSORY ATAXIA, CERVICAL VERTEBRAL INSTABILITY)

### Synopsis

**Etiology** Unknown.

**Epidemiology** Sporadic or endemic disease of young horses. Young, rapidly growing male horses are most commonly affected. Separate presentation in middle-aged horses in which it is sporadic.

**Clinical signs** Spinal ataxia evident as truncal sway, ataxia and paresis usually more severe in the hind limbs. Radiographic evidence of narrow spinal canal.

**Clinical pathology** None.

**Lesions** Malacia and Wallerian degeneration in the cervical spinal cord.

**Differential diagnosis** Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis, West Nile encephalomyelitis, equine herpesvirus-1 myelopathy, aortoiliac thrombosis, congenital vertebral malformation, diskospondylitis, and ryegrass staggers.

**Diagnostic confirmation** Radiography. Positive contrast myelography. Necropsy.

**Treatment** Anti-inflammatory drugs. Surgical fusion of vertebrae.

**Control** None.

## ETIOLOGY

The cause of neurologic disease is compression of the cervical spinal cord, hence the term compressive myelopathy. The compression may be **static**, that is the compression is present constantly with the neck in a neutral position, or **dynamic** and only present intermittently when the neck is either flexed or extended. The second situation is often referred to as cervical vertebral instability. The etiology of equine cervical stenotic myelopathy (CSM) in most cases is not known. Several basic syndromes of compressive myelopathy, based on age of occurrence, are recognized:

- Equine stenotic myelopathy (ESM) in immature horses (<3 years of age, depending on breed) that is often associated with developmental joint disease in the axial and appendicular skeleton. The fundamental underlying

defect appears to be a narrow diameter of the cervical vertebral canal.

- Cervical vertebral instability (CVI), a disease of horses less than 1 year of age, is often associated with malformations of one or more of the cervical vertebrae.<sup>1</sup>
- Compressive myelopathy in mature horses, >4 years (usually >7 years) of age, associated with osteoarthritis of the articular facets of the caudal cervical vertebrae, with subsequent impingement of the vertebral canal by bony and soft tissue proliferative lesions.
- Miscellaneous causes of cervical cord compression by neoplasia (melanoma, sarcoma, lymphoma),<sup>2-4</sup> trauma (cervical vertebral fractures), arachnoid or synovial cysts<sup>1</sup> or, rarely, diskospondylitis.<sup>5</sup>

An alternative categorization is based on the nature of the bony lesion and not on the cause of compression of the spinal cord. **Type I cervical vertebral malformation** occur in horses <2 years of age that have vertebral changes that likely began in the first few months of life, and include malformations causing stenosis of the vertebral canal, malformations at the articulations of the vertebrae including osteochondrosis, and enlarged physal growth regions.<sup>6</sup> **Type II cervical vertebral malformations** tend to occur in older horses with severe osteoarthritic lesions of the vertebral articulations.<sup>6</sup>

## EPIDEMIOLOGY

### Occurrence

The disease in mature horses occurs sporadically throughout the world.

The disease in young horses is sometimes endemic on farms or studs, and in particular lines of horses. There is a suggestion of a familial tendency for the disease, although this has not been well documented.

The **morbidity rate** may be as high as 25% of each foal crop on individual Thoroughbred farms, although the overall frequency of the disease in the general horse population is much lower.<sup>7</sup>

### Risk factors

Animal risk factors

The disease in young horses is commonly recognized in Thoroughbred, Standardbred, Warmblood, and Quarter horses, but other breeds can be affected. Ponies are rarely, if ever, affected. The disease occurs in horses less than 4 years of age, with most cases occurring in 1-3-year-old horses. Males are more commonly affected than are females. Horses with cervical stenotic myelopathy have a narrower spinal canal than do unaffected animals and this condition, with degenerative joint disease of

the articular facets and thickening of the ligamentum flavum, contributes to the greater likelihood that the horse will have spinal cord compression.<sup>7-9</sup>

It is suspected that predisposition to the disease is heritable, but this has not been demonstrated by appropriate studies. The stenotic myelopathy is believed to be the result of a combination of fast growth rate and over nutrition, and dietary restriction may reduce the incidence of the disease.<sup>7</sup> A relationship of ESM to developmental bone disease (osteochondrosis) and dietary copper has been suggested, but is unproven.

The disease in mature horses tends to be in horses used for athletic endeavours, and is uncommon in brood mares or retired animals.

## PATHOGENESIS

The disease is attributable to injury to the spinal cord as a result of compression by either soft tissue (joint capsule, intervertebral ligaments, or, rarely, intervertebral disk material) or cartilage and bone.

Constant or intermittent pressure on the spinal cord causes necrosis of white matter and neurons at the site of compression, and degeneration of fibers of ascending tracts cranial to the site of compression, and of descending tracts caudal to the compression.<sup>10</sup> The ascending tracts are those associated with general proprioception whereas the descending tracts are upper motor neurons. These tracts are located superficially in the dorsolateral aspect of the cervical spinal cord and damage to them results in signs of ataxia and weakness. Tracts from the caudal limbs are more superficial, and therefore more easily injured, than are tracts associated with the cranial limbs. Consequently, clinical signs are usually more severe in the hind limbs. The spinal cord lesions are usually, but not always, bilaterally symmetrical, as are the clinical signs.<sup>10</sup> Proprioceptive pathways are disrupted, causing the signs of ataxia (incoordination) typical of the disease. Clinical signs vary depending on the site of the lesion (see below).

## CLINICAL FINDINGS

The onset of clinical signs is sometimes acute in both ESM and CVI in young horses and there may be a history of trauma, such as falling. However, the onset of clinical signs in ESM in both young and mature horses is usually gradual and insidious and in mildly affected horses the nervous disease may be mistaken for lameness of musculoskeletal origin. Affected horses are bright and alert and have a normal appetite. There may be evidence of pain on manipulation of the neck, especially in mature horses, or on firm pressure over the lateral facets.

The severity of clinical signs varies from barely detectable to recumbency. There are no defects of cranial nerves, with the exception of the cervicofacial reflex.

**Mildly affected horses** may have deficits that are difficult to detect and only apparent under saddle or at high speed. The owner may complain of poor performance of a race horse or dressage animal, of an animal that frequently changes leads or that is poorly gaited. Careful examination may reveal excessive circumduction of the hind feet, stumbling, and pacing when the head is elevated.

**Moderately affected** animals have truncal sway, the body of the horse and hind quarters swaying laterally when the horse is walked in a straight line, and excessive circumduction of the hind feet. Having the horse move in a very tight circle about the examiner often causes the circumduction to become worse in the outside hind leg and the horse to place one foot on top of the other. Affected horses will sometimes pace when walked in a straight line with the head elevated. Blindfolding the horse does not exacerbate the signs. Affected horses will stumble when walked over low objects, such as a curb, and will **knuckle** at the fetlocks and stumble when walked down a steep hill.

**Severely affected** horses often fall easily when moved or are unable to stand. The horses are bright and alert, but anxious, and display marked truncal sway and ataxia. When standing they will often have their legs in markedly abnormal positions.

Mature horses with disease secondary to arthritis of the articular facets can have hypalgesia of the skin overlying those regions and atrophy of the cervical musculature.

Horses with lesions in the cervical spinal cord cranial to C6–C7 have signs in both fore and hind limbs. The hindlimbs are more severely affected and the signs are usually, but not always,<sup>10</sup> bilaterally symmetrical. Lesions of the cervical intumescence (C6 to T2) may cause signs that are more severe in the forelimbs than in the hindlimbs. Lesions at this site may also cause signs typical of brachial plexus injury. Focal muscle atrophy is not characteristic of ESM or CVI and there are never signs of cranial nerve, cerebral, or cerebellar disease.

After initial progression the clinical signs usually stabilize or partially resolve. However, complete spontaneous recovery is very unusual. Death is unusual unless it is by misadventure, although many affected animals are killed for humane reasons.

#### Ancillary diagnostic tests

The 'slap test', in which the response of the arytenoid cartilages to a slap on the

thorax is examined through an endoscope, has poorer sensitivity and specificity for detecting spinal cord disease than does a routine neurological examination.<sup>11</sup>

Acupuncture has no proven value in the diagnosis of ESM or CVI and should not be used for this purpose.

#### Radiographic examination

Radiographic examination of cervical vertebral column of affected horses reveals narrowing of the spinal canal.<sup>7,8</sup> This has diagnostic utility, e.g. a ratio of spinal canal to vertebral body diameter of less than 50% for C4 is associated with a 28-fold increase in the probability of ESM.<sup>8</sup> Other measures of spinal canal diameter are useful in the detection of stenosis and compressive myelopathy.<sup>12–14</sup> Other radiographic signs consistent with ESM or CVI include:

- Encroachment of the caudal vertebral physis dorsally into the spinal canal ('ski jump lesion')
- Extension of the arch of the vertebra over the cranial physis of the next vertebra
- Sclerosis of the spinal canal
- Kyphosis between adjacent vertebra
- Degenerative joint disease of the articular facets.

However, these signs are also common in normal horses and have poor predictive value.<sup>1,8,12,13</sup>

**Myelography** has been considered to provide the definitive ante mortem confirmation of spinal cord compression.<sup>4</sup> However, the sensitivity of this technique, using a 50% reduction in the width of the dorsal dye column as a cut-off for diagnosis of the disease is 53% (95% confidence interval 34–72%,  $n = 22$ ) and the specificity is 89% (95% confidence interval of 84–93%,  $n = 228$ ).<sup>16</sup> Others have found similar values for sensitivity and specificity.<sup>12</sup> These results indicate that a positive finding on myelography is highly suggestive of the disease, but that a negative finding does not eliminate the possibility of the disease. The false-positive rate is increased to 12–27% for compression at mid-cervical sites during neck flexion.<sup>16</sup> Myelography is superior in diagnosing compressive lesions at C6–C7 than at more proximal sites.<sup>16</sup> Occasionally the compression is lateral rather than dorso-ventral and is not readily apparent on routine myelography.

#### CLINICAL PATHOLOGY

Hematological and serum biochemical values are usually within reference ranges in affected horses. Cerebrospinal fluid from affected horses may have increased protein concentration, but this finding is neither characteristic nor specific for ESM or CVI. However, other causes of spinal

ataxia may cause characteristic changes in the cerebrospinal fluid. Measurement of creatine kinase activity in CSF has no diagnostic value in horses.<sup>17</sup>

#### NECROPSY FINDINGS

Gross examination reveals degeneration of the articular facets in many affected horses.

Impingement of soft tissues, especially the ligamentum flavum and joint structures, or cartilage and osteophytes into the spinal canal may be apparent. The spinal canal may be narrow. The spinal cord may be indented and soft at the site or sites of compression. Histologically, there is nerve fiber swelling, widespread degeneration of myelin, and astrocytic gliosis. Cranial to the compressive lesion, Wallerian degeneration is evident in the dorsal and lateral funiculi, while caudal to the compression these changes are most evident in the ventral and central lateral funiculi.<sup>10</sup> Slight atrophy of cervical muscles is sometimes evident. There is histological evidence of stretching and tearing of the ligamentum flavum and joint capsule at affected joints especially C6 or C7.

#### DIFFERENTIAL DIAGNOSIS

Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis (*Hypoderma* spp., *Setatia* sp., *Halicephalobus deletrix*), equine herpesvirus-1 myelopathy, aorto-iliac thrombosis, West Nile encephalomyelitis, congenital vertebral malformation (especially in Arabian foals), discospondylitis, tumors involving the spinal canal (melanoma, lymphoreticular neoplasia), and rye-grass staggers. See Table 36.3.

#### TREATMENT

Medical treatment of the acute disease consists of rest and administration of anti-inflammatory drugs (dexamethasone 0.05–0.25 mg/kg, IV or IM every 24 hours; flunixin meglumine 1 mg/kg, IV every 8–12 hours; phenylbutazone 2.2–4.4 mg/kg, orally every 12–24 hours; and/or dimethyl sulfoxide, 1 g/kg as a 10% solution in isotonic saline, IV every 24 hours for 3 treatments).

Treatment of arthritis of the facets of mature horses can be achieved by injection of the articular facet joints with corticosteroids (40 mg methylprednisolone acetate).<sup>18</sup> Injection of the joint is facilitated by ultrasonographic guidance.<sup>18</sup> Injection of the joints with anti-inflammatory drugs is assumed to result in reduction in inflammation and soft tissue swelling with consequent reduced compression of the cervical spinal cord.

Table 36.3 Differential diagnosis of disease causing spinal ataxia in horses

Disease	Etiology and epidemiology	Clinical signs and lesions	Treatment and prognosis
Cervical compressive myelopathy (cervical stenotic myelopathy, cervical vertebral instability)	Sporadic. Young, rapidly growing males. More common in Thoroughbreds, Standardbreds, and Warmblood horses. Syndrome in mature horses caused by arthritis or articular facets.	Symmetrical ataxia often of sudden onset. May be associated with trauma. Hind limbs most severely affected. Compression of cervical spinal cord demonstrated by myelography. CSF normal.	Medical treatment of rest and antiinflammatory drugs. Poor prognosis. Surgical correction by ventral stabilization. Guarded prognosis.
Equine degenerative myelopathy	Young horses (<3 years). Familial incidence of increased requirement for vitamin E.	Gradual onset symmetric ataxia that stabilizes at about 3 years of age. No radiographic abnormalities in cervical spinal cord. CSF normal.	Vitamin E 5–20 iu/kg per day in feed may prevent progression. No cure. Death uncommon.
Equine protozoal myeloencephalitis	<i>Sarcocystis neurona</i> in spinal cord or brain. Americas only. Infectious but not contagious.	Any sign of central nervous system dysfunction. Usually gradual onset of asymmetric spinal ataxia, focal muscle atrophy or weakness. CSF contains antibody to <i>S. neurona</i> , but also found in normal horses.	Ponazuril 5–10 mg/kg orally daily for 28 days. Older, but effective, treatment is pyrimethamine, 1 mg/kg orally and sulfadiazine, 20 mg/kg orally every 24 hours for 90–120 days. Nitazoxonide 25 mg/kg orally once daily for 2 days followed by 50 mg/kg orally for 26 days. Vaccination not recommended.
Equine herpesvirus-1 myeloencephalopathy	EHV-1. Infectious and contagious. Sporadic. Outbreaks occur often preceded by fever or upper respiratory tract disease.	Ascending paralysis with fecal and urinary incontinence, recumbency, normal mentation. CSF xanthochromic and increased protein concentration. Lesion is vasculitis and malacia.	Corticosteroids controversial. Nursing care. Poor prognosis. Vaccination minimally effective.
West Nile encephalitis	West Nile virus. Transmitted by bite of infected mosquito. Horse is 'dead end' host and does not develop sustained viremia. Enzootic to Mediterranean littoral and North America. Peak disease risk is late summer.	Weakness, muscle fasciculations, altered mentation. Recumbency.	No specific treatment. Nursing care. Corticosteroids controversial. Hyperimmune serum available in some areas. Interferon has been used but efficacy uncertain.
Trauma	Sudden onset. More common in young horses.	Spinal ataxia, varying degrees of weakness and proprioceptive deficits. Recumbency. Radiographic lesions present occasionally. CSF may contain red blood cells.	Anti-inflammatory drugs. Rest.
Rye grass staggers	Intoxication by lolitrems produced by <i>Acremonium lolii</i> growing on perennial rye grass. Outbreaks of disease in horses on affected pasture.	Ataxia, stiff gait, tremor, hypersensitivity, recumbency. No histologic lesions.	Remove source of toxin. Rapid recovery without other treatment.
Parasite migration	Sporadic. <i>Strongylus</i> sp., <i>Hypoderma</i> sp., and filarioids ( <i>Setaria</i> sp.).	Wide variety of clinical signs. Progressive ataxia. CSF may contain eosinophils.	Ivermectin 200 µg/kg. Antiinflammatory drugs.
Congenital anomalies	Sporadic. Cause spinal cord compression or lack of neural tissue, e.g. spina bifida.	Recumbency, ataxia present at birth.	No treatment.

A 'paced growth' program of slowed growth achieved by nutritional restriction of young horses (foals and weanlings) has been suggested as conservative treatment for immature horses with compressive myelopathy or at high risk of developing the disease.<sup>19</sup>

**Surgical fusion** of cervical vertebrae is useful in the treatment of mildly to moderately affected horses,<sup>20,21</sup> although because of issues of safety of future riders there are concerns by some authorities about the advisability of this treatment.

## CONTROL

Control measures are not usually employed, although insuring an appropriate diet and growth rate of at-risk animals would be prudent. Because of the possible inherited nature of the disease, a corrective breeding program may be advisable.

## STRINGHALT

Stringhalt is an involuntary, exaggerated flexion of the hock during walking. It can affect one or both hindlimbs. Classic

stringhalt occurs sporadically, is usually unilateral, and is usually irreversible without surgical intervention. Stringhalt can also occur secondarily to injury to the dorsal metatarsus.<sup>1</sup>

A clinically identical disease, Australian stringhalt, occurs in outbreaks in Australia, New Zealand, California, Japan, and Chile.<sup>2,3</sup> The outbreaks tend to occur in late summer or autumn and are related to drought conditions or overgrazing of pasture with consequent ingestion of plants that would otherwise not be eaten.<sup>4</sup> Outbreaks in Australia, California, and Virginia are related to the ingestion of *Hypochaeris radicata* (flatweed, cats ear).<sup>4-8</sup> Other plants suspected to play a role in the etiology include *Taraxacum officinale* (dandelion), *Arctotheca calendula* (capeweed) or *Malva parviflora* (mallow) but good evidence of the role of any of these plants is lacking.

The abnormal movement is only elicited when the horse begins to move forward. The characteristic movement occurs in mildly affected horses when they are backed or turned. Most cases are manifested by a flexion of the hock that can be violent enough for the horse to kick itself in the abdomen. The hoof is held in this position for a moment and then stamped hard on the ground. If both hind legs are affected progress is very slow and difficult and the horses often use a 'bunny hopping' gait. In the most severe cases the horse is unable to rise without assistance. The horse's general health is unaffected although it may be difficult for it to graze. Some cases have other signs of neurologic disease such as stiffness of the forelimbs or respiratory distress due to laryngeal paralysis. Many affected horses have unilateral (usually left) laryngeal hemiplegia evident on endoscopic examination of the larynx. Electromyographic examination reveals markedly abnormal activity including prolonged insertion activity, fibrillation potentials, and positive waves at rest and enhanced EMG activity in the right lateral digital extensor muscle on muscle contraction consistent with denervation. The changes are most severe in the long digital extensor muscle.<sup>6</sup> Most horses recover without treatment, although complete recovery might not occur for over 1 year.<sup>2,5</sup>

There are no characteristic abnormalities in a complete blood count or serum biochemical profile. Pathological findings are restricted to a peripheral neuropathy in the tibial, superficial peroneal and medial plantar nerves and in the left and right recurrent laryngeal nerves.<sup>9,10</sup> Lesions in affected muscles are consistent with denervation atrophy and fiber type grouping.

The signs of the disease are characteristic. Differential diagnosis of the disease

involving one leg is ossifying myopathy of the semimembranosus and semitendinosus muscles. Lead toxicosis can induce similar signs in horses.

Treatment with phenytoin (15 mg/kg orally daily for 14 days) effected some improvement but the signs recurred within 1 or 2 days after treatment was discontinued.<sup>11</sup> Myotectomy of the lateral digital extensor muscle and tendon is reported to provide immediate relief in affected horses, even in those horses with severe bilateral disease.<sup>12</sup> However, recovery is spontaneous in most cases and there might only be a need for surgery in the most severely affected horses. Control involves the prevention of overgrazing of pastures, particularly during droughts.

## OVINE 'KANGAROO GAIT'

### Synopsis

**Etiology** Not known  
**Epidemiology** Seasonal occurrence involving only adult female sheep that are lactating, or in some cases, pregnant. Spontaneous recovery following cessation of lactation.  
**Clinical findings** Bilateral forelimb locomotor disorder  
**Lesions** Axonal degeneration of the radial nerve followed by regeneration.  
**Treatment** Supportive  
**Control** None recognized

## ETIOLOGY

A neuropathy of unknown cause.

## EPIDEMIOLOGY

### Occurrence

This condition is recorded in New Zealand and the United Kingdom and is manifest with acute onset of bilateral radial nerve paralysis followed by spontaneous recovery.

### Risk factors

It occurs only in adult ewes with an onset in late pregnancy or early lactation.<sup>1-5</sup> Spontaneous recovery occurs following cessation of lactation<sup>1-3</sup> but also occasionally while ewes are still nursing lambs.<sup>4</sup> Average annual cumulative incidence varies between flocks but is less than 1%.<sup>5</sup>

In the areas of northern England and southern Scotland the condition is significantly more common in upland and lowland flocks than in those hill grazing. Stocking density is higher in affected flocks than that in non-affected flocks. Onset occurs while on pasture between March and June with a separate smaller peak in October. This seasonal occurrence could be a reflection the parturition status of flocks or an effect of seasonal influences.<sup>5</sup>

## PATHOGENESIS

Clinical signs can be attributed to the generalized polyneuropathy affecting principally the radial nerves. Subsequent to the axonal degeneration a remyelination of the radial nerve occurs, explaining the clinical recovery. Bilateral compression of the radial nerves appears to be the cause but there is no indication of how such an injury can occur.<sup>3</sup>

## CLINICAL FINDINGS

The name comes from the gait exhibited by affected ewes which are unable to move their forefeet except in a synchronized bounding action. There is bilateral forelimb paresis, a palpable loss of muscle bulk in the forelimbs, and some cases also have proprioceptive deficits. The hind limbs are normal. Affected ewes lie down more frequently and may graze on their knees but continue to eat and effectively suckle their lambs.

## CLINICAL PATHOLOGY

There are no consistent abnormalities in haematology, blood biochemistry, or trace element analysis of affected sheep.<sup>4</sup>

## NECROPSY FINDINGS

There is axonal degeneration of the myelinated fibers of the radial nerve fibers and regeneration in recovering cases.<sup>1-3</sup> Ventral root gangliopathy and neuronal degeneration within the spinal cord is reported<sup>1-3</sup> but may not be evident in all cases.<sup>4</sup>

## DIFFERENTIAL DIAGNOSIS

Foot rot or foot abscess involving the front feet can have the same grazing behaviour but there is no problem in differentiation when the limbs and feet are examined.

Hypocalcemia in sheep occurs in late pregnancy or during lactation and in the developing stages there is incoordination and muscle weakness. However there is rapid progression to complete muscular paresis and a dramatic response to treatment.

Spinal abscess or fracture.

## TREATMENT

Without the knowledge of etiology there is no specific treatment. Easy access to food and water should be provided.

## EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease is a recently recognized **neurodegenerative disease** of horses in the US and Canada, with a small number of cases being recorded in Europe and South America. The disease affects horses of all breeds, with Quarter horses most commonly affected, and the incidence of the disease increases with age.<sup>1</sup> Horses older than 2 years of age are affected. The disease is associated with stabling and lack of access to pasture, and the risk of the disease increases with decreasing serum vitamin E concentration.<sup>2,3</sup> The etiology of the disease is unknown but is suspected to be due to oxidative injury to neurons subsequent to vitamin E deficiency.<sup>3</sup> The clinical signs are attributable to degeneration of motor neurons in the ventral horns of the spinal cord, with subsequent peripheral nerve degeneration and widespread neurogenic muscle atrophy.

The onset of clinical signs is usually gradual but in a small proportion of affected horses the first sign is an acute onset of profound muscle weakness. Chronically affected horses have weight loss in spite of a normal or increased appetite, pronounced trembling and fasciculation of antigravity muscles, increased recumbency, and a short-strided gait; they often assume a posture with all feet under the body and a low head carriage, and frequently shift weight – all signs attributable to muscle weakness.<sup>4</sup> The tail head is elevated in a large proportion of severely affected horses, likely a result of atrophy of the *sacrocaudalis dorsalis medialis* muscle. Retinal examination often reveals accumulation of lipofuscin-like pigment in the tapetal fundus.<sup>5</sup> Electromyography, under either general or regional anesthesia, is a useful diagnostic aid.<sup>6,7</sup> Characteristic findings include spontaneous fibrillation potentials and trains of positive sharp waves. The prognosis is poor and most affected horses do not return to normal function and are destroyed, although the disease stabilizes in some cases that can then live for a number of years after diagnosis.

There is often a mild increase in serum creatine kinase activity. Horses with equine motor neuron disease have abnormal oral and intravenous glucose tolerance tests characterized by peak glucose concentrations that are lower than expected.<sup>8</sup> The lower peak plasma glucose concentration

is attributable to a 3x greater rate of glucose metabolism (removal from blood) in affected horses compared to normal horses.<sup>9</sup> There is also evidence that horses with equine motor neuron disease are more sensitive to insulin than are normal horses.<sup>9</sup> Affected horses often have serum vitamin E concentrations that are below the reference range (<1.0–2.0 µg/dL, <1.0–2.0 µmol/L).<sup>3</sup> Horses with equine motor neuron disease have higher spinal cord copper concentrations than do normal horses, but the diagnostic or clinical significance of this observation is unclear.<sup>10</sup> Examination of cerebrospinal fluid is not useful in arriving at a diagnosis.

Examination of muscle from horses with equine motor neuron disease reveals a coordinated shift from characteristics of slow muscle to those of fast twitch muscle including contractile and metabolic functions of muscle.<sup>11</sup> There is a lower percentage of myosin heavy chain type 1 fibers, higher percentages of hybrid IIX and IIX fibers, atrophy of all fibers, and reduced oxidative capacity, increased glycolytic capacity, and diminished intramuscular glycogen concentrations, among other changes, in affected horses compared to normal horses.<sup>11</sup>

**Diagnostic confirmation** can be achieved by examination of a biopsy of the *sacrocaudalis dorsalis medialis* muscle or the spinal accessory nerve.<sup>7,12</sup> The *sacrocaudalis dorsalis medialis* muscle is preferred because that muscle is predominantly composed of type 1 fibers and is severely affected by the disease.

Necropsy examination reveals moderate to severe diffuse muscle atrophy. Predominant histologic findings at necropsy examination include degeneration of neurons in ventral horns at all levels of the spinal cord.<sup>13</sup> Muscle atrophy is evident as angular fibers, with predominantly type 1 fibers, or a combination of type 1 and type 2 fibers, affected.<sup>10,11</sup> There is accumulation of lipofuscin in the fundus and in capillary endothelium of the nervous tissue.

**Treatment** consists of administration of vitamin E, although the efficacy of this treatment has not been determined. Administration of lyophilized, water soluble D-α-tocopherol is apparently superior to administration of the DL-α-tocopherol acetate in increasing concentrations of vitamin E in blood of horses. The usual dose is 4 iu of D-α-tocopherol per kg body weight orally once daily. Control measures should insure that horses have adequate access to pasture or are supplemented with good quality forage and/or vitamin E.

## CRUSHED TAIL HEAD SYNDROME IN CATTLE

The crushed tail head syndrome is a recently recognized neuromusculoskeletal disease of dairy cattle which has occurred in the US and UK.<sup>1–3</sup> It occurs most commonly in housed lactating dairy cattle in mid-lactation and that have calved 60 days or more previously. The onset is sudden and characterized clinically by hindlimb weakness, prolonged recumbency in alleyways, but still able to stand. The hindlimbs are drawn forward under the abdomen. Walking is awkward because of hindlimb weakness or pain and affected animals walk with a still rolling gait. Knuckling of the fetlocks and hock joints are characteristic. There is flaccid paralysis of the tail and defecation and urination are not usually affected. During urination and defecation the tail is not lifted and becomes covered with feces and wet with urine. The anal reflex is commonly diminished. There may be some evidence of traumatic injury to the sacral area of the vertebral column with either visible abnormal alignment of the sacral area on movement by the animal or if the animal is rocked from side to side. In other cases, there is no external evidence of trauma or misalignment of the sacrum. No other clinical abnormalities have been observed; appetite is normal, vital signs are normal, and rumen function and the feces are normal in amount and character.

The cause is unknown. In some cases, estrus activity was observed a few days before the onset of signs which suggests that affected animals were mounted by others in the herd causing injury to the tail head and sacrum. It is suggested that traumatic injury to the sacral nerves is the cause of the paresis.

Most cases respond spontaneously and recover within a few weeks. Some reports describe the successful use of long-acting corticosteroids<sup>4</sup> but there is insufficient clinical information available to make any useful recommendation.

## POLYNEURITIS EQUI (EQUINE CAUDA EQUINA SYNDROME)

Polyneuritis equi (formerly cauda equina neuritis) is a demyelinating, inflammatory disease of peripheral nerves of adult horses. The **etiology** of the disease is unknown although infectious (adenovirus, equine herpesvirus type 1), immune (autoimmune disease), and toxic etiologies have been suggested, without conclusive substantiation. Adenovirus was isolate from 2 of 3 horses with the disease, but this observation has not been repeated and it appears unlikely at this time that adenovirus is the cause of polyneuritis equi.<sup>1</sup> Equine herpesvirus-1 is not consistently isolated from affected horses.<sup>2</sup>

The disease occurs in adult horses in Europe and North America but has not been reported from the Southern Hemisphere. The disease is usually sporadic with single animals on a farm or in a stable affected. However, outbreaks of the disease can affect multiple horses from the same farm over a number of years.

The **pathogenesis** of the disease involves nonsuppurative inflammation of the extradural nerves and demyelination of peripheral nerves. Initial inflammation of the nerves causes hyperesthesia which is followed by loss of sensation as nerves are demyelinated. Both motor and sensory nerves are affected, with subsequent weakness, paresis, muscle atrophy, urinary and fecal retention and incontinence, and gait abnormalities.

The **acute disease** is evident as abrupt onset of hyperesthesia of the perineum and tail head, and perhaps the face, evident as avoidance of touching, and chewing or rubbing of the tail. The hyperesthesia progresses to hypalgesia or anesthesia of the affected regions.

The disease usually has a more **insidious onset** with loss of sensation and function occurring over days to weeks. The most common presentation is that of cauda equina syndrome with bilaterally symmetrical signs of posterior weakness, tail paralysis, fecal and urinary incontinence and retention, and atrophy of the gluteal muscles. Tail tone is decreased or absent and the tail is easily raised by the examiner. The anus is usually atonic and dilated. There are signs of urinary incontinence with urine scalding of the escutcheon and hind legs. Rectal examination reveals fecal retention and a distended bladder that is readily expressed. Male horses can have prolapse of the penis with maintained sensation in the prepuce – a finding consistent with the separate innervation of these

anatomic regions. Affected horses can also have ataxia of the hind limbs, but this is always combined with signs of cauda equina disease.

Signs of **cranial nerve dysfunction** occur as part of the disease, but not in all cases. Cranial nerve dysfunction can be symmetrical, but is usually asymmetric. Nerves prominently involved in the genesis of clinical signs are the trigeminal (cranial nerve V), facial (CN VII), and hypoglossal nerve (CN XII), although all cranial nerves can be affected to some extent. Involvement of the cranial nerves is evident as facial paralysis (CN VII), weakness of the tongue (CN XII), and loss of sensation in the skin of the face (CN V). There can be loss of movement of the pinnae (CN VII) and head tilt (CN VIII). Laryngeal paralysis can be present (CN X). The buccal branches of CN VII can be enlarged and palpable over the masseter muscles ventral to the facial crest.

Electromyography is consistent with denervation with prolonged insertion potentials, positive sharp waves, and fibrillation.

Not all clinical signs occur in all horses and, depending on the stage and severity of the disease, some animals can have loss of sensation as the only abnormality, especially during the early stages of the disease.

The disease is inexorably progressive, the prognosis for life is hopeless, and the course of the disease is usually less than 3 months.<sup>3</sup>

**Clinical pathologic** abnormalities are not diagnostic. There is sometimes a mild neutrophilic leukocytosis and hypergammaglobulinemia. Serum vitamin E concentrations are usually normal. Analysis of cerebrospinal fluid demonstrates mild mononuclear pleocytosis and increased protein concentrations, but these changes are not diagnostic of the disease. Horses with polyneuritis equi have antibodies to P2 myelin protein in serum, but the diagnostic value of this test has not been determined.<sup>4</sup>

**Necropsy findings** are definitive for the disease. Gross findings include thickening of the epidural nerve roots that is most severe in the cauda equina. The bladder and rectum can be distended. There can be evidence of fecal and urine scalding and self-trauma of the perineum. There can be thickening of the facial nerves. Microscopic changes are characterized by a granulomatous inflammation of the extradural nerves although radiculoganglioneuritis and myelitis can also occur. There is loss of axons with demyelination and signs of remyelination. The inflammatory cells are initially lymphocytes, plasma cells, and macrophages. As the inflammation becomes more

severe or chronic there is extensive proliferation of fibroblasts and fibrocytes in addition to infiltration of lymphocytes and macrophages.<sup>2</sup> There is axonal degeneration with proliferation of the perineurium. The chronic inflammatory changes result in loss of peripheral neural architecture. Lesions are present in many regions of the spinal cord, but are most severe in the sacral division and cauda equina.<sup>2</sup> Lysosomal accumulations are present in the semilunar, geniculate, and sympathetic chains and granulomatous lesions in the celiaco-mesenteric ganglion.<sup>5</sup> Lesions of the cranial nerves similarly involve infiltration with lymphocytes and histiocytes, and the inflammation can extend to the terminal branches of the nerves.<sup>3</sup>

The **diagnosis** of polyneuritis equi is based on the presence of clinical signs of the disease, rule out of other diseases causing similar clinical signs, and necropsy examination. Diseases with manifestations similar to polyneuritis equi include:

- Equine herpesvirus-1 myeloencephalopathy
- Migrating parasites (Table 36.3)
- Sorghum–Sudan grass neuropathy
- Equine protozoal myeloencephalitis
- Rye grass staggers (*Acremonium lolii*) Dourine
- Trauma to the sacral vertebral column
- Abscess or neoplasia involving the sacral or caudal lumbar vertebral column
- Meningitis
- Intentional alcohol sclerosis of tail head nerves in Quarter horses.

There is no definitive **treatment** for polyneuritis equi. Administration of anti-inflammatory agents, including corticosteroids, appears to be without sustained benefit. Supportive care includes evacuation of the rectum and bladder and maintenance of hydration and provision of adequate nutrition. Feeding a diet that softens feces, or administration of fecal softeners or lubricants can be beneficial. Bethanacol (0.05 to 0.1 mg/kg q8–12 hours, orally) might increase bladder tone. Topical administration of petroleum jelly or similar products can protect the skin of the perineum and escutcheon from fecal and urine scalding.

## HEAD SHAKING IN HORSES

Headshaking by horses is a perplexing and troubling syndrome for which there is often no readily identifiable cause or treatment. The disorder is characterized by repeated, sudden shaking or tossing of the head.

### ETIOLOGY

The etiology is complex and often unclear and conditions associated with head shaking include:<sup>1,2</sup>

- Ear mites
- Otitis interna/externa
- Ophthalmic disease (uveitis)
- *Trombicularis autumnalis* (chiggers) infestation of the muzzle
- Guttural pouch disease (mycosis)
- Stylohyoid arthropathy
- Osteitis of the petrous temporal bone
- Dental disease (wolf teeth, ulceration, periodontal disease, periapical abscess)
- Behavioral abnormalities
- Trigeminal neuralgia
- Optic neuritis
- Photic head shaking (optic-trigeminal summation)
- Neck pain
- Rhinitis or sinusitis
- Ethmoidal disease including hematoma
- Infraorbital neuritis
- Excessive neck flexion by rider
- Equine protozoal myeloencephalitis
- Ill-fitting tack including bit and bridle
- Obstructive airway disease (heaves, laryngeal hemiplegia, epiglottic cysts, etc.).

Most cases of the disease are idiopathic despite intensive investigation of affected horses.<sup>1</sup> Photic head shaking is a common cause of the disease.<sup>3</sup> Most cases have some seasonal distribution, though the reason for this is undetermined. Trigeminal neuralgia is considered an important cause of the disease.<sup>3</sup>

### EPIDEMIOLOGY

The epidemiology of the disease is not well defined. The syndrome occurs in horses throughout the world.<sup>4</sup> The syndrome is sporadic, usually affects only one horse on a farm, and does not occur as outbreaks. The syndrome has a seasonal occurrence in approximately 60% of horses with the majority first demonstrating head shaking, or being most affected, during spring and summer.<sup>4,5</sup> Head shaking is worst on sunny days and less severe on cloudy days, in approximately 60% of horses.<sup>5</sup> Seventy five percent and 80% of affected horses have less severe signs at night or when ridden indoors, respectively.<sup>5</sup>

Affected horses are usually mature adults with onset of head shaking at 7–9 years of age in over one-half of cases,<sup>4,5</sup> although signs can occur in horses as young as 1 year. The disease is reported twice as often in geldings as in mares.<sup>4,5</sup> There is an apparent predisposition to the disease in Thoroughbred horses<sup>4</sup> but this is not consistently reported.<sup>5</sup> Most affected horses are used for general riding, although this might represent an age effect because the syndrome tends to occur in older horses which are not used for racing.<sup>5</sup> There is no apparent association of temperament and risk of head shaking.

### PATHOGENESIS

The pathogenesis of headshaking depends on the cause, but is assumed to involve the trigeminal nerve in most cases because of its role in sensory function of the nose and nasal mucosa.<sup>2</sup> Headshaking is related to exposure to bright light in some animals, a condition referred to as photic or optic-trigeminal summation because of its similarity to a syndrome in people. Trigeminal neuralgia is believed to cause acute, sharp, and intense pain in the face. Although this cannot be definitively diagnosed in horses, its presence is inferred from the horse's behavior and response to analgesia of the infraorbital or posterior ethmoidal nerves.

### CLINICAL FINDINGS

The **clinical signs** of head shaking are unmistakable. Movements of the head are sudden and apparently spontaneous and involve lateral, dorsal, ventral, or rotatory movement of the nose usually during exercise. Horses rarely have the behavior only at rest, with most being affected both at rest and during exercise and about 10% exhibiting signs only during exercise.<sup>4,5</sup> The action often resembles that of a horse trying to dislodge something from its nose. Approximately 90% of horses have vertical movement of the head (as if flipping the nose).<sup>5</sup> The headshaking can be so severe as to cause lateral, dorsal, or ventral flexion of the neck to the level of the caudal cervical vertebrae, although more commonly on the rostral one-third of the neck is involved, if it is involved at all. Some horses rub their nose on objects, the ground, or their front limbs, sometimes during exercise. Affected horses often snort or sneeze. There can be twitching of the facial muscles and flipping of the upper lip. The movements are sudden and at times appear to catch the horse by surprise. The frequency and/or severity of movements are usually increased during exercise. Severely affected horses can stumble and fall if headshaking occurs during exercise, rendering the horse unsafe to ride.

A grading system to classify the severity of signs is<sup>1</sup>:

0. No signs of head shaking
  1. Intermittent and mild clinical signs. Facial muscle twitching. Rideable.
  2. Moderate clinical signs. Definable conditions under which head shaking occurs. Rideable with some difficulty.
  3. Rideable to unpleasant to do so. Difficult to control.
  4. Unrideable and uncontrollable.
  5. Dangerous with bizarre behavior patterns.

This system might be useful for assessing response to therapy and concisely describing the severity of the signs.

**Ancillary testing** involves radiography of the skull; endoscopic examination of both nostrils and ethmoidal regions, nasopharynx, larynx, and guttural pouches; otoscopic examination of the external auditory canal and tympanic membrane (difficult to achieve in a conscious horse, a small endoscope is necessary); desensitization of the infraorbital and posterior ethmoidal nerves; biopsy of the nasal mucosa (in horses with suspected rhinitis); radiographic examination of the neck; and therapeutic trials including application of contact lenses or masks, or administration of medications (see 'Treatment').

### CLINICAL PATHOLOGY

There are no characteristic hematologic or serum biochemical abnormalities.

### NECROPSY FINDINGS

There are no characteristic findings on necropsy, apart from those of any underlying disease. Evidence of lesions in the trigeminal nerve is lacking.

### DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from the stereotypic weaving that occurs during stabling and not during exercise.<sup>6</sup>

### TREATMENT

The principles of treatment include relief of specific underlying diseases, removal of management or environmental conditions that cause head shaking, and administration of medications.

If underlying conditions are detected, such as ear mites, dental disease, and others listed under 'Etiology', then these conditions should be treated effectively. Effective treatment of these conditions will alleviate head shaking, if in fact the condition was the cause of the disease. However, most horses with head shaking have seasonal or photic disease and treatment is more difficult. A survey of owners of 254 horses with head shaking revealed that

only 129 horses had been treated by a veterinarian and, of those, only 6% had complete resolution of head shaking, whereas 72% had no response to treatment.<sup>7</sup> Other treatments used were on the advice of lay 'back specialists', homeopathy, alternative therapies or face or head masks. Success rates for these interventions varied between 6 and 27%, with the most success obtained by use of a nose net (27%).<sup>7</sup> Nose nets provided better control of signs than did face or eye masks. These figures on the success of treatment illustrate the refractory, and therefore frustrating, nature of the disease.

Fitting of **nose masks** alleviates or lessens head shaking in some horses.<sup>7,8</sup> The design of the nose mask does not appear to be important at least in regard to whether it covers the entire rostral face or just the nostrils.<sup>8</sup> The nose masks were most effective for treatment of up-and-down head shaking, but not for side-to-side or rubbing behavior.<sup>8</sup>

Blue tinted **contact lenses** have been suggested for use in horses with photic head shaking.<sup>9</sup> Others have not found this intervention useful.<sup>4</sup>

**Sclerosis** of the infraorbital or posterior ethmoidal nerves is performed in those horses that have reduced or eliminated head shaking after injection of local anesthetic into the infraorbital foramen or around the posterior ethmoidal nerve.<sup>1</sup> Sclerosis is achieved by injection of 5 mL of 10% phenol in oil.<sup>1</sup> Care must be taken to ensure that the phenol is deposited only around the nerve. The procedure should be done under general anesthesia.

**Cyproheptadine** (0.3 mg/kg, orally q12 hourly) improved head shaking in 43 of 61 horses, based on owner reported efficacy.<sup>4</sup> Responses were usually observed within 1 week of the start of therapy. Others have not replicated this success<sup>1</sup> but found that the combination of **carbamazepine** (4 mg/kg orally q6–8 hours) and cyproheptadine improved clinical signs in 7 horses within 3 to 4 days of starting treatment.<sup>1</sup>

**Acupuncture** and **chiropractic** manipulation appear to be minimally effective.<sup>4,7</sup>

Prevention of exposure to bright light is an obvious recommendation, but not practical for most horse owners.

## CONTROL

There are no recognized measures for preventing development of the disease.

## CONGENITAL NECROTIZING ENCEPHALOPATHY IN LAMBS

This condition is reported as the most common diagnosis of neurological disease in lambs under 7 days of age by VLA diagnostic laboratories in the north of England and is defined by its pathology.<sup>1</sup> Affected flocks have single or multiple cases with up to 10% morbidity in lambs of a flock. Cases have all come from ewes carrying multiple fetuses. There is variation in the clinical manifestations between sibling lambs. The most severely affected may be stillborn. Less severely affected lambs are born weak, are small, maybe unable to rise or show ataxia and head tremor. Some lambs survive but may have residual signs of cerebellar dysfunction. The common lesion is superficial cerebrocortical neuronal necrosis. A significant proportion also has necrosis of the Purkinje cells in the cerebellum and leucoencephalopathy of the thalamus and brainstem. It is possible that this syndrome reflects hypoglycemia consequent to negative energy balance in late pregnancy.

## Diseases characterized by involvement of the musculoskeletal system

### HYENA DISEASE OF CATTLE

Hyena disease of cattle occurs worldwide and is characterized clinically by a lateral body appearance similar to the hyena.<sup>1,2</sup> The cause is unknown but excessive intake of vitamins A and D may be contributing factors.

In some naturally occurring cases in yearlings from one large dairy herd approximately 1% of calves were affected annually. Affected calves had received vitamins A and D<sub>3</sub> immediately after birth, and from birth to weaning received the same vitamins from fresh milk, whole corn, a customized feed mix, and a milk supplement.<sup>2</sup> The mean daily intake of vitamin A from birth to 6 weeks of age was approximately 80 000 iu and 6300 iu of vitamin D<sub>3</sub>, and progressively less vitamin A and D<sub>3</sub> was fed from 6 weeks until weaning at 3 months. The National Research Council recommendations for daily vitamin intake are 2100 iu of vitamin A at birth, increasing to 6360 iu at 2 months and 330 iu of D<sub>3</sub> increasing to 990 iu over

the same period.<sup>2</sup> Experimentally, the IM injection of vitamins A and D (2 000 000 iu and 300 000 iu, respectively) on the first day after birth followed by 30 000 iu/kg BW added to the milk replacer daily results in gross lesions in the proximal tibial growth plates in 3 weeks.<sup>3</sup> Excessive vitamin A and vitamin D<sub>3</sub> administration to young calves can cause hyena disease by suppression of the activity of differentiation and proliferation in chondrocytes and osteoblasts.<sup>4,5</sup> The administration of excessive amounts of vitamins A, D<sub>3</sub>, and E to Holstein sucking calves can cause hyena disease characterized clinically by severe emaciation, generalized alopecia, dome-like cranial deformation, and high mortality.<sup>6</sup>

There is premature closure of the growth plates of the long bones resulting in a marked dissimilarity in growth and development between the forequarters and the hindquarters, the latter being comparatively underdeveloped. This gives the animal the classic contours of the hyena and this resemblance is heightened by a crest of thick, stiff bristles along the back in the midline. An aggressive attitude also develops. Affected calves are normal at birth and only develop the abnormality at 5–6 months of age. There is no apparent abnormality of sex hormones. The femur and tibia are shorter in affected than in normal animals. There are accompanying difficulties of locomotion with a tendency to fall sideways, and to frequently adopt a position of lateral recumbency. The gait is described as 'bunny-hopping'.

German Simmental, Charolais, Black Pied, German Holstein-Friesian, and German Red Pied cattle have been involved. Genetic analysis appears to indicate that the disease is inherited as a simple recessive with incomplete penetrance but this is obviously not so in some herds.

The lesion is a chondrodystrophy affecting particularly the long bones and the lumbar vertebrae. Gross examination and radiography of the longitudinal slabs of the humeri, tibiae, and femurs reveal focal to almost complete closure of the physes and physes subjected to compression are affected more than those subjected to tension.<sup>2</sup>

## ASYMMETRIC HINDQUARTER SYNDROME OF PIGS

This condition was first reported in Germany<sup>1</sup> and Belgium<sup>2</sup> and was recognized in the UK in 1968 and reported later.<sup>3</sup> In these cases perineurial fibrosis was a feature and it was thought that the condition resulted from either a neurogenic atrophy or a periarticular fibrosis extending to the peripheral nerves. There is variable asymmetry of the hindquarters which is generally evident during the early grower period and obvious by 80 kg liveweight stage. An asymmetrical distribution of subcutaneous fat is also noted and possibly skin dimpling.<sup>4,5</sup> The muscle most frequently affected was the *M. semimembranosus*, followed by the *M. semitendinosus*, *M. biceps femoris*, *M. adductor femoris*, and *M. gracilis*. The muscles show changes that can be described as myofibre degeneration, interstitial fibrosis, and dystrophic changes. Several breeds, including Landrace, Large White, and Hampshire have been found affected but the problem is generally restricted to certain herds and to certain families within these herds, suggesting that a genetic liability exists for this condition.<sup>2</sup> The mechanism of inheritance studied from test matings is not simple.<sup>3</sup> Whatever the cause, there is a marked reduction in the number of muscle fibres. Both sexes may be involved and the condition may involve either hindlimb. Despite a marked reduction in muscle mass there is no detectable abnormality in gait. The cause is unknown, although it appears to result from suboptimal muscle growth rather than degenerative loss.<sup>6</sup> In the only cases recorded from outside Europe a group of 7 Australian pigs were examined in detail<sup>7</sup> and in one of these the affected *M. semitendinosus* weighed only 41% of the normal unaffected one. Perineurial fibrosis and myopathy have been observed in some cases but have not been found consistently.<sup>6</sup>

## SPLAYLEG SYNDROME IN NEWBORN PIGS

This syndrome is also called spraddle leg, but more usually myofibrillar hypoplasia. This may be an erroneous term as this hypoplasia occurs in many normal pigs and may be a normal feature of post-natal

muscle growth. This clinical condition of splayleg occurs in newborn piglets in most countries and is characterized by a temporary inability to stand with the hindlimbs.<sup>1</sup>

### ETIOLOGY

The etiology is unknown, but based on epidemiological evidence it is multifactorial.<sup>1</sup> The current hypothesis is that the disease is caused by an interaction of genetic and non-genetic factors, a polygenic mode or expression of many genes without dominance.

The studies of Czech workers<sup>2,3</sup> have suggested that the pathomorphology of the condition resembles that of glucocorticoid induced myopathy in man and animals.<sup>4</sup> Dexamethasone given to minisows from the first to the last days of pregnancy produced in newborn piglets a disorder characterized by the splayleg syndrome with retardation of both muscle growth and myofibrillogenesis.<sup>3,5</sup> It has also been experimentally produced following the administration of pyrimethamine.<sup>6</sup>

### EPIDEMIOLOGY

The prevalence of the disease in the UK is 0–4% and the morbidity in affected herds varies from 2 to 27%. The case fatality rate is approximately 50% and is due to crushing, chilling, and starvation because affected piglets are not able to move around normally. The disease is more common in the Pietrain, Welsh, Landrace, and Large White breeds of swine; Landrace pigs may be especially susceptible. This suggests a genetic basis, but test-matings, with the exception of a few, have not been successful in reproducing the disease.<sup>1</sup> On most farms the disease affects both male and female piglets. In a recent retrospective analysis of the incidence of the disease in a swine herd over a period of 5 years, the overall frequency was 1.74 times more in males than females and the birth weight of splayleg piglets tended to be subnormal.<sup>7</sup> The environmental factors which have been associated with some outbreaks include slippery floors, a dietary choline deficiency and the ingestion of **Fusarium toxin** by pregnant sows. Choline deficiency is unlikely to be a factor<sup>8</sup> and none of the other factors have been substantiated as etiological factors or epidemiological determinants.<sup>1</sup>

### PATHOGENESIS

The pathogenesis of the disease is unclear. In affected pigs there is myofibrillar hypoplasia<sup>9,10</sup> but this is also a feature of many muscles in normal pigs. There are simply too few maturing type 1 fibrils in the muscles, particularly of the foreleg, lumbar epaxial group and the hind limb to carry weight. The *Mm semitendinosus* appears to be the worst affected muscle. However,

because myofibrillar hypoplasia may also be present in normal unaffected littermates<sup>1</sup> it has been difficult to explain the pathogenesis of the muscular weakness. The use of morphometrics has enabled the detailed determination of the myofibrillar hypoplasia.<sup>11</sup> In addition to myofibrillar hypoplasia, in splayleg pigs there is a higher content of sarcoplasmic RNA, reflected ultrastructurally by the presence of numerous ribosomes.<sup>12</sup> The extramyofibrillar space was also filled with glycogen in splayleg pigs.<sup>13</sup> In myofibrillar hypoplasia induced with glucocorticoids given to the pregnant sow, none of the pigs had splaylegs but the extramyofibrillar space contained little glycogen. There were also many glycogen-filled phagosomes and residual bodies which indicate a difference in the metabolism of glycogen in the first 2 or 3 days after birth. In a study of natural cases there was hypoplasia but there was an increased accumulation of glycogen especially within the large extramyofibrillar spaces in comparison with the normal pigs.<sup>14</sup> These authors also found an anomalous distribution of glucose-6-phosphatase in splaylegged muscles in that the activity was concentrated at the periphery of the extremely dilated cisternae of the sarcoplasmic reticulum. In the normal muscles this enzyme activity was normal. This distribution could account for the slower utilization of glycogen in affected muscles and therefore would account for the build up.<sup>14</sup> Quantitative image analysis of skeletal muscle revealed that the arrangement of the myofibrils within the fascicles of affected and unaffected pigs was different.

Some studies have found both quantitative (hypoplastic-type) and qualitative (dystrophic-type) insufficiencies in affected pigs which represent a temporary perinatal developmental disturbance. This could explain the muscular weakness and the recovery which occurs.

### CLINICAL FINDINGS

Larger litters may be more affected possibly because these tend to be born earlier. The clinical signs are usually obvious in 2–3 hours after birth when the litter should be standing and walking around the creep area. Affected piglets are unable to stand, and their hindlimbs are splayed sideways or forwards and the animals are resting in sternal recumbency. Sometimes the fore limbs are also splayed. Most severely affected piglets are unable to move; less severely affected animals are able to move slightly. Many pigs have soiled hindlimbs and perineum as a result of being unable to stand. As a result, the piglets are likely to be crushed or have difficulty gaining access to their source of

nourishment. Affected piglets are normal in other respects and have a normal appetite and will suck the sow if placed near a teat. In the experimental induction<sup>5</sup> there was hypoplasia but there were no clinical signs, which is further evidence for suggestions<sup>15</sup> that the condition has a threshold for clinical signs and has strong maternal influences.

### TREATMENT

Treatment can be successful.<sup>16</sup> If the pigs are able to suck or if they are fed artificially for 2–4 days, recovery will occur within 1 week in about 50% of cases. The ambulatory capacity of affected pigs can be improved, and mortality reduced, by taping or loosely tying together the hindlimbs for a period of up to 1 week. The method of loose tying of the hindlimbs consists of a figure-of-eight bandage (2.5 cm wide adhesive tape) being fixed around the metatarsal bones, leaving a space between the legs of up to 7 cm depending on the size of the piglet. The legs should be tied together within a few hours after the syndrome is obvious; a delay of several hours will decrease the prognosis. The provision of a non-slip floor surface such as a carpet or sack may also be helpful. Many farmers will tell you that repeated massaging of the limbs will also improve the survival rate.

### CONTROL

Whether or not to cull the boar depends on the pedigree value of the animal, the incidence of the disease, and the probability that the boar is responsible. There is no evidence that the disease is monogenic. However, the incidence is highest in the Landrace breed, which suggests a hereditary predisposition. In deciding whether to use a suspected carrier animal, there is a need to distinguish between different situations. The consequences of disease are felt differently at the different levels of organization of the pig industry. A boar of high merit for performance traits may be more economical to retain as breeding stock even though some progeny are affected with the disease than a less superior boar whose progeny are unaffected. If stress of the pregnant sow is a factor, control of the disease may be dependent upon the selection of stress-resistant boars and sows.

Concurrent disease should be controlled as producers will tell you that after a period of PRRS infection they had a higher percentage of splayleg piglets. There are also suggestions that induced early farrowing and zearalenone poisoning may also be complicating factors to prevent.

### DEGENERATIVE JOINT DISEASE (OSTEOCHONDROSIS, OSTEOARTHRITIS, EPIPHYSEOLYSIS AND APOPHYSIOLYSIS, LEG WEAKNESS IN PIGS)

Leg weakness in pigs is a very loose term which includes a wide variety of conditions and is best discarded. In Finland 15% of gilts are culled due to leg weakness.<sup>1</sup> Degenerative joint disease would be a much better general term to describe the lameness of young rapidly growing pigs affected with a non-infectious joint disease which includes osteochondrosis (OC), epiphyseolysis, and degenerative osteoarthritis (OA). The disease is characterized by varying degrees of intermittent but progressive lameness in rapidly growing pigs from 4 to 8 months of age, and pathologically by the presence of OA and OC. The disease is of major economic importance because of the high culling rate of breeding age swine.

#### Synopsis

**Etiology** The cause is unknown.

**Epidemiology** Occurs in majority of breeds of rapidly growing pigs and young breeding females and males. Lesions are commonly present at slaughter. May be related to nutrition and rapid growth rate, genetic predisposition, and type of flooring but no reliable correlations.

**Signs** These may be no clinical findings or possibly lameness and inability to breed.

**Clinical pathology** Radiographic evidence of osteochondrosis.

**Lesions** Osteochondrotic lesions of varying degrees of development, severity and healing.

**Diagnostic confirmation** Lesions at necropsy.

### Differential diagnosis list

Other causes of lameness include:

- Polyarthritis due to infectious causes
- Laminitis
- Nutritional osteodystrophy due to calcium, phosphorus, and vitamin D imbalance
- Hypovitaminosis A causing hindlimb paresis.

**Treatment** None.

**Control** Uncertain. Select breeding stock with sound legs and gait.

### ETIOLOGY

The cause of the articular abnormalities is not known. The etiology and factors underlying these syndromes are poorly defined, partly because of the difficulty of definitive clinical examination of affected pigs and the frequent lack of apparent significant pathological changes in necropsy examination of mild cases. There are no specific associations between degenerative joint disease and infectious diseases.<sup>2</sup>

### EPIDEMIOLOGY

#### Occurrence

Recently, a study of 9411 newborn piglets showed that 9.8% were treated for lameness. For parity 3 sows, the level had risen to 11.4%, but by parities 4–7 only 8% were treated. The treatments were in pigs of less than 3 weeks of age in 73% of the cases. Litters with 12 or more pigs had the highest incidences of lameness.<sup>3</sup> Osteoarthritic changes are strongly associated with osteochondrotic changes in the humeral and femoral condyles.<sup>4</sup> Osteochondrosis has been recorded as early as 1 day of age so the lesions may be congenital. There may be some degree of change in up to 85% of pigs.

The intensification of the swine industry has required that pigs grow rapidly and with high feed efficiency. Under such intensified conditions, rapidly growing pigs develop lesions of the bones and joints, especially the femur. Most pigs near market weight have varying degrees of osteochondrosis (OC). Except for severe lesions, which usually occur in a relatively small proportion of the total population examined, the lesions seen at slaughter often have no detrimental effect on growth rate of pigs up to market weight. An advanced degree of OC however, can result in severe degenerative joint disease and lameness in breeding stock. It is not associated with adventitious bursitis.<sup>5</sup>

The disease occurs in both male and female pigs and the incidence of lame pigs can be as high as 20–30%. It is a particular problem in gilt and boar testing stations where it may necessitate slaughter of affected animals before the testing period is complete. The lesions develop

most commonly in growing pigs, particularly boars from 20 to 30 weeks of age, raised in confinement. The onset occurs when pigs are between 4 and 8 months of age which coincides with a period of maximal growth rate. The peak period of clinical manifestation is from the late grower stage until 18 months of age, although the effect of OA may carry through to the adult period. Extensive multicentric degenerative joint disease in adult sows and boars can cause severe lameness which often warrants euthanasia.<sup>6</sup> However, sows ranging in age from 1.5 to 3.0 years and culled for impaired reproductive performance, with no history of lameness may have lesions of the femoral condylar surface.<sup>7</sup>

### Risk factors

Numerous risk factors contribute to the disease. They include nutrition and rate of growth, genetic, and breed predisposition, sex, type and quality of floor, and exercise and confinement. The pig carries 53–51% of its weight on the fore limbs and 46–48% on the hind but the weight supported on the hind is higher at 90 and 105 kg body weight.<sup>8</sup> In a study of gilts and sows in Denmark about 12% of gilts showed stiff locomotion but at some point 53% of gilts had at some time showed the same sign. Buck-kneed forelegs, upright pasterns, legs turned out wide, standing under position, and swinging hindquarters were associated with stiff locomotion or lameness. Weak pasterns on the hind feet were associated with stiff locomotion and lameness.<sup>9</sup> Weak pasterns on hindlegs and splayed digits on forelegs were associated with brisk movement (freedom from locomotor problems). The following leg weakness signs at the gilt stage were found to have a significant effect on the longevity of the sows: buck-kneed forelegs, swinging hindquarters, and standing under position on the hind legs.

**Nutrition and rate of growth.** The disease is associated with rapid early growth,<sup>10</sup> but it does not appear to be related to protein, vitamins A and D or calcium and phosphorus imbalance in the ration.<sup>11</sup> Maximal mineralization of bones is not necessary to prevent leg weakness. Only almost complete absence of calcium and phosphorus causes lameness. Disturbances of the Ca:P ratio below 0.5 or over 3.0 are necessary to produce lameness. Recently, it has been suggested that long-term acidosis may be associated, as bone is not formed as phosphorus is removed from the bone. In this context the acidification of pig diets has been suggested as a contributory cause. It has also been shown that the presence of deformed forelimbs is not associated with low levels of vitamin C in plasma.<sup>12</sup> Rapid

growth, especially during the early period, was thought to have a significant influence on the occurrence<sup>13</sup> and there is also some breed variation in susceptibility. However, in some feeding trials of pigs from weaning to slaughter weight there was no direct effect of rapid growth rate on the incidence and severity of OC. In other feeding trials, average daily gain of gilts was an important factor in the severity of lesions of OC. Decreasing the rate of gain by restricting energy intake appeared to decrease the prevalence and severity of OC when gilts were slaughtered at 110 kg.<sup>14</sup> However it was shown that when pigs were fed waste food, and grew more slowly, they had an increased prevalence and score for OC when compared with pigs fed a commercial feed concentrate.<sup>15</sup> Decreasing the concentration of protein in the diet of gilts from 16 to 12% resulted in less longitudinal bone growth but did not decrease the incidence of OC.<sup>16,17</sup> A simple association between growth rate and the incidence or severity of joint lesions has not been consistently demonstrated and a reduction in growth rate of pigs does not control the disease. A significant favourable association between leg action and daily gain has been noted.<sup>18</sup> There has also been speculation that growth hormone could influence the development of lesions of OC by exerting a direct effect on differentiation and colonization of epiphyseal chondrocytes. There is no consistent relationship between the incidence of osteochondrosis and selection of pigs for lean tissue growth rate.<sup>19</sup> It may be simply that more feed means more growth which makes stress on developing cartilage worse and therefore predisposes to OC.

**Genetic and breed predisposition.** It has been proposed for many years that selection of pigs for increased growth rate resulted in a concomitant increase in the incidence and severity of musculoskeletal disease. Genetic studies indicate that the heritabilities of leg weakness are low to moderate (0.1–0.3).<sup>20</sup> A more recent study suggested from 0.01 to 0.42 for leg weakness and OC and that both are associated with production traits (lean% and backfat thickness).<sup>14</sup> Genetic analysis of the incidence of OC and leg weakness in the Swedish pig progeny testing scheme revealed a low to moderate heritability. Genetic control of leg weakness has been achieved by various researchers and thus inheritance is probably an important risk factor for this disease complex. The genetics of leg weakness have been described in Finnish Large White and Landrace populations.<sup>21</sup> Meaty breeds are worst affected including the Duroc and the Dutch and Swedish Landrace.

Osteochondrosis also occurs in cross-bred Wild boar-Yorkshire pigs with a genetically decreased growth rate, raised under the same conditions as finishing pigs.<sup>22</sup> The distribution and extent of OC was similar to that of purebred Swedish Yorkshire pigs. This suggests that it is not limited to rapidly growing pigs. Synovial bursae at the hock joints were higher in Large White pigs with straight or bowed hind legs and in Landrace with sickle shaped hind legs.<sup>23</sup> There are significant breed differences in the peri-articular and meniscal ossifications seen on X-ray.<sup>24</sup> Recently, the quantitative trait loci for locomotion and osteochondrosis-related traits have been identified in Large White × Meishan pigs.<sup>25</sup> Correlations between breeding values for longevity and for OC were low but significant, and in a favourable direction. Higher OC scores were associated with a higher risk of being culled.<sup>26</sup> It has been seen in wild boar in Slovenia.<sup>27</sup>

**Sex.** The differences in the incidence and severity of OC between the sexes of different breeds has also been analyzed. The degree of leg weakness and OC of one sex in a breed can neither be translated to the other sex within that breed nor to the same sex of another breed.

**Type of floor.** Insecure footing because of unfavorable floor surfaces and the presence of foot lesions may change the posture of the animal and cause local overloading of certain joints. The effect of the quality of floor has been examined and there is no clear evidence that hardness of floor contributes to an increased incidence of leg weakness associated with joint disease. However, the incidence and severity of joint lesions may be related to the duration of confinement in pigs confined individually. Exercise will prevent abnormalities such as bow legs, flexion of the carpus and sickle-legs from impairing the mobility of boars, but does not influence the severity of joint lesion. The milder syndromes of poor movement and lameness associated with defects in leg conformation in the grower stage are not necessarily associated with bone or joint lesions and may regress spontaneously or improve if affected pigs are placed on pasture. However, severe lameness at this age, and that which occurs in replacement stock and young adults is frequently associated with severe bone and joint lesions which may be irreversible. A recent study has looked at type of floor (solid floor plus straw, solid floor no straw, and fully slatted).<sup>28</sup> The slatted floors were worst for leg weakness and the floors with straw best. The different types of floor affected leg weakness and claw disorders differently.

**Exercise and confinement.** There is some limited evidence that high lean growth rate may predispose toward leg weakness under confinement rearing. Trauma during handling, penning, and transportation may be associated with a relatively high frequency of OC but the evidence is very limited.<sup>29</sup> A high stocking density had an adverse effect on 4 of the leg weakness signs (knock knees, turned out front or hind limbs, standing with the legs under the body).<sup>28</sup> A recent study of housing and treadmill training did not show any adverse effects on leg weakness.<sup>30</sup> It has even been seen in pigs on grass, on deep litter and in wild boar

#### Economic importance

In Scandinavia, breeding pigs culled because of lameness had a 100% frequency of OC or OA, and up to 40% of boars in a performance test station had osteochondrosis or osteoarthritis.<sup>6</sup> A conservative estimate suggests that 3% of sows and 10% of boars are culled for unsoundness associated with OC and OA.<sup>6</sup> The hidden costs include a reduced pool for selection of high-performance boars and gilts, the maintenance of pigs which cannot be used for breeding, increased mortality among piglets crushed by lame sows, reduced feed intake and growth rate in lame pigs, and transportation costs of replacement stock.

#### PATHOGENESIS

The condition has been seen as early as 1 day and with age the lesions develop. The essential lesion is the necrosis of cartilage canals and surrounding cartilage.<sup>31,32</sup> They may be seen to be developing and healing at the same time. In growing animals, the superficial layer of joint cartilage is articular cartilage, and the deeper layer is epiphyseal cartilage which undergoes endochondral ossification as the animal matures. The articular cartilage persists in the mature animal while the epiphyseal cartilage becomes a layer of calcified cartilage and underlying subchondral bone. The cartilage of the physis is known as the growth plate and is involved in metaphyseal growth. The normal growth plate cartilage has a well-ordered structure with the chondrocytes of the proliferative and hypertrophic regions arranged into columns.

Osteochondrosis is a generalized disease in which there are focal areas of failure of endochondral ossification in the physal (metaphyseal growth) and epiphyseal growth cartilages. The underlying defect may be an abnormality of the chondrocytes which do not undergo normal hypertrophic ossification. They accumulate rough endoplasmic reticulum, lipid droplets and mitochondria. The surrounding matrix contains deposits of electron-dense material which

may prevent normal vascularization and therefore ossification. The hypertrophic region is disorganized and greatly extended compared to normal tissue.<sup>33</sup> The matrix surrounding the clustered chondrocytes is altered compared to that in normal cartilage.<sup>34</sup> The primary abnormality is an increased thickness of the joint cartilages combined with degenerative changes which result in infoldings and erosion of articular cartilages. Defects of the growth plates (physes) result in short deformed bones.

Pathologically, severe clinical cases are characterized by osteochondrosis and secondary degenerative joint disease especially involving the medial aspects of the larger joints, epiphyseolysis and lumbar intervertebral disc degeneration and spondylosis. Osteochondrosis has been used to encompass lesions involving the physes and the articular epiphyseal complexes. However, because of morphological changes that have been observed in growing pigs, dyschondroplasia is now the preferred term to be used generically and then qualified by the location and nature of the morphological description since the causes may be different.

Osteochondrosis occurs commonly in growing pigs at predilection sites of the medial condyle of the humerus and femur, the epiphyseal plates of the distal ulna and the femoral head and the intervertebral joints. The 6th–8th costochondral junctions may also be affected. It may heal spontaneously or it may progress to *osteochondritis dissecans* and OA. Its progression in either direction is influenced by local loading and by joint stability which depends upon joint shape and muscle and ligamentous support. The age-related changes and OC in the articular and epiphyseal cartilage have been described.<sup>35</sup> The cartilage increases with age up to 5 weeks and then begins to decrease in thickness. Deleterious influences such as defects in conformation, heavy muscling with skeletal immaturity, muscular weakness resulting from myofibrillar hypoplasia, myopathies or lack of exercise, inadequate flooring or even simple trauma may adversely affect this progression and lead to severe skeletal change.

Porcine synovial fluid contains both hyaluronic acid and chondroitin sulfate and the chondroitin sulfate-to-hyaluronic acid ratio is not influenced by relatively advanced stages of osteochondrosis. Treatment of lame boars with glycosaminoglycan polysulfate improves leg soundness score and results in an increase in the hyaluronic acid concentration of the cubitus joint synovial fluid, and an increase in the proportion of aggregated proteoglycans in the articular cartilage of the medial femoral condyle. It is suggested that the

hyaluronic acid accounts for most of the viscosity of synovial fluid and for efficient lubrication of the joint.

Well-established lesions typical of OC associated with the physes can be found in young pigs between 25 and 30 days of age.<sup>6</sup> The earliest change associated with a dyschondroplasia of the physis is a focus of persistent hypertrophied chondrocytes which do progress but heal. Lesions associated with physes and articular epiphyseal complexes develop continuously and regress as pigs grow older. Changes in cartilage canal vessels appear to be important in the pathogenesis.<sup>36</sup> There is no evidence that vascular damage is a factor in the pathogenesis of the lesions.

Because foci of dyschondroplastic lesions are associated with physes of pigs between birth and the stage of rapid growth, they could be regarded as part of the usual growth patterns in contemporary commercial swine. However, clinical signs of dyschondroplasias, or degenerative joint disease secondary to dyschondroplasias, usually do not appear until pigs are almost 6 months of age.

#### Radiological monitoring of lesions

Osteochondrosis can be diagnosed radiologically.<sup>13</sup> Radiologically the lesions were similar in Yorkshire, and Landrace<sup>37</sup> but more severe in the Landrace and similar to the Danish Landrace.

The development of epiphyseal osteochondrosis in pigs from 42 to 147 days of age has been followed radiologically.<sup>38</sup> Osteochondrotic lesions were seen radiologically in the articular-epiphyseal (A–E) complexes of the humeral condyles of 42-day-old pigs and in the femoral condyles at 63 days of age in contrast to earlier reports which indicated that lesions were not visible radiologically until 100 days of age. The osteochondrosis lesions of the A–E complexes develop, become progressive, and subsequently become either stable, regressive, or even more progressive as the pigs grow. This supports the observations that the lesions develop and become progressive and regress as the pigs grow. The humeral medial condyles have more pronounced lesions and are more frequent than the lateral ones.

Radiological monitoring of the development and sequelae of physal osteochondrosis lesions of the growth plate cartilage and A–E complexes of the fore and hind limbs in young breeding swine found that the majority of distal ulna lesions healed by 18–20 months and some started fusing at 18–21 months. The distal ulna healed without complications in most animals and the most severe lesions healed faster than the mild or moderate ones.<sup>38</sup> In a recent study periarticular ossifications at the elbow joint

were found in the radiographs at a prevalence of 0.9%.<sup>4</sup> Meniscal ossifications were seen as single or multiple foci at the cranial aspect of the joint at a prevalence of 2.6% and had a bilateral occurrence of 20%.<sup>4,39</sup> Meniscal ossifications were associated with hind legs turned out and stiff locomotion in the hind leg and negatively associated with growth rate.

### CLINICAL FINDINGS

The syndrome is called leg weakness and varies in severity from locomotor abnormality that results from conformation and leg defects such as narrow lumbar area and broad hips, hyperflexion of the carpus, bowing of the forelimbs and 'knock knees', hyperextension of the phalanges, lateral angulation of the foot and sickle hocks to more severe lameness and, in the extreme, inability to rise and paresis. Nine leg weakness signs were described.<sup>28</sup> The signs listed include buck kneed forelegs, steep hock joints, fore and hind limbs turned out, upright pasterns on the hind legs, stiff locomotion, standing under on the hind limbs, swaying hindquarters, goose stepping hind legs, lameness and tendency to slip,<sup>4</sup> and the four most common signs were buck knees, small inner claws on forefeet, small inner claws on hind feet, and upright pasterns on the hind legs.<sup>4,40</sup>

The clinical syndrome is a locomotor disorder usually involving the hindlimbs. Often the most rapidly growing pigs are lame. The lameness may be acute, intermittent, chronic, progressive, or a combination of these. An insidious onset is common, and pigs are unwilling to move, the stride is shortened, and the limbs are held in partial flexion. The carpal joints may be under extended, the metacarpophalangeal joints are overextended, giving the limb an abnormal S-shaped profile.<sup>6</sup> The pelvic limbs are commonly held straight and the back is slightly arched. In some cases, affected animals will assume a kneeling position with flexed carpal joints and walk on those joints.

Mild cases show stiffness, especially immediately after a period of lying down and lameness. Slowness to rise and a tendency to walk with short steps on tiptoes frequently in association with a marked inward curve of hindlimb motion during forward progression and side-to-side motion of the buttocks is frequently seen. More severely affected pigs sit on their hindquarters and are reluctant to stand. They carry one or both hindlimbs more forward under the body and walk with a short goose-stepping gait. Wasting is not a feature except in severely affected animals and the locomotor disorder may be minor unless exacerbated by physical exertion.

The syndrome is of particular importance in breeding animals where it may interfere with successful mating. Boars may show initial interest in mounting but subsequently slide off the sow or dummy before mating is complete, presumably due to the pain of the limb lesions. In Europe this problem has been called *impotentia coeundi*.

There may be no meaningful association between visual scores for physical soundness in the live animal and the degree of joint damage.<sup>41</sup> Some pigs with severe lesions are not lame and conversely other pigs are severely lame with minor lesions. Epiphyseolysis of the femoral head produces severe unilateral lameness and if bilateral is usually manifest by marked reluctance to rise and severe locomotor disability. Initial signs are frequently deceptively mild and follow physical exertion such as mating, transport, farrowing, or fighting but they progress to severe lameness over a 7–10-day period.

Epiphyseolysis of the tuber ischii (Apophyseolysis) may also occur following physical exertion but is more common in second or third parity sows and is manifest by 'paralysis' with the hindlimbs in forward extension under the body of the sow.<sup>42</sup> These animals 'dog sit', and are unable to rise. In many instances the injury occurs when the animals arrive on the farm or are first mated.

Because of the pain and muscle contraction, it is frequently difficult to determine the site and severity of the lesion by simple clinical examination, and palpation following general anesthesia or radiography may be required for proper clinical assessment. Physical examination should include complete palpation of all limbs for warmth, swelling, and pain. The palpable parts of the pelvis should be examined with particular emphasis on the ischial tuberosities. Passive flexion, extension and rotation of each limb along with auscultation over the joint may reveal evidence of crepitus or a pain response.

While the lesions of the physes and articular epiphyseal complexes are detectable in pigs under 14 days of age they are not detectable radiographically in live animals until the pigs are over 100 days of age. Only 21% of the lesions associated with the physes and 22% of the lesions associated with the articular epiphyseal complexes were detectable in radiographs of bones of live pigs.

Meniscal ossifications were observed as simple or multiple small smooth firm and irregular swellings in the cranial horn of the lateral meniscus.<sup>24</sup> The peri-articular osseous foci were seen as focal firm swellings at the cranio-medial aspect of the elbow joint.<sup>24</sup>

### CLINICAL PATHOLOGY

The carpal, elbow, tarsal, and stifle joints can be radiographed for evidence of joint lesions, and the lesions scored according to a system.<sup>38</sup> It is also possible to use ultrasonics for diagnosis.<sup>43</sup>

### NECROPSY FINDINGS

The histological, radiological, and angiographic findings of dyschondroplasias of the growth cartilages in crossbred commercial pigs at 1 and 15 days of age have been described. The bone lesions in clinically normal and lame pigs have been described.<sup>44,45</sup> The scapulohumeral, humeroradioulnar, carpal, coxofemoral, femorotibial, and tarsal joints should be examined. Typically, in osteochondrosis, the changes are feathery hypertrophy of villi, focal full-thickness cartilage buckles, ulcers of flaps, and no change in the draining lymph node. Joint mice and synovitis may also be seen. Deformation may take place in the long bones or even fractures. Histologically, osseous trabeculae may be seen with clusters of chondrocytes, and between the trabeculae lined by flat osteoblasts there are adipocytes. The osseous center was formed of mineralized cartilage that blended into more or less fibrous cartilage but towards the joint cavity the meniscal ossifications were covered by hyaline cartilage.<sup>24</sup>

Occasional cases involve the patella in breeding age pigs.<sup>16</sup>

The ultrastructural characteristics of normal epiphyseal cartilage of the articular epiphyseal cartilage complex in growing swine has been examined and found to be different from the articular cartilage and the cartilage of the physis.<sup>46</sup> Histochemical techniques are now used to characterize lesions of osteochondrosis and the lesions associated with articular-epiphyseal cartilage complexes should be considered as different entities.<sup>35</sup> Osteopenic lesions have been described.<sup>47</sup>

### DIFFERENTIAL DIAGNOSIS

The syndrome must be differentiated from other diseases which cause lameness and paralysis in growing and young adult pigs which includes: infectious polyarthritis, laminitis, traumatic foot lesions, foot lesions produced by biotin deficiency and footrot, osteodystrophy resulting from calcium, phosphorus and vitamin D imbalance in rations, vitamin A deficiency and viral encephalomyelitis.

### TREATMENT

There is no effective treatment. Early cases may recover spontaneously after being placed outside on pasture or housed individually inside on deep straw litter. Recently, it has been suggested that meloxicam at a dosage of 0.4 mg/kg is

efficacious and safe for the treatment of non-infectious locomotor disorders in pigs. Treatment with 2,5-D vitamin D had no effect on the incidence and severity of OC/OA lesions.<sup>48</sup> Animals that are affected with clinical signs should be removed from the herd quickly and, if necessary, should be humanely destroyed as soon as possible.

### CONTROL

Because the etiology is unknown, it is not possible to provide specific control measures. The hereditary nature of the disease suggests that the selection of breeding stock with sound legs and a low incidence of lesions would be an effective long-term control measure. Genetic control of leg weakness has been documented by various researchers.<sup>41</sup> Selection of boars for leg soundness has dramatic effects on the structural soundness of their crossbred progeny and therefore selection of structurally sound replacements must be maintained if leg weakness in market or breeding pigs is to be avoided.<sup>49</sup> Divergent selection for leg soundness in Duroc pigs has been dramatic.<sup>49</sup> Progeny of leg-soundness sires had significantly better measures for all leg traits at 104 kg than did progeny of leg-weakness sires.<sup>35</sup> Differences between the two progeny groups indicated that the realized heritability for front leg soundness exceeded 0.50.<sup>35</sup>

Selection of breeding stock will require careful genetic selection, examination of all pigs which are to be retained for breeding, necropsy of siblings of affected pigs and of the same gender, to identify genetic lines of pigs which have a low incidence of lesions. A recent study showed that the increase in wild boar alleles in crosses with Large White pigs reduced the prevalence of OC.<sup>50</sup> It has been suggested that the selection of pigs based on the joint lesion score could lead to a better leg and joint condition both optically and pathologically.<sup>51</sup> The reduction of growth rate and exercise may help but are not a real method of control. Increase in calcium and phosphorus in the diet also does not help.

### SPORADIC LYMPHANGITIS (BIGLEG, WEED)

This is a non-contagious disease of horses characterized by acute fever, lymphangitis

and severe swelling of one or both hindlegs - forelimbs are rarely, if ever, affected. The disease commences abruptly with fever (40.5-41°C, 105-106°F), shivering and a rapid pulse rate and respiration. Pain in the acute disease can be severe. There is severe pain on palpation of the affected leg and lameness may be so severe that the horse may refuse to put its foot to the ground. The limb is swollen and hot; the swelling extends from the top of the leg and down to the coronet. There is cording of the lymphatics on the medial aspect of the leg and palpable enlargement of the lymph nodes in some horses. The acute disease resolves into a chronic phase with persistent and variable swelling of the leg, intermittent fever, and variable lameness. Occasionally abscesses develop in the lymph nodes and vessels but usually there is no localization of the infection. There is a tendency for the disease to recur and cause chronic fibrotic thickening of the lower part of the limb extending to the level of the stifle in many horses. Swelling of the leg is often exacerbated by late pregnancy.

Sporadic lymphangitis can be associated with superficial wounds and ulcers on the lower parts of the limbs, but often there are no wounds detected. The disease is thought to develop as a lymphangitis and, potentially, lymphadenitis of the deep inguinal nodes as a result of these wounds. The affected lymph nodes and swelling of the limb obstruct lymphatic and venous drainage causing lymphatic obstruction, edema and, in some cases, cellulitis.<sup>1</sup> Ultrasonographic examination reveals distended lymph vessels that contain fluid that is not echogenic. Ultrasound guided aspiration of this fluid yields fluid with a low total protein concentration and mild neutrophilia (high proportion of the cells present in the fluid are neutrophils, although the absolute count is usually less than  $1.0 \times 10^9$  cells/L. Culture of the fluid is recommended, and *Actinobacillus* sp. have been obtained. The clinical significance of results of culture of the fluid is unknown, but results could be used to guide choice of antibiotics. Radiographic examination is usually unremarkable apart from demonstrating the soft tissue swelling. Affected horses, in both the acute and chronic stages, have a mild neutrophilia and hyperfibrinogenemia.

Acutely affected horses should be treated aggressively. The principles of treatment are control of the presumed infection, reduction of inflammation, and reduction of swelling. Penicillin or other antimicrobials should be administered parenterally to control the infection. Non-steroidal antiinflammatory drugs (phenylbutazone, flunixin meglumine, carprofen, or similar) should be administered to

control the inflammation and provide pain relief. The limb should be hosed with cold water once to twice daily to reduce heat and provided with gently massage therapy. Manual massage of the limb might be beneficial. Supportive, compressive bandaging of the limb can reduce the swelling. The horse should be exercised as much as is practical and humane.

Horses with chronic disease should be treated with prolonged courses of antimicrobials (penicillin, sulfonamide-trimethoprim combinations, enrofloxacin, or rifampin in combination with sulfonamides-trimethoprim), non-steroidal drugs, and local therapy. Acute exacerbations can be managed by administration of dexamethasone (40 µg/kg orally or parenterally, once daily for 5 days, and then gradually tapering). This dose is not abortifacient in pregnant mares. Exercise and supportive bandaging are important in minimizing the swelling. The chronic disease requires prolonged and intermittent therapy, often for the rest of the horse's life.

Prevention of the disease necessitates prompt and careful treatment of all wounds of the lower limbs. Provision of daily exercise, restriction of the diet during prolonged rest periods and dry standing in the stable also help to prevent the disease.

### LAMINITIS OF HORSES

#### Synopsis

**Etiology** Degeneration of the sensitive laminae of the hoof.

**Epidemiology** Disease involving single animals. As a sequela to severe systemic disease including colic, diarrhea, metritis, and grain engorgement. Horses or ponies at pasture. Horses worked on hard surfaces. Obese horses and ponies. Horses with unilateral lameness may develop laminitis in the contralateral, supporting limb.

**Clinical signs** Lameness, ranging from mild to sufficiently severe to cause the horse to be recumbent, involving both front feet, and occasionally all four feet.

**Clinical pathology** None characteristic of the disease.

**Diagnostic confirmation** Physical examination. Radiography.

**Treatment** There is no single effective treatment. Non-steroidal anti-inflammatory drugs, dimethyl sulfoxide, vasodilatory agents, anticoagulants, frog and sole support, and corrective hoof trimming and shoeing are all used with variable success.

**Control** Prophylaxis for acute, severe diseases. Aggressive treatment of metritis, colic and diarrhea. Prevent unrestricted access to feeds rich in soluble carbohydrates. Maintain optimal body condition.

#### ETIOLOGY

Laminitis is caused by **acute degeneration of the sensitive primary and secondary laminae** of the hoof. The cause of this degeneration is unknown although a number of theories have been propounded and are summarized under 'Pathogenesis'. Situations that are associated with increased risk of laminitis include access to lush pasture (suspected as the cause in 46% of field cases), grain overload (7%), retained placenta (2%), and colic or diarrhea (3%).<sup>1</sup> Ingestion of large quantities of soluble carbohydrate, such as grain, bread, calf feed, or exposure to shavings of black walnut (*Juglans nigra*) causes laminitis.

#### EPIDEMIOLOGY

##### Occurrence

Single sporadic cases are the rule for horses in which the disease is usually related to individual risk factors such as obesity, systemic illness, or lameness. An estimated 13% of horse operations in the United States have a horse with laminitis at any one time, and laminitis accounts for 7.5 to 15.7% of all lameness in horses.<sup>1</sup> Laminitis accounts for up to 40% of hoof problems in horses, depending on the use of the horse.<sup>1</sup> Approximately 5% of horses with laminitis die or are euthanized.<sup>1</sup> Among cases occurring in the field (as opposed to veterinary hospitals) approximately 74% recover and become sound, with 8% improving but continuing to be lame.<sup>1</sup> However, approximately 10% of horses that developed laminitis had a permanent change in their primary use as a result of having developed laminitis.<sup>1</sup>

##### Risk factors

Animal risk factors

With the exception of overweight ponies and horses with systemic disease, there are only a few identified innate factors that predispose individual horses to the development of laminitis:

- Any association between the disease and age, sex or breed is weak, again, with the exception of ponies.<sup>2</sup> There is no difference in risk among horses used for pleasure riding, showing, breeding, racing, or farm and ranch work.<sup>1</sup>
- The disease is more common in the United States during spring and summer (1.3% in spring and 0.4% in winter in the central US).<sup>1</sup>
- The disease is very uncommon in foals and horses < 8 months of age, and then increases in frequency with increasing age such that horses >20 years of age have an incidence of the disease roughly 3 times that of horses between 5 and 20 years of age.<sup>1</sup>
- **Overweight ponies** appear to be most susceptible and the disease

occurs four times as commonly in them as in other classes of horse.<sup>3</sup>

Fat ponies at pasture and getting little exercise commonly develop the chronic form of the disease.

- Laminitis is common in horses with tumors of the intermediate lobe of the pituitary (pars intermedia dysfunction, equine Cushing's disease).

##### Trauma and other physical factors

such as excessive work on hard surfaces, increased weight bearing on one limb, and persistent pawing contribute to the development of the disease in horses. Standing for periods of days during transport may predispose to laminitis. For horses that are severely lame, and not bearing weight in the affected limb, the risk of developing laminitis in the contralateral limb is related solely to the duration of lameness and not to body weight.<sup>4</sup>

Laminitis is associated with many **systemic illnesses** of horses. Horses with illness attributable to colic, diarrhea, pleuropneumonia, and metritis are prone to develop laminitis. **Potomac horse fever** (equine neorickettsiosis) is frequently a cause of laminitis in horses and laminitis is the major cause of mortality from this disease. Approximately 28% of horses with **anterior enteritis** (duodenitis/proximal jejunitis) develop laminitis, usually within 2 days of developing enteritis.<sup>5</sup> There are anecdotal reports that suggest that administration of **corticosteroids** (dexamethasone, triamcinolone) causes or exacerbates laminitis, but this association has not been proved. Laminitis is common in horses that engorge on grain or similar feeds containing a high concentration of soluble carbohydrates. Ingestion of large quantities of lush pasture has been anecdotally associated with increased risk of laminitis, especially amongst ponies. It is believed that the presence of a high concentration of soluble carbohydrates fructans in the grass is responsible for the increased risk of laminitis.<sup>6</sup> Fructans are metabolized in the large colon and may mimic the situation after ingestion of a large quantity of soluble carbohydrate.

##### Importance

Death is unusual, but the severe lameness may cause a great deal of inconvenience and affected horses may develop permanent deformities of the feet. Many have to be euthanized.

#### PATHOGENESIS

The basic lesion of laminitis is the separation of the sensitive laminae of the third phalanx from the interdigitating laminae lining the internal surface of the hoof, so that the third phalanx drops through the hoof and comes to rest on the sole. Exactly

what the mechanism is that links the risk factors listed above to the laminar degeneration, the basis of the separation, is unknown. Briefly, the theories are:

- o Ischemia of the laminae with subsequent necrosis. Proposed causes of ischemia include vasoconstriction, development of arterio-venous shunts, interstitial edema, and presence of microthrombi in digital vessels.<sup>7-13</sup> Ischemia due to microthrombus formation is considered an unlikely cause of laminitis.<sup>7,8</sup> However, there is evidence from experimental laminitis that changes in circulating concentrations of vasoactive amines or contractile activity of vessels in the hoof might contribute to ischemia. Alternatively, increases in capillary filtration pressure, resulting from venoconstriction, might cause edema and increased interstitial pressure with subsequent ischemia of the laminae.<sup>13</sup> It is plausible that there is a combination of these mechanisms, beginning with digital venoconstriction and ending in arteriovenous shunting and development of microthrombi.<sup>14</sup> There is evidence in horses with gastrointestinal disease treated by emergency celiotomy that endotoxemia after surgery is associated with lower digital blood flow and higher concentrations of endothelin-1, providing evidence for a role of decreased laminar blood flow in the pathogenesis of the natural disease.<sup>15</sup>
- o Inflammation, with subsequent degeneration of sensitive laminae.<sup>16-18</sup>
- o Enzymatic digestion of laminae by matrix metalloproteins (MMPs) induced by circulating factors including products of *Streptococcus bovis* infection.<sup>19,20</sup>
- o Abnormalities in local (hoof) metabolism of corticosteroid resulting in increased glucocorticoid activity in lamellar tissues.<sup>21</sup>

There is evidence of each of these mechanisms. The evidence is often based on experimental models of laminitis and the findings differ somewhat with respect to the model used and markedly with the stage of disease studied. More recent studies, focusing on the developmental stage before clinical signs are apparent, have identified evidence of inflammation associated with a marked increase in expression of cyclooxygenase-2, an enzyme critical in the metabolism of vasoactive and inflammatory prostaglandins and inhibited by non-steroidal antiinflammatory drugs.<sup>16</sup>

It is speculated that a **pain-hypertension-vasoconstriction** cycle develops in horses with acute laminitis. The pain associated with the laminar degeneration causes release of vasoconstrictor substances such as the catecholamines, angiotensin II, and vasopressin. These substances then cause peripheral vasoconstriction with a subsequent reduction in blood flow to the foot, and systemic hypertension.

The common thread is that degeneration of the sensitive laminae. Loss of the connection between the third phalanx and hoof allows the third phalanx to **rotate** within the hoof capsule, likely in response to the torque applied by the deep digital flexor tendon, and to displace ventrally (**sink**) within the hoof as a result of weight transmitted through the third phalanx; or there may be a combination of these changes. Rotation of the third phalanx causes the sole to be pushed downward or 'dropped', and the point of the toe of the third phalanx may actually penetrate the sole. Serum accumulates in the space created by degeneration of the laminae and displacement of the third phalanx and there is breakdown of the white line.

Many of the inciting causes of laminitis are diseases that may be associated with **endotoxemia**, and in experimental models endotoxin was detectable in the blood of horses that developed laminitis, suggesting that endotoxin may contribute to the development of the disease. However, infusions of endotoxin do not cause laminitis, although endotoxin does impair endothelium-dependent relaxation and augments adrenergic contraction of palmar digital arteries.<sup>22</sup>

The disease occurs in 3 distinct phases: (1) a developmental stage in which lesions are detectable in the sensitive laminae but during which there are no clinical signs; (2) the acute phase from the development of the first clinical signs through to rapid resolution or to rotation or ventral displacement of the third phalanx; and (3) the chronic stage evidenced by rotation of the third phalanx with or without ventral displacement and characterized by variable but persistent pain.

#### CLINICAL FINDINGS

The disease presents as both an acute disease and as a chronic disease. The severity of the acute disease varies considerably from very mild with rapid (5-7 days) recovery, to severe with progression to the chronic, refractory stage.

**The acute disease** develops rapidly; apparently normal horses can founder within hours. Signs of the disease are entirely attributable to pain in the feet. All hooves may be affected, but more commonly the fore feet are affected and the

hind feet are spared. The disease is rarely unilateral except in cases in which the disease develops because of severe lameness in the contralateral limb or repeated pawing. Mild, or early, disease is apparent as a resistance to movement and repetitive and frequent shifting of weight from one foot to the other. There is a characteristic shuffling gait.

**More severe disease** is apparent as refusal to move or to lift a hoof. At this stage the horse wears an expression of great **anxiety**, accompanied by **muscle fasciculation**, **sweating**, a marked increase in heart rate to as high as 75/min, rapid, shallow respiration, and a moderate elevation of temperature. There is a **characteristic posture** with all four feet being placed forward of their normal position, the head held low, and the back arched. There is usually a great deal of difficulty in getting the animal to move and when it does so the gait is shuffling and stumbling and the animal evidences great pain when the foot is put to the ground. The act of lying down is accomplished only with difficulty, often after a number of preliminary attempts. There is also difficulty in getting the animals to rise and some horses may be recumbent for long periods. It is not unusual for horses to lie flat on their sides. In occasional cases the separation of the wall from the laminae is acute and the hoof is shed. There may be exudation of serum at the coronet and this is considered a sign of impending sloughing of the hoof and a poor prognosis.

**The diagnostic signs** in laminitis include pain on palpation around the coronet and a marked withdrawal response when hoof testers are applied to the hoof. The **intensity of the pulse** in the palmar digital artery, palpable over the abaxial aspects of the proximal sesamoid, of affected feet is markedly increased over normal. In horses in which the third phalanx is displaced distally (sinks), a concavity may be palpable at the coronary band. Infiltration of the palmar digital nerves at the level of the proximal sesamoid with local anesthetic agents provides marked, but not complete, relief.

**In the chronic stages** of the disease there is separation of the wall from the sensitive laminae and a consequent dropping of the sole. The hoof wall spreads and develops marked horizontal ridges, and the slope of the anterior surface of the wall becomes accentuated and concave. Horses with chronic or refractory laminitis may continue to feel much pain, lose weight, and develop **decubitus ulcers** over pressure points because of prolonged recumbency. Loss of integrity of the sole and disruption of the white line may

allow **infection** to develop in the degenerate laminae. The infection may spread to involve the pedal bone, causing a septic pedal osteomyelitis. The lameness may abate but the animal becomes lame easily with exercise and may suffer repeated, mild attacks of laminitis.

**Radiographic examination** of the feet may not reveal, initially and in mild cases, changes in the position of the pedal bone. Radiographs of more severe or advanced cases will demonstrate **rotation of the pedal bone** within the hoof, evident as a tilting of the most distal aspect of the third phalanx toward the sole. The space created by rotation of the pedal bone may fill with gas or serum and be evident as a radiolucent line between the pedal bone and the dorsal hoof wall. **Displacement of the pedal bone** toward the sole will be evident in approximately 25% of cases as a thickening of the dorsal hoof wall and reduction of the distance between the sole and solar aspect of the pedal bone. Chronic or refractory cases may have **osteopenia** of the pedal bone with proliferation of bone at the toe.

**Prognosis.** The **radiographic examination** provides information of **prognostic value**. Horses that return to their previous level of athletic function after a bout of laminitis have pedal bone rotation of less than 5.5°, whereas horses that can no longer perform as athletes usually have more than 11.5° of rotation.<sup>23</sup> However, there is considerable overlap between groups and these values should only be used as rough guidelines. The general rule is that the greater the degree of rotation, the worse the prognosis for return to function and pain-free living.

Objective radiographic variables include the distance between the proximal aspect of the hoof wall (marked on the radiographic image by a piece of wire or strip of metal stuck to the dorsal hoof wall) and the proximal limit of the extensor process of the distal phalanx (the 'founder' distance), and the distance between the dorsal hoof wall and the dorsal cortex of the distal phalanx.<sup>24</sup> While values for these measures vary among breeds and with the size of the horse, most normal horses will have a 'founder' distance of  $4.1 \pm 2.2$  (standard deviation) mm and a wall thickness of  $16.3 \pm 2.4$  mm.<sup>24</sup>

#### CLINICAL PATHOLOGY

There are no changes that are characteristic of the disease.

#### NECROPSY FINDINGS

The disease is not usually fatal but if a necropsy examination is carried out on an acute case, the stomach usually contains excessive amounts of grain, which has a pasty, mealy consistency and an odor

suggestive of putrefaction of protein. Retained placenta and metritis may be present in postparturient laminitis in mares. No other reliable gross findings are visible, although the vessels of the sensitive laminae of the digital cushion may appear engorged if the cut surface of the hoof is examined.

In subacute and chronic cases the diagnosis can easily be confirmed by gross examination of sagittal sections of the foot. This permits assessment of the horny, soft, and osseous components of the foot. In some cases the degree of rotation of P3 results in perforation of sole.

Histological examination is required only in acute cases and confirmation of the diagnosis in such instances demands that the foot be cut into slab sections and fixed shortly after the death of the animal, before even moderate autolysis can ensue. Microscopically, the sequence of acute changes in experimentally induced laminitis begins with the loss of some of the keratogenic structures of the epidermal laminae. This is followed by vascular engorgement, edema and some necrosis of laminar tissues.

#### DIFFERENTIAL DIAGNOSIS

##### Horses

Rhabdomyolysis, tetanus, colic, and spinal ataxia may all mimic the immobility and pain of laminitis, but there is no pain in the feet in these diseases, and other distinguishing characteristics are apparent on careful clinical examination.

#### TREATMENT

**Acute laminitis is an emergency** and treatment should be started without delay, as early and aggressive therapy might enhance the chances of recovery.

The adage 'where facts are few experts are many' (Donald R. Gannon) applies well to the treatment of laminitis. There are no well-designed studies of the treatment of naturally occurring laminitis and thus the choice of treatment is based on personal experience, extrapolation from our imperfect understanding of the pathogenesis of the disease, the availability of certain drugs, and current fashion. In general, the treatments can be grouped into several classes, based on the intended intervention. These are:

- **Removal of the causative agent or treatment of the inciting disease**
- **Pain relief and minimization of inflammation**
- **Vasodilation of blood vessels in the foot**
- **Prevention of formation of microthrombi in dermal capillaries**
- **Prevention of rotation or distal displacement of the pedal bone**

#### • Promotion of keratinization and hoof growth.

The efficacy of administration of analgesic, anti-inflammatory, anticoagulant and vasodilatory drugs, local therapy such as ice baths of the hoof or having the horse stand in cold water, and mechanical support of the hoof has never been demonstrated in appropriate clinical trials.

#### *Treatment of inciting disease*

The inciting disease should be treated aggressively and every attempt made to remove any causative agent. Horses with traumatic laminitis should be rested and housed in stalls that are well bedded with sand or soft shavings. Horses suspected of having a tumor of the intermediate lobe of the pituitary gland should have the diagnosis confirmed and appropriate therapy instituted.

#### *Analgesics and anti-inflammatory drugs*

A mainstay of the treatment of both acute and chronic laminitis is the use of non-steroidal anti-inflammatory drugs (NSAIDs). Apart from the obvious humane requirement of providing pain relief, the use of NSAIDs is speculated to be beneficial by breaking the pain-hypertension-peripheral vasoconstriction cycle that may be important in the pathogenesis of laminitis. Furthermore, recent evidence suggesting that inflammation mediated by COX-2 plays a role in the developmental phase of laminitis supports the early and aggressive use of NSAIDs.<sup>16</sup> **Phenylbutazone**, at doses of 2.2–4.4 mg/kg intravenously or orally every 12–24 hours, is an effective analgesic in cases of mild to moderate laminitis. Higher doses (6.6 mg/kg every 12–24 hours) may be required in severe cases. However, the potential for phenylbutazone toxicosis, evident as colic, gastrointestinal ulceration, nephrosis, hypoproteinemia, leukopenia, and hyponatremia, is dose related and high doses of phenylbutazone should only be used for at most several days and only in severely painful horses. **Flunixin meglumine** (1.1 mg/kg, IM or IV every 8–12 hours) and **ketoprofen** (2.2 mg/kg, IM every 12–24 hours) are also effective analgesics.<sup>25</sup> Their concurrent use with phenylbutazone may enhance pain relief but also increases the risk of NSAID toxicosis. The use of aspirin is dealt with under Anticoagulants.

**Dimethyl sulfoxide (DMSO)**, a putative anti-inflammatory drug that is also reputed to scavenge free radicals, has been used in the treatment of acute laminitis, again without clear demonstration of its efficacy. DMSO is administered at a rate of 1 g/kg, intravenously as a 10% solution in isotonic sodium chloride. The treatment can be repeated daily for several days.

**Narcotic analgesics** such as butorphanol and meperidine (pethidine) provide some pain relief but in general are not as effective as the NSAIDs. Similarly,  $\alpha$ -2 agonists such as **xylazine and detomidine** provide only brief respite from the pain, and may be contraindicated because of the vasoconstriction associated with their use.

**Local analgesia** of the foot with agents such as lidocaine or bupivacaine provides marked pain relief. However, analgesia is usually only brief, depending on the agent used, and has the disadvantage of causing the horse to bear more weight on the affected limbs. Local analgesia may be useful in facilitating relocation of the horse, hoof trimming, corrective shoeing, or application of sole and frog support but not as a routine treatment.

Because of suspicion that **corticosteroids** induce or exacerbate laminitis, at this time their use is contraindicated in the treatment of laminitis.

#### *Vasodilatory drugs*

Vasodilatory drugs are used on the premise that vasoconstriction is an important mechanism underlying the development or progression of acute laminitis. Several classes of drugs have been used including  $\alpha$ -adrenergic antagonists such as phenoxybenzamine and phentolamine, drugs with multiple mechanisms of action such as acetylpromazine and isoxuprine, and nitric oxide donors including glyceryl trinitrate (nitroglycerine) and L-arginine.<sup>26</sup> None of the vasodilatory drugs should be used in horses with compromised cardiovascular function or dehydration.

Phenoxybenzamine and phentolamine are not readily available and have limited use. Phenoxybenzamine causes sedation. **Acetylpromazine** is a potent vasodilator, principally because of its  $\alpha$ -adrenergic antagonist activity, that is currently used frequently in the treatment of acute laminitis. Acetylpromazine increases blood flow to the digit, but its effect on nutritive flow to the laminae is unknown, as is the case for all the vasodilators.<sup>27</sup> The effect of acetylpromazine persists for approximately 90 minutes after intravenous administration.<sup>27</sup> Acetylpromazine can be administered at dose rates ranging from 0.01 to 0.05 mg/kg, IM, every 6–12 hours. Sedation may be considerable at the higher doses and/or with more frequent administration. **Isoxuprine** is a combined  $\alpha$ -antagonist and  $\beta$ -agonist that increases blood flow to the leg but not to the foot in normal horses.<sup>27,28</sup> It has been used at doses of 1–1.5 mg/kg orally every 12 hours. Pentoxifylline (4.4 mg/kg orally q8 hours) does not increase digital blood flow in normal horses.<sup>27</sup>

Application of **glyceryl trinitrate**, a nitric oxide donor, to the palmar digital

arteries of affected horses has been reported to increase or not affect blood flow to the dorsal hoof wall.<sup>29,30</sup> However, the effect of these substances on the course of the disease is unknown. In spontaneous cases of acute laminitis glyceryl trinitrate has been applied to the skin over both palmar digital arteries of affected feet at a dose of 15–30 mg per artery, once daily. However, because of lack of evidence of efficacy and the potential for systemic hypotension secondary to systemic absorption of the drug, its use is no longer recommended.

#### *Anticoagulants*

Anticoagulant drugs are administered to prevent the development of microthrombi within the hoof. **Aspirin and heparin** are commonly used. Aspirin is a very poor analgesic in horses but is used because it reduces platelet aggregation in normal horses by blocking formation of thromboxane A<sub>2</sub>. However, thromboxane may not be an important cause of platelet aggregation in horses.<sup>31</sup> Aspirin is administered at a dose of 10 mg/kg orally every 48 hours.

**Heparin** in sufficient doses prolongs blood clotting, provided that there is adequate antithrombin III in the patient's blood. Heparin has been reported to prevent or to have no effect on the development of laminitis in horses with anterior enteritis or colic, respectively. Heparin can be administered at 40 to 80 iu/kg IV or subcutaneously every 8–12 hours for 3–5 days. Anemia may develop during heparin administration, but resolves rapidly when administration of the drug is stopped.

#### *Mechanical support*

Mechanical support to provide pain relief and in an attempt to prevent rotation or distal displacement of the pedal bone is an important part of the care of horses with acute laminitis.

**Support of the frog and/or sole** can be achieved using packing material such as dental acrylic or firm plastic that is molded to conform to the shape of the sole. Some clinicians prefer to use **wedge pads** to elevate the heel and reduce tension in the deep digital flexor tendon with the aim of preventing rotation of the pedal bone.

Housing the horse on sand or other soft bedding is frequently recommended.

Corrective shoeing of horses with chronic laminitis is widely practiced and there are proponents of a wide variety of shoe types (fullered egg-bar, heart bar, glue-on shoes). Appropriate hoof care, which might include shoeing, is important in managing horses with chronic laminitis. Interestingly, there was not a difference among shoe types in efficacy for pain relief in horses with chronic laminitis.<sup>32</sup>

#### *Promotion of healing*

**Methionine** has been given to both acute and chronic laminitis cases on the known requirement for methionine in the chondroitin complex of collagen. There is some rationale for the treatment but it seems more appropriate as a supportive than as a principal treatment. The recommended oral dose rate is 10 g/day for 3 days followed by 5 g/day for 10 days.

**Antibiotics** may be indicated to prevent secondary infection of the degenerate laminae.

**Rest** is important in the convalescent phase. Horses with no rotation or sinking of the pedal bone should be given 21 days of rest after resolution of the clinical signs. Return to work should be gradual. Horses that develop rotation or sinking of the pedal bone should be monitored both by physical examination and radiographic examination. It will be many months before horses with even mild rotation can be returned to work. Horses with severe rotation will likely never resume active work, although they may become pasture sound.

#### **Summary of treatment of acute laminitis**

Depending on the cause, treatment of acute laminitis should include:

- The administration of non-steroidal anti-inflammatory drugs (preferably phenylbutazone)
- Vasodilators (acetylpromazine)
- Support of the frog and/or sole
- Housing on sand or similar soft bedding
- The inciting disease should be treated aggressively
- After the acute phase has passed, likely in 5–7 days, attention should be given to trimming the hoof and corrective shoeing.

#### *Chronic, refractory laminitis*

The **prognosis** for chronic or refractory laminitis (laminitis of more than 1 week's duration) is poor (see above for the use of radiography to determine prognosis). Treatment includes NSAIDs for pain relief, corrective shoeing (egg bar or heart bar shoes), and trimming of the hoof (shortening the toe or complete removal of the dorsal hoof wall). **Tenotomy** of the deep digital flexor may provide temporary relief but does not affect the long-term prognosis.

#### **CONTROL**

The disease is not readily subject to control because of its sporadic nature. Heavily fed or fat horses should be given some exercise when not working; if possible, horses in transit should be removed from the transport vehicle, given light exercise and rested for several hours at the end of each day; retained placenta in mares should

be treated promptly. Heavy carbohydrate feeding should be avoided. Susceptible ponies should have limited access to pasture either by limiting the time that they spend at pasture or by application of a grazing muzzle.

## LAMINITIS IN RUMINANTS AND PIGS

### Synopsis

**Etiology** Degeneration of the sensitive laminae of the hoof.

### Epidemiology

**Cattle:** An endemic disease of some herds of high producing dairy cattle, and in feedlots. Associated with ruminal acidosis, either clinical or subclinical.

### Clinical signs

**Cattle:** Inapparent to severe lameness, most common in the hind feet. Predisposition to other infectious or traumatic diseases of the foot.

**Clinical pathology** None characteristic of the disease.

**Diagnostic confirmation** Physical examination. Radiography.

### Treatment

**Cattle:** Non-steroidal anti-inflammatory drugs. Corrective hoof care.

### Control

**Cattle:** Dietary control to prevent ruminal acidosis. Correction of housing and flooring problems.

## ETIOLOGY

Laminitis is caused by acute degeneration of the sensitive primary and secondary laminae of the hoof. The cause of this degeneration is unknown. The disease is less well characterized than that of horses and several conditions are often classified as laminitis.

## EPIDEMIOLOGY

### Occurrence

In **cattle** the disease may occur as clusters in herds and on farms where a predisposition appears to be inherited or where access to large quantities of soluble carbohydrate are available such as for high producing dairy cows or feedlot cattle. On farms of high-producing dairy cattle the prevalence may be as high as 78%.<sup>1</sup> The disease is also reported in calves and first calf heifers.

### Risk factors

Cattle and sheep

**Subclinical laminitis** that predisposes to the development of other diseases of the hoof occurs in calves and first calf heifers and is common in intensively fed feedlot cattle.<sup>2</sup> Laminitis, conditioned by the inheritance of an autosomal recessive gene, is recorded in Jersey heifers.<sup>3</sup> There may be an association between the disease in feedlot ruminants and **ruminal acidosis**.

Beef cattle being prepared for shows are often grossly overfed on high grain rations and become affected with a chronic form of the disease which markedly affects their gait and may cause permanent foot deformity. The disease occurs in dairy cattle fed improper rations, and especially first calf heifers and cattle of herds attempting to increase milk production<sup>1,4</sup> and it is not uncommon for the disease to present as a herd problem.

Among **dairy cattle** the heifers are usually worst affected and the disease usually develops soon after calving, with more than 50% of cases occurring in the period 30 days before and 30 days after calving. There may be a relationship between being introduced to the herd, with the frequent harassment by dominant cows, when heavily pregnant and when the surface of the yards is rough. Housing may be important including standing in slurry or having to twist and turn in narrow passageways and races, and there is an

association between the prevalence of the disease and rough concrete floors.<sup>5,6</sup>

Diet is an important risk factor for development of laminitis in heifers. Diets of wet, fermented grass silage are associated with a greater risk of laminitis than are diets rich in dry unfermented straw and a concentrate.<sup>7</sup> Furthermore, transition from a low net energy diet to a high net energy diet immediately after calving increases the risk of subclinical mastitis in Holstein dairy cows.<sup>8</sup>

The disease is also reported to occur after metritis, retained placenta, mastitis, and mammary edema but the incidence is not usually very high.

### Pigs

Laminitis has been recorded in pigs but the disease is difficult to diagnose in this species and many cases secondary to other diseases, e.g. postparturient fever, may be missed. The disease is also recorded when pigs are fed very heavy concentrate diets.

### Importance

Subclinical laminitis of dairy cattle predisposes to other hoof disease that may decrease milk production.

## PATHOGENESIS

The pathogenesis of laminitis in cattle, sheep, and pigs is unclear, but likely has some similarity to that in horses (see Laminitis in horses). Subclinical laminitis can predispose to white line disease.

## CLINICAL FINDINGS

Cattle and sheep

In these species the clinical picture is similar to but less marked than that observed in the horse.

In **calves 4-6 months** of age, and in heifers, an acute syndrome similar to that seen in the horse has been described. Affected animals lie down much of the time, and are reluctant to rise. When they attempt to rise they remain kneeling for long periods. Their standing posture is with all four feet bunched together and the back is arched; they shift their weight from foot to foot frequently and walk with a shuffling painful gait. The feet are painful when squeezed and later become flattened and enlarged and look as though slippers are being worn. There is severe ventral rotation of the third phalanx.

In **adult cows** some cases have acute signs, others show only local lesions. These include sole ulcers and patchy changes in the horn including softening, waxy yellow discoloration, and red-brown patches suggestive of previous hemorrhage. The cow is chronically lame.<sup>9</sup>

**Young bulls** are very susceptible to laminitis and may develop abnormalities

of gait and posture, such as a stilted gait and frequent knuckling of the fetlocks, which may mislead the diagnostician.

**Chronic laminitis in adult cows** is characterized by a smaller anterior hoof wall-sole angle, down from 558 to 358, a concave anterior wall, and the appearance of horizontal grooves (growth arrest lines) around the entire claw. The sole is usually dropped a little and bruising and sole ulcers may be present. Overgrowth of the sole of the lateral claw may reach the point of creating a false or double sole. The white line is greatly widened and disrupted and stones and other debris may be impacted in it.<sup>10</sup>

Chronic, traumatic laminitis is most common in heifers when they are first introduced into the milking or dry herds. Housing them on concrete and exposing them to frequent confrontations with bossy cows lead to the development of sole hemorrhages and inflammation of the laminae.

**Radiographic signs** in cattle include rarefaction of the pedal bone, particularly the toe, and the development of osteophytes at the heel and on the pyramidal process.

#### Pigs

In sows the clinical signs are similar and include arching of the back, bunching of the feet, awkwardness of movement, increased pulsation in the digital arteries and pain when pressure is applied to the feet.

#### CLINICAL PATHOLOGY

There are no changes that are characteristic of the disease.

#### NECROPSY FINDINGS

Histological findings in the feet of cows affected by laminitis are similar to those in horses.

#### DIFFERENTIAL DIAGNOSIS

##### Cattle

White muscle disease, epiphysitis.

#### TREATMENT

Although similar principles to those used to determine treatment of laminitis in horses are likely to apply to cattle, treatment in cattle is usually limited to administration of NSAID (aspirin 0.3 grains/kg, orally every 12 hours, phenylbutazone 4.4 mg/kg orally every 48 hours or flunixin meglumine 1.0 mg/kg IV every 12 hours). The inciting cause (metritis, ruminal acidosis) should be treated aggressively.

#### CONTROL

Cattle and lambs which are brought into feedlots should be gradually introduced

to grain feeds and a higher forage:grain ratio provided in the feed. Calves should not be fed intensively on grain until they are 14 months old because of the high frequency of internal hoof lesions at the earlier ages. Some protection against laminitis in dairy cattle in intensive units is gained by careful planning of housing cubicles to make them more comfortable and less damaging to the feet, and by providing more straw in the cubicles. Exercise should be provided around calving time. Vaccination with a Gram-negative bacterin-endotoxoid combination vaccine has provided some protection against laminitis induced by grain overload. Dietary supplementation of biotin (20 mg per head per day) improves hoof health of primiparous dairy cows<sup>11</sup> and may be beneficial in reducing the incidence or severity of lameness in a herd. This treatment might not improve objective indicators of hoof health, but it does improve production.<sup>12</sup>

#### 'ACORN' CALVES

A non-inherited condition has been described in the US and Australia which resembles inherited dwarfism.<sup>1</sup> The disease occurs on poor range country and is thought to be due to a maternal nutritional deficiency during the middle trimester of pregnancy. The specific dietary factors involved have not been determined, although supplementary feeding during pregnancy eliminates the condition.

Abnormal osseous development of the head causes it to be either shorter or longer. Shortening of the shafts of the long bones of the limbs is accompanied by bending at the joints, and calves nurse and stand with difficulty. Incoordination, arching of the back and a tendency to bloat, which may cause death, also occur. The dentition is normal. Muscle spasticity, wry

neck, circling, falling backwards, and goose-stepping occur rarely.

Most of the calves are born alive and, in badly affected herds, as many as 15% of calves may be affected. The condition derives its name from the common occurrence of acorns in the diet of affected herds, although the acorns are not thought to have any etiological significance.

#### CONGENITAL JOINT LAXITY AND DWARFISM IN BEEF CALVES (DYSCHONDROPLASIA IN NON-INHERITED CONGENITAL DWARFISM IN BEEF CALVES)

Congenital joint laxity and dwarfism is a skeletal anomaly which has affected beef calves in Canada,<sup>1-3</sup> Australia,<sup>4</sup> and Ireland.<sup>5</sup> The disease has been recognized in beef cattle ranches in north central British Columbia and Alberta, and northwestern Ontario.<sup>1</sup>

#### ETIOLOGY AND EPIDEMIOLOGY

The etiology is unknown. Epidemiologically, the disease has been associated with feeding clover silage or grass silage without dry feed or grain supplementation to pregnant cows over the winter months.<sup>3</sup> The disease is seen almost exclusively in beef herds where pit silage makes up the bulk of the ration. In an outbreak in a beef herd in Prince Edward Island, Canada, feeding spoiled silage to pregnant cattle may have been a risk factor.<sup>3</sup> An apparent greater incidence in beef herds in the northern part of the UK may be associated with longer periods of winter feeding in the northern part of the country.<sup>6,7</sup> There is no evidence that manganese deficiency is a causative factor.<sup>3,5</sup>

The problem can be eliminated by supplementation of the silage diet with a combination of hay and rolled barley.<sup>2</sup> In one study, calves born to first-calf heifers were 3.2 times more likely to be affected compared to calves born to mature cows.<sup>8</sup> In the Australian report, the pregnant dams had experienced severe nutritional deficiency between 3 and 6 months of gestation.<sup>4</sup>

Controlled feeding trials have supported the epidemiological observations that the disease occurs in calves born to cows fed exclusively grass or clover silage over the winter months.<sup>2</sup> Supplementation of the grass and clover silage diet with hay (2.5-4.5 kg/head per day) and rolled barley (0.75-1.5 kg/head per day) eliminated the problem. Supplementation with grain but no hay reduced the risk of abnormal calves to a lesser degree. The period of gestation during which the fetus is

susceptible to the abnormality ranges from 107 to 230 days. It is suggested that irreversible injury to the fetus occurs by day 180 of gestation.

Prenatal rickets was considered as a possibility in the early stages of the investigations. The overgrowth of chondrocytes and delayed mineralization of the growth plates of affected calves in previous years were similar to those described for neonatal rickets. In addition, the vitamin D concentration of silage may be low and the wavelengths of ultraviolet light necessary for transformation of the provitamin 7-hydroxycalciferol to vitamin D<sub>3</sub> are almost entirely filtered out by the atmosphere during the winter months because of the acute angle of the sun in northern latitudes. In Canada, pregnant beef cows fed exclusively a diet of grass or clover silage during the winter months may have low levels of vitamin D. However, supplementation of pregnant cows with vitamin D<sub>3</sub> during one winter season did not reduce the risk of abnormal calves.

The disease resembles 'acorn calves' which have occurred in California and Australia. One possible hypothesis suggests that the two conditions may share a common pathway.<sup>2</sup> Certain unspecified seasonal and environmental conditions or stressors may convert forage into a teratogenic substance. In areas where acorn calves occur, supplementation feeding of the cows on pasture practically eliminates the problem.

#### CLINICAL AND PATHOLOGIC FINDINGS

The abnormalities are obvious at birth and characterized clinically by generalized joint laxity, disproportionate dwarfism and, occasionally, superior brachygnathia.<sup>2</sup> The anomaly has occurred in some beef herds for several consecutive years and has affected 2–46% of the calf crop.<sup>9</sup> In a case reported from Ireland, the affected beef herd consisted of Hereford, Simmental, and Friesian cows bred to a Hereford or Charolais bull. The pregnant cattle were self-fed grass silage preserved with Kofasalt (calcium formate, sodium nitrite, and hexamethylene tetramine). Affected calves, were characterized clinically by disproportionate dwarfism, varying degrees of micromelia, limb rotation, joint laxity, and skull abnormalities.<sup>5</sup> Inferior and superior brachygnathia were present. Radiographically, the diaphyses were grossly foreshortened and thickened, the epiphyses were enlarged, misshapen and flared with increased opacity on some radiographs.<sup>5</sup> Histologically, there was chondrodystrophic of the metaphysis of the dwarf long bones. Consistent changes in organ weights or in trace element

status were not present, and there was no evidence of infectious agents. There was no evidence of an inherited basis for the abnormal calves.

The epiphyses of the long bones are abnormal with overgrowth of chondrocytes and delayed mineralization. The common defect is one of growth plate maturation. The secondary ossification centers are slow to develop. Perinatal mortality is higher in affected calves than for normal calves in the same herd. The joint laxity may cause problems with dystocia. Within a few weeks after birth, the joints in surviving calves become stable, and calves walk normally.

#### SLIPPED CAPITAL FEMORAL EPIPHYSIS IN CALVES

This occurs in newborn calves of the well-muscled, rapidly growing European breeds, such as the Charolais, Maine-Anjou, and Simmental. It is characterized by varying degrees of lameness, palpable crepitus over the greater trochanter on passive manipulation of the affected limb, muscle atrophy in longstanding cases, and prolonged recumbency. Some calves carry the affected limb or drag the foot, whereas others tolerate slight weight-bearing during standing or walking. Most calves are lame at birth or within a few days after birth. About 75% of cases are associated with a dystocia and forced traction delivery.<sup>1</sup>

Laboratory stress testing of calf femurs found that mechanically induced fractures had configurations and locations similar to those found in clinical cases associated with forced extraction.<sup>2</sup> The breaking strength of all femurs was within the magnitude of forces calculated to be generated when mechanical devices are used to assist delivery during dystocia. It is suggested that the femur is compressed during force extraction when the pelvis of the calf is wedged in the pelvis of the dam in anterior presentation. Every effort must be employed to avoid premature engagement of the calf's stifle into the pelvic cavity to avoid or correct a 'stifle lock'.

Radiographically, there are varying degrees of displacement of the femoral neck from the head. In chronic cases there is partial resorption of the femoral head.

Excision arthroplasty has been attempted with some encouraging results.

The disease must be differentiated from perinatal **femoral nerve degeneration** and neurogenic atrophy of the quadriceps femoris muscle which also occurs most commonly in the same breeds of cattle. The right hindleg is most commonly affected and affected calves are unable to bear weight on the leg; there is obvious neurogenic atrophy of the quadriceps muscle.<sup>3</sup> The problem has been treated by stall rest, femoral head and neck excision, and open reduction by use of Knowles pins, multiple intramedullary pins, or interfragmentary compression screws.<sup>4</sup>

Slipped capital femoral epiphysis has also been reported in cattle 3–5 months and 1.5–2.3 years of age.<sup>3</sup> Trauma is the suspected cause. If early diagnosis can be made, intramedullary pinning can provide a good long-term prognosis in cattle when function as a breeding animal is important to their future value.

#### TAIL-TIP NECROSIS IN BEEF CATTLE

Tail-tip necrosis occurs in cattle housed in confinement on slatted floors. The disease has occurred in steers, heifers, and bulls being fed for beef production.<sup>1,2</sup>

The lesion is caused by a traumatic injury of the tail caused by tramping of the tail. The lesion begins at the tip of tail followed by varying degrees of extension proximally. Initially, the tip of the tail is swollen, followed by inflammation and suppuration. Histopathological changes are compatible with cutaneous ischemia as a pathogenetic mechanism.<sup>3</sup> Extension of the infection can result in metastases to other parts of the body, resulting in abscesses and osteomyelitis. Affected cattle do not grow normally and deaths from pyemia may occur. The morbidity is about 5%. Approximately 10% of affected animals may be condemned for osteomyelitis and abscessation.

#### Risk factors

These include slatted concrete floors, close confinement, warm seasons, and a body weight above 200 kg. The risk increases as the space allotment, expressed as kg animal per m<sup>2</sup> pen increases from approximately 165 kg/m<sup>2</sup>. Tail tramping is more frequent in slatted-floor pens with lower space allotment (1.5 m<sup>2</sup> per head) than in similar pens

with higher space allotment (2.4 m<sup>2</sup> per pen head). In an Ontario study, no case of tail-tip necrosis was diagnosed in solid-floor barns, while 1.36% of cattle in slatted-floor barns were either treated or slaughtered for tail-tip necrosis.<sup>2</sup> In a mail survey of feedlots in Ontario, 96% of 71 feedlots with slatted floors, but only 5% of 184 feedlots with solid floors, reported a problem with tail-tip necrosis from 1982 to 1986.<sup>3</sup> Of 441 tails inspected at slaughter plants, 34.5% were affected, with 3.4% involving skin lacerations and infection, and 4.3% amputated before slaughter.<sup>3</sup> Most cases occur from May to September when the temperature is above 18°C. This may be associated with increased contamination due to increased humidity and temperature under confinement conditions.

In slatted-floor barns, abnormal locomotor patterns occur from 20 to 25% of the times animals get up and lie down.<sup>2</sup> When animals get up abnormally, they first rise in their front, and consequently assume a dog-like sitting posture. In order to obtain momentum to rise in the rear, they then start to sway back and forth. The tail may become pinched between the hock of the rocking animal and the floor, resulting in blunt trauma to the tip of the tail.

#### TREATMENT

Treatment consists of early amputation combined with intensive antimicrobial therapy. Early detection is important. During warm months, cattle confined on slatted floors and weighing more than 200 kg should be closely inspected at least 2 or 3 times weekly. This includes palpation of all tail tips because early lesions are difficult to see.

#### CONTROL

This is dependent on providing sufficient space for housed cattle on slatted floors.

### TOE ULCER AND NECROSIS OF THE APEX OF THE PEDAL BONE OF CATTLE

#### ETIOLOGY

A toe ulcer is a defect in the white line at the apex of the sole in adult cattle.<sup>1</sup> Lameness does not occur in the early stages but discomfort gradually develops at which stage the animal carries the foot further forward than normal. The etiology is not well understood. In one series of cases, overtrimming using a grinding disc and/or perforation of the sole was considered a major cause (49%), laminitis in 30%, and traumatic injuries in 11%.<sup>2</sup>

#### EPIDEMIOLOGY

In South America, where dairy herds are pastured and supplemented with concentrate and corn silage, toe ulcers are common lesions in heifers from 15 to 60 days after calving.<sup>3</sup> Two types of toe lesions are usually presented. One is a single claw horn defect occurring in Zone 1 which after further examination, granulation tissue is often observed. This lesion responds well to local treatment and the application of an orthopedic block on the healthy claw. The second type of lesion is more severe and includes necrosis of the pedal bone, complicated by secondary infection.

#### CLINICAL SIGNS

Clinical signs of apical pedal bone necrosis vary widely depending on the severity of the lesions, the number of claws involved and the causative factors. A marked-to-severe lameness may occur in cows with one claw affected, and a severely stilted gait in cows with two or three affected claws. In some cases, the lameness is so severe that the initial impression from a distance was that of a neurological disease because of the severely stilted, convulsive limb movements at rest and walking. The involvement of the pedal bone can be determined by clinical examination, inserting a probe or by direct visualization of the discolored and exposed apex of the distal phalanx.

#### PATHOGENESIS

The gross pathological findings of affected claws vary from moderate topical inflammatory signs of the corium at the toe of the claw, to severe and extensive necrosis and osteomyelitis of the pedal bone.<sup>1</sup> Histologically, there are different types of demarcation of the necrotic bone. Mixed infections are common.

Radiographically, the degree of involvement of the distal phalanx can be clearly identified, facilitating the choice of surgical therapy.<sup>1</sup>

#### TREATMENT

Treatment options include excision of necrotic bone using a bone curette, resection of the necrotic apex of the distal phalanx, and digital amputation in severe cases.<sup>2</sup>

#### DIFFERENTIAL DIAGNOSIS

Toe ulcers must be differentiated from toe abscesses which occur in yearling cattle and beef calves grazing irrigated pastures in the fall at which time they may be lame due to a toe abscess.

### Diseases characterized by involvement of the skin

#### PITYRIASIS ROSEA

Pityriasis rosea is a condition of man. The condition in pigs is not the same because of a prominent component of eosinophils and confluent zones of epidermal necrosis. Dermatopathological authorities have suggested that the condition be renamed pustular psoriasiform dermatitis of pigs.<sup>1</sup>

This skin disease of pigs resembles ringworm closely but skin scrapings do not reveal the presence of fungal hyphae or spores, and cultures for fungal growth are usually negative. Treatment with standard preparations used for ringworm is usually ineffective, although spontaneous recovery may occur.

The disease occurs in sucking pigs<sup>2</sup> and young pigs in the 10-14 weeks age group. Up to 50% of each litter and herd may be affected and in large groups of feeder pigs there may be only individual pigs or the majority of the group with lesions. The disease is usually innocuous, although digestive disturbances, particularly anorexia and, to a lesser extent, diarrhea and vomiting may accompany the appearance of lesions and affected pigs lose some body weight. There is no fever. Usually the condition resolves spontaneously after 2-4 months.

Lesions occur most commonly on the ventral abdomen but may spread to the rest of the body. They commence as small, red nodules which enlarge to flat plaques and become covered with thin, dry, brown scales. The lesions appear to enlarge centrifugally, leaving a center of normal appearance surrounded by a narrow zone of elevated, erythematous skin covered by typical scales. Individual lesions are generally circular except that they often coalesce to produce a large, irregular lesion. There is little irritation and the skin lesions, although obvious, are superficial. There is no loss of bristles. Histologically, the lesions show a progression from acute to chronic with a dense superficial and deep perivascular infiltrate of eosinophils, lymphocytes, and histiocytes.<sup>1</sup>

The cause is unknown, although infectious, genetic and allergic causes have been suggested and there is strong evidence of familial susceptibility, either through inheritance or by vertical transmission of an infectious agent.<sup>3,4</sup> Transmission experiments have been unsuccessful and the disease has been observed in SPF pigs

produced by cesarean section.<sup>5</sup> By analogy with a similar condition affecting man, it may be a viral infection. Treatment appears to be completely ineffective but in general consists of the local application of a salve containing 5% salicylic or iodized mineral oil. Affected pigs should be isolated from the group. Spontaneous recovery occurs in 6–8 weeks in most instances.

### ANHIDROSIS (NON-SWEATING SYNDROME, PUFF DISEASE, DRY COAT)

Reduced ability to sweat affects horses in hot and humid climates. Affected horses are unable to maintain their body temperature within safe limits, especially during or after exercise, and suffer heat stress and a reduction in athletic performance. The only effective treatment is to move the horses to a cooler environment.

#### ETIOLOGY

The etiology of anhidrosis is unknown, but involves a reduction in the sensitivity of the sweat gland to  $\beta$ -2 adrenergic stimulation, the normal stimulus for sweating in the horse.<sup>1</sup> Hypothyroidism does not contribute to anhidrosis.<sup>2</sup>

#### EPIDEMIOLOGY

The disease occurs in horses, and rarely in cattle, in countries with hot, humid climates including tropical and semi-tropical regions.<sup>1</sup>

The overall prevalence is approximately 6% in Florida, with the highest prevalence (25%) in horses in training and the lowest prevalence (1%) in young horses.<sup>2</sup> There is no reported sex or color predilection. Both native and imported horses are affected, apparently with similar prevalence.<sup>3</sup> Among native horses the age of onset of the condition ranges from 1 year to 10 years.<sup>3</sup> Foals, especially of draft breeds, can be affected. Horses imported to endemic areas usually do not develop the disease within 1 year.<sup>3</sup> The incidence and severity of the disease are highest in the hotter season.

The disease is rarely fatal unless severely affected horses are exercised in the heat, in which case death from heat stroke can occur. The major importance of the disease is inability of affected horses to exercise and compete in athletic events.

#### PATHOGENESIS

Sweat is produced in horses by apocrine sweat glands that have a single type of secretory cell. The sweat glands are well

innervated, and sweating is controlled by a combination of hormonal ( $\beta$ -2 adrenergic) and neural factors.<sup>4</sup> Sweat production increases with increasing concentrations of epinephrine in blood up to a peak value, after which sweating rates decline.<sup>4</sup> Anhidrotic horses have lower initial and peak rates of sweat production, and lower overall sweat production, than do normal horses during intravenous infusion of epinephrine.<sup>5</sup> Suggested, but unproved, mechanisms for decreased sweat production by anhidrotic horses includes diminished glandular sensitivity to epinephrine, failure of secretory function, blocking of sweat gland ducts, fatigue of the gland, and gland atrophy.

Sweating is the predominant means by which horses dissipate heat. Reduction in the capacity to produce sweat results in an inability to effectively control body temperature during exercise and when temperature and humidity are high. The elevation in body temperature results in tachypnea in an attempt to dissipate heat through the respiratory tract. Hyperthermia impairs performance and, if severe, can result in heat shock, a systemic inflammatory response syndrome, and death.

#### CLINICAL FINDINGS

The most apparent clinical sign is lack of sweating in response to an appropriate stimulus, such as exercise. In severely affected horses, sweating may be limited to the perineum, brisket, and areas under the mane and saddle. Less severely affected horses have a diminished sweat response and may not lather during exercise. The skin becomes dry and scurfy and loses its elasticity, and there may be alopecia, especially of the face.

Affected animals become extremely tachypneic when heat stressed, leading to the colloquial term for the disease 'dry puffer'. The animal's appetite declines and it loses weight. Athletic performance is severely compromised. High body temperatures are observed after exercise, sometimes reaching 41.5–42°C (107–108°F) and persist for long periods.

The **prognosis** is poor for athletic function for affected animals that remain in hot and humid environments, but the condition may resolve if the horse is moved to a cool climate.

#### CLINICAL PATHOLOGY

Plasma epinephrine concentrations are reported to be higher in affected horses than in unaffected horses,<sup>6</sup> but this has not been a consistent finding among studies.<sup>5</sup>

**Diagnostic confirmation** is achieved by demonstrating reduced sweating in response to **intradermal injection of epinephrine**, or the  $\beta$ -2 adrenergic agonists, terbutaline and salbutamol.<sup>7</sup> A

crude test involves the intradermal injection of 0.1 mL of a 1:1000 dilution of epinephrine. If the horse sweats then it is not considered to be completely anhidrotic. A **semiquantitative test** using epinephrine, terbutaline, or salbutamol may be useful in identifying partially anhidrotic horses.<sup>7</sup> Normal horses sweat when 0.1 mL of 1:1000 000 epinephrine is injected, while partially anhidrotic horses sweat only with higher concentrations (1:10 000 or 1:1000). Injections are usually made using small gauge needles (25 g) into the skin over the lateral aspects of the neck.

#### NECROPSY FINDINGS

There are no characteristic gross lesions at necropsy. Histologic examination of the skin of affected horses reveals abnormalities in sweat gland morphology including flattening of cells and loss of luminal microvilli and a reduction in the number of secretory vesicles. These findings are thought to be a consequence, rather than a cause, of the disease.

#### TREATMENT AND CONTROL

There is **no specific treatment** that restores the horse's ability to sweat, other than movement to a cooler climate. Affected horses for which translocation to a cooler environment is not feasible benefit from housing in air conditioned stables so that exposure to high ambient temperatures is minimized. Exercise of affected horses during the coolest periods of the day is sensible. Affected horses are frequently administered **electrolyte supplements**, but without demonstrated benefit. However, as with all working horses, an adequate intake of sodium, potassium, and chloride should be insured.

Administration of **thyroid hormone supplements** is not warranted, and may be dangerous by increasing the metabolic rate, and therefore heat production, of affected horses. **Vitamin E** administration has no demonstrated efficacy.

Removal of affected animals to cooler climates is often necessary, although air conditioning of stables and maintenance of horses in higher country where they can be returned after a day's racing may enable susceptible horses to be kept locally.

## BOVINE OCULAR SQUAMOUS-CELL CARCINOMA

Ocular squamous-cell carcinoma, often referred to as 'cancer eye', is one of the most common neoplasms of cattle.

### Synopsis

**Etiology** Genetic-environmental interaction. Lack of pigmentation around the eye and solar radiation.

**Epidemiology** One of most common neoplasms of cattle; mostly in beef cattle breeds (Herefords, Simmental) lacking pigment around the eye; animals over 5 years of age.

Solar radiation major risk factor.

**Signs** Precursor lesions, single or multiple plaques on eyelid or conjunctiva except the cornea or pigmented lid may regress, or lead to carcinomas of sclera resembling papillomas with crumbly, necrotic ulcerated mass attached to the eyelid causing irritation to eye and conjunctiva and excessive lacrimation and pus. Invasion of surrounding tissues of eye and possibly to nearby lymph nodes.

**Clinical pathology** Histology of lesion.

**Lesions** Squamous cell carcinoma.

**Diagnostic confirmation** Biopsy and histology.

### Differential diagnosis list

- Pinkeye
- Lymphoma of periorbital tissues.

**Treatment** Excision by cryosurgery. Radical surgery may be necessary. Immunotherapy with vaccines has been attempted.

**Control** Breeding program to increase degree of pigmentation in Hereford cattle.

## ETIOLOGY

A genetic-environmental interaction has been proposed as the cause. A relative **lack of circumocular and corneoscleral pigmentation**, both of which are heritable, increases the probability of lesion development when the animal is exposed to a carcinogenic agent like the **ultraviolet component of sunlight**. The carcinoma has been regarded as a papilloma-associated tumor because papilloma virus can be found in the precursor lesions, and papillomavirus DNA in the carcinomas. However, advanced virological techniques have failed to reveal any association between the virus and the tumor.<sup>1</sup>

The p53 gene product is highly expressed in bovine BOSCC, which provides support for its role in BOSCC tumorigenesis.<sup>2</sup>

## EPIDEMIOLOGY

### Occurrence

Bovine ocular squamous cell carcinoma is a common neoplasm of the eyelids and the eyeball of cattle and one of the most common neoplasms of cattle. The disease is most common in beef cattle which are

exposed to more sunlight than dairy cattle. The tumors are uncommon in cattle younger than 5 years and are hardly ever seen in cattle younger than 3 years. The condemnation rate of cattle with ocular squamous cell carcinoma in Canada is about 30% of cases.<sup>3</sup> A squamous cell carcinoma of the anal and perianal area of a 15-year-old bull has been recorded.<sup>4</sup>

### Risk factors

The heritabilities, phenotypic, and genetic correlations of lid and corneoscleral pigment and eye lesions associated with eye cancer were investigated in 2831 Herefords from 34 herds in 21 states of the US and one Canadian province. The results indicated that lid and corneoscleral pigment were heritable and genetically correlated.<sup>5</sup> These findings lead to the general conclusion that the genetic effect on pigment determines to a large extent the degree to which the eye is susceptible to some carcinogenic agent such as ultraviolet light.

In Zimbabwe, ocular squamous cell carcinoma was frequently observed in five breeding herds of Simmental cattle.<sup>6</sup> In these herds, initial signs of the disease were evident in cattle about 3 years of age and gradually the prevalence increased to over 50% in animals over 7 years of age.<sup>6</sup> It is suggested that because most cattle in Zimbabwe are slaughtered by 10 years of age, that more than 67% of cattle without periorbital skin pigmentation would develop the tumor. The tumors were multiple and commonly bilateral. Simmental cattle have a complete or partly white face and the lack of facial pigmentation risks exposure to intense solar radiation when they are kept at a high altitude (1500 m) in a sunny and warm climate. The prevalence was much lower in white-faced Friesian cattle in the same environment which suggests a genetic predisposition for the tumors in Simmental cattle. In Zimbabwe, the tumor is not recorded in fully-pigmented cattle breeds.

The association between ocular squamous cell tumors and various measures of solar radiation indicate a significant association between increasing risks of developing eye cancer and increasing levels of radiation.<sup>7</sup> Ultraviolet light is generally regarded as an important risk factor. Most tumors are located only in the sun-exposed mucocutaneous areas not protected by hair. Tumors are predominantly localized in the third eyelid and the lateral limbus, and tumor growth usually starts at the outer edge which receives the most sunlight. Cattle exposed to high levels of radiation develop the disease at younger ages.<sup>7</sup>

### Economic importance

The disease results in serious economic consequences through lessened productivity and carcass condemnations.

Commercial cattle can be culled early without much loss, because only the head is condemned. Purebred cattle are more of a problem because of the difficulty of deciding when euthanasia must be the humane decision, rather than another attempted extirpation of the eye.

## PATHOGENESIS

The initial lesion may be on the eyelid or any structure in the conjunctival sac, except the avascular cornea or pigmented eyelid. Lesions can encroach on these tissues from others nearby, carrying a blood supply with them.

The lesions develop through three stages. The first two, a plaque and then a papilloma, are non-malignant and have high regression rates. The third stage is the squamous cell carcinoma which does not regress. The tumor is located in the sclera adjacent to the lateral limbus, in the membrana nictitans (third eyelid), or in the lower eyelid. It is an invasive tumor, metastasizing along the draining lymphatics into cervical lymph nodes. Primary lesions of the lids are most likely to metastasize to these nodes.

Animals do not appear to develop resistance to the cancer; only a few cows with the disease develop measurable antibodies in their sera. It is one of the characteristics of this disease that the carcinomas appear to produce immunosuppressive substances, and removal of tumor mass reduces blood levels of them.

In countries and in herds where ocular carcinoma is common, it is not unusual to encounter lesions on the labia of the vulva especially if there are patches of unpigmented skin.<sup>8</sup>

## CLINICAL FINDINGS

**Typical precursor lesions** are single or multiple plaques of gray-white, smooth or rough, hyperplastic to hyperkeratinized tissue anywhere in the conjunctiva.

**Plaques** may develop into papillomas and acanthomas of the skin of the eyelids, also included as precursor lesions. Squamous-cell carcinomas may develop from any of these precursors which may also regress spontaneously. The proportion that regresses is of the order of 80%.

**Classic BOSCC lesions** resemble papillomas with a fleshy, sometimes crumbly, often necrotic and ulcerated mass attached to the lid or the orbit by a wide base. They are visible even when the eyelids are closed, and cause obvious irritation to the surrounding conjunctiva, resulting in increased lacrimation and sometimes in the discharge of pus. Invasion of surrounding tissues is common but metastases to nearby lymph nodes and to viscera occur in only a few cases and then only late in the course of the disease.

## CLINICAL PATHOLOGY

Differentiation between carcinomas and precursor lesions is difficult clinically and cytological examination or biopsy is recommended for definitive diagnoses. The cytology of squamous cell carcinomas in domestic animals has been described.<sup>9</sup>

## DIFFERENTIAL DIAGNOSIS

One of the difficulties encountered in the field is the clinical differentiation of benign precursor lesions from the malignant carcinomas; failure to do so may account for the high rates of spontaneous regression recorded, especially in Hereford cattle, where a spontaneous recovery rate of 88% is recorded. To avoid this inaccuracy, exfoliative cytology by the examination of smears of lesions is helpful. Combined with a clinical assessment this is the recommended method of confirming the diagnosis. Differentiation from similar lesions that are not BOSCC can only be achieved by proper laboratory examination of tissues.

BOSCC must be differentiated clinically from:

- Pink eye and its complications which results in excessive lacrimation and purulent material, and
- Lymphoma of the periorbital tissues which usually manifests as exophthalmos.

## TREATMENT

Excision, sometimes by cryosurgery, is widely practiced in cattle. Results are good and treatment by the use of radioactive implants has also aroused favorable comment. Recurrence, or the development of new lesions at the same site, is a common sequel. Radical surgery, including removal of the local lymph nodes and parts of the salivary gland, may be desirable in some bovine cases. It is often combined with immunotherapy, e.g. with BCG vaccine injected systemically or into the lesion, or with vaccination with BOSCC tumor material. That there is a significant immune body response at the normal tissue-corneal interface has been demonstrated, but whether this plays any part in the rejection of the tumors is not known. One controlled trial in cattle showed that intralesional injection of BCG vaccine can interrupt neoplastic progression and prevent malignant disease. A permanent regression after BCG vaccination can be expected in 37% of cases, recurrence at the same site in 26%, and continued growth in 37%.<sup>10</sup>

A favorable response to a single injection of a saline phenol extract of fresh tumor tissue can induce a high rate of regression of ocular tumors with a higher recovery rate after the use of 200 mg of lyophilized tumor extract as compared with an injection of 100 mg. The injection may need to be repeated. Occasional tumors show

enhancement of growth after vaccination, especially if it is repeated. The vaccine does not need to be autologous, and only one injection is required. A freeze-dried preparation of tumor antigen has been used successfully. In general, the use of a vaccine seems likely to provide a satisfactory method for controlling an esthetically distressing and financially important disease. Reports on the effect of vaccination with a tumor vaccine on the vulvar form of squamous-cell carcinoma vary.<sup>11</sup>

Other treatments which have received favorable comment, but need to be evaluated in the light of the known natural recovery rate of the benign precursor lesions, include electrothermal hyperthermia and combinations of the above procedures.

## CONTROL

Because of the strong correlation between absence of pigmentation of the eyelids and the occurrence of the disease, and because of the high heritability of this pigmentation in Hereford cattle, it is suggested that a breeding program aimed at increasing the degree of pigmentation of eyelids could quickly reduce the incidence of the disease in this breed.<sup>5</sup> A positive approach to the problem would be to crossbreed susceptible *Bos taurus* cattle with *Bos indicus* cattle which always have pigmented eyelids and have much less eye cancer. In Ayrshires there is a corresponding predilection for squamous-cell carcinomata of the vulva, but the neoplasm does not occur on both sites in the one cow. Selection on the basis of the occurrence of lesions alone results in only limited reduction in incidence.

## EQUINE OCULAR SQUAMOUS-CELL CARCINOMA

Squamous cell carcinoma is one of the most common neoplasms of the horse and is the most common tumor of the eye and orbit but the rate of occurrence is low. The reported frequency has been highest in animals lacking periocular pigmen-

tation and is more common in Appaloosa, albino, and color dilute horses. An increased prevalence for ocular and adnexal SCC has been reported in draft horse breeds, Appaloosas, Paint Horses, Thoroughbreds, and Quarter Horses. A predisposition for the development of ocular and adnexal SCC has also been reported in geldings.<sup>1</sup> The risk has been higher in draft breeds than in other pigmented breeds, probably related to the large expanses of white skin on the face and around the eye of the heavy draft breeds. The overall mean age range of affected animals is 8-10 years.<sup>2</sup> In a series of limbal neoplasms in horses admitted to the Veterinary Teaching Hospital in the Netherlands, squamous cell carcinoma was the most predominant tumor type and Haflinger horses accounted for 69% whereas their occurrence in the hospital population was 5%.<sup>3</sup>

In a retrospective study of 50 cases submitted to the University of Florida Veterinary Medical Teaching Hospital, the Appaloosa accounted for the majority of cases<sup>4</sup> which may be a reflection of the high level of solar radiation in southeastern US. The average age at which the tumor was diagnosed initially was 11.8 years; males accounted for 64% and females 36% of the cases. The rate of metastasis was 18%.

In the Florida study, higher cure rates were associated with surgical excision followed by radiation therapy for a cure rate of 75%; whereas with only surgical excision the cure rate was 55%.<sup>4</sup> Best results with treatment are seen when surgical intervention is early.<sup>5</sup> In horses, treatment is largely surgical but all of the immunological techniques developed for cattle have been used including local irradiation therapy with <sup>90</sup>Sr or <sup>222</sup>Rn.<sup>2</sup>

The most frequent site for ocular involvement is the nictitating membrane and conjunctiva but the eyelids and cornea are also involved. A case of limbal squamous cell carcinoma with invasion into the cornea and uvea of 12-year-old Haflinger gelding has been described.<sup>6</sup> On initial presentation, a light-pink raised mass on the temporal limbus and conjunctiva of one eye was observed. Squamous cell carcinoma was confirmed histologically after keratectomy and cryotherapy. Seven months later, a smooth pink, progressively enlarging mass was observed within the cornea. Ultrasonographically, the mass was found infiltrating the corneal stroma and the anterior chamber. The globe was surgically removed. Histologically, a diagnosis of corneal ocular squamous cell carcinoma with deep stromal invasion, infiltration of the uveoscleral meshwork and iridocorneal angle and resulting intraocular extension was made.

A pigmented squamous cell carcinoma of the conjunctiva of a 17-year-old horse has been described.<sup>7</sup>

Treatment of ocular and adnexal SCC has included various types of therapy, with and without adjuvant radiation therapy. Types of treatment without adjuvant radiation therapy include excision, cryotherapy, radiofrequency hyperthermia, immunotherapy, chemotherapy with cisplatin, and carbon dioxide laser ablation. Treatment with adjuvant radiation therapy includes use of strontium 90 (<sup>90</sup>Sr) cobalt 60 (<sup>60</sup>Co), gold 198, iridium 192 (<sup>192</sup>Ir), cesium 137, iodine 125 (<sup>125</sup>I), and radon 222 (<sup>222</sup>Rn).<sup>1</sup> In a series of 157 cases of ocular and adnexal squamous cell carcinoma, those treated with adjuvant radiation therapy had a significantly lower recurrence rate, compared with those treated without adjuvant radiation therapy, independent of anatomic location.<sup>1</sup>

Superficial keratectomy followed by cryosurgery is a simple and effective procedure for the treatment of small-sized limbal tumors (less than 2 cm) in horses.<sup>3</sup> Sophisticated equipment is not required and the legal restrictions associated with the use of radioactive substances in many countries are not a consideration.

Ocular pseudotumors have been described in horses. They are proliferative inflammatory lesions involving the eye, adnexa or orbit, which clinically mimics true neoplasms.<sup>8</sup> Cases are characterized by a unioocular, pink proliferative limbal or perilimbal lesion. Affected horses may be from 5 to 9 years of age. Most cases occurred during the summer months and none of the affected animals had a history of trauma or recent deworming. The dorsal bulbar conjunctiva was most commonly affected, followed by the third eyelid. Lesions were relatively flat with indistinct margins or discrete and nodular. Histologically, the lesion is inflammatory characterized by predominantly lymphocytic infiltrates. The cause is unknown but an immune-mediated pathogenesis is suspected based on the preponderance of immunocytes consisting primarily of lymphocytes. Treatment consists of surgical excision alone, partial resection with anti-inflammatory therapy, or anti-inflammatory therapy alone.<sup>8</sup>

## OCULAR SQUAMOUS CELL CARCINOMA IN GOATS

A well-differentiated ocular squamous cell carcinoma has been described in twin goats.<sup>1</sup> The twin goats, one male and one female, were 3 years of age. Both animals had pigmented eyelids and had been reared at an altitude of 760 m above sea level in Italy. The lesions were very advanced when first examined. There was a history of bilateral ocular disease and impaired vision of 24 months duration. In the affected eyes, a firm mass with a fleshy appearance was evident, covering the entire cornea and protruding through the palpebral fissure. A bilateral ocular mucopurulent discharge, associated with corneal plaques, neovascularization and edema, was also present in both animals.

Histologically, cords and islands of squamous epithelial cells proliferated deeply throughout the cornea and invaded the basal layer, limbus, iris, and ciliary body, and other features, characteristic of a well-differentiated ocular squamous cell carcinoma.

Biomolecular studies to the identification of *Papillomavirus*-related DNA sequences within the neoplastic ocular parenchyma of both animals but immunohistochemical and ultrastructural examinations did not demonstrate viral particles.

## 'COCKLE'

This is a superficial nodular dermatitis of sheep recorded only in New Zealand that results in nodules in the skin that are of economic importance to the leather industry. The presence of cockle downgrades the value of the pelt.

Cockle is not usually diagnosed clinically but examination by close inspection of the skin over the upper shoulder region after close shearing has high specificity for detection.<sup>1</sup> The lesions are the result of an immune response in some sheep to infestation with the biting louse *Bovicola ovis*. The occurrence of cockle and its severity is positively correlated with the severity of the louse infestation<sup>2</sup> and sheep that develop lesions have *B. ovis*-specific homocytotrophic antibody. Serum histamine concentrations are significantly higher in louse-infested lambs than louse-naive lambs.<sup>3</sup>

Lesions commence on the neck and shoulders and may extend over the entire pelt. Widely distributed lesions, 'scatter cockle', are attributed to infestation with *B. ovis*, and this is the most common cause

but 'rib cockle' may be a hypersensitivity to infestation with the sheep ked *Melophagus ovinus*. Pelt lesions in the dorsal midline region are usually due to infection with *Dermatophilus congolensis*.<sup>1</sup>

## CONTROL

This rests with the control of *B. ovis*. For cockle control sheep should be treated off-shears with pour-on or spray-on insecticide and, as soon as practical after shearing, treated by saturation dipping. Saturation dipping is required to significantly reduce louse populations.<sup>4</sup> Prelambing dipping is also recommended to reduce the risk of lambs acquiring louse infestations.

## WOOLSLIP, WOOL LOSS

Woolslip is a condition in which housed ewes, shorn in winter, lose part of their fleece and develop bald patches over a large area of the **rear half of the back**.<sup>1</sup> This commonly starts at the base of the tail and progresses to the rump and back and less commonly the neck. There is no systemic disease; the skin is normal. Histological examination of skin biopsies show that in affected sheep the wool follicles are in the active anagen stage rather than the inactive telogen phase of unaffected cohort sheep and the wool regrows immediately following loss.<sup>1</sup> The loss of wool **starts 2-3 weeks after shearing**. All breeds are equally susceptible and there is no effect of age or whether the sheep are carrying single or twin lambs; up to 40% of a flock may be affected. The wool loss occurs because of a premature and synchronized shedding of wool fibers and not because of a pathological process which damages the wool fiber. Wool shedding can be induced experimentally by prolonged treatments with corticosteroids and the current explanation for the wool shedding that occurs with the woolslip syndrome is that blood corticosteroid levels rise after the stress of shearing and are maintained for a long period because of the trauma of being housed and shorn and kept in the cold. Blood zinc concentrations in woolslip affected sheep are within the normal range and there is no epidermal change as occurs in zinc deficiency.

The **prevention** of the condition is aimed at reducing the severity and length of the stress period by shearing the sheep at the time of entry to winter housing and insuring a good nutritional plane in the post-shearing period.<sup>1</sup> This hypothesis as to cause may not be correct as the syndrome has also been seen in the

summer in Wiltshire shorn sheep which had little history of stress in the period immediately preceding the woolslip.<sup>2</sup>

Woolslip should not be confused with the normal shedding of wool that occurs in breeds such as the Wiltshire or Shetland in the spring period. Loss of wool along the backline also occurs in older longwool sheep and may be exacerbated by lambs playing or sleeping on the ewe.<sup>3</sup>

**Impairment of wool growth** and a **thinning of fiber diameter** can occur during the course of any **severe disease** such as bluetongue, pregnancy toxemia, or foot rot temporarily affecting the growth of the fleece. This results in a segment of the wool fiber that has decreased tensile strength and the condition has the name **tender wool**. Following recovery from the inciting disease the wool growth is normal but there is a line of wool with poor tensile strength in the staple. This can be observed in the intact fleece as a line of decreased fibre diameter, often with a change in crimp character and discoloration due to entrapment of dust. The wool may break if the staple on either side of this break is sharply snapped between the fingers. The fleece may subsequently be shed in part or in whole at the level of the defect, a condition known as **wool break**. Tender wool downgrades the value of a fleece and has economic significance in wool-producing sheep.

Zinc deficiency can reduce keratinization, reduce wool growth and occasionally result in fleece loss in sheep.<sup>4,5</sup> Wool loss associated with pruritus occurs in association with external parasite infestations (Ch. 27) and with scrapie and pseudorabies in ruminants.

**Pelodora dermatitis**, characterized by thickening of the skin and complete wool loss in affected skin areas is recorded in winter-housed sheep where there was poor bedding management. The condition affected the majority of the ewes at risk. The parasite, *Peladora (Rhabditis) strongyloides* is a free living nematode commonly present in decaying organic material but can invade hair follicles to produce an inflammatory response. Histological examination of the skin showed the presence of the parasite in wool follicles and infiltration of eosinophils and mast cells in connective tissue. Affected skin areas were those that had contact with the bedding when the sheep were lying down and large numbers of the nematode were found in the bedding. Clinical signs regressed with the more frequent provision of new bedding and disinfection of the stable.<sup>6</sup>

### WOOL EATING

Wool eating can occur as a result pica associated with micronutrient deficiency. A condition called **shimao zheng**, occur-

ring in a region of the Gansu province of China has wool eating as its primary manifestation. The disease has a seasonal occurrence with the peak incidence in January through April. Both goats and sheep are affected but the incidence and severity is much higher in goats where 90% may show signs. Affected animals bite the wool or hair off their own or other animals bodies particularly in the hip, belly, and shoulder areas. Histology on biopsies shows heavily keratinized epithelial cells, a decreased number of hair and aggregated foci of lymphocytes in the dermis. Controlled trials have shown the condition can be corrected by supplementation with sulphur, copper, and iron.<sup>7,8</sup> Wool eating is also recorded in Israel possibly associated with trace element copper and zinc deficiency.<sup>9</sup> Wool and hair loss in individual sheep and cattle in association with excessive licking is recorded and are postulated as psychogenic dermatoses.<sup>10</sup>

## Appendix 2

### REFERENCE LABORATORY VALUES

Reference values for some frequently measured variables in blood and serum are provided as a guide. Values of these variables from healthy animals vary depending on many factors including age, breed, sex, diet, geographical habitat and methods of sample collection and laboratory measurement. The values listed below are compiled from a variety of sources including the clinical laboratories of the Western College of Veterinary Medicine at the University of Saskatchewan, the College of Veterinary Medicine at The Ohio State University, and Kaneko JJ. *Clinical biochemistry of domestic animals*, 5th edn. New York: Academic Press, 1997.

Tables of reference values for newborn foals and calves are provided elsewhere.

#### HEMATOLOGY

## Appendix 3

### DRUG DOSES AND INTERVALS FOR HORSES AND RUMINANTS

Suggested drug doses and intervals for horses and ruminants. Dosages listed are general recommendations and might not be optimal or efficacious in all instances and might need to be adjusted depending on the disease, its severity, patient factors including but not limited to age or diet, and because of regulatory considerations regarding milk and meat withholding times in animals intended as human food. Manufacturer's recommendations should be checked before administering any drug and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that could be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, iu = international units). Drugs given as total doses, such as intramammary preparations, are denoted by TD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), intrarticular (IA), intramammary (IMM), intraperitoneal (IP), inhalation (IH), per rectum (PR), topically (TO), or subconjunctivally (IO). Drugs recommended not to be given to certain species are indicated by NR.

Drug	Horses			Ruminants (cattle, sheep, goats)		
	Dose (mg/kg)	Interval (h)	Route	Dose (mg/kg)	Interval (h)	Route
Acepromazine maleate	0.04–0.1	SD	IM, IV, SC	0.03–0.1	SD	IM, IV, SC
Acetazolamide	2.2	6–12	PO			
Acetic acid				10–20	SD	PO
Acetylcysteine	8 g, TD (for retained meconium)	SD	PR			
	140	24	PO			
Acetylsalicylic acid (aspirin)	10–20	48	PO	50–100	12	PO
Acyclovir	10	12	IV as 1 h infusion			
Adrenaline <i>see</i> Epinephrine						
Albendazole	25–50	SD–12	PO	10–15	PO	SD
Albuterol	0.001–0.008	4–8	IH			
Alcuronium chloride	0.05	SD	IV			
Altranogest	0.044	24	PO			
Aluminum hydroxide	60	6–8	PO	15–60	SD, 8–24	PO
Amantadine hydrochloride	5	4	IV			
Amikacin sulfate	22	24	IM, IV	7.0 22	8 24	IM, IV
Aminocaproic acid	20	SD	IV			
Amiodarone	Intravenous infusion of 5 mg/kg/h for 1 h, then 0.8 mg/kg/h for 23 h, then 1.9 mg/kg/h. For atrial fibrillation					
Aminophylline	5–12	8–12	PO			
Aminopropazine fumarate	0.5	SD	IM, IV			
Amitraz	NR			Goats. 11 mL of 19.9% solution diluted in 7 liters		Topical
Ammonium chloride	20–520 6	24 6	PO PO	50–200	12–24	PO

## Appendix 4

### DRUG DOSES AND INTERVALS FOR PIGS

Suggested drug doses and intervals for pigs, and concentrations of medicaments in feed. Dosages listed are general recommendations and may not be optimal or efficacious in all instances and may need to be adjusted depending on the disease, its severity, patient factors such as age or diet, and because of regulatory considerations regarding milk and meat withholding times in food animals. Manufacturer's recommendations should be checked before administering any drug and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that may be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, iu = international units). Drugs given as total doses are denoted by TD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), or intraperitoneal (IP). One ton = 1016 kg.

<i>Drug</i>	<i>Pigs Dose (mg/kg) or (Concentration in feed or water)</i>	<i>Interval (h)</i>	<i>Route</i>
Acepromazine maleate	0.03–0.5	SD	IM, IV, SC
Acetazolamide	6–8	SD	IV, IM, PO
Acetylsalicylic acid (aspirin)	10	4	PO
Albendazole	5–10	SD	PO
Amoxicillin trihydrate	6.6–22	8–24	IM
	6.6–22	12–24	PO
Ampicillin sodium	6–8	8	IM, SC
Ampicillin trihydrate	4.4–22	8–24	IM
Amprolium hydrochloride	25–65	12–24	PO
Apramycin sulfate	10–20 (150 g/ton)	24	PO
Arsanilate, sodium	(700 mg per 4 L drinking water for 7 days)		
Aspirin	<i>see</i> Acetylsalicylic acid		
Atropine sulfate	0.02–0.04	SD	IM
Azaperone	1–2	SD	IM
Bacitracin zinc	(10–50 g/ton)		
Bacitracin methylene disalicylate	(250 g/ton)		
Baquiloprim/sulfadimidine	10	24	IM
Bismuth subsalicylate	2–5 mL, TD (piglets) (900)	6–12	PO
Bromhexine hydrochloride	0.2–0.5	24	IM, PO
Calcium gluconate	150–250	SD	IV, IM, SC, IP
Carbadox	(50 g/ton)		
Ceftiofur sodium	3–5	24	IM
Ceftiofur hydrochloride	3–5	24–158	IM
Chloramphenicol palmitate	NR		
Chloramphenicol sodium succinate	NR		
Chlorpromazine hydrochloride	0.6–3.3	SD	IV, IM
Chlortetracycline	10–20 (50–100 g/ton)	24	PO
Cimetidine hydrochloride	300, TD	12	PO
Cloprostenol sodium	0.18, TD	SD	IM
Dantrolene sodium	3.5	SD	IV
Dexamethasone	0.06 (1–10, TD)	SD, 24	IM
Dexamethasone sodium phosphate			
<i>see</i> Dexamethasone			
Dexamethasone 21-isonicotinate	0.02–0.1	SD, 96	IM
Diazepam	0.55–5.5	SD	IM
Dichlorvos	17 (334–500 g/ton)	SD	PO

<i>Drug</i>	<b>Pigs</b>		
	<i>Dose (mg/kg) or Concentration in feed</i>	<i>Interval (h)</i>	<i>Route</i>
Dimetridazole	10–25	24	PO
Dinoprost tromethamine	15 TD then 10 TD (estrus induction)	separate doses by 12 hours	IM
	5–10 TD (abortifacient)	SD	IM
	10–25 TD (induce parturition)	SD	IM
Diprenorphine	0.03	SD	IV
Dipyron	50	SD	IM, IV, SC
Doxapram hydrochloride	5–10	SD	IV
Doxylamine succinate	0.5	8	PO, IM, SC
Edrophonium chloride	0.5–1.0	SD	IV
Enrofloxacin	2.5	SD	IM
Epinephrine (1:1000)	0.01–0.02 mL	SD	IM, SC
(1:10 000)	0.1–0.2	SD	IV
Erythromycin estolate, ethylsuccinate	2.2–22	24	IM
Fenbendazole	5	SD	PO
	3	24	PO
	(10–80 g/ton)		
Ferrous sulfate	0.5–2	24	PO
Flunixin meglumine	1.1–2.2	8–12	IV, IM, SC
Follicle stimulating hormone	1000–1500 iu TD	SD	IM
Furazolidone	5–20 (piglets)	24	PO
Gallamine triethiodide	4 then 0.8 to effect	SD	IV
Gentamicin sulfate	2.2	24	PO, IM
	5.0	SD	PO, IM
Griseofulvin	20	24	PO
Guaifenesin	44–88	SD	IV
Hygromycin B	(12 g/ton)		
Iron dextran	100–200, TD (piglet)	SD	IM
Ivermectin	0.3	SD	IM / PO
	1.8–11.8 g/ton		
Kaolin pectate	0.2 mL	4	PO
Ketamine hydrochloride (after appropriate premedication)	11	SD	IM
Levamisole	8	SD	PO
	0.8 g/kg		
Lincomycin hydrochloride	11	24	IM
	2–10	24	PO
	(40–200 g/ton)		
Luprostiol	7.5 TD	SD	IM
Mannitol	1–3	SD	IV
Marbofloxacin	2	24	IM, IV, SC
Mineral oil	2–8	SD	PO
Morphine sulfate	0.2–0.9	SD	IM
Moxidectin	0.4	SD	SC, PO
Neomycin sulfate	7–12	12	PO
Neostigmine	0.06	SD	IM
Oxibendazole	15	SD	PO
Oxfendazole	3–4.5	SD	PO
Oxymorphone	0.075 (with ketamine and xylazine)	SD	IV
Oxytetracycline	2–10 / 10–30	12–24 / 12–24	IM, SC / PO
Oxytocin	0.1–0.2 (agalactia) (2–10 iu)	3–4	IM

<b>Pigs</b>			
<i>Drug</i>	<i>Dose (mg/kg) or Concentration in feed</i>	<i>Interval (h)</i>	<i>Route</i>
Pancuronium	0.11	SD	IV
Penicillin G, benzathine	4.5 (11 000–22 000 iu)	48–96	IM
Penicillin G, procaine	6–20 (6000–40 000 iu)	12–24	IM
Pentazocine	2.0	SD	IM
Pentobarbital	30 (to effect)	SD	IV
	120–200 FOR EUTHANASIA	SD	IV
Pentobarbitone <i>see</i> pentobarbital			
Phenylbutazone	4	24	PO, IV
Phytomenadione (vitamin K1)	0.5–2.5	SD	IM, IV (slow)
Piperazine	110	SD	PO
Prednisolone sodium succinate	0.2–1.0	SD, 24	IV, IM
Pyrantel pamoate	22	SD	PO
	6.6 (pot bellied pigs)	SD	PO
Pyrantel tartrate	22	SD	PO
	(96 g/ton)		
Pyrilamine maleate	0.5–1.0	SD	IM
Roxarsone	182 g/ton		
Sodium arsanilate <i>see</i> arsanilate, sodium			
Sodium chloride (hypertonic, 7.0%)	4 mL	SD	IV
Sodium sulfate	0.25–0.5	SD	PO
Spectinomycin HCl	10	12–24	PO
	6.6–22	24	IM
Streptomycin	13	12–24	IM
Sulfachlorpyridazine	44–70	24	PO
Sulfadiazine/trimethoprim	48	24	PO
Sulfadoxine/trimethoprim	15	12–24	IM
Sulfonamide/trimethoprim	15–30	24	IM, PO
Suxamethonium chloride	2	SD	IV
Tetracycline hydrochloride	10–40	12/24	PO
Thiabendazole	50–75	SD	PO
Thiamine hydrochloride (vitamin B1)	5–100	SD	IV, IM, PO
Thiamylal sodium	6.6–11	SD	IV
Tiaprost	0.3–0.6 TD	SD	IM
Thiopental	5.5–11	SD	IV
Tiamulin	2–10 / 10–15 (35–200 g/ton)	24 / 24	PO / IM
Tilmicosin	10–20	24	PO
	(180–360 g/ton)		
Tripelenamine hydrochloride	1	8–12	IV, IM
Tubocurarine chloride	0.4 then 0.08	SD, to effect	IV
Tylosin	5–10 / 2–5	24 / 24	IM / PO
	(40–100 g/ton)		
Valnemulin	1.25–10	24 / 24	PO
Virginiamycin	(25–100 g/ton)
