The MHC-II molecule consists of two chains embedded in the membrane as type I proteins, an α chain and a β chain. The α and β chains both consist of two major extracellular domains, $\alpha 1$ and $\alpha 2$, and $\beta 1$ and $\beta 2$, respectively, each linked to a transmembrane domain and cytoplasmic sequences. An initial analysis of both MHC-I and MHC-II molecules suggests that they are noncovalently assembled heterodimers consisting of four extracellular domains, the two membrane proximal domains (α 3 and β 2m for MHC-I and $\alpha 2$ and $\beta 2$ for MHC-II) of each molecule are Ig-like, while the two amino terminal domains (α 1 and α 2 of MHC-I and $\alpha 1$ and $\beta 1$ of MHC-II) possess what is known as the MHC-fold. The α 1 domains of both MHC-I and MHC-II lack the intradomain disulfide bond characteristic of the other extracellular domains. The cytoplasmic domain of MHC-I molecules can be regulated by splicing and differential phosphorylation or other modification, and is likely to play a role in cell surface stability and cycling between the cell surface and other intracellular compartments.^{366–372} However, analysis of directed mutants of MHC-I in some systems indicates that the cytoplasmic domain is not required for cytoskeletal association or surface recycling.³⁷³ (The cytoplasmic domain of MHC-I molecules is the target for the Nef protein of HIV, and the Nef/MHC interaction results in MHC-I downregulation in HIV-infected cells.^{374,375} The MHC-II transmembrane and cytoplasmic domains have clear effects on the level of cell surface expression, the efficiency of antigen presentation, and the rate of lateral diffusion of the molecules in the cell membrane.^{376,377} Single particle tracking of MHC-II molecules indicates that such lateral diffusion is governed, at least in part, by interaction with the actin-based membrane skeleton.378 Amino acid sequence alignments of MHC-I and MHC-II proteins, particularly of the human molecules, are available in a number of databases such as www.ebi.ac.uk/imgt/hla/ and http://www .ebi.ac.uk/ipd/mhc/.

Identification of Peptides Bound by MHC Molecules

Although initial understanding of MHC molecules indicated that they are heterodimers, a complete understanding of their structure and resulting function requires the appreciation that they are, in fact, heterotrimers, in which the third component is a short peptide ranging from eight to roughly 15 amino acids in length. This characteristic of mature MHC-I and MHC-II molecules makes them a unique class of protein molecules because an integral part of their peptide composition and resulting structure derive from a heterogeneous array of peptides delivered to the assembling molecules during their maturation. Many different lines of evidence coalesced over a short period of time to demonstrate that MHC molecules function by binding peptides. From functional experiments, MHC-II-restricted T-cell responses to protein antigens were shown to be dependent on peptide fragments.³⁷⁹ The first direct evidence of MHC/peptide interactions was that purified MHC-II proteins could

bind synthetic peptides in a specific, saturable, and stable manner^{380,381} with measurable affinity and a remarkably slow dissociation rate.³⁸¹ For MHC-I molecules, the results were at first less clear, but the realization that some cell lines defective in MHC-I surface expression could be induced to express higher levels of surface MHC-I molecules by exposure to the appropriate peptides³⁸² led the way for direct measurement of MHC-I peptide binding.³⁸³

Several laboratories succeeded in developing methods for the partial purification and identification of the peptides that copurified with MHC molecules. A viral, antigenic peptide was identified bound to the MHC-I molecule H2-K^b by recovering MHC molecules from virus infected cells, fractionating the bound peptides chromatographically, identifying a peak of functional biologic activity in a cytotoxic T-cell assay, and determining the amino acid sequence of the recovered peptide by radiochemical techniques.³⁸⁴ Another method that was applied to the identification of both virusderived peptides as well as the "motif" of self-peptides by particular MHC-I molecules involved first the isolation of a large amount of detergent solubilized MHC-I using appropriate antibodies, the elution of the bound peptides, their partial purification as pools by reverse phase high pressure liquid chromatography, and the determination of the amino acid sequence of the bound peptides by classic amino terminal sequencing.^{385–387} The unpredicted and surprising result obtained from these studies of MHC-I-derived peptides was that specific amino acid residues were favored at particular positions of the sequence, depending on the MHC-I molecule from which the peptides were obtained, and that the length of the bound peptides was well defined and short, ranging from 8 to 10 amino acids. From such experiments, a number of peptide "motifs" of peptides bound to particular MHC-I molecules and allelic products were identified. Often, specific amino acids were identified at particular Edman degradation steps, indicating a common, highly preferred residue at the same spacing from the amino terminus of the peptide. Thus, the peptide "motif" could be determined even from heterogeneous pools of peptides eluted from particular MHC-I molecules. Further refinements in methodology have included the application of mass spectrometry to the identification and sequencing of individual peptides.388,389 Alternative approaches for identifying peptide motifs include the use of soluble analogs of MHC-I molecules to ease the purification^{390, 391} or the use of peptide display libraries to identify those peptides that can bind the MHC.^{392,393} With steady improvements in technology, including the use of transfected soluble versions of MHC-I molecules, immunoaffinity purification of the MHC-I molecules of interest, tandem reverse phase high pressure liquid chromatography and further identification and sequencing by tandem mass spectrometry, particularly MHC-I motifs, as well as tumor antigen peptides, may now be identified routinely.³⁹⁴ A summary of MHC-I peptide motifs is given in Table 21.9. Regularly maintained online databases of MHC-I peptide motifs may be found at several sites (www.imtech.res.in/raghava/ mhcbn/links.html and www.syfpeithi.de).³⁹⁵ Antigenic peptides that represent those observed as tumor antigens

Motif refers to those amino acid residues that are MHC-restricted peptide and "anchor" residues is an imporhtm. In addition, the immune epitope database (www.im-

The identification of MHC-II–bound self-peptide-or antigenic peptides by biochemical methods similar to those employed for MHC-I molecules has been proved more difficult because the MHC-II molecules do not have the rigorous requirements for a defined amino terminus or restricted length. Whereas MHC-I molecules bind peptides with a particular motif residue at a specific position as defined by the amino terminus, resulting in the ability to identify the dominant residue at a particular step in the Edman degradation even amidst a pool of peptides, MHC-II molecules bind peptides with "ragged ends," and little information is obtained from the standard methods of sequencing of pools of peptides.³⁹⁸⁻⁴⁰¹ Thus, more precise fractionation of the

antigenic peptides from new proteins. The site www.imtech summary of identified peptide-binding motifs for MHC-II gest that a pocket at P7 [i + 6] may also contribute to the general conclusion is that MHC-II molecules all have bindthose peptides bound by particular MHC-II molecules, the sis of MHC-II binding peptides is not straightforward and peptides that may bind to particular MHC-II molecules.⁴⁰⁷ elaborate schemes have been devised for predicting those degeneracy of peptide motifs for MHC-II molecules, more energy of binding.) Because of the complexity and potential spaced at position P1, P4, P6, and P9 (or i, i + 3, i + 5, i + 9). some alleles, such as HLA-DR1 and IA^d, these pockets are ing pockets identifiable for the particular allelic product. bound to MHC molecules bind with the amino terminus at the lefthand side of the peptide-binding groove, in the canonical structural representation that will be described in further detail subsequently. However, a recent analysis employing both x-ray crystallography and nuclear magnetic resonance indicates that the CLIP peptide may undergo orientational inversion, binding dynamically in the carboxyl to amino as well as the amino to carboxyl direction.⁴⁰⁸

High-Resolution Structures

MHC-I Molecules

A most graphic description of the relationship of form to function of the MHC molecules was made by Bjorkman et al.409,410 who determined the three-dimensional structure of the human MHC-I molecule, HLA-A*02:01, by x-ray crystallography. For these studies, the extracellular, soluble portion of the type I membrane-associated molecule was purified by papain cleavage from the surface of tissue culture cells. At the time, there was not a clear appreciation of the role of peptide either in the assembly of the molecule or of the nature of the recognition of the MHC molecule by TCRs or, for that matter, NK receptors. Despite the fact that the first purified HLA-A2 molecules possessed a heterogeneous mixture of bound peptides, protein from these preparations crystallized readily, and electron density maps calculated from the diffraction data were interpretable, allowing modelling of the backbone molecular structure. The most important insight in the interpretation of the derived electron density map was that part of the electron density, and thus part of the structure, was due to this mixture of peptides bound tightly by the molecule, and that this density could not be modeled based on the known amino acid sequence of HLA-A2.

This first MHC-I structure clarified several important aspects of the mechanism by which the MHC-I molecule carries out its peptide binding function. The amino terminal domains ($\alpha 1$ and $\alpha 2$) form a unitary binding site for peptide. This domain unit (also called a "superdomain") consists of a floor of eight strands of antiparallel β -pleated sheet that supports two α -helices, one contributed from the α 1 domain and one from the $\alpha 2$ domain, aligned in an antiparallel orientation. The membrane proximal α 3 domain has an Ig C-type fold and pairs asymmetrically with the other Ig domain of the molecule contributed by $\beta 2m$. The nature of recognition by T-cells was suggested by comparing the location of those amino acid residues that had been characterized as being strong elements in T-cell recognition, residues that distinguished closely related allelic gene products, and amino acid residues that had been identified as those that were responsible for the transplant rejection of the mutants of the H2-K^b series.⁴⁰⁹ Amino acid residues of the MHC-I molecule responsible for T-cell recognition were clearly classified into one of two categories or an overlapping set: those residues that were "on the top of the molecule," exposed to solvent and available for direct interaction with the TCR, and those residues whose side chains pointed into the peptide binding groove and might be considered crucial in the peptide-binding specificity of the particular MHC molecule. The original publications, based on a structure determined to a resolution of 3.5 Å, focused mainly on the general structural outline of the molecule. More recently, structures of a wide variety of MHC-I molecules of different species including human, mouse, rat, and chicken, complexed with specific peptides, have been determined. Ribbon diagrams of HLA-A2 as seen from the side (Fig. 21.6A) and from the top (Fig. 21.6B), complexed with a unique synthetic peptide, indicate the design of the entire molecule: the peptide-binding site is supported by the β -sheet floor, and the floor in turn is supported by the two Ig-like domains, the α 3 domain of the heavy chain and the β 2m light chain. (In the canonical view of the MHC-I, HLA-A2 molecule shown in Fig. 21.6B through D, the amino terminal residue of the bound peptide lies to the left, and the carboxyl terminal residue lies to the right.)

The comparison of this structure with that of the closely related human MHC-I molecule, HLA-A*68:01 (see Table 21.2), suggested that surface depressions in the groove of the MHC-I molecule, now designated pockets A through F, would be available for interactions with some of the side chains of the bound peptide.^{411,412} These six pockets are illustrated in Fig. 21.6C and with bound peptide in Fig. 21.6D. Concomitant with the determination of the x-ray structure of the human MHC-I molecule, HLA-B*27:05,^{413,414} the motif of the peptides that were recovered from this molecule was determined, permitting the more precise modeling of the bound peptide in the cleft of the MHC-I. For HLA-B27, this was of particular interest because the bound peptides had a strong overrepresentation of arginine at position 2,

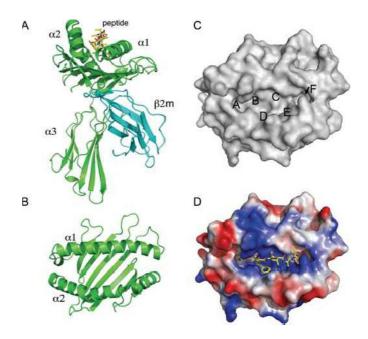

FIG. 21.6. Structure of HLA-A*02:01. A: Ribbon representation of HLA-A2 heavy chain (green), β2m light chain (cyan), and bound peptide (yellow). B: Ribbon representation of the peptide-binding groove. C: Surface representation of the binding groove with pockets labeled. D: Surface representation of binding groove colored by electrostatic charge (red, acidic; blue, basic) with peptide shown in stick illustration. Figure generated from protein data bank⁵⁵⁹ structure 2BSV using PyMOL⁵⁶⁰

and scrutiny of the HLA-B27 structure suggested that the amino acid residues lining the B pocket, particularly glutamic acid at position 45 as well as cysteine 67, were complementary to the long, positively charged arginine side chain of the peptide amino acid at that position. Structural studies supported a view of MHC-I/peptide binding in which the side chain of the carboxyl-terminal residue of the bound peptide sits deep in the F pocket. In addition, the amino terminal amino group of the peptide forms hydrogen bonds with the hydroxyl groups of conserved amino acids tyrosine 59 and tyrosine 171 that line the A pocket. A hydrogen bond from the amino group of conserved tryptophan 147 to the backbone carbonyl oxygen of the penultimate peptide amino acid (usually position 8) also seems important, as do charge interactions and hydrogen bonds of the free carboxyl group at the carboxyl terminus of the peptide with tyrosine 84, threonine 143, and lysine 146.

Other structures of MHC-I molecules were determined involving complexes produced with homogeneous peptide, assembled either in vitro from bacterially expressed proteins with synthetic peptide415 or exploiting MHC proteins expressed in insect cells.^{416,417} The structures determined with homogeneous peptide confirmed the impression obtained from the structures obtained from molecules with heterogeneous self-peptides. Examination of the H2-K^b molecule complexed with synthetic, known antigenic peptides derived either from Sendai virus, vesicular stomatitis virus, or chicken ovalbumin revealed that the same MHC molecule can bind peptides of different sequence, length, and structure by virtue of their conserved motif residue side chains. Although small conformational changes of the MHC are detectable on binding the different peptides, the main distinction in the recognition of different peptides bound by the same MHC molecule is due to the location, context, size, and charge of amino acid side chains that are anchored in the MHC pockets. Conversely, solventexposed side chains contribute to the unique structure of the surface of the molecule available for interaction with TCR and other receptors.

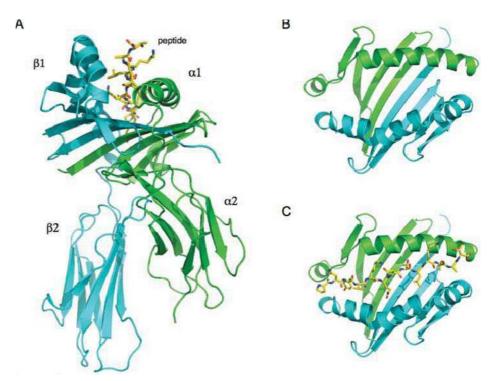

The most consistent rule learned from the first x-ray structures and complemented by peptide recovery and early binding studies was that the carboxyl-terminal amino acid side chain of the MHC-I-bound peptide was embedded in the F pocket. A recent study revealing that the MHC-I molecule H2-D^b binds a pentapeptide well anchored in the F pocket, but lacking amino terminal interactions, is consistent with this view.⁴¹⁸ However, other studies indicate that MHC-I molecules may bind longer peptides that extend beyond the residue anchored in the F pocket, 419 an observation confirmed by a crystallographic structure.⁴²⁰ More recently, the lack of an absolute requirement for a free C-terminal amino acid has been exploited in the engineering of single chain molecules in which peptide, $\beta 2m$, and the MHC-I heavy chain are covalently linked. These molecules have unusual thermal stability and are effective MHC/peptide immunogens.421 An additional variation on the theme of MHC-I binding peptides based on particular anchor residues includes the demonstration that glycopeptides, bound to MHC-I via amino acid side chains and termini, can

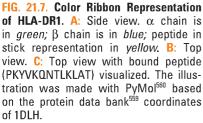

expose their carbohydrate moieties to solvent and be available for TCR interaction.⁴²²⁻⁴²⁴ An example of a 13-residue peptide bound to its MHC-I-presenting element, the rat MHC-I molecule, RT1-Aa, was crystallized and shown to produce a peptide/MHC complex with a large central bulge. Two different complexes consisting of the same MHC and peptide reveal significantly different conformations in this central bulge region.⁴²⁵ "Bulged" viral peptides have also been characterized in complex with human MHC-I structures of HLA-B35 allotypes complexed with 13-mer and 11-mer peptides.426,427 TCR recognition of such bulged peptides can involve conformational adjustments of the TCR in recognizing a fairly rigid peptide426 or "crumplings" of the bound peptide by a largely rigid face of the TCR upon binding the MHC-I/peptide complex.428 Another set of modified peptides that can be bound by MHC-I molecules and presented to TCR includes self-peptides modified by phosphorylation.^{429,430} Although the fundamental topology of MHC-I structure and its interactions with antigenic peptide have been solved by the classic structures mentioned previously, many more MHC-I/peptide complexes have been studied crystallographically in order to define the details of particular interactions with antigenic peptides. A number of structures at a resolution of 1.40 Å or better have been deposited in the protein database. Structure determination of representative single-chain peptide-B2m-MHC-I,431 and of MHC-I molecules containing photolabile peptides that can be exchanged with other peptides easily,432 reinforce our basic understanding of the structure of MHC-I/peptide complexes.

MHC-II Molecules

Before any MHC-II structure had been determined experimentally, a model was constructed based on the alignment of amino acid sequences and the available MHC-I three-dimensional structure.⁴³³ This model made several valid predictions that were borne out by the subsequent x-ray structure determination of HLA-DR1.⁴³⁴ MHC-II clearly showed similarity to MHC-I and formed its binding groove by the juxtaposition of the α 1 and β 1 domains. The position of the electron density representing the heterogeneous peptide that copurified with the HLA-DR1 was identified. Figure 21.7A and C show a ribbon diagram of HLA-DR1 with a homogeneous bound peptide. In comparison to the MHC-I structure (see Fig. 21.6), the peptides bound to the MHC-II molecule extend through the binding groove rather than being anchored at both ends.

A comparison of the α -carbon backbone of the peptide-binding region of an MHC-I structure with that of an MHC-II structure is shown in Figure 21.8. The structures are very similar although the binding domain is built of the α l and α 2 domains from the same chain (for MHC-I) or of the α l and β 1 domains that derive from two chains (for MHC-II). The location of polymorphic residues can be determined by variability plots based on multiple sequence alignments, as originally suggested by Wu and Kabat.⁴³⁵ The current bioinformatics approach to variability prefers to calculate *Shannon entropy*, a function that describes the degree of unpredictability of an event.^{436,437} For protein sequence

alignments, Shannon entropy provides a sensitive measure of the diversity of particular amino acid positions.⁴³⁸ Several online tools are available for implementing and displaying the results of such calculations (http://bio.dfci.harvard.edu/ Tools/svs_help.html; http://imed.med.ucm.es/Tools/svs_ help.html; and http://consurfdb.tau.ac.il/). Comparative ribbon diagrams (Fig. 21.9), in which the location of the amino acid residues that are polymorphic for the human MHC-I and MHC-II chains are indicated with a color map, show that the bulk of MHC polymorphism derives from amino acid variability in regions that line the peptidebinding groove. This suggests that MHC polymorphism is required to allow the MHC molecules, and as a result, the organism and its species, to respond to a changing antigenic environment.

As with MHC-I, a further understanding of the details of the interactions of peptides with the MHC-II molecule came from crystallographic studies of molecules prepared with

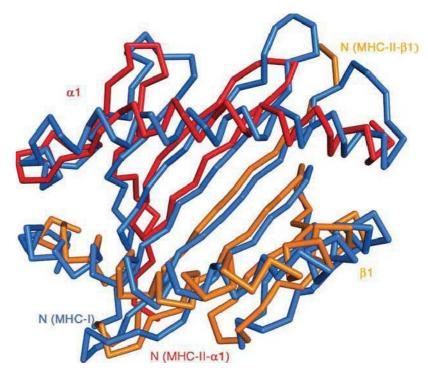

FIG. 21.8. Comparison of α -Carbon Backbone of MHC-I and MHC-II molecules. The $\alpha 1 \alpha 2$ domains of MHC-I (human leukocyte antgien [HLA]-A2, PDB 3HLA) and the $\alpha 1$ and $\beta 1$ domans of MHC-II (HLA-DR1, PDB 1DLH) were superposed with PyMOL⁵⁶⁰ and displayed as a C α carbon representation. MHC-I is *blue*, the $\alpha 1$ domain of MHC-II is *red*, and the $\beta 1$ domain of MHC-II is *orange*.

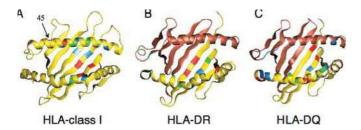

FIG. 21.9. Location of Polymorphic Amino Acid Residues in MHC-I and MHC-II molecules. Variability plots were calculated as described by Kabat and Wu⁴³⁵ and level of variability illustrated on ribbon diagrams (generated in QUANTA 2000 [Accelrys] of 3HLA⁴¹² [HLA-class I], 1DLH⁴³⁹ [HLA-DR], and 1JK8 [HLA-DQ]) where greatest variability is *red*, intermediate is *green*, and least is *blue*.

homogeneous peptide—in the first case HLA-DR1 complexed with an antigenic peptide derived from the hemagglutinin of influenza virus.⁴³⁹ Based on this structure, a set of pockets was initially designated, numbered for the peptide position that is bound. For the influenza peptide studied in this example, the major interactions were from peptide positions 1, 4, 6, 7, and 9 that are indicated in Figure 21.10. The deep P1 pocket accommodates the tyrosine (the third position of the peptide PKYVKQNTLKLAT) and the pockets indicated by 4, 6, 7, and 9 fit the Q, T, L, and L residues, respectively. MHC-II exploits a similar mode of binding as compared with MHC-I, but there are key differences. MHC-II lacks the requirement for free amino and carboxyl termini of the peptide, the peptide conformation is relatively extended (like that of a type II polyproline helix), and the MHC-II forms number of hydrogen bonds between conserved amino acids that line the binding cleft and the main chain (ie, amino nitrogen and carbonyl oxygen) atoms of the peptide. Although the pocket designations refer specifically to the features of the MHC-II molecule surface, occasionally the cognate peptide positions that reside in such pockets are given the same names.

Among the most provocative observations from the first MHC-II structures was that the molecule was visualized as a dimer of dimers, and this moved a number of investigators to consider the possibility that activation of the T cell via its receptor might require the dimerization or multimerization of the TCR, an event thought to be dependent on the propensity of the MHC/peptide complex to self-dimerize. The simple elegance of this dimer of dimers is illustrated in Figure 21.11. Several arguments support the dimerization hypothesis: the finding of a dimer of dimers in the crystals of HLA-DR that formed in several different space groups,434,439 the observation that a TCR $V\alpha$ domain formed tight dimers and in its crystals formed dimers of the dimers,440 the demonstration of the ability to immunoprecipitate MHC-II dimers from B cells,⁴⁴¹ the apparent requirement for purified MHC-I dimers for stimulation of a T cell in an in vitro system,442 and the finding that MHC-II/peptide/TCR complexes could form higher order multimers in solution as detected by quasielastic light scattering.⁴⁴³ However, a number of strong counterarguments draw this hypothesis into question. Many MHC-II molecules other than HLA-DR1 that have been crystallized do not seem to form the same kind of

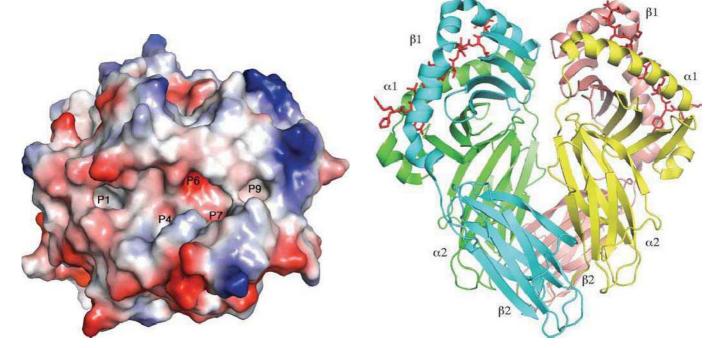

FIG. 21.10. Location of Pockets in HLA-DR1 Based on the Cocrystal of HLA-DR1 with a Peptide Derived from the Influenza Hemagglutinin. An electrostatic surface representation of HLA-DR1 (1DLH) generated in PyMOL⁵⁶⁰ is shown with the positions of pockets P1, P4, P6, P7, and P9 indicated.

FIG. 21.11. Ribbon Diagram of the Structure of HLA-DR1 showing the dimer of dimers and the individual domains of the protein. α chains are in *green* and *yellow;* β chains are in *blue* and *salmon*. Peptide in stick representation is in *red*. The illustration was generated from PDB 1DLH with PyMOL.

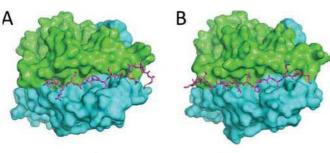

dimer of dimers in their crystals.^{444,445} Modes of MHC-II dimerization with distinct topology that would preclude simultaneous interaction with multiple TCRs on the same T cell have been observed. None of the MHC-I molecules that have been examined by x-ray crystallography show dimers in the same orientation as the MHC-II ones reported. A different V α domain fails to dimerize even at high concentration.⁴⁴⁶ Many reported x-ray structures of MHC/peptide/TCR complexes^{447–450} fail to show dimerization. Despite the simple elegance of the dimer hypothesis, it is clear that additional experimentation will be required to understand the topologic requirements for T-cell activation through the $\alpha\beta$ TCR.

Recent additions to the library of MHC-II structures include the I-A^{g7} molecule, a unique MHC-II that provides one link in the susceptibility to insulin-dependent diabetes in the mouse model.^{451,452} Although the structure fails to provide direct evidence to explain the linkage to diabetes, it suggests that the novel repertoire of peptides bound by this MHC-II molecule reveals unique features of a wider peptide binding groove and resulting relatively low-affinity interaction with peptide. Until recently, all of the MHC-II/peptide structures revealed bound peptide in a canonical left to right, amino to carboxyl orientation. A detailed analysis of HLA-DR1 molecules bound to the CLIP 106 to 120 peptide revealed crystals in two different forms, which on solution and refinement indicated that this peptide could interact in either of two distinct orientations (Fig. 21.12).408 This exception to the general rule of left to right, amino to carboxyl orientation, may reflect the unique role that the CLIP peptide must play in protecting the MHC-II-binding site while simultaneously being available for DM-mediated peptide exchange in the endosome.

MHC-lb Molecules

H2-M3

To this point, our description of MHC-I molecules has focused on the classical MHC-Ia molecules, represented by HLA-A, HLA-B, and HLA-C in the human, and by H2-K, H2-D, and H2-L in the mouse. Several MHC-Ib molecules for which three-dimensional structures have

The structures of HLA-DR1 bound to the CLIP 106 to 120 peptide in either the N to C (A) or C to N (B) orientation is illustrated. α 1 domain is in *green*; β 1 domain is in *cyan*. Peptide sequences are shown at the bottom. been determined are of particular interest, the CD1 mol-ecules,^{453,454} H2-M3,^{137,455} MICA,^{456,457} FcRn,⁴⁵⁸ and Rae-1.⁴⁵⁹ Other molecules that are thought to show structural relatedness to the MHC-I fold but whose x-ray structures have not yet been reported include the stress-induced molecules H-60¹⁷³ and MULT1,⁴⁶⁰ and the mucosally expressed MR1 molecule that selects invariant T cells in the gut.⁴⁶¹ H2-M3 is of particular note because of its ability to bind and present peptide antigens that contain amino terminal N-formyl groups. H2-M3 was originally identified as the MHC-Ib molecule that presents an endogenous peptide derived from the mitochondrially encoded protein ND1 known as maternally transmitted factor.^{137,462} Thus, it was of interest to understand in structural terms how this molecule binds such N-formylated peptides.455,463 The crystal structure of H2-M3 complexed with an N-formylated nonamer peptide, fMYFINILTL, revealed that the structure of the A pocket, highly conserved among MHC-Ia molecules, which have tyrosine 7, tyrosine 59, tyrosine 159, tryptophan 167, and tyrosine 171, is quite different so that it can accommodate the N-formyl group in the A pocket. In particular, H2-M3 has an A pocket reduced in size and lined by hydrophobic residues, leucine at 167 and phenylalanine at 171, and leucine 16. These structural features cause the amino terminal nitrogen of the formylated peptide to be positioned where the peptide position 2 amino nitrogen would lie in a MHC-Ia molecule. Thus, the unique peptide selectivity of H2-M3 is explained in structural terms.

CD1

Another MHC-Ib molecule of great interest is CD1, representative of a class of MHC-I molecules that map outside of the MHC, that have limited tissue-specific expression, and that are capable of interaction with both $\alpha\beta$ and $\gamma\delta$ T cells.⁴⁶⁴ In the human, there are two clearly distinct groups of CD1 molecules: one consisting of CD1a, CD1b, CD1c, and CD1e; and another of CD1d alone.⁴⁶⁵ In the mouse and rat, only CD1d is expressed.⁴⁶⁶ As a group, these are β 2m-associated chains that bind hydrophobic antigens, primarily glycolipids, with the lipid moiety embedded in the CD1 heavy chain and the carbohydrate portion exposed to solvent. CD1a, CD1b, and CD1c are capable of binding and presenting various nonpeptidic mycobacterial cell wall components such as mycolic acid containing lipids and lipoarabinomannan lipoglycans.^{467,468} NK T cells, a subset of $\alpha\beta$ -TCR-bearing T cells, of independent lineage and defined by the expression of the NK1.1 marker, are restricted to CD1 recognition.⁴⁶⁹ The crystal structures of both mouse and human CD1d1 have been determined,^{453,470} revealing classic MHC-I structures with the basic protein fold and $\beta 2m$ association quite similar to that of the MHC-Ia molecules. Consistent with its apparent biologic function of binding hydrophobic lipid-containing molecules, its binding groove is somewhat narrower and deeper than that of either MHC-Ia molecules or MHC-II molecules. The backbone configuration of the $\alpha 1 \alpha 2$ domain structure of CD1 is shown in Figure 21.13, where it is compared to the homologous region of H2-K^b, HLA-DR1, and another MHC-Ib molecule, a neonatal Fc receptor (FcRn). The structure of a number of CD1-glycolipid complexes

have been determined, and human and mouse CD1 molecules bound to different glycolipids have been compared.⁴⁶⁶ The depth of the groove of CD1 results from the merging of pockets to form what have been termed the *A' and F' pockets* in place of the MHC-Ia A through F pockets. This A' pocket is about the size of the binding site of a nonspecific lipid binding protein.

In an effort to understand more precisely how CD1 molecules bind lipid antigens, Gadola et al.⁴⁵⁴ crystallized human CD1b complexed with either phosphatidylinositol or ganglioside GM2 and determined their x-ray structures.

The structures were essentially identical for the CD1b heavy chain and $\beta 2m$ in the two complexes, and revealed a network of four hydrophobic channels at the core of the $\alpha 1\alpha 2$ domain, which accommodate four hydrocarbon chains of length from 11 to 22 carbon atoms. These channels are called A', C', and F' for the three analagous to the A, C, and F pockets of the MHC-Ia molecules, and a fourth, termed T' which is a distinct tunnel. Illustrations of the binding groove with the bound alkyl chains is shown in Figure 21.14, which shows views of the binding pockets of CD1a, b, and d with different ligands. These structures illustrate how the

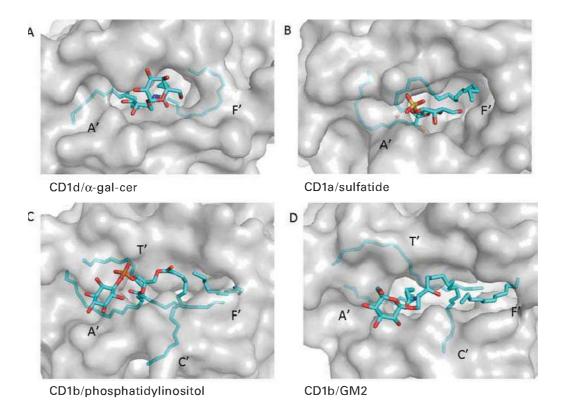

FIG. 21.14. Tunnels and Pockets of CD1 Molecules. Structures of (A) CD1d with α -galactosyl ceramide (1Z5L), (B) CD1a with sulfatide (10NQ), (C) CD1b with phosphatidylinositol (1GZQ), and (D) CD1b with ganglioside GM2 are shown, with pockets A', C', and F' indicated and tunnel T'.

binding site of a classical MHC-I molecule may have evolved from (or to) the binding site of molecule like CD1 to provide antigen selectivity for a distinct set of molecules that would be common to a set of important mycobacterial pathogens. Complexes of CD1 with their cognate NK TCR have been reported and will be discussed subsequently.^{471–474}

Neonatal Fc Receptor

Another example of an MHC-Ib molecule, noteworthy because it exemplifies a novel function of MHC molecules, is the FcRn. Originally described in the rat as a molecule of the intestinal epithelium that is involved in the transport of colostral Ig from the lumen to the bloodstream, 475,476 homologues in the mouse and human have also been described,⁴⁷⁷⁻⁴⁷⁹ and the structure of the rat molecule has been determined crystallographically⁴⁵⁸ (Fig. 21.15). As suggested by the amino acid sequence similarity of the FcRn to MHC-I proteins, the three-dimensional structure revealed considerable similarity to MHC-Ia molecules.⁴⁵⁸ Specifically, $\alpha 1$ and a 2 domains have similar topology to the MHC-I molecule, although, as discussed previously, what would be the peptide-binding groove in the MHC-Ia molecules is closed tightly and lacks space sufficient for a ligand. The most provocative feature of the structure of the FcRn/Fc complex is that the MHC-I-like FcRn interacts with the Fc through contacts from the $\alpha 2$ and $\beta 2m$ domains to interact with the Fc $C_{\gamma}2$ - $C_{\gamma}3$ interface. As compared to the structure of the unliganded Fc, the complex reveals both conformational changes in the Fc and the presence of several titratable groups in the interface that must play a role in the pH-dependent binding and release of Ig molecules from the FcRn. The FcRn has taken the MHC-I fold and diverted its function for an interaction with the Fc of the Ig. Amino acids at what would classically be considered the "righthand side" of the peptide-binding groove make contact with the Fc interface that lies between $C_{\gamma}2$ and $C_{\gamma}3$ domains. The FcRn

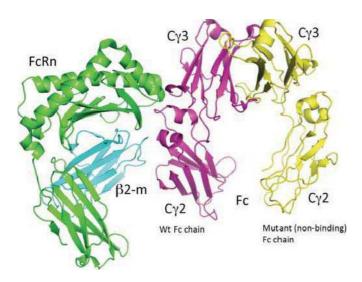

FIG. 21.15. Structure of the Rat Neonatal Fc Receptor Complexed with Fc. Ribbon diagram of rat neonatal Fc receptor complexes with the Fc heterodimer consisting of the wild-type and nonbinding chains. This is from PDB 111A.

serves as an excellent example of similar structures in the immune system being diverted for alternate purpose. The importance of the FcRn has been underscored by observations of differences in the serum half-life of Ig in animals that, as a result of an induced deletion of $\beta 2m$, lack the normal expression FcRn as well and seem to metabolize serum Ig aberrantly.⁴⁸⁰

MILL MHC-Like Molecules

A novel set of MHC-Ib–like genes designated *Mill* (*M*HC class *I-l*ike located near the *l*eukocyte receptor complex) has recently been identified in both mice and rats.^{481–483} These encode MICA/B-like glycophosphatidylinsol-linked cell surface molecules that are associated with β 2m and do not require TAP for cell surface expression. Their function remains unclear, although further examination indicates the presence of two family members, Mill1 and Mill2, observed on cycling thymocytes, proliferating smooth muscle cells and fibroblasts.⁴⁸⁴

M10 Proteins

The robust MHC fold seems to possess both the stability and flexibility requisite for the molecular function of binding ligands such as peptides, glycopeptides, phosphopeptides, and glycolipids as well as for subsequent interactions with macromolecular receptors such as NK receptors and TCRs. Likely, these qualities have allowed its adaptation for distinct function related to a class of MHC-Ib molecules, the M1 and M10 families, some members of which are associated with the V2R mouse pheromone receptors. The structure determination of M10.5 revealed a β 2m-associated MHC-I–like molecule with clear three-dimensional similarity to the MHC-I molecule H2-D^d.⁴⁸⁵

MHC-Iv Molecules

Because viruses are constantly engaged in a struggle for survival in their interplay with the immune system of their hosts, there is little surprise to note that pathogenic eukaryotic viruses can evolve numerous approaches to evade the immune response. MHC and structurally related molecules are produced not only by vertebrates but also by CMVs, large DNA viruses of the β -herpesvirus family, which have coevolved with their vertebrate hosts over millennia and are exquisitely adapted to persist in the face of host immune responses.² Viral MHC-I-like molecules have been identified bioinformatically from amino acid sequences of the open reading frames predicted from genome sequence data. A number of putative MHC-Iv molecules, including UL18 and UL142 of the human CMV,^{327,486} members of the "m145 family" of the mouse CMV1487,488 the 2L molecule of tanapox,489 and the U21 molecule of human herpesvirus 7,490 may modulate the immune response of the host. In some cases, such as the UL18 protein of human CMV and the m144 protein of mouse CMV, the sequence homology to bonafide MHC-I molecules is sufficiently strong to unambiguously identify them as MHC-I like. However, in most cases, such as with the m145 family of mouse CMV, the sequence homology to MHC-I is very weak, and relatedness to MHC-I was originally based on structure prediction algorithms alone. We term these virally encoded MHC-I-like molecules MHC-Iv

to reflect their distinct evolutionary history, their structural deviation from typical MHC-I molecules, and their role in evading host immune responses. A survey of DNA sequences of 11 genes obtained from 26 wild murine CMV isolates and laboratory strains indicated that several of the *MHC-Iv* genes (m144, m145, and m155) revealed significant sequence variation, consistent with the view that this variation may offer some immune-evasive benefit to the virus.⁴⁹¹

Structural characterization of MHC-Iv molecules begins with an evaluation of the requirement for $\beta 2m$ and/or peptide for stable expression. The UL18 is associated with both β 2m and peptide, whereas m144 may be associated only with $\beta 2m$ but does not require $\beta 2m$ for cell surface expression. The structure of m144 has been reported,⁴⁸⁷ revealing the preservation of all structural elements of the MHC-I fold (Fig. 21.16). The cleft of m144 does not seem capable of binding peptides as the groove is narrow and critical tyrosine residues are not conserved, results consistent with earlier biochemical studies.⁴⁹² A unique disulfide anchors the α 1 helix to the β sheet. The structure of m157, a CMV MHC-I-like immunoevasin that binds the Ly49H activation receptor of C57BL/6 mice and the Ly49I inhibitory receptor of 129/J mice, has been reported.⁴⁹³ This β 2m-independent, peptide-free MHC-Iv molecule reveals the major features of the MHC-I fold with some unique aspects, in particular a novel amino terminal α helix. How it binds its Ly49 ligands remains unclear. The m153 protein of mouse CMV, also a member of the m145 family, reveals novel adaptations of the MHC-I fold.¹ The m153 protein does not require β 2m or peptide and, in contrast to other MHC-I molecules, is a noncovalent dimer. The monomers are associated in a headto-tail fashion. An extended N-terminus contains a unique disulfide that anchors it to the α 3 domain. The m153 structure hints tantalizingly of more surprises to come as structures of other MHC-Iv molecules become available. Other MHC-Iv proteins whose structure have been determined include the 2L tanapox virus protein that binds the inflammatory cytokine TNF- α^{489} and the mouse CMV-encoded m152, which sequesters both classical MHC-I and the stressinduced NKG2D ligand, RAE-1, from the cell surface.494

In those cases where functions have been elucidated, MHC-lv molecules have been shown to act as immunoevasins that inhibit the NK cell to enable virus survival and persistence in the host. Both UL18 and UL142 inhibit human NK function, the former by binding to the inhibitory receptor LIR-1. The mode of action of UL142 remains to be determined.³²⁷ The m157 binds to the inhibitory NK receptor Ly49I in mouse strains susceptible to viral infection but remarkably serves as a target for the activating NK receptor Ly49H expressed in resistant strains. The m144 protein has also been shown to inhibit NK activation,^{495,496} but the ligand remains to be identified.

Complexes of MHC Molecules with Ligands

The most recent and exciting developments in MHC biology include the detailed description of the interactions of MHC-I and MHC-II molecules with their receptors and coreceptors on cells of the innate and adaptive immune system. Our structure/function survey will be completed by brief descriptions of the interactions of MHC-I and MHC-II molecules with $\alpha\beta$ TCRs, with the T-cell coreceptors CD8 and CD4, and of MHC-I molecules with NK receptors. Details of the interactions of a number of CD1 molecules with their glycolipid antigens and specific NK T-cell receptors shed light on the biology and evolution of these molecules. A brief description of interactions of MHC-II molecules with superantigen will follow. Each of these structural studies complements a host of biologic experiments that have led to an appreciation of the importance of understanding the structural basis of these immune reactions.

MHC/T-Cell Receptor Interactions

Second to the initial visualization of the structure of the MHC-I molecule HLA-A2 by crystallographic analysis, the images of TCR/MHC/peptide complexes initially reported some 15 years ago clarified the phenomenologic details of T-cell recognition, antigen specificity, and MHC restriction. The initial structures were determined in several systems,^{447–449,497,498} and there remains ongoing interest in the details of particular TCR/MHC interactions. The first examples were of MHC-I–restricted TCR, one from the mouse⁴⁴⁸ and one from the human.⁴⁴⁷ The mouse MHC-I molecule H2-K^b was analyzed in complex with a self-peptide, dEV8, and a TCR known as 2C,^{448,499} and the human

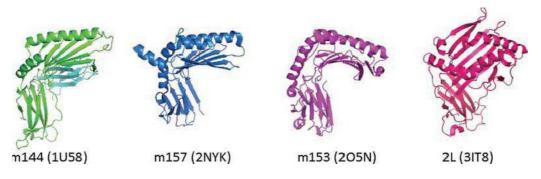

FIG. 21.16. Comparison of MHC-Iv Molecules. Structures of MHC-Iv chains of m144 (1U58), m153 (205N), m157 (2NYK), and the 2L protein of tanapox virus (3IT8) were superposed and are illustrated as ribbon diagrams.

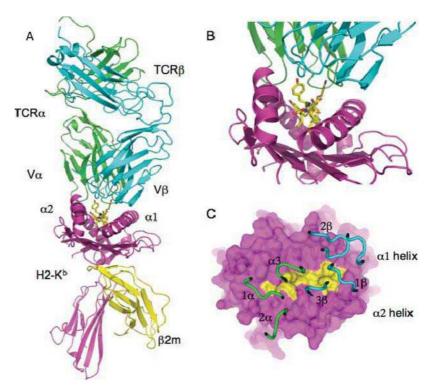

FIG. 21.17. Structure of an MHC-I/Peptide/T-Cell Receptor (TCR) Complex and the TCR Footprint on the MHC/Peptide. The structure of the H2-K^b/dEV8/2CTCR complex (2TCR) is displayed. A: The complex complex. B: A close-up of the MHC/peptide/TCR interface. C: The surface of the MHC (magenta)/peptide (yellow) complex with the complementarity determining region loop of the TCR V α (green) and V β (blue) shown and labeled.

HLA-A2 complexed with the Tax peptide was studied with its cognate TCR derived from a cytolytic cell known as A6.447 These structures offered a consistent first glimpse at the orientation of the TCR on the MHC/peptide complex, but additional structures, including that involving a murine MHC-II-restricted TCR suggest that more molecular variations may exist. As a canonical example of the MHC/ peptide/TCR complex, we include an illustration of the H2-K^b/dEV8/2CTCR complex⁴⁹⁹ (Fig. 21.17). This illustration shows that the complementarity determining regions (CDRs) of the TCR (labeled 1α , 2α , 3α for CDRs of V α and 1 β , 2 β , and 3 β for the CDRs of V β , respectively) sit symmetrically on the MHC/peptide complexes. For the H2-K^b/ dEV8/2CTCR complex, the region contacted by the CDRs of the V α domain of the TCR lie to the left and that contacted by the CDRs of the V β domain lie to the right. The regions contacted by CDR3, labeled 3α and 3β , are at the center of the bound peptide, whereas the regions contacted by CDR1 and CDR2 of both V α and V β lie peripherally. Footprints of other TCR have been reviewed elsewhere.357

With the publication of additional MHC/peptide/TCR structures,³⁵⁷ additional points have emerged: 1) There is considerable variability in the orientation of the TCR V α and V β domains with respect to the MHC/peptide complex. Although the first MHC-II/peptide/TCR structure suggested that an orthogonal disposition, in which V β makes the great majority of contacts with the MHC-II α l domain and the V α predominantly interacts with the β l domain, might be the preference for MHC-II/TCR interactions,⁴⁴⁹ additional MHC-II/peptide/TCR structures^{450,497} suggest that this disposition is not indicative of MHC-II as compared to MHC-I but rather reveals the wide variety of possibilities. 2) Considerable plasticity in the conforma-

tion of the CDR loops of the TCR, particularly long CDR3 loops, is observed in the comparison of TCR free or bound to their cognate MHC/peptide ligands.^{499,500} A striking example of this is illustrated by the structure of the KB5-C20 TCR alone as compared to its complex with H2-K^b/peptide (Fig. 21.18).

Structural Insights into Alloreactivity

During T-cell development, TCRs destined to be useful to the host are selected for weak reactivity with one or more self-peptides complexed with cell surface host major histocompatibility (MHC/peptide) molecules. TCR selection is customized in each individual because of extensive polymorphism in MHC molecules that is designed to diversify peptide repertoire and optimize immune responsiveness. Thymic selection and MHC polymorphism conspire to generate antimicrobial T-cell responses that are genetically restricted to recognizing host MHC molecules while retaining Ag-specificity. MHC restriction has been a central paradigm of T-cell immunity and was the basis for the 1996 Nobel Prize awarded to Peter Doherty and Rolf Zinkernagel.

Unfortunately for transplant clinicians and their patients, the rule of MHC restriction is violated when T cells are exposed to allogeneic MHC/peptide complexes. Remarkably, up to 10% of naive T cells react strongly against allogeneic MHC/peptide in vitro (mixed lymphocyte reaction) and in vivo leading to allograft rejection and GVHD. This reaction, known as T-cell alloreactivity, is why MHC molecules were initially called transplantation or histocompatibility molecules and has puzzled immunologists for decades.

There are two main historical theories to explain the high frequency of alloreactive T cells. The first, proposed in 1977,¹⁸³ postulated that a single allogeneic MHC molecule

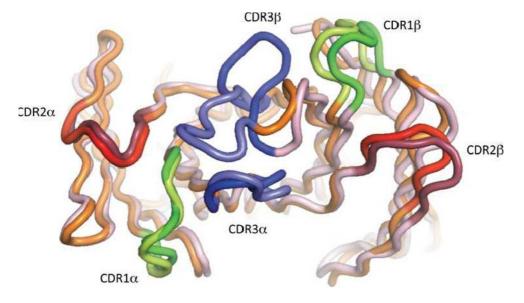

FIG. 21.18. Complementarity Determining Region (CDR)3 Plasticity. Backbone tracings of the KB5-C20 T-cell receptor CDR loops free (1KB5) or bound to the major histocompatibility/peptide complex (1KJ2) are superposed. Unliganded forms are in *darker colors*. The largest conformational difference is seen in the CDR3β loop.

could give rise to multiple binary complexes with cell surface molecules, creating "neoantigenic determinants" recognized by clonally distinct T cells. This has been reinterpreted in a "peptide-centric" hypothesis whereby as a single MHC molecule presents disparate peptides recognized by multiple different T-cell clones. The "multiple binary complex" model implies the TCR interacts with a set of amino acids shared by self- and allogeneic MHC molecules, so the crossreaction depends crucially on the peptide antigen. However, it was later suggested that alloreactive T cells might focus on polymorphic residues exposed on the allogeneic MHC molecule itself, the so-called high determinant density model in which the TCR focus is "MHC centric," and the peptide is largely irrelevant.⁵⁰¹

Colf et al.⁵⁰² solved the structure of the 2C TCR in complex with its known allogeneic ligand, H2-L^d-QL9, and then compared it to the structure of 2C in complex with its positively selecting ligand, H2-K^b-dEV8, and thus were able to provide important insight into the structural basis of alloreactivity. These two TCR footprints were typical of known MHC/peptide/TCR structures but differed from each other in a number of ways. For instance, each chain of 2C made contacts with one MHC α helix of H2-L^d-QL9, whereas both chains contacted both α helices in H2-K^b-dEV8. The geometry of 2C adopted a more perpendicular orientation on H2-L^d-QL9, and there was a relative rotation of H2-K^b-dEV8 by 20 degrees. The alloreactive complex reveals that both peptide-centric and MHC-centric interactions underpin direct T-cell allorecognition by the 2C receptor but with a heavy emphasis on MHC-centric interactions. Most surprising, however, was the small number of shared contacts between the two structures, implying a limited role for mimicry between cognate and allogeneic MHC/peptide. The H2-K^b and H2-L^d have 31 amino acid differences, and there is no sequence similarity between the H2-K^b-restricted octamer self-peptide, dEV8, and the H2-L^d-restricted nonamer, QL9. Given these differences, it was a fair bet that the cross-reactivity of 2C on H2-K^b-dEV8 and H2-L^d-QL9 would depend upon plasticity in the CDR3 regions of the TCR as documented in comparisons of bound and free TCRs, including 2C. Surprisingly, this was not the case as the TCR actually adopted very similar conformations in the two structures. In contrast to the findings with the alloreactive murine, 2C TCR, alloreactivity of the natural human LC13 TCR is based on striking molecular mimicry between the cognate and alloantigens.⁵⁰³ The LC13 recognizes an Epstein-Barr viral peptide complexed with self-HLA-B*08:01 but also alloreacts with B44 allotypes (HLA-B*44:02 and 44:05) bound to an endogenous allopeptide from an adenosine triphosphatebinding cassette protein ABCD3. HLA-B*08:01, and the closely related allotypes HLA-B*44:02 and HLA-B*44:05, are distinguished by numerous polymorphisms and the LC13-reactive viral and endogenous peptides are unrelated in their sequence. Nonetheless, the LC13 TCR bound the allogeneic and cognate virus-specific HLA-peptide structures in a very similar manner.⁵⁰³ Moreover, there was mimicry of the viral peptide by the allopeptide. Hence, this study demonstrates that recognition of allogeneic and cognate HLApeptide structures can occur via molecular mimicry, even in the face of polymorphism and disparate peptide ligands.⁵⁰³ Interestingly, another HLA-B*08:01-restricted TCR (CF34) with the identical Epstein-Barr virus-peptide specificity as LC13 lacks B44 reactivity because it arises when HLA-B44 is coinherited in trans with HLA-B8. Docking of the CF34 TCR focused on the N-terminus of the HLA-B*08:01-peptide while LC13 docked over the C-terminus of the viral peptide bound by HLA-B*08:01.504 This corresponds with CF34 engagement of a polymorphic region distinguishing HLA-B8 from HLA-B44, revealing a topographical image of shifting TCR specificity to accommodate T cell self-tolerance.⁵⁰⁴

The role of molecular mimicry and the relative importance of peptide-centric versus MHC-centric bias in T-cell allorecognition is likely to vary in different systems. Hence, it is likely that the nature of the polymorphisms between cognate and allogeneic MHC allotypes will affect TCR focus. Thus, closely related MHC allotypes that differ by as little as one amino acid (eg, H2-K^b mutants in mice; HLA-A2, B44, and B27 families in humans) are set up for MHC mimicry to be a key component of T-cell allorecognition where specificity is likely to be peptide centric. For example, HLA-B*44:02 and B*44:03 allotypes differ by only a single amino acid and yet stimulate strong mutual allogeneic T-cell responses. Indeed, the potency of T-cell alloresponses between closely related MHC allotypes probably occurs because positive selection of host T cells is purposely designed to create a repertoire responsive to subtle changes in peptide display. Therefore, closely related MHC allotypes, with differences in both peptide repertoire and MHC/peptide conformation of a shared repertoire, play straight into nature's design for T-cell recognition.

Important questions concerning the nature of T-cell signaling mediated by engagement of the TCR by MHC/ peptide complexes remain. What are the molecular and biophysical determinants of agonist as compared with antagonist activity of particular MHC/peptide ligands? Although it is clear that a number of parameters such as binding kinetics, half-life, and affinity (both two dimensional and three dimensional) as well as coreceptor contributions may play a role in the outcome of TCR engagement by MHC/peptide complexes, and the additional role of receptor clustering may contribute to such signaling, the precise contribution of each of these factors has not been established. A provocative approach to the question of the role of the geometry of docking of the TCR onto the MHC/peptide complex has been addressed in the analysis of the relationship of stimulatory parameters of four different peptides bound to H2-L^d with respect to the three-dimensional structure of the relevant MHC/peptide/TCR complex.⁵⁰⁵ One of the four peptides failed to induce signaling, and remarkably, the TCR docked onto the MHC/peptide in a unique docking geometry. The authors interpreted these results to demonstrate the relationship between TCR/pMHC docking geometry, peptide cross-reactivity, and signaling as well as explaining the basis for germline bias in TCR/MHC interactions.

MHC/Coreceptor Complexes

The major coreceptors for recognition by $\alpha\beta$ TCRs are CD8, which interacts with MHC-I molecules, and CD4, which interacts with MHC-II. Coreceptor function plays a role in signaling the T cell in addition to contributions the MHC/ coreceptor interaction may provide in increasing apparent avidity between the MHC/peptide and the TCR. CD8, the coreceptor on MHC-I–restricted $\alpha\beta$ T cells, exists as a cell surface homodimer of two α chains or a heterodimer of α and β chains and plays an important role both in the activation of mature peripheral T cells as well as in the thymic development of MHC-I–restricted lymphocytes.^{506,507} Mature peripheral CD8 T cells express significant amounts of CD8 $\alpha\beta$, whereas other lymphocytes, such as intraepi-

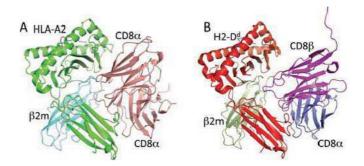

FIG. 21.19. CD8 $\alpha\alpha$ and CD8 $\alpha\beta$ Bind the Same Site on the MHC-I α 3 Domain. The MHC-I interactions with the CD8 $\alpha\alpha$ (PDB 1AKJ) homodimer (A) and CD8 $\alpha\beta$ (PDB 3DMM) heterodimer (B) are shown.

thelial lymphocytes in the gut, predominantly express the CD8 $\alpha\alpha$ homodimer. The CD8 $\alpha\beta$ heterodimer is considered the relevant functional coreceptor on peripheral T cells. The three-dimensional structures of human and mouse MHC-I/CD8 $\alpha\alpha$ complexes have been described, 508,509 and more recently, a complex of mouse MHC-I/CD8 $\alpha\beta$ has been reported.⁵⁸ These structures localize the binding site of the CD8 Ig-like $\alpha\alpha$ homodimer or CD8 $\alpha\beta$ heterodimer to a region on an exposed loop of the MHC-I α3 domain. This interaction is illustrated in Figure 21.19, which shows the flexible loop of residues 223 to 229 clamped into the CD8 combining site. This is one of relatively few examples of an non-Ig, Ig-like molecule exploiting an Ig-like heterodimer interface to bind another ligand. The structural identification of the CD8 $\alpha\alpha$ and CD8 $\alpha\beta$ on the MHC-I provides a context for understanding the contribution of CD8, which binds the kinase Lck through the cytoplasmic domain of its α chain to T-cell signaling.

The T-cell coreceptor associated with cells restricted to MHC-II antigens, CD4, has also been the subject of detailed structural studies, in part, because of its role as a receptor for attachment and entry of HIV.⁵¹⁰ The x-ray structure determination of the complete extracellular portion of the molecule (domains D1 through D4) indicates a degree of segmental flexibility between domains D2 and D3, and both crystallographic and biochemical data suggest that dimerization of cell surface CD4 occurs.⁵¹¹ These results have been interpreted to support a role for CD4-mediated MHC-IIdependent dimerization in facilitating TCR dimerization and signaling. Although a mixed species structure of human CD4 D1-D2 domains with a mouse MHC-II molecule was reported at low resolution some years ago,⁶³ only recently, employing an affinity matured human CD4 molecule have diffraction quality crystals of human MHC-II/ human CD4 D1-D2 molecules been obtained⁶⁴ (Fig. 21.20). This recently determined human MHC-II/hCD4 structure is remarkably similar to the low-resolution mixed species structure determined more than 10 years earlier. Both structures reveal the focus of the CD4 interaction on a stretch of amino acid residues on the Ig-like $\beta 2$ domain of the MHC-II molecule. Earlier mutagenesis and functional studies of CD4-dependent MHC-II-mediated T-cell activation

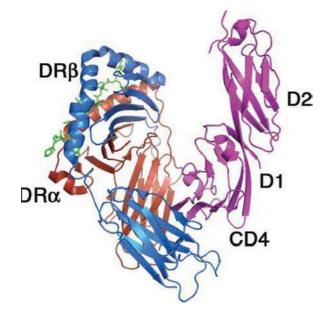

FIG. 21.20. CD4 Interacts Directly with the β 2 Domain of MHC-II. A ribbon illustration of a complex of human CD4 with HLA-DR1 (PDB 3S5L) is shown. The HLA-DR α chain is in *firebrick*, HLA-DR β chain in *blue*, peptide in *green*, and CD4 in *magenta*.

also implicated a region on the α 2 domain of MHC-II.^{61,512} Although the α 2 domain residues do not directly interact with CD4 in these structures, it is conceivable that they play some indirect role in MHC multimerization that may contribute to signaling.

MHC/Natural Killer Receptor Complexes

NK cells provide a first line of defense against virus-infected and host cells, and their recognition of such targets is dependent on a balance of NK activating and inhibitory receptors.^{513,514} In addition to their expression on NK cells, some of the NK receptors are also expressed on subsets of T cells and other hematopoietic cells. In general, each of these classes of NK receptors also falls into two different structural groups: the Ig-like receptors and the C-type lectin–like receptors. Because of their functional interactions with MHC-I and MHC-I–like molecules, and because several different systems have evolved to recognize MHC-I molecules differently, it is worthwhile to examine the recently determined structures of several MHC-I/NK receptor complexes.

In the human, the major NK receptors fall into several categories: those of the NKG2 family, the NKp molecules, and the KIRs. The NKG2 family molecules are C-type lectin–like molecules that recognize ligands grouped broadly as the NKG2D ligands, which include the MHC-like molecules, MICA and MICB, as well as the ULBP family of stress-induced molecules. NKp molecules include NKp30, NKp44, and NKp46, all members of the Ig superfamily. The KIR molecules, also Ig superfamily members, bind either HLA-C, or for the KIR3 subfamily, HLA-B molecules. Because the focus of this chapter is members of the MHC protein family, we will restrict our discussion of the

human NK receptor/ligand interactions to the NKG2/MIC and ULBP complexes and to the KIR2D and KIR3D/MHC interactions.

The activating receptor, NKG2D, interacts with MICA, a stress-induced MHC-I–like molecule, allowing NK cells to eliminate virus-infected or tumor cells that are marked by the surface expression of MICA. The structure of the human NKG2D/MICA complex reveals that the homodimeric binding site of NKG2D recognizes the surface α -helical superdomain, in an orientation similar to that by which TCR see MHC-I molecules⁴⁵⁶ (Fig. 21.21). This structure shows remarkable similarity to that of the hNKG2D bound to another MHC-Ib protein, ULBP3.⁵¹⁵ Similarly, the mouse NKG2D interacts, in a similar orientation, with the murine stress-induced molecule, RAE-1 β .⁴⁵⁹

The short KIRs (eg, KIR3DS and KIR2DS molecules) are considered activating receptors because they have the potential to interact with the DAP12 signal-transducing molecule, and the long KIRs (eg, KIR3DL and KIR2DL) are inhibitory because they have cytoplasmic domains that contain immunoreceptor tyrosine-based inhibitory motifs. KIR2DL1 and KIR2DL2 have been studied extensively. They interact with the human MHC-I molecules HLA-C*04 and HLA-C*03, respectively, and show some preferences for MHC-I molecules complexed with particular peptides. Among the polymorphic amino acid residues that distinguish HLA-C*03 and HLA-C*04 are Asn80 of -C*03 and Lys80 of -C*04. Thus, it was of interest when the structures of HLA-C*03/KIR2DL2¹⁰⁴ and HLA-C*04/KIR2DL1 complexes were reported.¹⁰⁵ The KIR2DL2/HLA-C*03 interaction is illustrated in Figure 21.22. The important conclusions from this structure and those of similar KIR2DL complexes is that the recognition of MHC-I is via amino acid residues of the

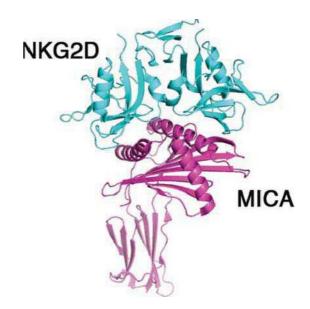

FIG. 21.21. The NKG2D sees the MHC-Ib MICA α -Helical Superdomain. The structure of the human NKG2D/MICA complex (PDB 1HYR) reveals the homodimer NKG2D sitting asymmetrically astride the MICA α -helical superdomain. The NKG2D domains are in *cyan* and MICA in *magenta*.

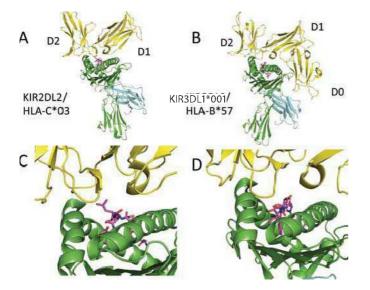

FIG. 21.22. KIR2DL2 and KIR3DL1 Interact Similarly with Their MHC-I/p Ligands. KIR2DL2 complexed with HLA-C*03 (PDB 1EFX) (A,C) and KIR3DL1 complexed with HLA-B*57:01 (PDB 3VH8) (B,D) are shown to illustrate the overall interactions (A,B) and close-ups of the contact with bound peptide (C,D).

elbow bend joining the two Ig-like domains of the KIR, and that residues that vary among different KIRs determine the molecular specificity of the interaction with the particular allelic product of HLA-C. In addition, the interaction of the KIR with the HLA-C is also modulated by the particular bound peptide, explaining the results of binding/peptide specificity studies. Structural understanding of the KIR3 molecules, which have three extracellular Ig-like domains, eluded the field for many years. Recently, a molecular complex of HLA-B*57:01 with KIR3DL1 has been reported (see Fig. 21.22). This structure reveals the contribution of the D0 amino terminal domain of KIR3DL1 in recognizing a region of the MHC-I with limited polymorphism, the D1 domain accommodates a region with sequence variation, and the D2 domain shows high complementarity.

The mouse exploits a set of NK receptors of a different structural family to provide the same function. In particular, the predominant, and best studied, mouse NK receptors are those of the Ly49 family. Functional experiments had demonstrated that Ly49A interacts with the MHC-I molecule, H2-D^d, and also that for appropriate interaction, H2-D^d needs to be complexed with a peptide. In contrast to human NK recognition, however, surveys of H2-D^d-binding peptides revealed little if any peptide preference or specificity. This would explain the function of the NK inhibitory receptor in that they are at baseline chronically stimulated by normal MHC-I on somatic cells, turning off the NK cell. When MHC-I is dysregulated by tumorigenesis or by pathogenic infection, the lower level of surface MHC-I diminishes the NKIR-mediated signal, and the NK cell is activated. The structure of the mouse Ly49A inhibitory receptor in complex with its MHC-I ligand, H2-D^d (Fig. 21.23), reveals several crucial features of the interaction: 1) the Ly49A C-type lectin-like molecule is a homodimer; 2) the Ly49A molecule

makes no direct contact with residues of the MHC-bound peptide; and 3) in the x-ray structure, there are two potential sites for Ly49A interaction with the MHC molecule: site 1 at the end of the α 1 and α 2 helices, and site 2, an extensive region making contact with the floor of the peptide binding groove, the α 3 domain of the MHC-I molecule, and the β 2m domain as well. The ambiguity suggested by the x-ray structure has been resolved by extensive mutagenesis studies that are consistent with the view that site 2 is functionally significant.^{516,517} Recently, several other NK receptors have been studied structurally. These include the Ly49I inhibitory receptor, which interacts functionally with H2-K^b. The Ly49I has been crystallized without a ligand, revealing a basic fold similar to that of Ly49A but with a somewhat different dimeric arrangement.⁵¹⁸ The Ly49C, another murine NK inhibitory receptor, has been examined in complex with its H2-K^b ligand.⁵¹⁹ Differences between H2-K^b/Ly49C and H2-D^d/Ly49A suggest different modes of NK receptor binding to MHC-I depending on whether the interaction is "cis" (ie, between the NK receptor and the MHC-I on the same NK cell) or "trans" (between the NK receptor on the NK cell and the MHC-I on its target).⁵²⁰

MHC-II Superantigen Complexes

Superantigens are molecules, frequently toxic products of bacteria, which bind MHC molecules on the cell surface and are then presented to a large subset of T cells, usually defined by the expression of a particular family of TCR V regions.⁵²¹ Most of the known superantigens bind MHC-II molecules, although one, the agglutinin from *Urtica dioica*, the stinging nettle, can be bound by both MHC-I and MHC-II molecules and presented to T cells of the V β 8.3 family.⁵²² Its structure in complex with carbohydrate ligand has been reported.^{523,524} MHC-II interactions with superantigens, such as those derived from pathogenic bacteria, are the first step in the presentation of the multivalent array of the APC-bound superantigen to T cells bearing receptors of the family or class that can bind the superantigen.⁵²¹

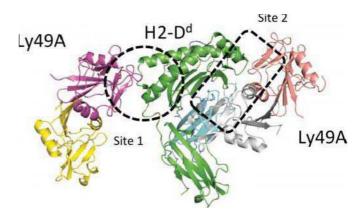

FIG. 21.23. Structure of the H2-D^d/Ly49A Complex Reveals an Alternate Site for MHC/Natural Killer Receptor Interaction. The structure of the complex (PDB 1003) is shown, illustrating both potential sites of interaction.

of superantigen both with their MHC-II ligands and with TCR have been reported.⁵²⁵ Structural analysis of crystals derived from staphylococcal enterotoxin B complexed with HLA-DR1526 and from toxic shock syndrome toxin-1 complexed with HLA-DR1527 revealed that the two toxins bind to an overlapping site, primarily on the MHC-II α chain, and indicated that the staphylococcal enterotoxin B site would not be expected to be influenced by the specific peptide bound by the MHC, although the toxic shock syndrome toxin-1 site would. The view that superantigens exert their biologic effects by interaction with conserved regions of the MHC-II molecule as well as with conserved regions of the TCR has been challenged by the determination of two structures, that of S. aureus enterotoxin H complexed with HLA-DR1528 and that of streptococcal pyrogenic toxin C in complex with HLA-DR2a.⁵²⁹ Both of these studies indicate that these superantigens can interact with the MHC-II β chain through a zinc-dependent site that includes superantigen contacts to bound peptide. Our understanding of superantigen interactions has been augmented by the determination of ternary structures of MHC-II/superantigen/ TCR complexes for two examples, that of the Mycoplasma arthritidis mitogen in complex with HLA-DR1 and TCR,⁵³⁰ and that of Staphylococcus aureus enterotoxin H complexed with HLA-DR1 and TCR.⁵³¹ In both of these cases, the superantigen interacts with the MHC-II and with both TCR Va and VB domains.

MOLECULAR INTERACTIONS OF MHC MOLECULES Assays for Molecular Interactions

Whereas the crystal structures provide a vivid static illustration of the interactions of MHC molecules with their peptide, FcRn, CD8, CD4, superantigen, NK receptor, and TCR ligands, the dynamic aspects of these binding steps can be approached by a variety of biophysical methods.⁵³² It is important to note that affinities and kinetics of interaction of MHC/peptide complexes for TCR have been determined by several methods in a variety of systems.⁵³³⁻⁵⁴⁰ In addition, MHC interactions with NK receptors101,102,541,542 have been quantified by similar techniques. Although there are clear differences in the affinity and kinetics of binding of different TCR and NK receptors for their respective cognate MHC/peptide complexes, the generally consistent findings are that the affinities are low to moderate (ie, $K_d = 5 \times 10^{-5}$ to 10⁻⁷ M) and are characterized by relatively rapid dissociation rates (ie, $k_d = 10^{-1}$ to 10^{-3} sec⁻¹). Recently, attention has been drawn to the differences in measuring interactions with one component in solution (three-dimensional affinity) as compared with measurements made between multivalent displays of the interactions on two surfaces, such as might mimic the apposition of two cells. Methods exploiting microscopic techniques^{543,544} or a micropipette adhesion frequency assay545,546 suggest that the biologic readout of T-cell activation may be more readily correlated with twodimensional rather than three-dimensional measurements of MHC/TCR affinities.

Multivalent MHC/Peptide Complexes

A major development in the past several years has been the engineering and application of multivalent MHC/peptide complexes for the identification, quantification, purification, and functional modulation of T cells with particular MHC or MHC/peptide specificity. Two general approaches have been exploited: one based on the enzymatic biotinylation of soluble MHC/peptide molecules generated in bacterial expression systems that are then multimerized by binding of the biotinylated molecules to the tetravalent streptavidin,547 and another based on the engineering of dimeric MHC/Ig fusion proteins.⁵⁴⁸ These reagents can be used in flow cytometric assays that permit the direct enumeration of MHC/peptide-specific T cells taken directly ex vivo. In either of these methods, multivalent MHC/peptide complexes are generated, and the relatively weak intrinsic affinity of the MHC/peptide complex for its cognate TCR is effectively magnified by the gain in avidity obtained by the increase in valency. For MHC-I molecules, the technology has been so reliable in producing multivalent (tetrameric) molecules loaded homogeneously with synthetic peptides that a wide variety of specific MHC-I/peptide multimers are available either from a resource facility sponsored by the National Institute of Allergy and Infectious Diseases (www .niaid.nih.gov/reposit/tetramer/index.html) or from commercial suppliers that offer either the tetramer, Ig multimer, or a pentamer preparation. The MHC-I/peptide multimers have also been exploited for identification of specific populations of NK cells and for assignment of various NK-receptor specificities.⁵⁴⁹⁻⁵⁵² For some MHC-II molecules, similar success has been achieved in the production of such multimers, using insect cell or mammalian cell expression systems for molecules produced by either the tetramer or Ig chimera strategy.^{553–557} MHC-II/peptide tetramers can be effectively used for a variety of CD4 T-cell applications, but some TCRs (particularly those involved in autoimmune diseases) have an affinity for their cognate MHC-II/peptide that is beneath the threshold for detection.⁵⁴⁵ Also, the potential for the same peptide binding to one MHC-II in multiple frames generates difficulties in the engineering and preparation of effective MHC-II tetramers.406

CONCLUSION

We have surveyed the *Mhc* as a genetic region and a source for molecules crucial to immune regulation and immunologic disease. These genes reflect the panoply of mechanisms involved in the evolution of complex systems and encode cell surface proteins that interact via complex orchestration with small molecules including peptides and glycolipids as well as with macromolecular receptors on T cells and NK cells. The MHC-I molecules provide the immune system with a window for viewing the biologic health of the cell in which they are expressed, and MHC-II molecules function as scavengers to taste and display the remnants of the cellular environment. Viruses and bacterial pathogens contribute enormously to the genetic dancethey modulate and compete in the control of MHC expression, sometimes exploiting MHC mimics that they have acquired—and the host by adjusting its T-cell and NK-cell repertoire on the time scale of both the individual organism and the species, resisting the push to extinction. The immune system, dynamically, resourcefully, and creatively provides, through the concerted action of its MHC molecules, TCRs, NK receptors, and antibodies as well as a host of other regulatory molecules, an organ system vital not only to the survival of the individual but also to the success of the species. As we understand better the molecular functions of the MHC, we should better understand rational approaches to manipulating the immune system in the prevention, diagnosis, and treatment of immunologic and infectious diseases.

CHAPTER

Antigen Processing and Presentation

Ted H. Hansen • Paul A. Roche

ANTIGEN PRESENTATION PATHWAYS

22

As part of the adaptive immune response, T cells mount immune responses to diseased cells and abnormal cells. Remarkably, the mechanism by which T cells discriminate self from non-self is based on pathogen- or tumorderived proteins displayed on the cell surface by self-major histocompatibility complex (MHC) molecules. More specifically, when T cells detect diseased cells displaying MHC molecules loaded with peptides derived from foreign peptides, effector mechanisms are initiated to eliminate the diseased cell. By contrast, T cells that detect cells displaying MHC molecules loaded with peptides derived from self-proteins are either eliminated during ontogeny by negative selection or suppressed by peripheral tolerance mechanisms. Thus, at the molecular level, the T-cell receptors on T cells discriminates MHC loaded with self- versus non-self-peptides displayed at the cell surface of normal and diseased cells. The mechanisms by which peptide ligands for MHC molecules are generated is referred to as antigen processing, whereas the mechanism by which peptide/MHC complexes are displayed at the cell surface is called antigen presentation.

To assure the appropriate effector mechanism is generated to detect cells infected with pathogens in the cytosol or endocytic compartments, the antigen presentation pathways for classical cluster of differentiation (CD)8+ versus CD4+ T cells are different. More specifically, antigen derived from intracellular pathogens is typically bound to MHC-I proteins that are uniquely detected by CD8 T cells, whereas antigen derived from extracellular pathogens is typically bound to MHC-II proteins that are uniquely detected by CD4 T cells. To preferentially bind peptides derived from proteins synthesized inside the cell, the processing of peptides that bind MHC-I proteins occurs in the cytosol and the loading of these peptides occurs in the endoplasmic reticulum (ER). This pathway is commonly referred to as the classical MHC-I antigen-binding pathway. By contrast, to preferentially bind peptides from proteins synthesized outside the cell, the processing and loading of antigenic peptide ligands for MHC-II proteins occurs in an endocytic pathway terminating in the lysosomes. This pathway is typically referred to the classical MHC-II antigen-binding pathway. The differences between the MHC-I and MHC-II antigen presentation pathways are determined by their differential interaction with molecular chaperones. These same molecular chaperones enforce the quality control of antigen presentation to assure appropriate T cells

are activated for detection and elimination of pathogeninfected cells or tumors.

ANTIGEN PROCESSING AND PRESENTATION BY MAJOR HISTOCOMPATIBILITY CLASS I (MHC-I) PROTEINS

Origin of MHC-I binding peptides

As detailed in Chapter 21, MHC-I proteins preferentially bind peptides of 8 to 10 amino acid lengths, and which peptides bind is determined by MHC-I allele-specific polymorphic residues that form the architecture of its peptide binding groove. Each MHC-I allele typically binds peptides with a consensus binding motif requiring a relatively specific amino acid central anchor and a C-terminal hydrophobic amino acid. Given the lack of restraints in most peptide positions and the large number of proteins synthesized by each cell relative to the number of MHC molecules, the selective processes controlling which peptides get presented is of considerable importance for the detection of pathogens and malignancies.

The source of the peptides that get presented during infection has been a question of considerable investigation. It has been known for some time that MHC-I-binding peptides are derived from membrane-bound, secreted, cytosolic, and nuclear proteins that are almost exclusively generated by the proteasome in the cytosol. However, the uncertainty of peptide source is based on two apparently incongruent observations. Most proteins from which MHC-I-binding peptides are derived have slow rates of turnover in cells ranging from hours to days; viral-derived peptides are presented by infected cells to CD8 T cells within a few minutes. This disparity between the degradation versus presentation kinetics is potentially explained by cumulative observations that a fraction of newly synthesized polypeptides are rapidly degraded, providing a peptide reservoir sufficient to support a robust CD8 T-cell response. Supporting evidence for this conclusion comes from studies that block protein synthesis with cycloheximide and detected a rapid decrease in the peptide supply for MHC-I binding.^{1,2} One of the more elegant ways to monitor peptide transport into the ER was by transporter associated with antigen presentation (TAP) mobility in the ER membrane by photobleaching; establishing TAP mobility was proportional to the peptides in the cytosol. This assay was used to show a 90% reduction in peptide supply after 30 m treatment with cycloheximide, thus kinetically linking presentation closely to translation.³ Indeed, there are now several reports that within 30 minutes after synthesis, antigenic peptides are presented at the cell surface at levels that activate T cells.^{4,5} What remained unclear from these studies is the biochemical and mechanistic basis for the generation of these rapidly transcribed proteins from which MHC-I–binding peptides are derived.

In a model that has gained wide acceptance, Yewdell and colleagues proposed that a rapid supply of MHC-I ligands is derived from aberrant protein production they termed defective ribosomal products or DriPs.^{6,7} In their model, it was speculated that DriPs could be derived from unfolded or misfolded proteins of the proper sequence and length, proteins with errors in sequence or posttranslational modifications, prematurely terminated proteins, and proteins translated from the wrong start codon.⁸ Regarding aberrant translations, there is evidence that MHC-presented peptides can arise from alternative reading frames, generating what has been called cryptic epitopes.⁹ For example, Schwab et al. showed that inhibition of the eukaryotic translational initiation factor eIF2 resulted in the synthesis of cryptic peptides and intriguingly, viruses inhibit host translation by inactivating $eIF2\alpha$.^{10,11} However, most MHC-I-presented peptides have native amino acid sequence and are derived from standard messenger ribonucleic acid (mRNA) translation products, suggesting cryptic epitopes represent only a minor component of MHC-presented peptides. In addition, the contribution of peptides derived from misfolded proteins in the secretory pathway is also likely modest. Although antigenic peptides from misfolded tyrosinase were found to be preferentially presented,¹² other studies show that several mutations causing misfolding do not lead to enhanced antigen presentation. Furthermore, ER quality control is typically too slow to account for the rapid supply of MHC-I-binding peptides.¹³ The reason for this kinetic delay is that substrates for ER-associated degradation (ERAD) must be 1) translocated into the ER, 2) detected presumably by ER chaperones as being misfolded, 3) ubiquitinated and extracted from the ER, and 4) degraded by the proteasome in the cytosol. Thus the predominance of MHC-I-presented peptides likely does not come from cryptic epitopes or misfolded ER proteins identified by ER quality control.

To obviate trafficking into the ER, misfolded secretory proteins could be degraded rapidly based on degron detection such as unshielded hydrophobicity.¹⁴ Alternatively, early in translation a lack of signal recognition particle engagement could lead to the mistargeting of secretory proteins to the cytosol. In support of this model, Schlosser et al.¹⁵ showed that an epitope encompassing the signal peptidase cleavage site was efficiently presented by MHC-I proteins. To rapidly generate peptides, it has been speculated that cells may have select ribosomes called "immunoribosomes."¹⁶ Such immunoribosomes might be more adept at generating peptides with TAP access perhaps by compartmentalization and/or targeting proteins to the 20S proteasome for immediate destruction. In any case, there is considerable evidence that antigenic peptides can be rapidly presented by MHC-I within minutes after translation of the protein source. The physiologic significance of this rapid kinetics of antigen presentation is that it allows CD8 T cells to kill virus-infected cells before viral replication is completed and progeny are released. However, whether the production of peptides bound to MHC class I molecules is a deliberate process for degrading defective translation products and/or a stochastic event of normal protein translation remains to be determined.¹⁷

Peptide Trimming in the Cytosol

Degradation of cellular and antigenic peptides bound to MHC-I is largely mediated in the cytosol by the proteasome. The proteasome is responsible for the degradation of the majority of cytosolic and nuclear proteins, and in most cases proteasome targeted proteins are ubiquitinated. Ubiquitin (Ub) is typically coupled to internal lysine residues of proteins substrates, but coupling can also occur at the N terminus or on internal cysteine, serine, or threonine residues.¹⁸⁻²¹ In this orchestrated process, activated Ub is transferred from one predominant Ub-activating enzyme (E1) to one of 30 to 40 mammalian Ub conjugating enzymes (E2s) and then to the substrate that is bound by one of hundreds of different ubiquitin protein ligases (E3s). The E3s are the major determinant of substrate specificity. This process can be repeated to form polyUb chains whereupon the next Ub moiety is added to one of the seven internal lysine residues of Ub. Proteins coupled with polyUb chains of four or more Ub moieties linked through Lys48 Ub residues are the prototypic signal for proteasome mediated degradation.

The cylindrical 20S catalytic particle (CP) of the proteasome is formed by four stacked rings of seven subunits each. The inner two rings of the 20S proteasome are assembled from the beta subunits, three of which have catalytic activity with chymotryptic, tryptic, or caspase activity. Thus each proteasome has six active sites with the ability to cleave after most types of peptide bonds, although to differing efficiencies based on flanking residues. The catalytic sites are exposed to the interior of the central chamber of the 20S cylinder. The two outer rings of the 20S proteasome are assembled from alpha subunits forming a pore of 13 Angstrom, mandating protein substrates be partially denatured prior to entering the interior of the chamber. The gate of the 20S CP is normally closed, and access to the interior of the 20S proteasome is controlled by the complex of proteins termed the 19S regulatory particle that binds to each end of the 20S cylinder. The full assemblage of 19S-20S-19S complex constitutes the 26S proteasome. The lid of the 19S regulator particle binds and deubiquitinates protein substrates before they gain entry in the 20S CP; the base of the 19S regulatory particle contains ATPases that promote substrate unfolding and open the gate of the 20S CP to provide access of denatured protein substrates to the catalytic activity of the inner chamber.

The evolutionarily conserved function of the proteasome is for recycling amino acids and ubiquitin moieties. However, in mammals, modifications to the proteasome have been made to promote antigen presentation. In response to interferon (IFN) γ stimulation that occurs during inflammation, three catalytic subunits of the constitutively expressed proteasome are replaced by IFN γ -induced homologs forming what is called the immunoproteasome. More specifically, subunits β 1, β 2, and β 5 of the constitutive proteasome are replaced by subunits β 1i (LMP2), β 2i (MECL-1), and β 5i (LMP7) of the immunoproteasome. Suggesting an immunologic function, LMP2 and 5 are genetically encoded within a central region of the mouse and human MHCs juxtaposed to genes encoding the TAP heterodimer. Consistent with their immunologic relevance, the immunoproteasomes display enhanced cleavage of protein substrates after hydrophobic and basic amino acids, thus generating peptides with C-terminal residues preferred for binding to many MHC-I alleles. IFNY stimulation also induces the expression of PA28 α and PA28 β that form the 11S regulatory particle, which can also bind to either end of the 20S CP. Interestingly, the PA28 regulatory particle does not contain ATPases, but it does induce conformational changes to open the 20S CP gate. Thus, PA28 may function to prevent the overdigestion of short peptides. This is an important issue, as it has been estimated that a nonamer peptide in the cytosol has a half-life of only 7 seconds.²² However, studies testing PA28 α/β -deficient mice demonstrated that PA28 α/β is not required for overall antigen presentation during virus infection, but may affect degradation of select substrates.²³ In any case, the inclusion of the IFNYinducible β subunits into the 20S CP of immunoproteasome enhances antigen presentation by generating peptides with preferred C-terminal anchor residues, and in some same cases inclusion of the PA28 regulatory particle may prevent overdegradation of immunologically relevant proteins.

The proteasome generates the final C-terminal cleavage of most MHC-I-binding peptides. A recently reported exception to this is the generation of the tumor antigen MAGE-A3 by insulin-degrading enzyme.²³ Whereas insulin degrading enzyme is solely responsible for the generation of the human leukocyte antigen (HLA)-A1-restricted MAGE-A3 epitope, the HLA-B40-restricted MAGE-A3 epitope was proteasome dependent. Although there are several N-terminal proteases in the cytosol, they have only a limited role in generation of the MHC-I-binding peptides. More specifically, tripeptidyl peptidase II, leucine amino peptidase, bleomycin hydrolase, and puromycin-sensitive aminopeptidase have all been found to affect generation of select MHC-I-binding epitopes, but these proteases have an overall negative effect on antigen presentation by MHC-I. Interestingly, the metalloprotease nardilysin that cleaves substrates on the N-terminus of arginine residues in dibasic pairs was implicated in three cytotoxic T lymphocyte epitopes and may be more generalizable given the preference for basic N-terminal resides for MHC-I binding.²⁴ However, as noted in the following, significant N terminal trimming of MHC-I-binding peptide occurs after transport from the cytosol into the ER.

Peptide Transport into the Endoplasmic Reticulum

Landmark studies of the mutagenized and immunoselected mouse cell line RMA-S resulted in the discovery of how peptides are transported from the cytosol into the ER lumen.^{25–27} The low level of surface expression of MHC-I molecules by RMA-S that could be rescued by either low temperatures or culturing with known MHC-I–binding peptides was attributed to lack of peptide transport by TAP. TAP is a member of the adenosine triphosphate (ATP) binding cassette family. Mechanistically, hydrolysis of ATP is required both for peptide binding to the cytosolic face of TAP as well as peptide transport into the ER. Structurally, TAP is a heterodimeric complex of TAP1 and TAP2 subunits both encoded within the central region of the MHC of mouse and human. The translocation pore of TAP is formed by six transmembrane domains of each subunit, whereas the remaining transmembrane domains (four for TAP1 and three for TAP2) are involved in interaction with peptide loading complex (PLC).²⁸ Awaiting transport, both the N- and C-termini of peptides are bound to TAP²⁹; peptides with higher affinity for binding TAP have a greater likelihood of transport, MHC binding, and presentation to T cells during infection.^{30,31} TAP typically transports peptides of 8 to 16 residues, although longer peptides are less efficiently transported. As discussed in the next section, peptides with N-terminal extensions are trimmed in the ER.

Peptide Trimming in the Endoplasmic Reticulum

As noted previously, TAP transports many peptides with C-terminal hydrophobic residues required for MHC binding, but with N-terminal extensions, which need to be cleaved to conform to the MHC-binding motif of the expressed alleles. It is now clear that N-terminal trimming within the ER is carried out by the ER-associated aminopeptidase (ERAAP; ERAP1 in mice and ERAP1 in humans). Interestingly, unlike other aminopeptidases, ERAP1 preferentially cleaved peptides of 9 to 16 amino acids thus matching the same peptide length preference as transported by TAP.³² More specifically, ERAP1 was found to degrade a model 13-mer to a 9-mer and then stop, an apparent adaptation to maximize optimal MHC-I binding. The length preference of ERAP1 could be explained by extended peptides binding to MHC-I before N-terminal trimming. However, this model is not supported by structural analyses of ERAP1 and the location of its active site.³³ Alternatively, recent analyses support a "molecular ruler" model. In this model, a hydrophobic pocket of ERAP1 binds the C-terminal peptide residue thereby positioning the peptide so that N-terminal cleavage occurs about nine amino acids away.^{32,33} Thus, ERAAP/ERAP1 has unique structural features explaining its ability to trim extended peptide precursors while sparing ones of optimal length for MHC-I binding. As further evidence of their specialized functions in antigen presentation by MHC-I proteins, ERAP1 preferentially binds and processes peptides with hydrophobic C-terminal residues consistent with the majority of the TAPtransported MHC-I-binding peptides. Interestingly, humans have a second ER-associated peptidase with homology to ERAP1 designated ERAP2.³⁴ ERAP2 preferentially binds peptides with C-terminal basic residues and thus may function in human cells to provide peptides for HLA-A3, -Aw68, and -B27 alleles that bind such peptides. Additionally, in humans the combined activity of both ERAP1 and ERAP2 (most likely as heterdimers) is required for the presentation of certain epitopes.³⁵ By contrast, in mice ERAAP/ERAP1 is sufficient to service their MHC-I alleles, all of which bind peptides with hydrophobic C-termini. As additional evidence for their tailoring for MHC-I-antigen presentation, the expression and trimming activity of ERAP1 and ERAP2 are upregulated upon IFNy stimulation.

The impact of ERAP on specific epitopes and the overall MHC-binding peptide repertoire has been analyzed using

cell lines^{36,37} and ERAAP-knockout mice.^{38,39} These studies have shown that cytotoxic T lymphocyte detection of some but not all MHC-I/peptide complexes are ERAP1-dependent. For example, in vitro ribonucleic acid interference experiments suggested that ERAP1 is involved in formation of onethird of peptide/MHC-I complexes.36,37 ERAAP-deficient mice had a 20% lower expression of K^b, D^b, K^d, and D^d alleles at the cell surface but a 70% lower expression of L^d. Of these mouse alleles, only L^d preferentially binds peptides with the motif of Pro in the second position, although about 20% of human HLA alleles also prefer peptides with a Pro in the second position. Notably, peptides with Pro in the second position are only transported by TAP with N-terminal extensions and are thus dependent upon ERAP1 for their generation. In vivo relevance of this conclusion was demonstrated by the observation that ERAAP-deficient BALB/c mice were

found to be susceptible to *Toxoplasma gondii* infection resulting from the fact that the immunodominant epitope presented to CD8 T cells is L^d restricted.⁴⁰ Interestingly the ERAAP-deficient mice were also found to present several unique peptides that elicited potent CD8 T-cell responses demonstrating ERAAP functions, as a peptide editor altering the repertoire of peptides presented.³⁸

Chaperone-assisted Peptide Loading in the Endoplasmic Reticulum

Full assembly of the MHC-I heavy chains (HCs) with β 2m and peptide within the ER is orchestrated by molecular chaperones that keep folding intermediates in a conformation capable of attaining full assembly (Fig. 22.1). Nascent HCs are transiently associated with the membrane-anchored

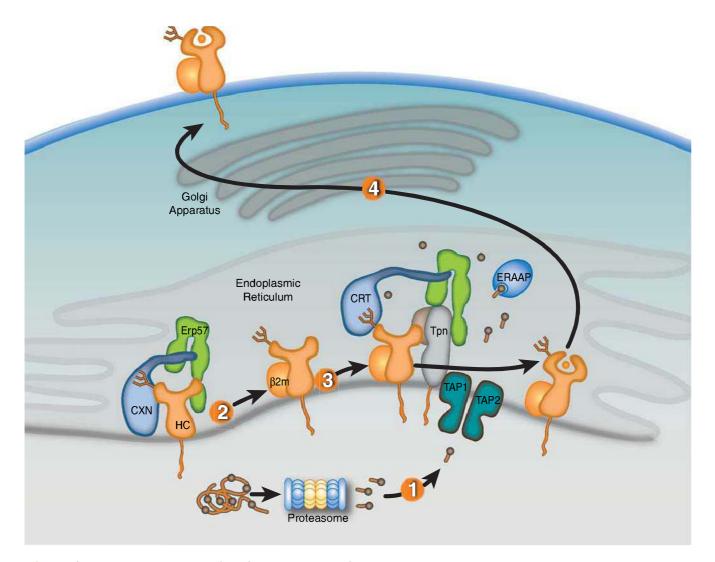

FIG. 22.1. Schematic Representation of the Sequential Events of Antigen Processing and Presentation by Major Histocompatibility Complex (MHC)-I Proteins. 1: Peptides are processed by the proteasome and translocated into the ER by TAP1/TAP2 heterodimers. 2: MHC-I heavy chains (HCs) awaiting assembly with β2m are bound to calnexin (CXN)/ERp57 complexes. 3: After assembly with β2m, HC/β2m heterodimers enter the peptide loading complex wherein tapasin (Tpn) bridges HC with transporter associated with antigen presentation (TAP)/TAP2, and calreticulin (CRT)/ERp57 complexes bridge HC with Tpn. 4: Following the binding of a suitable peptide, which may require final N-terminal trimming by ERAAP, fully assembled MHC-I proteins (HC/β2m/peptide) traffic to the plasma membrane via the secretory pathway.

lectin calnexin (CXN) that, like its soluble paralog calreticulin (CRT), functions as a general chaperone for assembly of oligomeric glycoproteins. Quality control of glycoprotein assembly by CXN and CRT is carried out by monitoring terminal glucose residues on their N-linked glycans. More specifically, the folding sensor UDP-glucose glycoprotein glucotransferase allows incompletely assembled substrates to reassociate with CXN or CRT, and cycles of glucose addition and removal continue until substrates are either correctly folded and assembled or targeted for ERAD. After the MHC-I HC assembles with β 2m, the HC/ β 2m heterodimer exchanges CXN for CRT and enters the PLC consisting of CRT, ERp57, tapasin (Tpn), and TAP.41-44 Optimal antigen presentation by MHC-I is dependent upon all four components of the PLC (Tpn, TAP, CRT, and ERp57) that function to improve peptide loading in MHC-I proteins and their surface display.45,46

Knockout cell lines, genetically deficient mouse strains, and mutagenesis studies have provided key insights in the selective roles of PLC components in MHC-I assembly. CRT association with MHC-I proteins is dependent upon the N-linked glycan at residue Asn86 of the HC. Interestingly, the location of the glycan is important for CRT but not CXN association with HCs, likely reflecting geometric constraints imposed by PLC assembly. CRT-deficient cells have suboptimal peptide loading resulting in reduced surface MHC-I expression.47 ERp57 is a thiol oxidoreductase that mediates disulfide bond formation of different substrates and is commonly associated with CXN and CRT. Interestingly, however, the function of ERp57 as a component of the PLC appears to be independent of the MHC-I redox state. ERp57 forms a disulfide bond with Tpn that is required for PLC construction.^{48,49} It was originally proposed that the ERp57-Tpn complex prevents reduction of the $\alpha 2$ disulfide HC bond, thereby keeping HC in a peptide-receptive state.⁵⁰ However, other studies have detected little evidence the ERp57 controls redox state of MHC-I and more recently, the crystal structure of the ERp57-Tpn complex suggests that the role of the ERp57 in the PLC is structural, facilitating recruitment of peptide-accessible MHC-I.^{49,51,52} As a likely reflection of its fundamental role in PLC construction, ERp57-deficient cells were found to have impaired peptide loading, surface expression, and antigen presentation by MHC-I proteins.

Tpn, an MHC-I-dedicated molecular chaperone, is required to bridge β 2m-assembled HCs with TAP.⁵³ Playing a redundant role with other members of the PLC, Tpn also functions in ER retention of MHC with suboptimal peptide cargo.^{54,55} Perhaps most importantly, Tpn functions as a peptide editor by stabilizing peptide-accessible MHC-I proteins and optimizing peptide cargo before release from the PLC. The mechanism of peptide editing by Tpn of MHC-I proteins was revealed using recombinant Tpn tethered to HLA,56 and using recombinant Tpn-ERp57 conjugates added to Tpn-deficient cells.⁵⁷ These and other reports support the model that Tpn promotes the peptide exchange of MHC molecules in an affinity-dependent manner. The consensus model is that Tpn stabilizes the peptide binding groove of MHC-I in an "open" peptide-accessible conformation. The association of Tpn with peptide-accessible

MHC-I then promotes peptide exchange until a peptide of suitable affinity binds to complete the folding of the ligand binding groove. This peptide-induced folding then induces the release of fully assembled MHC-I from the PLC. Logistically, how peptide editing by Tpn might occur was provided by mutagenesis studies of the MHC-I/Tpn interaction site. Two sites on the HC are critical for Tpn interaction: one site is in the α 3 domain (residues 227 and 229) and the other in the $\alpha 2$ domain (residues 128-136)^{43,58,59} (Fig. 22.2A). Based on the location of the latter site and molecular dynamic modeling, it has been theorized that the α 2 interaction site might function as a folding sensor for C-terminal peptide anchoring in the MHC-I F pocket.^{60,61} Consistent with this model, polymorphisms within the F pocket can have a profound effect of Tpn dependencies of different MHC-I alleles.⁶² Based on mutagenesis and structural analyses, a credible model was constructed by Dong et al. of the MHC-I/PLC interactions⁵² (see Fig. 22.2).

Although Tpn within the PLC is thought to enforce most of the quality control of antigen presentation by MHC-I, there are also adjunct pathways. For example, the sensor UGT1 that adds a terminal glucose to unfolded ER proteins for rebinding CRT has been recently implicated in the quality control of antigen presentation by MHC-I. In support of this conclusion, using in vitro assays with recombinant components, UTG1 was reported to preferentially reglucosylate MHC-I proteins loaded with suboptimal peptides.⁶³ Also, as a post-ER quality control pathway, CRT was reported to use a KDEL-dependent mechanism to recycle suboptimally loaded MHC-I proteins from the early Golgi back the ER for improved peptide binding.⁶⁴

Viral Immune Evasion of Antigen Presentation

As noted previously, several molecular components of antigen presentation were coopted from physiologic pathways of protein degradation and quality control. Using elegant mechanisms, viruses express diverse proteins that coopt these same pathways of protein degradation and quality control to evade immune detection by CD8 T cells.⁶⁵ Indeed, the specificity and potency of immune evasion proteins impairing antigen presentation makes them efficacious probes for physiologic pathways of relevance for MHC expression. Most of the well-characterized immune evasion proteins are expressed by deoxyribonucleic acid viruses with large genomes, particular viruses capable of latency or host coexistence. Strikingly, immune evasion proteins block several different steps of the antigen presentation pathway by MHC-I proteins (Fig. 22.3). For example, Epstein-Barr virus and Kaposi sarcoma-associated herpesvirus express proteins during latency that escape cytotoxic T lymphocyte detection by containing sequences that inhibit proteasome processing.^{66–70} Alternatively, blocking peptide transport by inhibiting TAP function is a commonly used immune evasion strategy. For example, ICP47 of herpes simplex virus binds the cytosolic side of TAP and blocks peptide and not ATP binding,⁷¹⁻⁷⁶ whereas US6 of human cytomegalovirus (HCMV) binds the luminal side of TAP and induces a conformational change resulting in inhibition of ATP hydrolysis

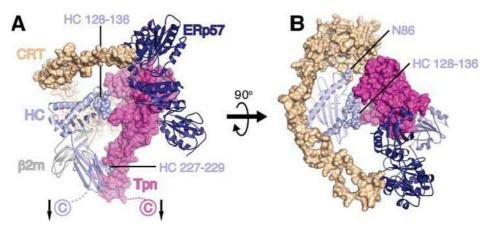

FIG. 22.2. A Model of the Peptide Loading Complex Based on Known Structures and Mutagenesis Data of Interaction Sites.⁵² Heavy chains (HCs), β2m, and ERp57 are shown as ribbons, while calreticulin (CRT) and tapasin (Tpn) are shown as Connolly surfaces (1.4 Å probe). HCs and Tpn are membrane anchored as indicated with arrows, whereas transmembrane interactions between Tpn and TAP (not shown) attach the phospholipase C (PLC) components to TAP. HC sites predicted by mutagenesis studies to interact with Tpn (residues 227 to 229 and 128 to 136) and CRT (N86) are indicated as spheres. The long flexible P domain of CRT extends above the major histocompatibility complex (MHC)-I peptide binding platform before it noncovalently binds to ERp57, which is covalently attached to Tpn. A: PLC components are shown from the side to highlight Tpn contacts to the HC $\alpha 2$ and $\alpha 3$ domains. B: PLC components shown from above reveal coordinated chaperone binding of both MHCI α -helices near the antigenic peptide's C-terminus. The figure was rendered by Drs. William McCoy IV and Daved Fremont using Protein Data Bank (PDB) files kindly provided by Drs. Karin Reinisch and Peter Cresswell. The structures of the Tpn/ ERp57 complex was published in Dong et al.,⁵² the structure of CRT was modeled using PHYRE2²³ on its homolog calnexin,²³⁶ and human leukocyte antigen-A2²³⁷ is shown as a representative HC. It should be noted that the HC conformation shown is that attained after peptide occupancy, as the peptide-accessible HC conformation that binds the PLC has not been resolved.

and peptide translocation.^{77–81} As a third mechanism of TAP blocking, UL49.5 of bovine herpesvirus induces TAP degradation.⁸² There are also published examples of immune evasion proteins inhibiting Tpn function. For example, US3 of HCMV binds to Tpn and impairs optimization of peptide loading,^{83,84} whereas E3-19K of AdV inhibits the ability of Tpn to bridge MHC-I with TAP.⁸⁵

Immune evasion proteins also employ strategies to misdirect trafficking of MHC-I proteins. For example, the aforementioned E3-19K protein of AdV binds MHC-I proteins and blocks their transport out of the ER.⁸⁶⁻⁹⁰ Interestingly, cowpox virus expresses two different immune evasion proteins targeting MHC-I proteins that function in tandem. Cowpox virus 12 is a TAP function blocker that curtails peptide supply, whereas cowpox virus 203 returns fully assembled MHC-I proteins from the Golgi back to the ER.⁹¹⁻⁹⁴ To also misdirect assembled MHC-I proteins, the Nef protein of human immunodeficiency virus and gp48 protein of murine cytomegalovirus shuttle assembled MHC-I proteins from the Golgi to the lysosome.⁹⁵⁻⁹⁷

Interestingly, the aforementioned immune evasion proteins for the most part do not have cellular homologs, making it difficult to track their evolution. Striking exceptions to this generality are the viral ER ubiquitin ligases called the viral MARCH (*m*embrane-*associated RING-CH*) proteins. The extensive family of MARCH proteins includes viral and cellular homologs that share a transmembrane orientation and a highly conserved atypical RING domain that confers E3 ubiquitin ligase activity.98-100 Viral proteins mK3 of MHV68, and proteins kK3 and kK5 of Kaposi sarcomaassociated herpesvirus that function as immune evasion proteins were the founding members of the MARCH protein family.^{101–103} Mechanistically, mK3 binds to TAP and awaits the entry of MHC-I into the PLC after which mK3 ubiquitinates the cytosolic tail of MHC-I HCs and thus induces their dislocation to the cytosol and degradation in the cytosol (ie, ERAD).¹⁰⁴⁻¹⁰⁷ Of note, the extensively studied US2 and US11 proteins of HCMV also target ERAD of MHC-I proteins by recruiting cellular E3 ligases.¹⁰⁸⁻¹¹³ Indeed, studies of US2, US11 and mK3 continue to provide molecular insights into various mechanisms by which ERAD substrates are detected in the ER and dislocated to the cytosol.^{114,115} In contrast to ERAD, the kK3 and kK5 MARCH ligases of Kaposi sarcoma-associated herpesvirus induce endocytosis and lysosomal degradation of MHC-I proteins. Interesting, kK3 like mK3 appears to ubiquitinate only MHC-I proteins, whereas kK5 targets other surface receptors including the T cell costimulation molecule CD86 (B7.2) as well as natural killer cell ligands, MHC class I-related chain A or B (MICA, MICB), and newly defined ligand for NKp80, activationinduced C-type lectin (AICL).¹¹⁶ Inhibition of natural killer responses is of importance to the virus because downregulation of MHC-I proteins renders cells susceptible to natural killer cell lysis. Mechanistic studies of viral MARCH

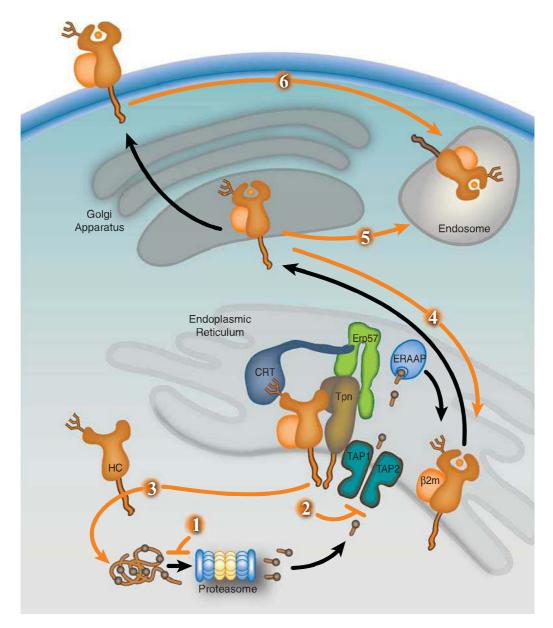

FIG. 22.3. Immune Evasion Strategies Used by Viral Proteins to Block Antigen Presentation by Major Histocompatibility Complex (MHC)-I Proteins. *Black arrows* demarcate physiologic pathways for antigen presentation, whereas the *numbered red arrows* demarcate reported immune evasion strategies by virus proteins. 1: Blocking of antigen processing by the proteasome (examples are the EDNA1 protein of Epstein-Barr virus or the LANA1 protein of Kaposi sarcoma–associated herpesvirus). 2: Blocking peptide transport by transporter associated with antigen presentation (examples include the ICP47 protein of herpes simplex virus, US6 protein of human cytomegalovirus, cpxv12 protein of cowpox virus, UL49.5 protein of bovine herpesvirus, and BNFL2a protein of Epstein-Barr virus). 3: Dislocation of MHC-I proteins from the endoplasmic reticulum (ER) to the cytosol for proteasome-mediated degradation (examples are US2 and US11 proteins of human cytomegalovirusand mK3 protein of MHV68). 4: ER retention and retrieval of MHC-I proteins (examples are E3-19K protein of AdV and the cpxv203 protein of cowpox virus). 5: Mistrafficking of MHC-I proteins from the Golgi to an endosomal compartment (examples include gp48 protein of murine cytomegalovirus and Nef protein of human immunodeficiency virus-1). 6: Rapid internalization of MHC-I proteins from the cell surface to an endosomal compartment (examples are KK3 and kK5 proteins of Kaposi sarcoma–associated herpesvirus).

proteins have provided several molecular insights into ubiquitin-dependent degradation pathways of particular relevance to antigen processing. In addition, there are about 10 cellular MARCH protein homologs in humans and mice, many of which detect immune receptors.^{98–100} For example, as mentioned in the MHC-II section, MARCHI regulates MHC-II expression in B cells and dendritic cell (DC) subsets.^{117–119} Thus, viral MARCH proteins were stolen from the host and adapted by the virus to function as immune evasion proteins using similar mechanisms.

ANTIGEN PROCESSING AND PRESENTATION BY MAJOR HISTOCOMPATIBILITY CLASS II (MHC-II) PROTEINS

Source of Antigen for MHC-II Presentation

As a general rule, the antigen-processing machinery that is utilized by MHC-I is specialized for the degradation, importation, and binding of peptides that are derived from antigens present in the cytosol of host cells. Although many viruses and bacteria thrive in the cytosol of infected cells, there are pathogens (such as Toxoplasma gondii) that reside in membrane-encapsulated intracellular compartments and do not access the cytosol.¹²⁰ Furthermore, almost any foreign material (including live or dead pathogens, fragments of apoptotic cells, or soluble proteins) can enter the cell by endocytosis and are therefore sequestered from the cytosol. It is for recognition of antigens such as this that MHC-II molecules exist; MHC-II binds peptides derived from antigens that gain access to intracellular compartments in cells by a variety of endocytic pathways.¹²¹ Fluid-phase macropinocytosis is a process whereby extracellular fluid is taken up by plasma membrane protrusions that bring extracellular fluids and soluble proteins into the cell by endocytosis. Once internalized, macropinosomes fuse with early endosomes, thereby releasing their contents to the endocytic pathway. Immature (resting) DCs are particularly efficient in their capacity for macropinocytosis that enhances their significance as "sentinals" of the immune system.¹²² Upon activation by encounter with foreign organisms, DCs greatly suppress macropinocytosis,^{122–124} thereby limiting the ability of the activated DCs to sample their microenvironment and restricting the repertoire of antigenic peptides presented to T-lymphocytes.

As one can imagine, macropinocytosis is not a particularly efficient mechanism of antigen uptake. B cells possess antigen-specific receptors (immunoglobulins) that permit specific antigen internalization and presentation to T cells that can be 1000 times more efficient than fluid-phase endocytosis.¹²⁵ Curiously, the function and fate of B cells that generate specific MHC-II peptide complexes following immunoglobulin-mediated antigen uptake versus fluid-phase uptake of the same antigen differ significantly,¹²⁶ highlighting the importance of the receptor-mediated antigen uptake pathway in B cells. Similarly, macrophages and DCs express Fc receptors and complement receptors that allow efficient phagocytosis of large extracellular particles such as antibody-coated organisms or even apoptotic cells. Following endocytosis, the phagosome fuses with the membrane of a lysosome, forming a degradative phagolysosome that neutralizes and degrades internalized antigens into peptides.¹²⁷ Other surface receptors, such as mannose receptors^{122,128,129} and DEC-205¹³⁰ on DCs, also allow for efficient antigen binding and uptake onto the endocytic pathway, and these receptors have been exploited as a vehicle to efficiently deliver bring foreign vaccine antigens into the MHC-II processing pathway in antigen-presenting cells (APCs).¹³¹

While antigens entering the endocytic pathway by phagocytosis, macropinocytosis, and receptor-mediated endocytosis give rise to the majority of peptides that bind to MHC-II, there is increasing evidence that cytosolic antigens are capable of entering endosomal MHC-II processing compartments and are degraded there into MHC-II-binding peptides. The most likely cellular mechanism responsible for this phenomena is process termed autophagy.^{132,133} Macroautophagy is constitutively active in DCs and is a process that leads to the "engulfment" of aggregated cytosolic protein complexes to form an autophagosome. Like phagosomes from extracellular antigens, the autophagosome fuses with a lysosome and results in the degradation of autophagosome contents into antigenic peptides.^{134,135} A related process, termed chaperone-mediated autophagy, results from the direct import of cytosolic proteins into the lumen of endo/lysosomes and is facilitated by the chaperone protein hsc-70 and the lysosomal integral membrane protein Lamp2a.¹³⁶ Once inside this organelle, the imported protein is degraded into antigenic peptides just like "conventionally" internalized antigens. While this pathway clearly functions in vitro, the extent to which autophagy participates in MHC-II-restricted immune responses remains to be established.

MHC-II Assembly and Transport to the Endosomal Pathway

Because MHC-II is specialized to bind peptides generated in the endocytic pathway, there must be mechanisms in APCs to prevent the premature binding of peptides to MHC-II as the molecules assemble in the ER and traffic through the Golgi apparatus before their delivery to endosomal peptide loading compartments. In addition to the inability of MHC-II to bind to TAP/tapasin and other members of the MHC-I-peptide loading complex, MHC-II is unique in that it binds to a transmembrane chaperone protein termed the invariant chain (Ii). It is the association of Ii with the MHC-II-peptide binding site that prevents MHC-II molecules in the early secretory pathway from binding peptides.137,138 Indeed, failure of newly synthesized MHC-II to bind Ii allows for the presentation of ER-imported peptides to CD4 T cells by MHC-II.¹³⁹ A specific region of Ii, termed the class II-associated Ii peptide (CLIP), serves to block the peptide-binding groove of nascent MHC-II molecules until it is ready for removal in endo-/lysosomes. The MHC-II-CLIP complex has been crystallized, and as one might expect, the structure of this complex is nearly identical to that of a MHC-II molecule containing an "antigenic" peptide.¹⁴⁰ As the name implies, unlike the highly polymorphic MHC-II molecule itself, Ii is nonpolymorphic. However, the human Ii mRNA can initiate protein synthesis using one of two translation initiation sites (Fig. 22.4A), leading to generation of a major 33 kDa form of Ii (Ii-p33) as well as a minor population of larger Ii molecules whose translation is initiated using an upstream methionine (Ii-p35¹⁴¹). The use of alternative translation initiation sites appears to be unique to humans, as it is not seen in rodents.¹⁴² Furthermore, alternative mRNA splicing in all species examined can give rise to an additional 8 kDa domain in each form of Ii, leading to the production of Ii-p41 and (in humans) Ii-p43.^{143,144} This additional exon encodes a domain (see subsequent discussion) that regulates the activity of proteases in endo-/lysosomes.

The Ii molecule itself forms a trimer even in the absence of MHC-II, and each constituent subunit of this trimer contains either Ii-p33, -p35, -p41, or -p43 isoforms (see Fig. 22.4B).

Ii homotrimers and mixed heterotrimers are generated, and each trimer contains an Ii molecule whose presence in the trimer is proportional to its level of expression.^{145–147} Onto this "scaffold" of an Ii trimer, pairs of MHC-II $\alpha\beta$ heterodimers assemble, ultimately forming a mature, nine-chain MHC-II-Ii complex.¹⁴⁸ The partially formed MHC-II-Ii complex containing an Ii trimer and only one or two $\alpha\beta$ heterodimers is retained in the ER by interacting with the chaperone calnexin,¹⁴⁹ presumably allowing the MHC-II molecule additional time to form a fully functional MHC-II-Ii nonamer. In addition, the longer p35 and p43 forms of human Ii contain an ER retention motif, and free Ii trimers containing one of these longer Ii forms are retained in the ER.^{150,151} Curiously, completely folded MHC-II-Ii nonamers containing one of

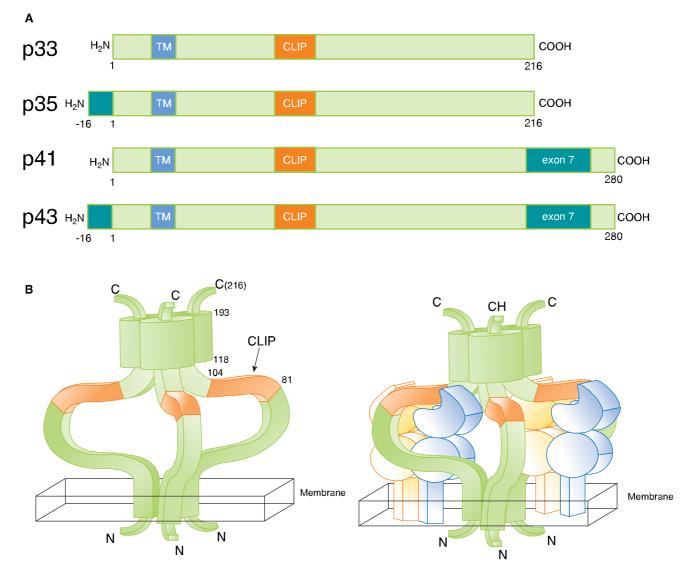

FIG. 22.4. Structure of Invariant Chain (Ii) and Major Histocompatibility Complex (MHC)-II–Ii Complexes. A: The major 216 amino acid form of human Ii is the 33 kDa Ii-p33 isoform. The use of an upstream initiation methionine results in the generation of Ii-p35 (which contains an endoplasmic reticulum–retention motif), and alternative splicing of each of these isoforms leads to the generation of Ii-p41 and Ii-p43 forms of Ii that possess proteinase inhibitor activity. The relative positions of the transmembrane domain (TM) and class II-associated Ii peptide region of each isoform of Ii are indicated. B: Models of Ii trimer (*left panel*) and the MHC-II–Ii complex (*right panel*). Only two of the three pairs of MHC-II αβ dimers are shown bound to the Ii trimer. The model shows the peptide-binding groove of MHC-II αβ dimers occupied by the CLIP region of Ii. (From Cresswell P. The biochemistry and cell biology of antigen processing. In: Paul WE. *Fundamental Immunology*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003:613–629, reprinted with permission).

these longer Ii isoforms are capable of exiting the ER and moving to antigen-processing compartments,^{147,152} demonstrating that assembly with MHC-II masks the ER-retention motif on the Ii trimer.

Ii association does more for MHC-II than simply prevent premature peptide binding. Assembly with Ii is critical for some alleles of MHC-II to fold property and achieve competence to leave the ER, thus revealing a role for Ii as an assembly/folding molecular chaperone.¹⁵³ After leaving the ER, the MHC-II-Ii complex moves through the Golgi apparatus and is targeted to the endosomal pathway^{150,154} (Fig. 22.5A). It is likely that MHC-II-Ii complexes arrive in the endocytic pathway by two distinct mechanisms and the relative contribution of each pathway may be cell-type specific. Some MHC-II-Ii complexes target directly from the trans-Golgi network to endosomes,^{155,156} while other complexes move from the trans-Golgi network directly to the plasma membrane and enter endosomes only after endocytosis.¹⁵⁷ The movement of MHC-II-Ii complexes to the endosomal pathway is facilitated by recognition of two dileucine sorting motifs present in the cytosolic domain of every isoform of Ii.^{158,159} The machinery that recognizes these motifs in the trans-Golgi network remains to be defined; however, it is clear that these motifs are recognized at the plasma membrane by the AP-2 adaptor protein complex.^{160,161} This protein complex serves as a linker between Ii and the clathrin-mediated endocytosis pathway and serves to deliver plasma membrane-localized MHC-II-Ii to the early endosomes. Recognition and internalization of MHC-II-Ii from the plasma membrane is efficient and rapid,¹⁵⁷ and as a consequence of this, very little MHC-II-Ii is present on the plasma membrane of APCs at any given moment.

Removal of Invariant Chain in Antigen-Processing Compartments

Regardless of the mechanism responsible for delivering MHC-II-Ii to endosomes, Ii must be removed in order to allow antigenic peptides to bind to nascent MHC-II. Ii is

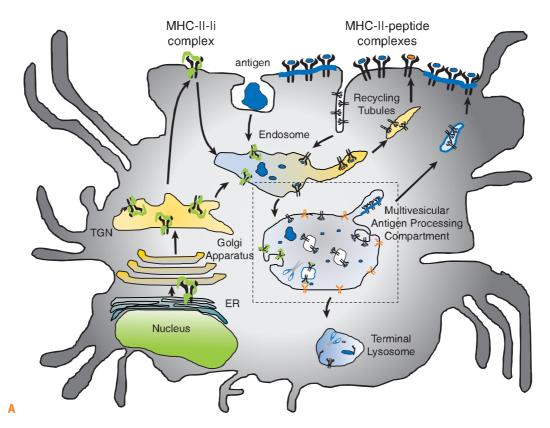

FIG. 22.5. Transport of Major Histocompatibility Complex (MHC)-II in Antigen-Presenting Cells. A: MHC-II associates with II in the endoplasmic reticulum, moves through the Golgi apparatus to the plasma membrane, and enters the endocytic pathway by clathrin-mediated endocytosis. Some fraction of MHC-II can also access these endocytic compartments directly from the Golgi apparatus/trans-Golgi network. Antigens access these same endocytic compartments by a number of different endocytosis pathways. The MHC-II–invariant chain (Ii) complex moves to late endosomal/prelysosomal antigen-processing compartments in which II is degraded, the MHC-II–associated class II-associated II peptide (CLIP) fragment of II is removed by DM, and peptides derived from foreign antigens then bind to MHC-II (this compartments via vesicles or tubules that fuse with the plasma membrane, thereby delivering MHC-II–peptide complexes on the antigen-process can recycle between the plasma membrane and the endosomal system, potentially exchanging antigenic peptides. Some fraction of internalized MHC-II is also targeted for degradation in terminal lysosomes. (continued)

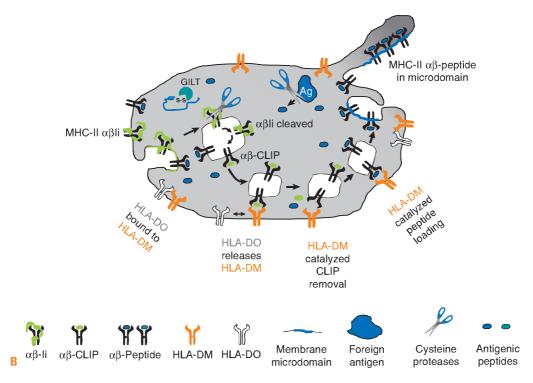

FIG. 22.5. (continued) B: Binding of peptides to MHC-II in antigen-processing compartments. The multivesicular antigen-processing compartment highlighted in *panel A* is shown here. MHC-II–Ii complexes are targeted to intraluminal vesicles of late endosomal multivesicular antigen-processing compartments where Ii proteolysis is initiated. This process results in the generation of MHC-II–CLIP complexes that are subject to editing by DM. D0 binds to DM during intracellular transport and dissociates at the low pH of these compartments, thereby liberating free DM that catalyzes the removal of CLIP from the MHC-II–CLIP complex. DM also stabilizes the structure of peptide-free MHC-II until highaffinity peptide binding. Disulfide bonds present in protein antigens can be reduced by IFN γ -induced thiol reductase, thereby enhancing the formation of antigenic peptides generated by proteolysis. In this cartoon MHC-II, DM, and D0 have particular membrane distributions; however, whether these distributions are maintained in all antigen-presenting cells and whether the reactions highlighted here occur on the indicated membranes remains to be determined. MHC-II molecules present in antigenprocessing compartments are present in distinct membrane microdomains, and after peptide binding, microdomain-associated MHC-II is transported to the plasma membrane in vesicles or tubules that bud from the limiting membrane of the antigen processing compartments (DM, HLA-DM; D0, HLA-D0).

degraded in discrete steps by proteolysis in acidic endosomes (see Fig. 22.5B), with proteolysis initiated at the luminal C-terminus of Ii in earlier endosomes and Ii degradation completed in more acidic late endosomal/prelysosomal structures. In vitro studies have shown that many different proteinases are capable of degrading Ii; however, in vivo, the initial cleavage of Ii is initiated by a proteinase whose activity in insensitive to the protease inhibitor leupeptin while additional cleavage is strictly leupeptin-dependent.¹⁶² Leupeptin treatment of living APCs results in the accumulation of a 21 kDa Ii degradation intermediate that retains the nonameric MHC-II-Ii stoichiometry and is unable to bind antigenic peptides.¹⁵² After the initial cleavage of Ii, a variety of proteinases can cleave the remaining MHC-IIassociated Ii molecule; however, the terminal stages of Ii degradation in B cells and DCs are dependent on the cysteine proteinase cathepsin S.¹⁶³ Inhibition of cathepsin S activity or analysis of DCs isolated from cathepsin S-deficient mice reveal the accumulation of a 10 kDa Ii degradation

product, highlighting the importance of this proteinase in Ii degradation. Curiously, MHC-II–expressing epithelial cells in the thymus do not rely on cathepsin S for Ii degradation but require cathepsin L for terminal Ii degradation.¹⁶⁴

Proteolysis of Ii from both the luminal C-terminus and from residues adjacent to the luminal Ii transmembrane domain ultimately leaves a small fragment of Ii bound to MHC-II. This class II-associated Ii polypeptide, termed CLIP, is bound to the peptide-binding groove of MHC-II and serves as a "placeholder" to occupy the peptide-binding site until antigenic peptides are available to bind (see Fig. 22.4). While some MHC-II alleles have a very low affinity for CLIP and CLIP spontaneously dissociates from MHC-II,¹⁶⁵ in most cases CLIP must be actively removed from the peptide-binding site of MHC-II prior to antigenic peptide binding. A seminal finding in antigen processing and presentation came in 1994 with the discovery of HLA-DM (DM).^{166,167} HLA-DM (known as H-2M in mice) is a nonpolymorphic transmembrane heterodimer whose α- and β-subunits are encoded in the MHC gene locus. Like MHC-II, DM is expressed exclusively in APCs. An important function of DM is to facilitate the removal of CLIP from the MHC-II-CLIP complex.^{168,169} DM functions enzymatically, and while the precise mechanism by which DM promotes CLIP dissociation from MHC-II remains to be completely elucidated, it is thought that DM disrupts the hydrogen bonding network in the peptide binding groove of MHC-II and thereby enhances the kinetics of CLIP dissociation from MHC-II.¹⁷⁰ Not only does DM catalyze CLIP removal from MHC-II, but DM also facilitates the dissociation of weakly bound antigenic peptides from MHC-II^{168,170,171}; it is for this reason that DM has been termed a "peptide editor." Unlike the MHC-II molecule itself, DM contains a tyrosine-based endocytic sorting motif in its cytosolic domain that directly interacts with clathrin-associated adaptor proteins.¹⁷² The presence of this signal allows for the entry of DM into the endocytic pathway after arrival at the cell surface. Most DM is localized in late endocytic compartments¹⁷³ that contain MHC-II-CLIP complexes,¹⁷⁴ and the activity of DM is enhanced by the low pH of these later endocytic compartments.^{168,169,175}

DM editing activity in APCs can be regulated by its association with another MHC-encoded transmembrane protein termed HLA-DO (DO; H-2O in mice¹⁷⁶). While the precise function of DO in antigen processing and presentation remains to be defined, in vitro studies have shown that DO binds to DM and inhibits the ability of DM to catalyze CLIP removal.^{177,178} Like DM, DO expression is relatively restricted to APCs. Unlike MHC-II-Ii or DM, DO does not contain any intrinsic endo-/lysosomal sorting motifs. Instead, DO associated with DM in the ER and DM serves to "escort" DO to antigen-processing compartments.¹⁷⁹ It is in the low pH of these compartments that DO dissociates from DM, thereby enhancing DM activity. In this respect, DO acts as an inhibitor of DM function in much the same way that the CLIP region of Ii acts as an inhibitor of MHC-II peptide binding.

Antigen Processing and Peptide Loading onto MHC-II

While MHC-II in lysosome-like antigen-processing compartments must be "prepared" for peptide binding (by degrading MHC-II-associated Ii and removing CLIP by DM), internalized foreign antigens must be similarly prepared for binding to the nascent MHC-II molecule. This task is initiated by proteolysis by any number of endocytic proteinases. Antigen-processing compartments have a pH between 4.5 and 6.5, and most proteinases in these compartments have enzymatic activity optima at this pH. There is remarkable diversity in the proteinase pool in these compartments and great redundancy in the ability of distinct proteinases to degrade particular proteins. For this reason, it has been difficult to identify specific proteinases whose activity is required to generate specific antigenic peptides. There are exceptions to this, however, as asparaginyl cysteine endoprotease is required for the generation of an immunodominant epitope to tetanus toxoid¹⁸⁰ and both cathepsin L and cathepsin S affect quantitative and qualitative differences in the repertoire of peptides bound to MHC-II molecules.¹⁸¹ It is also a known fact that many internalized

foreign (and self-) antigens contain intrachain disulfide bonds, and reduction of these bonds would alter protein conformation and render a protein more (or less) sensitive to proteolysis in antigen-processing compartments. As its name implies, the expression of IFN γ -induced thiol reductase, GILT, can be induced by exposure to IFN γ .¹⁸² This thiol reductase is expressed in antigen-processing compartments in APCs, and the activity of GILT is important for the presentation of antigenic epitopes that are generated from proteins that contain many intrachain disulfide bonds.¹⁸³

Just as important as generation of antigenic peptides is the ability of the antigen-processing compartment to limit excessive proteolytic degradation of antigenic peptides. While asparaginyl cysteine endoprotease positively regulates expression tetanus toxoid epitopes, this same proteinase destroys expression of the immunodominant epitope of myelin basic protein,¹⁸⁴ a protein thought to be involved in the demyelinating autoimmune disease multiple sclerosis. Clearly, the proteinase activity of antigen-processing compartments must be sufficient to generate antigenic peptides capable of binding to MHC-II but not so great as to completely destroy these same epitopes. Measurement of proteinase activity in various APC subtypes has revealed that macrophages have high proteinase activity and efficiently degrade proteins, but are relatively pool generators of antigenic peptides.¹⁸⁵ By contrast, DCs and B cells possess less proteinase activity, degrade proteins less efficiently, and are superb generators of antigen peptides.^{185,186} This specialization of limiting proteinase activity helps DCs function as initiators of naïve T-cell activation and B cell capacity for immunoglobulin class switching after encounter with antigen-specific T cells.

It has been proposed that binding to the MHC-II molecules can serve as a mechanism to preserve the integrity of antigenic peptides. The peptide-binding groove of MHC-II is open, and in vitro binding experiments have shown that MHC-II is capable of binding to unfolded (but otherwise intact) protein antigens.¹⁸⁷ The association of distinct regions within a full-length (unfolded) protein with the peptidebinding site of MHC-II could therefore protect these regions from proteolytic degradation by endo-/lysosomal proteinases. This model of "bind first trim later" has been championed as a major mechanism of peptide loading onto MHC-II¹⁸⁸ and has been supported by experimental studies in B cells¹⁸⁹; however, the extent to which "bind first trim later" versus "trim first bind later" predominates in distinct APC subsets and for different antigens remains to be determined.

Curiously, the Ii molecule itself also can serve to limit proteinase activity of antigen-processing compartments. The additional exon that is present in Ii isoforms that are products of alternative splicing (Ii-p41 and Ii-p43) encodes a domain that functions as an inhibitor of cathepsin L.^{190,191} In vitro studies showed that coexpression with Ii-p41 inhibits the kinetics of Ii-p33 degradation,¹⁹² a finding that is consistent with the role of Ii-p41 as a proteinase inhibitor. However, no defects in function have been identified using APCs isolated from mice expression only the Ii-p41,¹⁹³ leaving the importance of this domain in APC function an open issue.

DCs are particularly interesting APCs in that they can regulate their proteinase activity upon cell activation. Immature (resting) DCs are highly phagocytic and have a remarkable capacity for macropinocytosis. Nevertheless, these cells have little proteinase activity and are relatively inefficient generators of antigenic MHC-II-peptide complexes, potentially allowing them to serve as a "depot" for antigen internalized while the cell is in the quiescent state. It has even been shown that internalized proteins can re-main intact in immature DCs for days.^{194,195} Activation of the immature DC by any of a number of mechanisms (either by toll-like receptor signaling or stimulation by activated T cells) leads to a number of changes in the cell, with perhaps the most important being the activation of the vacuolar proton ATPase.¹⁹⁶ Activation of this ATPase leads to the acidification of antigen-processing compartments, enhances the activity of endo-/lysosomal proteinases that have low pH optima, and leads to the degradation of internalized antigens to form antigenic peptides capable of binding to MHC-II. Other changes also take place following activation of immature DCs, including downregulating expression of the endogenous cysteine proteinase inhibitor cystatin C¹⁹⁷ and reorganizing the internal membrane structure of the antigen processing compartments¹⁹⁸; however, it is likely that acidification of these compartments is the

major mechanism leading to enhanced antigen processing, peptide generation, and formation of MHC-II–peptide complexes upon DC activation.

Delivery of MHC-II to the Cell Surface

The sites of antigenic protein degradation and subsequent binding of peptides onto nascent MHC-II are commonly referred to as antigen-processing compartments. At one time, it was thought that APCs possessed a "special" compartment that served as the major antigen-processing compartment¹⁹⁹; however, it is now clear that "antigen-processing compartments" refer to a heterogenous collection of intracellular (generally acidic) organelles that permit peptide binding onto MHC-II.²⁰⁰ These organelles generally have characteristics of typical late endosomes/prelysosomes found in all cell types (Fig. 22.6); however, in APCs these organelles contain the specialized protein machinery required for antigen processing and presentation such as MHC-II, DM, DO, GILT, and Ii-processing enzymes. A "typical" antigenprocessing compartment is a late endosomal multivesicular body (MVB), an organelle that possesses intraluminal vesicles encapsulated in a limiting membrane.²⁰¹ These compartments can also have a multilamellar structure, containing numerous membrane sheets contained within an even

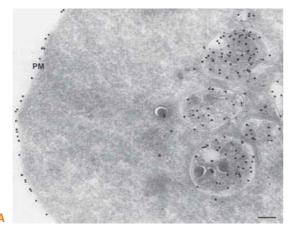

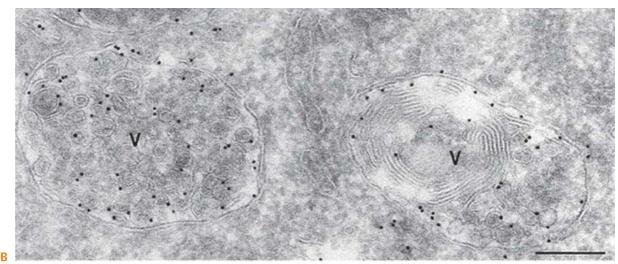

FIG. 22.6. Structure of Multivesicular Antigen-Processing Compartments. A: Ultrathin cryosections of a human B-cell line were stained with antibodies recognizing DM (10 nm gold) and total major histocompatibility complex (MHC)-II (15 nm gold). The plasma membrane stains almost exclusively for MHC-II while various forms of multivesicular antigen-processing compartments contain both MHC-II and DM (reprinted with permission Kleijmeer et al., *Methods*, 1996). B: Ultrathin cryosections of a mouse immature DC line were stained with antibodies recognizing MHC-II (10 nm gold). MHC-II staining is observed on the limiting membrane as well as in the intraluminal vesicles of a multivesicular body (*left*) and the numerous intraluminal membrane sheets in a multilamellar endosome (*right*) (reprinted with permission Kleijmeer et al.¹⁹⁸).

more acidic lysosome-like organelles. Curiously, the in DCs majority of MHC-II is present on the intraluminal vesicles of these MVBs while the CLIP editor DM and MHC-II–peptide complexes are enriched on the MVB-limiting membrane.¹⁹⁸ Although most MHC-II and DM are present on distinct MVB membranes, it is unclear on which membranes the process of Ii proteolysis, CLIP release, and peptide binding to MHC-II occurs. For example, while there is in vitro evidence that DM primarily interacts with MHC-II when these proteins are on the same membrane,^{202,203} whether this is the intraluminal vesicle or the MVB-limiting membrane remains to be determined.

The presence of MHC-II-peptide complexes on the intraluminal vesicles of MVB presents a topological problem for the APC, as direct fusion of the MVB with the plasma membrane would release the intraluminal vesicles from these compartments to the extracellular space. Such a process would effectively result in the secretion of MHC-II from the APC. This process does occur in DCs with some frequency, and these secreted intraluminal vesicles are termed exosomes that are capable of stimulating naïve T cells in vivo.²⁰⁴ While APC-derived exosomes are being utilized as cell-free vaccines,205 their physiologic role remains to be unambiguously determined. The majority of MHC-II in antigen-processing compartments is not released as exosomes, but is instead either degraded following fusion of the MVB with lysosomes or inserted into the plasma membrane by "vesicle"-mediated protein transport. While vesicles containing intracellular MHC-II have been observed to fuse with the plasma membrane,²⁰⁶ in APCs such as DCs it is likely that these "vesicles" are actually tubules that bud from the MVB membrane and subsequently fuse with the plasma membrane. The tubulation of these compartments is stimulated in DCs by APC activation,^{198,207,208} and the encounter of DCs with T cells leads to the fusion of these tubules directly to the plasma membrane region at the point of DC:T-cell contact,²⁰⁸ thereby delivering MHC-II-peptides generated in DCs directly to the site of T-cell receptor concentration at the immunologic synapse.

The cellular processes that govern the movement of MHC-II to the surface of APCs are similar to those that govern the movement of any late endosomal protein the surface of any cell. In some cases, the machinery regulating discrete transport steps remains a mystery while other steps are more well characterized. For example, the mechanism leading to the delivery of intraluminal vesicle-bound MHC-II back to the MVB0limiting membrane (from which tubules are formed) is termed back-fusion,²⁰⁹ and the proteins and lipids that regulate this curious process remain to be identified. By contrast, it is known that the ability of MHC-II to insert into the plasma membrane is regulated by the small GTPase ARL14/ARF7 that couples the tubulovesicle membrane with the actin cytoskeleton.²¹⁰ Like other vesicle-mediated protein transport steps, microtubules and dynein/kinesin motors²¹¹ as well as actin and myosin motors²¹² are important for the locomotion of MHC-II into and out of antigen-processing compartments.

Once at the plasma membrane, MHC-II-peptide complexes are poised to interact with antigen-specific T-cell receptors. MHC-II–peptide complexes are clustered on the plasma membrane^{195,213} and associate with distinct lipid raft-²¹⁴ and tetraspanin-membrane²¹⁵ microdomains, thereby locally concentrating MHC-II on the cell surface. Biochemical studies have revealed that MHC-II associates with these membrane microdomains while still present in antigen-processing compartments even before antigenic peptide binding.²¹⁶ This finding is consistent with the observation that MVBs contain large amounts of cholesterol, a major constituent of lipid raft membrane microdomains.²¹⁷ While lipid raft- and tetraspanin-microdomain associations are important for the T-cell stimulatory function of APCs,^{214,218} the molecular signals leading to membrane microdomain association of MHC-II remain to be determined.

MHC-II-peptide complexes are generated and reside in a relatively hostile (acidic, proteinase-rich) environment, and therefore it is not surprising that cell surface MHC-II has a relatively long half-life.^{219,220} While this is true on activated B cells and mature DCs, MHC-II on the surface of immature DCs has a significantly reduced half-life. This is likely due to rapid endocytosis and lysosomal degradation of surface MHC-II in resting (immature) DCs.^{221,222} The dichotomy between the endocytosis and survival of MHC-II in immature and mature DCs can be explained in part by the fact that internalized MHC-II is ubiquitinated in immature DCs and targeted for lysosomal degradation while internalized MHC-II is not ubiquitined in mature DCs and efficiently recycles back to the plasma membrane.^{223,224} The E3 ubiquitin ligase March-I, whose expression appears to be limited to APCs, ubiquitinates the cytosolic domain of the MHC-II β -chain in APCs,¹¹⁸ thereby preventing the recycling of internalized MHC-II and targeting ubiquitinated MHC-II for lysosomal degradation.²²⁵ This mechanism ensures that the kinetics of MHC-II synthesis and degradation in immature DCs are similar and provides a means to halt the degradation of relevant MHC-II-peptide complexes upon DC activation.

Simply because MHC-II has a long half-life in B cells and DCs does not mean that these molecules do not internalize. In these APC subtypes, internalized MHC-II efficiently recycles from early (recycling) endosomes back to the plasma membrane,²²¹ thereby limiting their delivery to lysosomes and prolonging MHC-II half-life. The ability of internalized MHC-II to exchange one peptide for another in endosomes has been demonstrated in vitro^{226,227}; however, it remains to be determined whether peptide exchange onto recycling MHC-II in vivo is a significant mechanism of peptide loading onto MHC-II. There is convincing evidence, however, that certain protein epitopes are primarily presented by recycling MHC-II.²²⁸ Unlike presentation of epitopes from "classically processed" antigens, presentation of these epitopes does not require neosynthesis of MHC-II and is independent of Ii expression or DM activity. A particularly intriguing example of this pathway can be found in the analysis of an immunogenic epitope presentation of the influenza virus hemagglutinin,²²⁸ in which presentation of one epitope is via the classical (late endosomal) processing and presentation pathway while another is presented via a nonclassical (early endosomal) recycling pathway.

Alternate Pathways of Antigen Presentation

In this chapter, we have reviewed what is typically called the classical MHC-I and MHC-II antigen-processing and -presentation pathways. In addition to these pathways, there are also interesting alternative antigen-presentation pathways. Although not the focus of this chapter, these nonclassical pathways provide clear evidence that antigen presentation is more complex than a simple dichotomy of the two classical pathways. The most extensively studied of these alternative pathways is cross-presentation, a process by which CD8 T cells present exogenous antigen taken up by professional APCs such as DCs. Cross-presentation is critical for initiating CD8+ immune responses to pathogens that do not infect professional APCs or tumors that do not arise in professional APCs. Although several details remain unsolved, cell biologic approaches suggest that the loading of crosspresented antigens occurs by several different pathways each with hybrid features of both of the classical pathways.^{229–231}

The presentation of lipid antigens by MHC-I like CD1 molecules also occurs by a nonclassical pathway.^{232,233} Human CD1a, CD1b, and CD1c isoforms present bacterial lipids to conventional $\alpha\beta$ T cells, whereas CD1d presents endogenous and microbial lipids to invariant natural killer T cells.

Interestingly, disparate targeting motifs in their cytoplasmic tails facilitate the binding of lipid antigens in the early endosomes by CD1a, in the late endosome/lysosome by CD1b and CD1d, and at both sites by CD1c. This diversity of location of lipid antigen binding by different human CD1 isoforms allows surveying of different endosomal compartments for microbes. The assembly of CD1 isoforms in the ER uses molecular chaperones CXN, CRT, and ERp57 similar to the classical MHC-I pathways. As expected, the processing and loading of lipid antigens presented by CD1 isoforms requires unique players.²³⁴ However, the trafficking of CD1 isoforms between the plasma membrane and endosomal compartments to acquire lipid antigens has parallels with the classical MHC-II pathway. In sum, with the underlying goal of providing maximal immunity for detection and protection against diverse pathogens, mammals have two classical and other nonclassical pathways of antigen presentation.

ACKNOWLEDGMENTS

The authors thank Drs. Peter Cresswell and Karin Reinisch for sharing Protein Data Bank (PDB) files with the model shown in Figure 22.3, Dr. William McCoy IV for his rendering of Figure 22.3, and Dr. Janet Connolly for professional editing.

Induction, Regulation, and Effector Functions of the Immune Response

Immunogenicity and Antigen Structure

Jay A. Berzofsky • Ira J. Berkower

THE NATURE OF ANTIGENIC DETERMINANTS RECOGNIZED BY ANTIBODIES

Haptens

SECTION

CHAPTER

In the antigen-antibody binding reaction, the antibodybinding site is often unable to accommodate the entire antigen. The part of the antigen that is the target of antibody binding is called an antigenic determinant, and there may be one or more antigenic determinants per molecule. To study antibody specificity, we need to have antibodies against single antigenic determinants. Small functional groups that correspond to a single antigenic determinant are called haptens. For example, these may be organic compounds, such as trinitrophenyl or benzene arsonate, a monosaccharide or oligosaccharide such as glucose or lactose, or an oligopeptide such as pentalysine. Although these haptens can bind to antibody, immunization with them usually will not provoke an antibody response (for exceptions, see Goodman¹). Immunogenicity often can be achieved by covalently attaching haptens to a larger molecule, called the carrier. The carrier is immunogenic in its own right, and immunization with the hapten-carrier conjugate elicits an antibody response to both hapten and carrier. However, the antibodies specific for hapten can be studied by equilibrium dialysis using pure hapten (without carrier) or by immunoprecipitation using hapten coupled to a different (and non-cross-reacting) carrier or by inhibition of precipitation with free hapten.

This technique was pioneered by Landsteiner² and helped to elucidate the exquisite specificity of antibodies for antigenic determinants. For instance, the relative binding affinity of antibodies prepared against succinic acid–serum protein conjugates shows marked specificity for the maleic acid analog, which is in the cis configuration, as compared to the fumaric acid (trans) form.³ Presumably, the immunogenic form of succinic acid corresponds to the cis form.³ This ability of antibodies to distinguish cis from trans configurations was reemphasized in later studies measuring relative affinities of antibodies to maleic and fumaric acid conjugates⁴ (Table 23.1A). Table 23.1B shows the specificity of antibodies prepared against p-azobenzenearsonate coupled to bovine gamma globulin.⁵ As the hapten is coupled through the p-azo group to aromatic amino acids of the carrier, haptens containing bulky substitutions in the para position would most resemble the immunizing antigen. In fact, p-methyl-substituted benzene arsonate has a higher binding affinity than unsubstituted benzene arsonate. However, methyl substitution elsewhere in the benzene ring reduces affinity, presumably due to interference with the way hapten fits into the antibody-binding site. Thus, methyl substitutions can have positive or negative effects on binding energy, depending on where the substitution occurs. Table 23.1C shows the specificity of antilactose antibodies for lactose versus cellobiose.⁶ These disaccharides differ only by the orientation of the hydroxyl attached to C4 of the first sugar either above or below the hexose ring. The three examples in this table, as well as many others,¹ show the marked specificity of antibodies for cis-trans, ortho-meta-para, and stereoisomeric forms of the antigenic determinant.

Comparative binding studies of haptens have been able to demonstrate antibody specificity despite the marked heterogeneity of antibodies. Unlike the antibodies against a multideterminant antigen, the population of antibodies specific for a single hapten determinant is a relatively restricted population due to the shared structural constraints necessary for hapten to fit within the antibody-combining site. However, the specificity of an antiserum depends on the collective specificities of the entire population of antibodies, which are determined by the structures of the various antibody-binding sites. When studying the cross-reactions of hapten analogs, some haptens bind all antibodies but with reduced K_A . Other hapten analogs reach a plateau of binding because they fit some antibody-combining sites quite

well but not others (see discussion of cross-reactivity in Chapter 7). Antibodies raised in different animals may show different cross-reactivities with related haptens. Even within a single animal, antibody affinity and specificity are known to increase over time following immunization under certain conditions.⁷ Thus any statements about the cross-reactivity of two haptens reflect both structural differences between the haptens that affect antigen–antibody fit and the diversity of antibody-binding sites present in a given antiserum.

Carbohydrate Antigens

The antigenic determinants of a number of biologically important substances consist of carbohydrates. These often occur as glycolipids or glycoproteins. Examples of the former include bacterial cell wall antigens and the major blood group antigens, whereas the latter group includes "minor" blood group antigens such as Rh. In addition, the capsular polysaccharides of bacteria are important for virulence and are often targeted by protective antibodies. A number of spontaneously arising myeloma proteins have been found to show carbohydrate specificity, possibly reflecting the fact that carbohydrates are common environmental antigens. In the days prior to hybridoma technology, these carbohydratespecific myeloma proteins provided an important model for studying the reaction of antigen with a monoclonal antibody.

Empirically, the predominant antigenic determinants of polysaccharides often consist of short oligosaccharides (one to five sugars long) at the nonreducing end of the polymer chain.⁸ This situation is analogous to a hapten consisting of several sugar residues linked to a large nonantigenic polysaccharide backbone. The remainder of the polysaccharide is important for immunogenicity, just as the carrier molecule was important for haptens. In addition, branch points in the polysaccharide structure allow for multiple antigenic determinants to be attached to the same macromolecule.

This is important for immunoprecipitation by lattice formation, as discussed in Chapter 5. Several examples illustrating structural studies of oligosaccharide antigens are given later.

the nonreducing end of the chain, this result also shows that the structure of the antigenic determinant of polysacchacharide chain. Besides showing the "immunodominance" of to block precipitation completely with a short oligosacchacharides. antigen and antibody is inhibited by adding short oligosacantibody should be used. rides depends on the sequence of carbohydrates and their ride corresponding to the nonreducing end of the polysaccific for a single antigenic determinant, it is often possible remain available for precipitation. Using antiserum more inhibitor is added, fewer antibody-combining sites but because they are monomeric, no precipitate forms. As with the same affinity and specificity as the polysaccharide, For optimal sensitivity, the equivalence point of antigen and must be made specific for a single antigenic determinant. hapten to be complete, the antigen–antibody system studied linkage, rather than their conformation. For inhibition by hibition.8 In this method, the precipitation reaction between genic determinants of polysaccharides is called hapten in-The technique used most widely to analyze the anti-These oligosaccharides are large enough to bind spe-

group B strains share determinant 4 (Table 23.2). However, within a group, each strain possesses additional O determinants, which serve to differentiate it from other members of that group. Thus, determinant 2 coexists with determinants 1 and 12 on *Salmonella paratyphi* A. This problem of

cross-reactivity based on sharing of a subset of antigenic determinants is commonly encountered in complex antigenantibody systems. The problem may be simplified by making antibodies monospecific for individual antigenic determinants. To do this, antibodies are absorbed to remove irrelevant specificities, or cross-reactive strains are chosen that share only a single determinant with the immunizing strain. The reaction of each determinant with its specific antibody can be thought of as an antigen-antibody system. Thus, for the strains shown in Table 23.2, antiserum to Salmonella typhi (containing anti-9 and anti-12 antibodies) may be absorbed with S. paratyphi A to remove anti-12, leaving a reagent specific for antigen 9 (see Table 23.2). Alternatively, the unabsorbed antiserum may be used to study the system antigen 12-anti-12 by allowing it to agglutinate S. paratyphi B, which shares only antigen 12 with the immunogen. Because the other determinants on S. paratyphi B were absent from the immunizing strain, the antiserum contains no antibodies to them.

Once the antigen-antibody reaction is made specific for a single determinant, a variety of oligosaccharides can be added

Blood Group Antigens

The major blood group antigens A and B were originally detected by the ability of serum from individuals lacking either determinant to agglutinate red blood cells bearing them (for reviews, see Kabat,⁸ Springer,¹⁰ Marcus,¹¹ and Watkins¹²). In addition, group O individuals have an H antigenic determinant that is distinct from A or B types, and individuals in all three groups may have additional determinants such as the Lewis (Le) antigens. Although the ABH and Le antigenic determinants are found on a carbohydrate moiety, the carbohydrate may occur in a variety of biochemical forms. On cell

surfaces, they are either glycolipids that are synthesized within the cell (AB and H antigens) or glycoproteins taken up from serum (Le antigens). In mucinous secretions, such as saliva, they occur as glycoproteins. Milk, ovarian cyst fluid, and gastric mucosa contain soluble oligosaccharides containing blood group reactivity. In addition, these antigens occur frequently in other species, including about half of the bacteria in the normal flora of the gut.¹⁰ This widespread occurrence may account for the ubiquitous anti-AB reactivity of human sera, even in people never previously exposed to human blood group substances through transfusion or pregnancy.

The immunochemistry of these antigens was simplified greatly by the use of oligosaccharides in hapten inhibition studies. Group A oligosaccharides, for example, would inhibit the agglutination of group A red blood cells by anti-A antibodies. They could also inhibit the immunoprecipitation of group A-bearing glycoproteins by anti-A antibodies. Because the oligosaccharides are monomeric, their reaction with antibody does not form a precipitate but does block an antibody-combining site.

ride type XIV, which contains structural elements shared quential addition of individual sugars at the end or at branch and the antigens appear to differ from each other by the sesubstance, has been isolated from ovarian cyst fluid. with blood group determinants, as shown at the bottom of with antiserum specific for pneumococcal polysacchacore oligosaccharide from each. This product cross-reacts support this relationship among the different determinants. points. Besides hapten inhibition, other biochemical data antigens all share a common oligosaccharide core sequence, inhibitory oligosaccharides for each antigen are indicated in N-acetylgalactosamine, and N-acetylglucosamine. The most Figure 23.2. In addition, this structure, known as precursor Enzymatic digestion of A, B, or H antigens yields a common Figure 23.2. As can be seen in Figure 23.2, the ABH and Le purified and found The inhibitory oligosaccharides from cyst fluid were to contain D-galactose, L-fucose,

Starting from precursor substance, the H determinant results from the addition of L-fucose to galactose, whereas Le^a determinant results from the addition of L-fucose to N-acetylglucosamine and Le^b from the addition of L-fucose to both sugars. Addition of N-acetylgalactosamine to H substance produces the A determinant, whereas addition of galactose produces the B determinant, in each case blocking reactivity of the H determinant.

The genetics of ABH and Le antigens is explained by this sequential addition of sugars via glycosyltransferases. The allelic nature of the AB antigens is explained by the addition of N-acetylgalactosamine, galactose, or nothing to the H antigen. The rare inherited trait of inability to synthesize the H determinants from precursor substance (Bombay phenotype) also blocks the expression of A and B antigens because the A and B transferases lack an acceptor substrate. However, the appearance of the Le^a antigen on red cells is independent of H antigen synthesis. Its structure, shown in Figure 23.2, can be derived directly from precursor substance without going through an H antigen intermediate. Comparing different individuals, the appearance of Le^a antigen on red blood cells correlates with its presence in saliva, as the Le^a

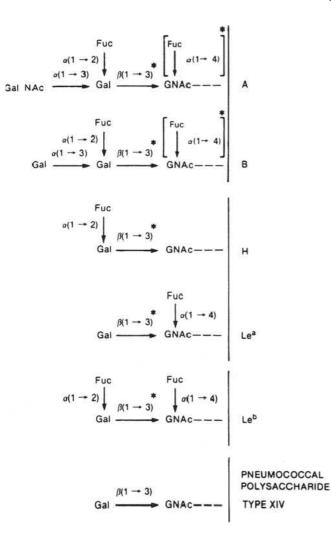

FIG. 23.2. Oligosaccharide Chain Specificity. Structure of the ABH and Le blood group antigens as determined by hapten inhibition studies.^{8,11} There are two variants of each of these determinants. In type 1, the Gal-GNAc linkage is $\beta(1 \rightarrow 3)$, whereas in type 2, the Gal-GNAc linkage is $\beta(1 \rightarrow 4)$. In addition, there is heterogeneity in the A and B antigens with respect to the presence of the Le fucose attached to the GAAc linkage is $\beta(1 \rightarrow 3)$ (type 1), the fucose must be linked $\alpha(1 \rightarrow 4)$, whereas the type 2 molecules, with the $\beta(1 \rightarrow 4)$ Gal-GNAc linkage, contain $\alpha(1 \rightarrow 3)$ -linked fucose. The *asterisks* indicate the sites of this variability in linkage.

antigen is not an intrinsic membrane component but must be absorbed from serum glycoproteins, which, in turn, depend on secretion. In addition to the independent synthetic pathway, the secretion of Le^a antigen is also independent of the secretory process for ABH antigens. Therefore, salivary nonsecretors of ABH antigens (which occur in 20% of individuals) may still secrete Le^a antigen if they have the fucosyl transferase encoded by the Le gene. In contrast, salivary secretion of ABH is required for red blood cells to express Le^b.

Dextran-Binding Myeloma Proteins

Because polysaccharides are common environmental antigens, it is not surprising that randomly induced myeloma proteins were frequently found to have carbohydrate specificities. Careful studies of these monoclonal antibodies support the clonal expansion model of antibody diversity: heterogeneous antisera behave as the sum of many individual clones of antibody with respect to affinity and specificity. In the case of the Ig A κ myeloma proteins W3129 and W3434, both antibodies were found to be specific for dextrans containing α -glu (1 \rightarrow 6)glu bonds.¹² Hapten inhibition with a series of monosaccharide or oligosaccharides of increasing chain length indicated that the percentage of binding energy derived from the reaction with one glucose was 75%, two glucoses 95%, three glucoses 95% to 98%, and four glucoses 100%. This suggests that most binding energy between antidextran antibodies and dextran derives from the terminal monosaccharide, and that oligosaccharides of chain length four to six commonly fill the antibody-combining site. Human antidextran antisera behaved similarly, with tetrasaccharides contributing 95% of the binding energy. These experiments provided the first measure of the size of an antigenic determinant, four to six residues.^{13,14} In addition, as was observed for antisera, binding affinity of myeloma proteins was highly sensitive to modifications of the terminal sugar and highly specific for $\alpha(1 \rightarrow 6)$ versus $\alpha(1 \rightarrow 6)$ \rightarrow 3) glycosidic bonds. However, modification of the third or fourth sugar of an oligosaccharide had relatively less effect on hapten inhibition of either myeloma protein or of antisera reacting with dextran.

Studies with additional dextran-binding myeloma proteins¹⁵ revealed that not all antipolysaccharide monoclonal antibodies are specific for the nonreducing end, as exemplified by QUPC 52. Competitive inhibition with monosaccharide and oligosaccharides revealed that <5% of binding energy derived from monosaccharides or disaccharides, 72% from trisaccharides, 88% from tetrasaccharides, and 100% from hexasaccharides, in marked contrast to other myeloma proteins. A second distinctive property of myeloma protein QUPC 52 was its ability to precipitate unbranched dextran of chain length 200. As the unbranched dextran has only one nonreducing end, and as the myeloma protein has only one specificity, lattice formation due to cross-linking between the nonreducing ends is impossible, and precipitation must be explained by binding some other determinant. Therefore, QUPC 52 appears to be specific for internal oligosaccharide units of three to seven chain length. The W3129 is specific for end determinants and will not precipitate unbranched dextran chains. Antibodies precipitating linear dextran were also detected in six antidextran human sera, comprising 48% to 90% of the total antibodies to branched chain dextran. Thus, antidextrans can be divided into those specific for terminal oligosaccharides and those specific for internal oligosaccharides; monoclonal examples of both types are available, and both types are present in human immune serum. Cisar et al.¹⁵ speculated as to the different topology of the binding sites of W3129 or QUPC 52 necessary for terminal or internal oligosaccharide specificity. Both terminal and internal oligosaccharides have nearly identical chemical structures, differing at a single C-OH or glycoside bond. Perhaps the terminal oligosaccharide specificity of W3129 is due to the shape of the antibody-combining site—a cavity into which only the end can fit—whereas the internal oligosaccharide-binding site of QUPC 52 could be a surface groove in the antibody, which would allow the rest of the polymer to protrude out at both ends. A more definitive answer depends on x-ray crystallographic studies of the combining sites of monoclonal antibodies with precisely defined specificity, performed with antigen occupying the binding site.

With the advent of hybridoma technology, it became possible to produce monoclonal antibodies of any desired specificity. Immunizing mice with nearly linear dextran (the preferred antigen of QUPC 52), followed by fusion and screening (with linear dextran) for dextran-binding antibodies, yielded 12 hybridomas,16 all with specificity similar to QUPC 52. First, oligosaccharide inhibition of all 12 monoclonals showed considerable increments in affinity up to hexasaccharides, with little affinity for disaccharides and only 49% to 77% of binding energy derived from trisaccharides.¹⁷ Second, all 12 monoclonals had internal $\alpha(1)$ \rightarrow 6) dextran specificity, as they could all precipitate linear dextran. Third, 9 out of 11 BALB/c monoclonals shared a cross-reactive idiotype with QUPC 52, whereas none shared idiotype with W3129.18 These data support the hypothesis that different antibodies with similar specificity and similar groove-type sites may be derived from the same family of germline $V_{\rm H}$ genes bearing the QUPC 52 idiotype.¹⁸

The large number of environmental carbohydrate antigens and the high degree of specificity of antibodies elicited in response to each carbohydrate antigen suggest that a tremendous diversity of antibody molecules must be available, from which some antibodies can be selected for every possible antigenic structure. Studies of a series of 17 monoclonal anti- $\alpha(1 \rightarrow 6)$ dextran hybridomas^{19,20} have investigated whether the binding sites of closely related antibodies were derived from a small number of variable region genes, for both heavy and light chains, or whether antibodies of the same specificity could derive from variable region genes with highly divergent sequences. Each monoclonal had a groove-type site that could hold six or seven sugar residues (with one exception), based on inhibition of immunoprecipitation by different length oligosaccharides. Thus, unlike monoclonals to haptenated proteins, the precise epitope could be well characterized and was generally quite similar among the entire series.

Studies of the V_{κ} sequences revealed that only three V_{κ} groups were used in these hybridomas. Use of each V_{κ} group correlated with the particular antigen used to immunize the animals, whether linear dextran or short oligosaccharides, so that 10 of the monoclonals from mice immunized the same way all used the same V_{κ} .

In contrast, the 17 V_H chains were derived from at least five different germline genes from three different V_H gene families.²¹ The two most frequently used germline V_H genes were found in seven and five monoclonals, respectively, with minor variations explainable by somatic mutations. The remarkable finding is that very different V_H chains (about 50% homologous) can combine with the same V_κ to produce antibody-binding sites with nearly the same size, shape, antigen specificity, and affinity. Even when different V_H sequences combine with different V_κ sequences, they can produce antibodies with very similar properties.

Dextran binding depends on the antigen fitting into the groove and interacting favorably with the residues forming the sides and bottom of the groove. The results indicate that divergent variable region sequences, both in and out of the complementarity-determining regions, can be folded to form similar binding site contours, which result in similar immunochemical characteristics. Similar results have been reported in other antigen–antibody systems, such as phenyloxazolone.²²

Additional studies of carbohydrate binding monoclonal antibodies have revealed significant information about how the antibody variable regions can bind a carbohydrate structure with high affinity and specificity. Several examples are now available of crystal structures of carbohydrates bound to antibodies.

For example, monoclonal antibody Se155-4 is specific for the group B determinant of the salmonella O antigen, which consists of the sugars Gal-Abequose-Man.^{23,24} The crystal structure of antibody bound to the polysaccharide shows that one hexose, abequose, fits into the binding pocket, while the rest of the interactions occur along the surface of the antibody, similar to the groove-type sites described previously. Binding energy depends on hydrogen bonds formed between the protein residues and the hydroxyl groups of the carbohydrate. The protein residues include aromatic amines, such as His 32, Trp 91, and Trp 96 of the light chain, as well as His 97 and His 35 of the heavy chain. In addition, one of the sugars is hydrogen bonded via a water molecule bridge to the amide bonds of the protein backbone. About three quarters of all sugar hydroxyl groups are involved in hydrogen bonds with the protein. Although each H-bond is relatively weak by itself, the combined effect of eight hydrogen bonds results in high-affinity binding. Antibody specificity derives from the fact that the carbohydrate fits into a binding pocket, where H-bond formation depends on precise interactions with amino acid residues that are oriented about the pocket. Surprisingly, most of these bonds are formed between sugar hydroxyls and aromatic amino acids that are neither charged nor very polar at neutral pH.

Similarly, monoclonal antibody BR96 and the humanized monoclonal hu3S193 are specific for the Le Y antigen, which resembles the Le B antigen described in Figure 23.2, except that the fucose-N-acetylglucosamine bond is $\beta(1 \rightarrow 3)$ instead of $\beta(1 \rightarrow 4)$. The Le Y antigen is commonly expressed on tumor cells of epithelial origin. The crystal structures have revealed the sources of the binding energy that results in affinity and specificity for this carbohydrate antigen.^{25,26} These two monoclonals bind Le Y antigen in a large, deep pocket, which accommodates all four hexoses and correspond to the cavity type binding site predicted by Kabat.¹⁵ The terminal fucose goes in first while the other three sugars are hydrogen bonded to amino acid side chains lining the pocket, including Tyr 33, Tyr 35, and Gln 52 of the heavy chain and His 27 of the light chain. Once again, hydrogen bonds between hydroxyl groups of the sugars and aromatic amines (Trp and Tyr) of the protein play a dominant role in determining affinity and specificity of binding. A smaller number of H-bonds depend on amide groups of the protein backbone.

A third example is provided by human monoclonal 2G12, which has neutralizing activity against a broad spectrum of human immunodeficiency virus (HIV) isolates. This antibody binds the mannose-rich oligosaccharide side chains that form a protective surface, called a glycoshield, on the envelope glycoprotein gp120. The crystal structure shows that the two terminal mannose sugars of each oligosaccharide bind end on into a deep pocket of the antibody, in a cavity-type site.^{27,28} Twelve hydrogen bonds form between the two terminal mannose residues and the protein, depending mainly on the amide groups of the protein backbone. Additional hydrogen bonds form between the third mannose residue and the side chain of Asp 100 of the heavy chain and between the fourth mannose residue and Tyr 94 of the light chain and Tyr 56 of the heavy chain. A unique feature of this antibody is the crossover of variable regions between heavy and light chains so that each binding site is made up of the V_H from one HL pair combining with the V_L chain of the opposite pair. This arrangement allows the antibody to bind one branch of an oligosaccharide and the opposite branch of a nearby oligosaccharide and makes it ideally suited for cross-linking the densely clustered oligosaccharides of gp120.

Immunogenicity of Polysaccharide Conjugates

Capsular polysaccharides are the main target of protective antibodies against bacterial infection, and, as such, are important vaccine antigens. In adults, the chain length of the polysaccharide is an important determinant of immunogenicity, and the polysaccharides induce a T-independent response that cannot be boosted on repeat exposure. In young children, whose maternal antibodies wane by 6 months of age and who most need immunity to pathogens such as Haemophilus influenzae type b and Streptococcus pneumoniae of multiple serotypes, the T-independent response to these polysaccharides is weak, regardless of chain length. To immunize children, the polysaccharides were coupled to a protein carrier to create a new T-dependent antigen that gained immunogenicity from T-cell help and boosted antibody titers with each successive dose. This strategy has produced highly successful conjugate vaccines against H. influenzae type b,²⁹ resulting in a markedly reduced incidence of meningitis caused by this agent in immunized children^{30,31} and evidence of herd immunity even among unimmunized children. The same strategy has produced an effective vaccine against invasive disease³² and otitis media³³ caused by the most prevalent serotypes of S. pneumoniae.

Protein and Polypeptide Antigenic Determinants

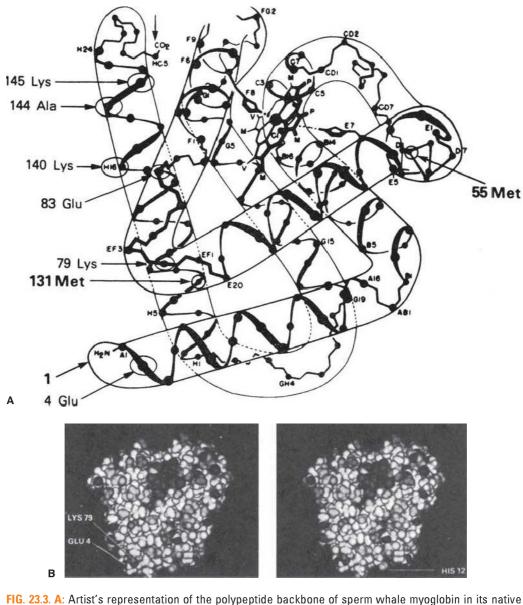

Like the proteins themselves, the antigen determinants of proteins consist of amino acid residues in a particular threedimensional array. The residues that make contact with complementary residues in the antibody-combining site are called contact residues. To make contact, of course, these residues must be exposed on the surface of the protein, not buried in the hydrophobic core. As the complementarity-determining residues in the hypervariable regions of antibodies have been found to span as much as 30 to 40 Å \times 15 to 20 Å × 10 Å (D. R. Davies, personal communication), these contact residues comprising the antigenic determinant may cover a significant area of protein surface, as measured by x-ray crystallography of antibody–protein antigen complexes.^{34–37} The size of the combining sites has also been estimated using simple synthetic oligopeptides of increasing length, such as oligolysine. In this case, a series of elegant studies^{38–40} suggested that the maximum chain length a combining site could accommodate was six to eight residues, corresponding closely to that found earlier for oligosaccharides,^{13,14} as discussed previously.

Several types of interactions contribute to the binding energy. Many of the amino acid residues exposed to solvent on the surface of a protein antigen will be hydrophilic. These are likely to interact with antibody contact residues via polar interactions. For instance, an anionic glutamic acid carboxyl group may bind to a complementary cationic lysine amino group on the antibody, or vice versa, or a glutamine amide side chain may form a hydrogen bond with the antibody. However, hydrophobic interactions can also play a major role. Proteins cannot exist in aqueous solution as stable monomers with too many hydrophobic residues on their surface. Those hydrophobic residues that are on the surface can contribute to binding to antibody for exactly the same reason. When a hydrophobic residue in a protein antigenic determinant or, similarly, in a carbohydrate determinant⁸ interacts with a corresponding hydrophobic residue in the antibody-combining site, the water molecules previously in contact with each of them are excluded. The result is a significant stabilization of the interaction. A thorough review of these aspects of the chemistry of antigen-antibody binding is in Getzoff et al.⁴¹

Mapping Epitopes: Conformation versus Sequence

The other component that defines a protein antigenic determinant, besides the amino acid residues involved, is the way these residues are arrayed in three dimensions. As the residues are on the surface of a protein, we can also think of this component as the topography of the antigenic determinant. Sela⁴² divided protein antigenic determinants into two categories, sequential and conformational, depending on whether the primary sequence or the three-dimensional conformation appeared to contribute the most to binding. On the other hand, as the antibody-combining site has a preferred topography in the native antibody, it would seem a priori that some conformations of a particular polypeptide sequence would produce a better fit than others and therefore would be energetically favored in binding. Thus, conformation or topography must always play some role in the structure of an antigenic determinant.

Moreover, when one looks at the surface of a protein in a space-filling model, one cannot ascertain the direction of the backbone or the positions of the helices (contrast Figs. 23.3A and 23.3B).⁴³⁻⁴⁷ It is hard to recognize whether two residues that are side by side on the surface are adjacent on the polypeptide backbone or whether they come from different parts of the sequence and are brought together by the folding of the molecule. If a protein maintains its native conformation when an antibody binds, then it must similarly

three-dimensional conformation. The α helices are labeled A through H from the amino terminal to the carboxyl terminal. Side chains are omitted, except for the two histidine rings (F8 and E7) involved with the heme iron. Methionines at positions 55 and 131 are the sites of cleavage by cyanogen bromide (CNBr), allowing myoglobin to be cleaved into three fragments. Most of the helicity and other features of the native conformation are lost when the molecule is cleaved. A less drastic change in conformation is produced by removal of the heme to form apomyoglobin, as the heme interacts with several helices and stabilizes their positions relative to one another. The other labeled residues (Glu 4, Lys 49, Glu 83, Lys 140, Ala 144, and Lys 145) are residues that have been found to be involved in antigenic determinants recognized by monoclonal antibodies.⁴³ Note that cleavage by CNBr separates Lys 79 from Glu 4 and separates Glu 83 from Ala 144 and Lys 145. The "sequential" determinant of Koketsu and Atassi⁴⁴ (residues 15 to 22) is located at the elbow, lower right, from the end of the A helix to the beginning of the B helix. (Adapted from Dickerson.45) B: Stereoscopic views of a computer-generated space-filling molecular model of sperm whale myoglobin, based on the Takano⁴⁶ x-ray diffraction coordinates. This orientation, which corresponds to that in Panel A, is arbitrarily designated the "front view." The computer method was described by Feldmann et al.⁴⁷ The heme and aromatic carbons are *shaded darkest*, followed by carboxyl oxygens, then other oxygens, then primary amino groups, then other nitrogens, and finally side chains of aliphatic residues. The backbone and the side chains of nonaliphatic residues, except for the functional groups, are shown in white. Note that the direction of the helices is not apparent on the surface, in contrast to the backbone drawing in Panel A. The residues Glu 4, Lys 79, and His 12 are believed to be part of a topographic antigenic determinant recognized by a monoclonal antibody to myoglobin.⁴³ This stereo pair can be viewed in three dimensions using an inexpensive stereoviewer such as the "stereoscopes" sold by Abrams Instrument Corp. (Lansing, MI) or Hubbard Scientific Co. (Northbrook, IL). (Adapted from Berzofsky et al.43)

be hard for the antibody to discriminate between residues that are covalently connected directly and those connected only through a great deal of intervening polypeptide. Thus, the probability that an antigenic determinant on a native globular protein consists of only a consecutive sequence of amino acids in the primary structure is likely to be rather small. Even if most of the determinant were a continuous sequence, other nearby residues would probably play a role as well. Only if the protein were cleaved into fragments before the antibodies were made would there be any reason to favor connected sequences.

This concept was analyzed and confirmed quantitatively by Barlow et al.,48 who examined the atoms lying within spheres of different radii from a given surface atom on a protein. As the radius increases, the probability that all the atoms within the sphere will be from the same continuous segment of protein sequence decreases rapidly. Correspondingly, the fraction of surface atoms that would be located at the center of a sphere containing only residues from the same continuous segment falls dramatically as the radius of the sphere increases. For instance, for lysozyme, with a radius of 8 Å, fewer than 10% of the surface residues would lie in such a "continuous patch" of surface. These are primarily in regions that protrude from the surface. With a radius of 10 Å, almost none of the surface residues fall in the center of a continuous patch. Thus, for a contact area of about 20 Å \times 25 Å, as found for a lysozyme–antibody complex studied by x-ray crystallography, none of the antigenic sites could be completely continuous segmental sites (see following discussion and Fig. 23.4). On the other hand, other analyses did not find a correlation of epitope residues with surface accessibility, suggesting that the situation is more complex.⁴⁹

Antigenic sites consisting of amino acid residues that are widely separated in the primary protein sequence but brought together on the surface of the protein by the way it folds in its native conformation have been called "assembled topographic" sites^{50,51} because they are assembled from different parts of the sequence and exist only in the surface topography of the native molecule. By contrast, the sites that consist of only a single continuous segment of protein sequence have been called "segmental" antigenic sites.^{50,51}

In contrast to T-cell recognition of "processed" fragments retaining only primary and secondary structures, the evidence is overwhelming that most antibodies are made against the native conformation when the native protein is used as immunogen. For instance, antibodies to native staphylococcal nuclease were found to have about a 5000fold higher affinity for the native protein than for the corresponding polypeptide on which they were isolated (by binding to the peptide attached to Sepharose).⁵² An even more dramatic example is that demonstrated by Crumpton⁵³ for antibodies to native myoglobin or to apomyoglobin. Antibodies to native ferric myoglobin produced a brown precipitate with myoglobin but did not bind well to apomyoglobin, which, without the heme, has a slightly altered conformation. On the other hand, antibodies to the apomyoglobin, when mixed with native (brown) myoglobin, produced a white precipitate. These antibodies so strongly favored the conformation of apomyoglobin, from which the heme was excluded, that they trapped those molecules that vibrated toward that conformation and pulled the equilibrium state over to the apo form. One could almost say, figuratively, that the antibodies squeezed the heme out of the myoglobin. Looked at it thermodynamically, it is clear that the conformational preference of the antibody for the apo versus native forms, in terms of free energy, had to be greater than the free energy of binding of the heme to myoglobin. Thus, in general, antibodies are made that are very specific for the conformation of the protein used as immunogen. Other more recent examples also show that antibodies can

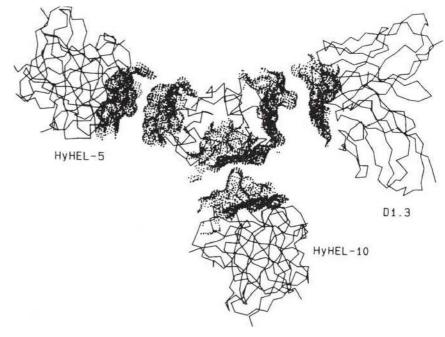

FIG. 23.4. Assembled Topographic Sites of Lysozyme Illustrated by the Footprints of Three Monoclonal Antibodies. Nonoverlapping Shown are the α -carbon backbones of lysozyme in the center and the Fv portions of three antilysozyme monoclonal antibodies D1.3. HyHEL-5. and HyHEL-10. The footprints of the antibodies on lysozyme and lysozyme on the antibodies (ie, their interacting surfaces) are shown by a dotted representation. Note that the three antibodies each contact more than one continuous loop of lysozyme and so define assembled topographic sites. Reproduced from Davies and Padlan³⁷ with permission.

enforce structures on disordered or denatured structures in proteins such as HIV-1 Tat⁵⁴ or influenza hemagglutinin.⁵⁵

Synthetic peptides corresponding to segments of the protein antigen sequence can be used to identify the structures bound by antibodies specific for segmental antigenic sites. To identify assembled topographic sites, more complex approaches have been necessary. The earliest was the use of natural variants of the protein antigen with known amino acid substitutions, where such evolutionary variants exist.50 Thus, substitution of different amino acids in proteins in the native conformation can be examined. The use of this method, which is illustrated later, is limited to studying the function of amino acids that vary among homologous proteins, that is, those that are polymorphic. It may now be extended to other residues by use of site-directed mutagenesis. A second method is to use the antibody that binds to the native protein to protect the antigenic site from modification⁵⁶ or proteolytic degradation.⁵⁷ A related but less sensitive approach makes use of competition with other antibodies.⁵⁸⁻⁶⁰ A third approach, taking advantage of the capability of producing thousands of peptides on a solid-phase surface for direct binding assays,⁶¹ is to study binding of a monoclonal antibody to every possible combination of six amino acids.⁶¹ If the assembled topographic site can be mimicked by a combination of six amino acids not corresponding to any continuous segment of the protein sequence but structurally resembling a part of the surface, then one can produce a "mimotope" defining the specificity of that antibody.⁶¹ Mimotopes have become widely used and can be combined with mutational analysis to map assembled topographic epitopes.⁶² Mimetics have even been made for quaternary structural epitopes.⁶³ Many mimotope approaches use phase display peptide libraries to map epit-opes of monoclonal antibodies.⁶⁴⁻⁶⁶ However, other studies have been less optimistic about the ability to predict assembled topographic or discontinuous epitopes from mimotope binding⁶⁷ or random peptide libraries.⁶⁸

Myoglobin also serves as a good model protein antigen for studying the range of variation of antigenic determinants from those that are more sequential in nature to those that do not even exist without the native conformation of the protein (see Fig. 23.3). A good example of the first more segmental type of determinant is that consisting of residues 15 to 22 in the amino terminal portion of the molecule. Crumpton and Wilkinson⁶⁹ first discovered that the chymotrypsin cleavage fragment consisting of residues 15 to 29 had antigenic activity for antibodies raised to either native or apomyoglobin. Two other groups^{44,70} then found that synthetic peptides corresponding to residues 15 to 22 bind antibodies made to native sperm whale myoglobin, even though the synthetic peptides were only seven to eight residues long. Peptides of this length do not spend much time (in solution) in a conformation corresponding to that of the native protein. On the other hand, these synthetic peptides had a several hundred-fold lower affinity for the antibodies than did the native protein. Thus, even if most of the determinant was included in the consecutive sequence 15 to 22, the antibodies were still much more specific for the native conformation of this sequence than for the random conformation peptide. Moreover, there was no evidence to exclude the participation of other residues, nearby on the surface of myoglobin but not in this sequence, in the antigenic determinant.^{71-74*}

A good example of the importance of secondary structure is the case of the loop peptide (residues 64 to 80) of hen egg white lysozyme.⁷⁵ This loop in the protein sequence is created by the disulfide linkage between cysteine residues 64 and 80 and has been shown to be a major antigenic determinant for antibodies to lysozyme.⁷⁵ The isolated peptide 60 to 83, containing the loop, binds antibodies with high affinity, but opening of the loop by cleavage of the disulfide bond destroys most of the antigenic activity for antilysozyme antibodies.⁷⁵

At the other end of the range of conformational requirements are those determinants involving residues far apart in the primary sequences that are brought close together on the surface of the native molecule by its folding in three dimensions, called assembled topographic determinants.^{50,51} Of six monoclonal antibodies to sperm whale myoglobin studied by Berzofsky et al.,43,76 none bound to any of the three cyanogen bromide (CNBr) cleavage fragments of myoglobin that together span the whole sequence of the molecule. Therefore, these monoclonal antibodies (all with affinities between 2×10^8 and 2×10^9 M⁻¹) were all highly specific for the native conformation. These were studied by comparing the relative affinities for a series of native myoglobins from different species with known amino acid sequences. This approach allowed the definition of some of the residues involved in binding to three of these antibodies. Two of these three monoclonal antibodies were found to recognize topographic determinants, as defined previously. One recognized a determinant including Glu 4 and Lys 79, which come within about 2 Å of each other to form a salt bridge in the native molecule (see Fig. 23.3A, B). The other antibody recognized a determinant involving Glu 83, Ala 144, and Lys 145 (see Fig. 23.3A). Again, these are far apart in the primary sequence but are brought within 12 Å of each other by the folding of the molecule in its native conformation. Similar examples have been reported for monoclonal antibodies to human myoglobin⁷⁷ and to lysozyme^{37,58} as well as the HIV-1 enve-lope protein (neutralizing epitopes)^{78,79} and the prion protein.⁸⁰ Other examples of such conformation-dependent antigenic determinants have been suggested using conventional antisera to such proteins as insulin,⁸¹ hemoglobin,⁸² tobacco mosaic virus,⁸³ and cytochrome c.⁸⁴ Moreover, the crystallographic structures of lysozyme-antibody^{34,36,37} and neuraminidase-antibody³⁵ complexes, as well as HIV-1 envelope antibody complexes,^{78,79} show clearly that, in both cases, the epitope bound is an assembled topographic site.

^{*}This is the only segmental antigenic determinant of myoglobin that has clearly been confirmed by more than one independent group of investigators. Crumpton and Wilkinson⁶⁹ did measure antigenic activity for a chymotryptic fragment 147 to 153 that overlaps one of the other reported sequential determinants.⁷¹ However, two of the other reported sequential determinants, ⁷¹ corresponding to residues 56 to 62 and 94 to 100, have not been reproducible when tested with other antisera, even raised in the same species.⁷² For related studies, see Hurrell et al.⁷³ and East et al.⁷⁴

In the case of the three monoclonal antibodies binding to nonoverlapping sites of lysozyme (Fig. 23.4), it is clear that the footprints of all three antibody-combining sites cover more than one loop of polypeptide chain, and thus, each encompasses an assembled topographic site.³⁷ This result illustrates the concept that most antibody-combining sites must interact with more than a continuous loop of polypeptide chain and thus must define assembled topographic sites.⁴⁸ Another important example is represented by neutralizing antibodies to the HIV envelope protein that similarly bind assembled topographic sites^{85,86} (see the end of this section).

How frequent are antibodies specific for topographic determinants compared to those that bind consecutive sequences when conventional antisera are examined? This question was studied by Lando et al.,⁸⁷ who passed goat, sheep, and rabbit antisera to sperm whale myoglobin over columns of myoglobin fragments, together spanning the whole sequence. After removal of all antibodies binding to the fragments, 30% to 40% of the antibodies remained that still bound to the native myoglobin molecule with high affinity but did not bind to any of the fragments in solution by radioimmunoassay. Thus, in four of four antimyoglobin sera tested, 60% to 70% of the antibodies could bind peptides, and 30% to 40% could bind only native-conformation intact protein.

On the basis of studies such as these, it has been suggested that much of the surface of a protein molecule may be antigenic,^{50,88} but that the surface can be divided up into antigenic domains.^{43,73,74,77} Each of these domains consists of many overlapping determinants recognized by different antibodies.

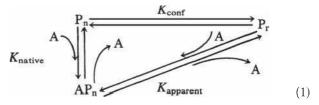

An additional interesting point is that in three published crystal structures of protein antigen–antibody complexes, the contact surfaces were broad, with local complementary pairs of concave and convex regions in both directions.^{34–37} Thus, the concept of an antigen binding in the groove or pocket of an antibody may be oversimplified, and antibodies may sometimes bind by extending into pockets on an antigen.

Further information on the subjects discussed in this section is available in the reviews by Sela,⁴² Crumpton,⁵³ Reichlin,⁸⁹ Kabat,⁹⁰ Benjamin et al.,⁵⁰ Berzofsky,⁵¹ Getzoff et al.,⁴¹ and Davis and Padlan.³⁷

Conformational Equilibria of Protein and Peptide Antigenic Determinants

There are several possible mechanisms to explain why an antibody specific for a native protein will bind a peptide fragment in random conformation with lower affinity. Of course, the peptide may not contain all the contact residues of the antigenic determinant so that the binding energy would be lower. However, for cases in which all the residues in the determinant are present in the peptide, several mechanisms still remain. First, the affinity may be lower because the topography of the residues in the peptide may not produce as complementary a fit in the antibodycombining site as the native conformation would. Second, the apparent affinity may be reduced because only a small fraction of the peptide molecules are in a native-like conformation at any time, assuming that the antibody binds only to the native conformation. Because the concentration of peptide molecules in native conformation is lower than the total peptide concentration by a factor that corresponds to the conformational equilibrium constant of the peptide, the apparent affinity is also lower by this factor. This model is analogous to an allosteric model. A third, intermediate hypothesis would suggest that initial binding of the peptide in a nonnative conformation occurs with submaximal complementarity and is followed by an intramolecular conformational change in the peptide to achieve energy minimization by assuming a native-like conformation. This third hypothesis corresponds to an induced fit model. The loss of affinity is due to the energy required to change the conformation of the peptide, which in turn corresponds to the conformational equilibrium constant in the second hypothesis. To some extent, these models could be distinguished kinetically, as the first hypothesis predicts a faster "on" rate and a faster "off" rate than does the second hypothesis.⁹¹ Such kinetic approaches have likewise been used to support an "encounter-docking" model related to this concept.⁹²

Although not the only way to explain the data, the second hypothesis is useful because it provides a method to estimate the conformational equilibria of proteins and peptides.^{52,93} The method assumes the second hypothesis, which can be expressed as follows:

where A = antibody, $P_n = native peptide$, and $P_r = random conformation peptide so that$

$$K_{apparent} = K_{conf} K_{native}$$
(2)

Thus, the ratio of the apparent association constant for peptide to the measured association constant for the native molecule should give the conformational equilibrium constant of the peptide. Note the implicit assumption that the total peptide concentration can be approximated by $[P_r]$. This will generally be true, as most peptide fragments of proteins demonstrate little native conformation, that is, $K_{conf} = [Pn] / [Pr]$ is much less than one. Also note that if the first hypothesis (or third) occurs to some extent, this method will overestimate K_{conf}. On the other hand, if the affinity for the peptide is lower because it lacks some of the contact residues of the determinant, this method will underestimate K_{conf} (by assuming that all the affinity difference is due to conformation). To some extent, the two errors may partially cancel out. When this method was used to determine the K_{conf} for a peptide from staphylococcal nuclease, a value of 2×10^{-4} (unitless because it is a ratio of two concentrations) was obtained.⁵² Similarly, when antibodies raised to a peptide fragment were used, it was possible to estimate the fraction of time the native nuclease spends in nonnative conformations.⁹³ In this case, the K_{conf} was found to be about 3000-fold in favor of the native conformation.

Antipeptide Antibodies that Bind to Native Proteins at a Specific Site

In light of the conformational differences between native proteins and peptides and the observed K_{conf} effects shown by antibodies to native proteins when tested on the corresponding peptides, it was somewhat surprising to find that antibodies to synthetic peptides show extensive cross-reactions with native proteins.94,95 These two types of cross-reactions can be thought of as working in opposite directions: The binding of antiprotein antibodies to the peptide is inefficient, whereas the binding of antipeptide antibodies to the protein is quite efficient and commonly observed. This finding is quite useful, as automated solid-phase peptide synthesis has become readily available. This has been particularly useful in three areas: exploitation of protein sequences deduced by recombinant deoxyribonucleic acid (DNA) methods, preparation of site specific antibodies, and the attempt to focus the immune response on a single protein site that is biologically important but may not be particularly immunogenic. This section focuses on the explanation of the cross-reaction, uses of the cross-reaction, and the potential limitations regarding immunogenicity.

The basic assumption is that antibodies raised against peptides in an unfolded structure will bind the corresponding site on proteins folded into the native structure.⁹⁵ This is not immediately obvious, as antibody binding to antigen is the direct result of the antigen fitting into the binding site. Affinity is the direct consequence of "goodness of fit" between antibody and antigen, whereas antibody specificity is due to the inability of other antigens to occupy the same site. How then can the antipeptide antibodies overcome the effect of K_{conf} and still bind native proteins with good affinity and specificity? The whole process depends on the antibodybinding site forming a three-dimensional space and the antigen filling it in an energetically favorable way.

Because the peptides are randomly folded, they rarely occupy the native conformation, so they are not likely to elicit antibodies against a conformation they do not maintain. If the antibodies are specific for a denatured structure, then, like the myoglobin molecules that were denatured to apomyoglobin by antibody binding,⁵³ the cross-reaction may depend on the native protein's ability to assume different conformational states. If the native protein is quite rigid, then the possibility of it assuming a random conformation is quite small; if it is a flexible three-dimensional spring, then local unfolding and refolding may occur all the time. Local unfolding of protein segments may permit the immunologic cross-reaction with antipeptide antibodies, as a flexible segment could assume many of the same conformations as the randomly folded peptide.95 On the other hand, peptides with more stable conformations may be more likely to elicit antibodies that bind both the peptide and the native protein.96 To this end, scaffolding has been used to maintain the conformation of peptides or protein fragments to be used as immunogens/vaccines, such as for respiratory syncytial virus⁹⁷ or HIV epitopes.98,99

In contrast, the ability of proteins to crystallize (a feature that allows the study of their structure by x-ray crystallog-raphy) has long been taken as evidence of protein rigidity.¹⁰⁰ In addition, the existence of discrete functional states of allosteric enzymes¹⁰¹ provides additional evidence of stable structural states of a protein. Finally, the fact that antibodies can distinguish native from denatured forms of intact proteins is well known for proteins such as myoglobin.⁵³

However, protein crystals are a somewhat artificial situation, as the formation of the crystal lattice imposes order on the components, each of which occupies a local energy minimum at the expense of considerable loss of randomness (entropy). Thus, the crystal structure may have artificial rigidity that exceeds the actual rigidity of protein molecules in solution. On the contrary, we may attribute some of the considerable difficulty in crystallizing proteins to disorder within the native conformation. Second, allosterism may be explained by two distinct conformations that are discrete without being particularly rigid. Finally, the ability to generate antiprotein antibodies that are conformation specific does not rule out the existence of antipeptide antibodies that are not. All antibodies are probably specific for some conformation of the antigen, but this need not be the crystallographic native conformation in order to achieve a significant affinity for those proteins or protein segments that have a "loose" native conformation.

Antipeptide antibodies have proved to be very powerful reagents when combined with recombinant DNA methods of gene sequencing.95,102 From the DNA sequence, the protein sequence is predicted. A synthetic peptide is constructed, coupled to a suitable carrier molecule, and used to immunize animals. The resulting polyclonal antibodies can be detected with a peptide-coated enzyme-linked immunosorbent assay plate (see Chapter 7). They are used to immunoprecipitate the native protein from a ³⁵S-labeled cell lysate and thus confirm expression of the gene product in these cells. The antipeptide antibodies can also be used to isolate the previously unidentified gene product of a new gene. The site-specific antibodies are also useful in detecting posttranslational processing, as they bind all precursors and products that contain the site. In addition, because the antibodies bind only to the site corresponding to the peptide, they are useful in probing structure-function relationships. They can be used to block the binding of a substrate to an enzyme or the binding of a virus to its cellular receptor.

Immunogenicity of Proteins and Peptides

Up to this point, we have considered the ability of antibodies to react with proteins or peptides as antigens. However, immunogenicity refers to the ability of these compounds to elicit antibodies following immunization. Several factors limit the immunogenicity of different regions of proteins, and these have been divided into those that are intrinsic to protein structure itself versus those extrinsic to the antigen that are related to the responder and vary from one animal or species to another.⁵¹ In addition, we consider the special case of peptide immunogenicity, as it applies to vaccine development. The features of protein structure that have been suggested to explain the results include surface accessibility of the site, hydrophilicity, flexibility, and proximity to a site recognized by helper T cells.

When the x-ray crystallographic structure and antigenic structure are known for the same protein, it is not surprising to find that a series of monoclonal antibodies binding to a molecule such as influenza neuraminidase choose an overlapping pattern of sites at the exposed head of the protein.¹⁰³ The stalk of neuraminidase was not immunogenic apparently because it was almost entirely covered by carbohydrate.

Beyond such things as carbohydrate, which may sterically interfere with antibody binding to protein, accessibility on the surface is clearly a sine gua non for an antigenic determinant to be bound by an antibody specific for the native conformation, without any requirement for unfolding of the structure.⁵¹ Several measures of such accessibility have been suggested. All these require knowledge of the x-ray crystallographic three-dimensional structure. Some have measured accessibility to solvent by rolling a sphere with the radius of a water molecule over the surface of a protein.^{104,105} Others have suggested that accessibility to water is not the best measure of accessibility to antibody and have demonstrated a better correlation by rolling a sphere with the radius of an antibody-combining domain.¹⁰⁶ Another approach to predicting antigenic sites on the basis of accessibility is to examine the degree of protrusion from the surface of the protein.¹⁰⁷ This was done by modeling the body of the protein as an ellipsoid and examining which amino acid residues remain outside ellipsoids of increasing dimensions. The most protruding residues were found to be part of antigenic sites bound by antibodies, but usually, these sites had been identified by using short synthetic peptides and so were segmental in nature. As noted previously, for an antigenic site to be contained completely within a single continuous segment of protein sequence, the site is likely to have to protrude from the surface, as otherwise residues from other parts of the sequence would fall within the area contacting the antibody.⁴⁸ However, inability of such surface or protrusion information to predict antigenic sites has also been encountered in some studies.49

Because the three-dimensional structure of most proteins is not known, other ways of predicting surface exposure have been proposed for the vast majority of antigens. For example, hydrophilic sites tend to be found on the water-exposed surface of proteins. Thus, hydrophilicity has been proposed as a second indication of immunogenicity.^{108–110} This model has been used to analyze 12 proteins with known antigenic sites: The most hydrophilic site of each protein was indeed one of the antigenic sites. However, among the limitations are the facts that a significant fraction of surface residues can be nonpolar,^{104,105} and that several important examples of hydrophobic and aromatic amino acids involved in the antigenic sites are known.^{42,83,111,112} Specificity of antibody binding likely depends on the complementarity of surfaces for hydrogen bonding and polar bonding as well as van der Waals contacts, whereas hydrophobic interactions and the exclusion of water from the interacting surfaces of proteins may contribute a large but nonspecific component to the energy of binding.¹¹³ Another study suggested that amino acid pairs were better predictors of epitopes.¹¹⁴

A third factor suggested to play a role in immunogenicity of protein epitopes is mobility. Measurement of mobility in the native protein is largely dependent on the availability of a high-resolution crystal structure, so its applicability is limited to only a small subset of proteins. Furthermore, it has been studied only for antibodies specific for segmental antigenic sites; therefore, it may not apply to the large fraction of antibodies to assembled topographic sites. Studies of mobility have taken two directions. The case of antipeptide antibodies has already been discussed, in which antibodies made to peptides corresponding to more mobile segments of the native protein were more likely to bind to the native protein.^{95,115} This is not considered just a consequence of the fact that more mobile segments are likely to be those on the surface and therefore more exposed because in the case of myohemerythrin (which was used as a model), two regions of the native protein that were equally exposed but less mobile did not bind nearly as well to the corresponding antipeptide antibodies.¹¹⁶ However, as is clear from the previous discussion, this result applies to antibodies made against short peptides and therefore is not directly relevant to immunogenicity of parts of the native protein. Rather, it concerns the cross-reactivity of antipeptide antibodies with the native protein and therefore is of considerable practical importance for the purposes outlined in the section on antipeptide antibodies.

Studies in the other direction-that is, of antibodies raised against native proteins-would be by definition more relevant to the question of immunogenicity of parts of the native protein. Westhof et al.¹¹⁷ used a series of hexapeptides to determine the specificity of antibodies raised against native tobacco mosaic virus protein and found that six of the seven peptides that bound antibodies to native protein corresponded to peaks of high mobility in the native protein. The correlation was better than could be accounted for just by accessibility because three peptides that corresponded to exposed regions of only average mobility did not bind antibodies to the native protein. However, when longer peptides-on the order of 20 amino acid residues-were used as probes, it was found that antibodies were present in the same antisera that bound to less mobile regions of the protein.¹¹⁸ They simply had not been detected with the short hexapeptides with less conformational stability. Thus, it was not that the more mobile regions were necessarily more immunogenic but rather that antibodies to these were more easily detected with short peptides as probes. A similar good correlation of antigenic sites with mobile regions of the native protein in the case of myoglobin¹¹⁷ may also be attributed to the fact that seven of the nine sites were defined with short peptides of six to eight residues.⁷¹ Again, this result becomes a statement about cross-reactivity between peptides and native protein rather than about the immunogenicity of the native protein. For reviews, see Van Regenmortel¹¹⁹ and Getzoff et al.⁴¹

To address the role of mobility in immunogenicity, an attempt was made to quantitate the relative fraction of antibodies specific for different sites on the antigen myohemerythrin.¹²⁰ The premise was that, although the entire surface of the protein may be immunogenic, certain regions may elicit significantly more antibodies than others and therefore may be considered immunodominant or at least more immunogenic. Because this study was done with short synthetic peptides from 6 to 14 residues long based on the protein sequence, it was limited to the subset of antibodies specific for segmental antigenic sites. Among these, it was clear that the most immunogenic sites were in regions of the surface that were most mobile, convex in shape, and often of negative electrostatic potential. Other more recent studies corroborate the greater immunogenicity of more flexible segments of protein structures.¹²¹ The role of these parameters has been reviewed.⁴¹

These results have important practical and theoretical implications. First, to use peptides to fractionate antiprotein antisera by affinity chromatography, peptides corresponding to more mobile segments of the native protein should be chosen when possible. If the crystal structure is not known, it may be possible to use peptides from amino or carboxyl termini or from exon-intron boundaries, as these are more likely to be mobile.¹¹⁵ Second, these results may explain how a large but finite repertoire of antibody-producing B cells can respond to any antigen in nature or even artificial antigens never encountered in nature. Protein segments that are more flexible may be able to bind by induced fit in an antibody-combining site that is not perfectly complementary to the average native structure.^{41,51} Indeed, evidence from the crystal structure of antigen-antibody complexes¹²²⁻¹²⁴ suggests that mobility in the antibody-combining site as well as in the antigen may allow both reactants to adopt more complementary conformations on binding to each other, that is, a two-way induced fit. A nice example comes from the study of antibodies to myohemerythrin,¹²³ in which the data suggested that initial binding of exposed side chains of the antigen to the antibody promoted local displacements that allowed exposure and binding of other, previously buried residues that served as contact residues. The only way this could occur would be for such residues to become exposed during the course of an induced fit conformational change in the antigen.^{41,123} In a second very clear example of induced fit, the contribution of antibody mobility to peptide binding was demonstrated for a monoclonal antibody to peptide 75 to 110 of influenza hemagglutinin, which was crystallized with or without peptide in the binding site and analyzed by x-ray crystallography for evidence of an induced fit.¹²⁴ Despite flexibility of the peptide, the antibody-binding site probably could not accommodate the peptide without a conformational change in the third complementarity determining region of the heavy chain, in which an asparagine residue of the antibody was rotated out of the way to allow a tyrosine residue of the peptide to fit in the binding pocket of the antibody.124

Regarding host-limited factors, immunogenicity is certainly limited by self-tolerance. Thus, the repertoire of potential antigenic sites on mammalian protein antigens such as myoglobin or cytochrome c can be thought of as greatly simplified by the sharing of numerous amino acids with the endogenous host protein. For mouse, guanaco, or horse cytochrome c injected into rabbits, each of the differences between the immunogen and rabbit cytochrome c is seen as an immunogenic site on a background of immunologically silent residues.^{50,84,125} In another example, rabbit and dog antibodies to beef myoglobin bound almost equally well to beef or sheep myoglobin.¹²⁶ However, sheep antibodies bound beef but not sheep myoglobin, even though these two myoglobins differ by just six amino acids. Thus, the sheep immune system was able to screen out those clones that would be autoreactive with sheep myoglobin.

Ir genes of the host also play an important role in regulating the ability of an individual to make antibodies to a specific antigen.¹²⁷ These antigen-specific immune response genes are among the major histocompatibility complex (MHC) genes that code for transplantation antigens. Structural mutations, gene transfer experiments, and biochemical studies¹²⁷ all indicate that Ir genes are actually the structural genes for MHC antigens. The mechanism of action of the MHC antigens works through their effect on helper T cells (described later in this chapter). There appear to be constraints on which B and T cells of a given specificity can help,^{128,129} a process called T–B reciprocity.¹³⁰ Thus, if Ir genes control helper T-cell specificity, they will in turn limit which B cells are activated and which antibodies are made.

The immunogenicity of peptide antigens is also limited by intrinsic and extrinsic factors. With less structure to go on, each small peptide must presumably contain some non– self-structural feature in order to overcome self-tolerance. In addition, the same peptide must contain antigenic sites that can be recognized by helper T cells as well as by B cells. When no T-cell site is present, three approaches may be helpful: graft on a T-cell site, couple the peptide to a carrier protein, or overcome T-cell nonresponsiveness to the available structure with various immunologic agents, such as interleukin 2.

An example of a biologically relevant but poorly immunogenic peptide is the asparagine-alanine-asparagine-proline (NANP) repeat unit of the circumsporozoite (CS) protein of malaria sporozoites. A monoclonal antibody to the repeat unit of the CS protein can protect against murine malaria.¹³¹ Thus, it would be desirable to make a malaria vaccine of the repeat unit of *Plasmodium falciparum* (NANP)_n. However, only mice of one MHC type (H-2^b) of all mouse strains tested were able to respond to (NANP)_n.^{132,133} One approach to overcome this limitation is to couple (NANP)_n to a site recognizable by T cells, perhaps a carrier protein such as tetanus toxoid.¹³⁴ In human trials, this conjugate was weakly immunogenic and only partially protective. Moreover, as helper T cells produced by this approach are specific for the unrelated carrier, a secondary or memory response would not be expected to be elicited by the pathogen itself.

Another choice might be to identify a T-cell site on the CS protein itself and couple the two synthetic peptides together to make one complete immunogen. The result with one such site, called Th2R, was to increase the range of responding mouse MHC types by one, to include H-2^k as well as H-2^b.¹³⁵ This approach has the potential advantage of inducing a state of immunity that could be boosted by natural exposure to the sporozoite antigen. As CS-specific T and B cells are both elicited by the vaccine, natural exposure to the antigen could help maintain the level of immunity during the entire period of exposure.

Another strategy to improve the immunogenicity of peptide vaccines is to stimulate the T- and B-cell responses artificially by adding interleukin 2 to the vaccine. Results with myoglobin indicate that genetic nonresponsiveness can be overcome by appropriate doses of interleukin 2.¹³⁶ The same effect was found for peptides derived from malaria proteins.^{137,137a}

One of the most important possible uses of peptide antigens is as synthetic vaccines. However, even though it is possible to elicit with synthetic peptides anti-influenza antibodies to nearly every part of the influenza hemagglutinin,⁹⁴ antibodies that neutralize viral infectivity have not been elicited by immunization with synthetic peptides. This may reflect the fact that antibody binding by itself often does not result in virus inactivation. Viral inactivation occurs only when antibody interferes with one of the steps in the life cycle of the virus, including binding to its cell surface receptor, internalization, and virus uncoating within the cell. Apparently, antibodies can bind to most of the exposed surface of the virus without affecting these functions. Only those antibodies that bind to certain "neutralizing" sites can inactivate the virus. In addition, as in the case of the VP1 coat protein of poliovirus, certain neutralizing sites are found only on the native protein and not on the heat-denatured protein.¹³⁸ Thus, not only the site but also the conformation that is bound by the antibodies may be important for the antibody to inactivate the virus. These sites may often be assembled topographic sites not mimicked by peptide segments of the sequence. Perhaps binding of an antibody to such an assembled site can alter the relative positions of the component subsites so as to induce an allosteric neutralizing effect. Alternatively, antibodies to such an assembled site may prevent a conformational change necessary for activity of the viral protein.

One method of mapping neutralizing sites is based on the use of neutralizing monoclonal antibodies. The virus is grown in the presence of neutralizing concentrations of the monoclonal antibody, and virus mutants are selected for the ability to overcome antibody inhibition. These are sequenced, revealing the mutation that permits "escape" by altering the antigenic site for that antibody. This method has been used to map the neutralizing sites of influenza hemagglutinin¹³⁹ as well as poliovirus capsid protein VP1.¹⁴⁰ The influenza escaping mutations are clustered to form an assembled topographic site, with mutations distant from each other in the primary sequence of hemagglutinin but brought together by the three-dimensional folding of the native protein. At first, it was thought that neutralization was the result of steric hindrance of the hemagglutinin-binding site for the cell surface receptor of the virus.¹⁴¹ However, similar work with poliovirus reveals that neutralizing antibodies that bind to assembled topographic sites may inactivate the virus at less than stoichiometric amounts, when at least half of the sites are unbound by antibody.¹⁴² The neutralizing antibodies all cause a conformational change in the virus, which is reflected in a change in the isoelectric point of the particles from pH 7 to pH 4.140,143 Antibodies that bind without neutralizing do not cause this shift. Thus, an alternative explanation for the mechanism of antibody-mediated neutralization is the triggering of the virus to self-destruct.

Perhaps the reason that neutralizing sites are clustered near receptor-binding sites is that occupation of such sites by antibody mimics events normally caused by binding to the cellular receptor, causing the virus to prematurely trigger its cell entry mechanisms. However, in order to transmit a physiologic signal, the antibody may need to bind viral capsid proteins in the native conformation (especially assembled topographic sites), which antipeptide antibodies may fail to do. Antibodies of this specificity are similar to the viral receptors on the cell surface, some of which have been cloned and expressed without their transmembrane sequences as soluble proteins. The soluble recombinant receptors for poliovirus¹⁴⁴ and HIV-1¹⁴⁵⁻¹⁴⁷ exhibit high-affinity binding to the virus and potent neutralizing activity in vitro. The HIV-1 receptor, cluster of differentiation (CD)4, has been combined with the human Ig heavy chain in a hybrid protein CD4-Ig,¹⁴⁸ which spontaneously assembles into dimers and resembles a monoclonal antibody, in which the binding site is the same as the receptor-binding site for HIV-1. In these recombinant constructs, high-affinity binding depends on the native conformation of the viral envelope glycoprotein gp120. Binding of CD4 to gp120 elicits a conformational change exposing a CD4-induced epitope, and fusions of CD4 domains to gp120 can be used as vaccines to elicit such antibodies.¹⁴⁹

For HIV-1, two types of neutralizing antibodies have been identified. The first type binds a continuous or segmental determinant, such as the "V3 loop" sequence between amino acids 296 and 331 of gp120.^{150–152} Antipeptide antibodies against this site can neutralize the virus.¹⁵⁰ However, because this site is located in a highly variable region of the envelope, these antibodies tend to neutralize a narrow range of viral variants with nearly the same sequence as the immunogen. Even for this highly variable site, more broadly neutralizing antibodies can be obtained that recognize conserved conformations.^{153–155} The second type of neutralizing antibody binds conserved sites on the native structure of gp120, allowing them to neutralize a broad spectrum of HIV-1 isolates. These antibodies are commonly found in the sera of infected patients,¹⁵⁶ and a panel of neutralizing monoclonals derived from these subjects has been analyzed.

These monoclonals can be divided into three types. One group, possibly the most common ones in human polyclonal sera, bind at or near the CD4 receptor-binding site of gp120.^{79,157–161} A second type of monoclonal, called 2G12, binds a conformational site on gp120 that also depends on glycosylation, but has no direct effect on CD4 binding.¹⁶² A third type, quite rare in human sera, is represented by monoclonal antibody 2F5163 and binds a conserved site on the transmembrane protein gp41. Although this site is contained on a linear peptide ELDKWA, antibodies such as 2F5 cannot be elicited by immunizing with the peptide, again suggesting the conformational aspect of this site.^{164,165} Indeed, the binding of antibodies to this membrane-proximal site has even been found to involve interaction of the antibody with the lipid membrane.¹⁶⁶ One might view this intriguing case as an example of a discontinuous or assembled topographic site created by the proximity of residues of the protein with structures in the lipid membrane, thus, spanning more than just different parts of the antigenic protein.

These monoclonals neutralize fresh isolates, as well as laboratory-adapted strains, and they neutralize viruses tropic for T cells or macrophages,¹⁶⁷ regardless of the use of CXCR4 or CCR5 as second receptor. These monoclonals, which target different sites, act synergistically. A cocktail combining all three types of monoclonals can protect monkeys against iv challenge or vaginal challenge with a simian immunodeficiency virus/HIV hybrid virus, indicating the potential for antibodies alone to prevent HIV infection.^{168,169} Because each of the three conserved neutralizing determinants depends on the native conformation of the protein,¹⁷⁰ a prospective gp120 vaccine (or gp160 vaccine) would need to be in the native conformation to be able to elicit these antibodies.

ANTIGENIC DETERMINANTS RECOGNIZED BY T CELLS

Studies of T-cell specificity for antigen were motivated by the fact that the immune response to protein antigens is regulated at the T-cell level. A hapten, not immunogenic by itself, will elicit antibodies only when coupled to a protein that elicits a T-cell response in that animal. This ability of the protein component of the conjugate to confer immunogenicity on the hapten has been termed the "carrier effect." Recognition of the carrier by specific helper T cells induces the B cells to make antibodies. Thus, the factors contributing to a good T-cell response appear to control the B-cell response as well.

"Nonresponder" animals display an antigen-specific failure to respond to a protein antigen, both for T cells and antibody responses. The "high responder" phenotype for each antigen is a genetically inheritable, usually dominant trait. Using inbred strains of mice, the genes controlling the immune response were found to be tightly linked to the MHC genes.^{127,171} MHC-linked immune responsiveness has been shown to depend on the T-cell recognition of antigen bound within a groove of MHC antigens of the antigen-presenting cell (APC) (discussed herein below and see Chapters 21 and 22). The recognition of antigen in association with MHC molecules of the B cell is necessary for carrier-specific T cells to expand and provide helper signals to B cells.

In contrast to the range of antigens recognized by antibodies, the repertoire recognized by helper and cytotoxic T cells appears to be limited largely to protein and peptide antigens, although exceptions such as the small molecule tyrosineazobenzene arsonate¹⁷² exist. Once the antigenic determinants on proteins recognized by T cells are identified, it may be possible to better understand immunogenicity and perhaps even to manipulate the antibody response to biologically relevant antigens by altering the helper T–cell response to the antigen.

Defining Antigenic Structures

Polyclonal T-Cell Response

Significant progress in understanding T-cell specificity was made possible by focusing on T-cell proliferation in vitro, mimicking the clonal expansion of antigen specific clones in vivo. The proliferative response depends on only two cells: the antigen-specific T cell and an APC, usually a macrophage, dendritic cell, or B cell. The growth of T cells in culture is measured as the incorporation of [³H]thymidine into newly formed DNA. Under appropriate conditions, thymidine incorporation increases with antigen concentration. This assay permits the substitution of different APCs and is highly useful in defining the MHC and antigen-processing requirements of the APCs.

Using primarily this assay, several different approaches have been taken to mapping T-cell epitopes. First, T cells immunized to one protein have been tested for a proliferative response in vitro to the identical protein or to a series of naturally occurring variants. By comparing the sequences of stimulatory and nonstimulatory variants, it was possible to identify potential epitopes recognized by T cells. For example, the T-cell response to myoglobin was analyzed by immunizing mice with sperm whale or horse myoglobin and testing the resulting T cells for proliferation in response to a series of myoglobins from different species with known amino acid substitutions.¹⁷³ Reciprocal patterns were observed in T cells from mice immunized with sperm whale or horse myoglobin. The response to the cross-stimulatory myoglobins was as strong as to the myoglobin used to immunize the mice. This suggested that a few shared amino acid residues formed an immunodominant epitope, and that most substitutions had no effect on the dominant epitope. A comparison of the sequences revealed that substitutions at a single residue could explain the pattern observed. All myoglobins that cross-stimulated sperm whale-immune T cells had Glu at position 109, whereas all that cross-stimulated horse-immune T cells had Asp at 109. No member of one group could stimulate T cells from donors immunized with a myoglobin of the other group. This suggested that an immunodominant epitope recognized by T cells was centered on position 109, regardless of which amino acid was substituted. Usually, this approach has led to correct localization of the antigenic site in the protein,¹⁷³⁻¹⁷⁵ but the possibility of long-range effects on antigen processing must be kept in mind (see the section on "Antigen Processing"). Also, this approach using natural variants is limited in that it can focus on the correct region of the molecule but cannot define the boundaries of the site. Site-directed mutagenesis may therefore expand the capabilities of this approach.

A second approach is to use short peptide segments of the protein sequence, taking advantage of the fact that T cells specific for soluble protein antigens appear to see only segmental antigenic sites not assembled topographic ones.^{127,176–180} These may be produced by chemical or enzymatic cleavage of the natural protein,^{178–186} solid-phase peptide synthesis,^{185,187–190} or recombinant DNA expression of cloned genes or gene fragments.¹⁹¹ In the case of class I MHC molecule–restricted cytotoxic T cells, viral gene deletion mutants expressing only part of the gene product have also been used.^{192–194}

In the case of myoglobin-specific T cells, mapping of an epitope to residue Glu 109 was confirmed by use of a synthetic peptide 102 to 118, which stimulated the T cells.^{189,195} The T cells elicited by a myoglobin with either Glu or Asp 109 could readily distinguish between synthetic peptides containing Glu or Asp at this position. Similar results were obtained with cytochrome c, where the predominant site recognized by T cells was localized with sequence variants to the region

around residue 100 at the carboxyl end of cytochrome.¹⁷⁴ Furthermore, the response to cytochrome c peptide 81 to 104 was as great as the response to the whole molecule. This indicated that a 24 amino acid peptide contained an entire antigenic site recognized by T cells. The T cells could distinguish between synthetic peptides with Lys or Gln at position 99, although both were immunogenic with the same MHC molecule.¹⁹⁶⁻¹⁹⁸ This residue determined T-cell memory and specificity, and so presumably was interacting with the T-cell receptor (TCR). A similar conclusion could be drawn for residue 109 of myoglobin. However, this type of analysis must be used with caution. When multiple substitutions at position 109 were examined for T-cell recognition and MHC binding, residue 109 was found to affect both functions.¹⁹⁹ The ultimate use of synthetic peptides to analyze the segmental sites of a protein that are recognized by T cells was to synthesize a complete set of peptides, each staggered by just one amino acid from the previous peptide, corresponding to the entire sequence of hen egg lysozyme.²⁰⁰ Around each immunodominant site, a cluster of several stimulatory peptides was found. The minimum "core" sequence consisted of just those residues shared by all antigenic peptides within a cluster, whereas the full extent of sequences spanning all stimulatory peptides within the same cluster defined the "determinant envelope." These two ways of defining an antigenic site differ, and one interpretation is that each core sequence corresponds to an MHC-binding site, whereas the determinant envelope includes the many ways for T cells to recognize the same peptide bound to the MHC.

In each case, the polyclonal T-cell response could be mapped to a single predominant antigenic site. These results are consistent with the idea that each protein antigen has a limited number of immunodominant sites (possibly one) recognized by T cells in association with MHC molecules of the high-responder type. If none of the antigenic sites could associate with MHC molecules on the APCs, then the strain would be a low responder, and the antigen would have little or no immunogenicity.

Monoclonal T Cells

Further progress in mapping T-cell sites depended on the analysis of cloned T-cell lines. These were either antigenspecific T-cell lines made by the method of Komoto and Fathman²⁰¹ or T-cell hybridomas made by the method of Kappler et al.²⁰² In the former method, T cells are allowed to proliferate in response to antigen and APCs, rested, and then restimulated again. After stimulation, the blasts can be cloned by limiting dilution and grown from a single cell in the presence of interleukin 2. In the second method, enriched populations of antigen-specific T cells are fused with a drug-sensitive T-cell tumor, and the fused cells are selected for their ability to grow in the presence of the drug. Then the antigen specificity of each fused cell line must be determined. The key to determining this in a tumor line is that antigen-specific stimulation of a T-cell hybridoma results in release of interleukin 2, even though proliferation is constitutive. T cells produced by either method are useful in defining epitopes, measuring their MHC associations and studying antigen-processing requirements.

Monoclonal T cells may be useful in identifying which of the many proteins from a pathogen are important for T-cell responses. For instance, Young and Lamb²⁰³ have developed a way to screen proteins separated by SDS–polyacrylamide gel electrophoresis and blotted onto nitrocellulose for stimulation of T-cell clones and have used this to identify antigens of *Mycobacterium tuberculosis*.²⁰⁴ Mustafa et al.²⁰⁵ have even used T-cell clones to screen recombinant DNA expression libraries to identify relevant antigens of *Mycobacterium leprae*. Use of T cells to map epitopes has also been important in defining tumor antigens.^{206–211}

Precise mapping of antigenic sites recognized by T cells was made possible by the fact that T cells would respond to peptide fragments of the antigen when they contain a complete antigenic determinant. A series of overlapping peptides can be used to walk along the protein sequence and find the antigenic site. Then, by truncating the peptide at either end, the minimum antigenic peptide can be determined. For example, in the case of myoglobin, a critical amino acid residue, such as Glu 109 or Lys 140, was found by comparing the sequences of stimulatory and nonstimulatory myoglobin variants and large CNBr cleavage fragments²¹² as previously discussed, and then a series of truncated peptides containing the critical residue was synthesized with different overlapping lengths at either end.^{185,189} Because solid-phase peptide synthesis starts from a fixed carboxyl end and proceeds toward the amino end, it can be stopped at various positions to produce a nested series of peptides that vary in length at the amino end. In this way, it was found that two of the Glu 109-specific T-cell clones responded to synthetic peptides 102 to 118 and 106 to 118 but not to peptide 109 to 118.¹⁸⁹ One clone responded to peptide 108 to 118, whereas the other did not. Thus, the amino end of the peptide recognized by one clone was Ser 108, whereas the other clone required Phe 106 and/or Ile 107. Similar fine specificity differences have been observed with T-cell clones specific for the peptides 52 to 61 and 74 to 96 of hen egg lysozyme,^{182,213,214} the peptide 323 to 339 of chicken ovalbumin,¹⁸³ and the peptide 81 to 104 of pigeon cytochrome c¹⁸⁸: The epitopes recognized by several T-cell clones overlap but are distinct. In addition, nine T-cell clones recognized a second T-cell determinant in myoglobin located around Lys 140, and each one responded to the CNBr cleavage fragment 132 to 153.215 Further studies with a nested series of synthetic peptides showed that the stimulatory sequence is contained in peptide 136 to 145.185

These findings can be generalized to characterize a large number of epitopes recognized by T cells from a number of protein antigens (Table 23.4).^{212–227} What these studies and others demonstrated about epitopes recognized by T cells is that in each case, the entire site is contained on a short peptide. MHC class I–restricted antigens also follow this rule,²²⁸ even when the protein antigen is normally expressed on the surface of infected cells. This applies to viral glycoproteins, such as influenza hemagglutinin, which are recognized by cytolytic T cells after antigen processing²²⁹ (see section on "Antigen Processing"). These peptides consist of no more than about 12 to 17 amino acid residues for class II MHC or 8 to 10 residues for class I. Within this size, they must contain all the information necessary to survive processing

within the APC, associate with the MHC antigen, and bind to the TCR, as discussed in the following sections.

Sequential Steps that Focus the T-Cell Response on Immunodominant Determinants

In contrast to antibodies that bind all over the surface of a native protein⁵⁰ (see "Protein and Polypeptide Antigenic Determinants" section), it has been observed that T cells elicited by immunization with the native protein tend to be focused on one or a few immunodominant sites.^{230–232} This is true whether one deals with model mammalian or avian proteins such as cytochrome c,¹⁷⁹ myoglobin,^{178,180} lysozyme,^{182,214,233,234} insulin,187,219 and ovalbumin,183 or with bacterial, viral, and parasitic proteins from pathogens, such as influenza hemagglutinin²¹⁷ or nucleoprotein (NP),²²⁸ staphylococcal nuclease,²³⁵ or malarial CS protein.^{135,236} Because the latter category of proteins shares no obvious homology to mammalian proteins, the immunodominance of a few sites cannot be attributed simply to tolerance for the rest of the protein because of homologous host proteins. Moreover, immunodominance is not simply the preemption of the response by a single clone of predominant T cells because it has been observed that immunodominant

sites tend to be the focus for a polyclonal response of a number of distinct T-cell clones recognizing overlapping subsites within the antigenic site or having different sensitivities to substitutions of amino acids within the site.^{182,183,188,189,200,213,214,237}

Immunodominant antigenic sites appear to be qualitatively different from other sites. For example, in the case of myoglobin, when the number of clones responding to different epitopes after immunization with native protein was quantitated by limiting dilution, it was observed that the bulk of the response to the whole protein in association with the high-responder class II MHC molecules was focused on a single site within residues 102 to 118195 (Fig. 23.5). When T cells in the (high \times low responder) F1 hybrid restricted to each MHC haplotype were compared, there was little difference in the responses to nondominant epitopes, and all the overall difference in magnitude of response restricted by the high versus low responder MHC could be attributed to the high response to the immunodominant determinant in the former and the complete absence of this response in the latter (see Fig. 23.5). Similar results were found for two different high-responder and two different low-responder MHC haplotypes.¹⁹⁵ Why did the response to the other sites not compensate for the lack of response to the immunodominant site in the low responders?

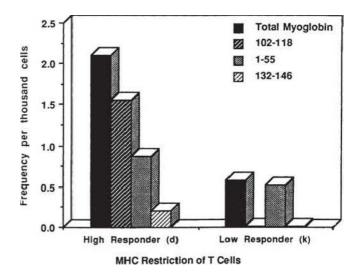

FIG. 23.5. Frequency of High- and Low-Responder Major Histocompatibility Complex (MHC)-Restricted T Cells in F1 Hybrid. High responsiveness may be accounted for by the response to a single immunodominant epitope. Lymph node T cells from (low-responder $[H-2^k] \times high-responder [H-2^d])$ F1 hybrid mice immunized with whole myoglobin were plated at different limiting dilutions in microtiter wells with either high- or low-responder presenting cells and myoglobin as antigen. The cells growing in each well were tested for responsiveness to whole myoglobin and to various peptide epitopes of myoglobin. The frequency of T cells of each specificity and MHC restriction was calculated from Poisson statistics and is plotted on the ordinate. Most of the difference in T-cell frequency between high- and low-responder restriction types (solid bars) can be accounted for by the presence of T cells responding to the immunodominant site at residues 102 to 118, accounting for more than twothirds of the high-responder myoglobin-specific T cells, in contrast to the absence of such T cells restricted to the low-responder MHC type. (Based on the data in Kojima et al.¹⁹⁵.)

The greater frequency of T cells specific for the immunodominant site may in part be attributed to the large number of ways this site can be recognized by different T-cell clones, as mentioned previously, but this only pushes the problem back one level. Why is an immunodominant site the focus for so many different T-cell clones? Because the answer cannot depend on any particular T cell, it must depend on other factors primarily involved in the steps in antigen processing and presentation by MHC molecules.

It has also been observed that some peptides may be immunogenic themselves, but the T-cell response they elicit is specific only for the peptide and does not cross-react with the native protein nor do T cells specific for the native protein recognize this site.^{238–240} These are called cryptic determinants.²⁴⁰ The reasons for these differences may involve the way the native protein is processed to produce fragments distinct from, but including or overlapping, the synthetic peptides used in experiments and also the competition among sites within the protein for binding to the same MHC molecules, as discussed further in the next section. To understand these factors that determine dominance or crypticity, one must understand the steps through which an antigen must go before it can stimulate a T-cell response.

Unlike B cells, T-cell recognition of antigen depends on the function of another cell, the APC.²⁴¹ Antigen must pass through a number of intracellular compartments and survive processing and transport steps before it can be effectively presented to T cells. Following antigen synthesis in the cell (as in a virally infected cell) or antigen uptake via phagocytosis, pinocytosis, or, in some cases, receptor-mediated endocytosis, the subsequent steps include 1) partial degradation ("processing") into discrete antigenic fragments that can be recognized by T cells, 2) transport of these fragments into a cellular compartment where MHC binding can occur, 3) MHC binding and assembly of a stable peptide-MHC complex, and 4) recognition of that peptide-MHC complex by the expressed T-cell repertoire. At each step, a potential antigenic determinant runs the risk of being lost from the process, for example, by excessive degradation or failure to meet the binding requirements needed for transport to the next step. Only those peptides that surmount the four selective hurdles will prove to be antigenic for T cells. We will now consider each step in detail, for its contribution to the strength and specificity of the T-cell response to protein antigens.

Antigen Processing

Influence of Antigen Processing on the Expressed T-Cell Repertoire. Several lines of evidence indicate that antigen processing plays a critical role in determining which potential antigenic sites are recognized and, therefore, what part of the potential T-cell repertoire is expressed upon immunization with a protein antigen. Because the T cell does not see the native antigen but only the products of antigen processing, it is not unreasonable that the nature of these products would at least partly determine which potential epitopes could be recognized by T cells.

One line of evidence that processing plays a major role in T-cell repertoire expression came from comparisons that were made of the immunogenicity of peptide versus native molecule in the cases of myoglobin²³⁸ or lysozyme.²³⁹ In the case of

myoglobin, a site of equine myoglobin (residues 102 to 118) that did not elicit a response when H-2^k mice were immunized with native myoglobin nevertheless was found to be immunogenic when such mice were immunized with the peptide.²³⁸ Thus, the low responsiveness to this site in mice immunized with the native myoglobin was not due to either of the classical mechanisms of Ir gene defects-namely, a hole in the T-cell repertoire or a failure of the site to interact with MHC molecules of that strain. However, the peptide-immune T cells responded only poorly to native equine myoglobin in vitro. Thus, the peptide and the native molecule did not cross-react well in either direction. The problem was not simply a failure to process the native molecule to produce this epitope because $(H-2^k \times H-2^s)$ F1-presenting cells could present this epitope to H-2^s T cells when given native myoglobin but could not present it to H-2^k T cells. Also, because the same results applied to individual T-cell clones, the failure to respond to the native molecule was apparently not due to suppressor cells induced by the native molecule. Similar observations were made for the response to the peptide 74 to 96 of hen lysozyme in B10.A mice.²³⁹ The peptide, not the native molecule, induced T cells specific for this site, and these T cells did not cross-react with the native molecule. With these alternative mechanisms excluded, we are left with the conclusion that an appropriate peptide was produced, but it differed from the synthetic peptide in such a way that a hindering site outside the minimal antigenic site interfered with presentation by presenting cells of certain MHC types. Further evidence consistent with this mechanism came from the work of Shastri et al.,²⁴² who found that different epitopes within the 74 to 96 region of lysozyme were immunodominant in H-2^b mice when different forms of the immunogen were used.

Another line of evidence came from fine specificity studies of individual T-cell clones. Shastri et al.²⁴³ observed that H-2^b T-cell clones specific for hen lysozymes were about 100-fold more sensitive to ring-necked pheasant lysozyme than to hen lysozyme. Nevertheless, they were equally sensitive to the CNBr cleavage fragments containing the antigenic sites from both lysozymes. Thus, regions outside the minimal antigenic site removable by CNBr cleavage presumably interfered with processing, presentation, or recognition of the corresponding site in hen lysozyme. Similarly, it was observed that a T-cell clone specific for sperm whale myoglobin, not equine myoglobin, responded equally well to the minimal epitope synthetic peptides from the two species.²³⁸ Also, residues outside the actual site must be distinguishing equine from sperm whale myoglobin. Experiments using F1-presenting cells that can clearly produce this epitope for presentation to other T cells proved that the problem was not a failure to produce the appropriate fragment from hen lysozyme²³⁹ or equine myoglobin.²³⁸ Thus, these cases provide evidence that a structure outside the minimal site can hinder presentation in association with a particular MHC molecule.

Such a hindering structure was elegantly identified in a study by Grewal et al.²⁴⁴ comparing hen egg lysozyme peptides presented by strains C57BL/6 and C3H.SW that share H-2^b but differ in non-MHC genes. After immunization with whole lysozyme, a strong T-cell response was seen to peptide 46 to 61 in C3H.SW mice but not at all in C57BL/6 mice. Because the F1 hybrids of these two strains responded, the lack of response in one strain was not due to a hole in the T-cell repertoire produced by self-tolerance. It was found that peptide 46 to 60 bound directly to the I-A^b class II MHC molecule, whereas peptide 46 to 61 did not, indicating that the C-terminal Arg at position 61 hindered binding. Evidently, a non–MHC-linked difference in antigen processing allowed this Arg to be cleaved off the 46 to 61 peptide in C3H.SW mice, in which the peptide was dominant, but not in C57Bl/6 mice, in which the peptide was cryptic.

Even a small peptide that does not need processing may nevertheless be processed, and that processing may affect its interaction with MHC molecules. Fox et al.²⁴⁵ found that substitution of a tyrosine for isoleucine at position 95 of cytochrome c peptide 93 to 103 enhanced presentation with $E\beta^{b}$ but diminished presentation with $E\beta^{k}$ when live APCs were used but not when the APCs were fixed and could not process antigen. Therefore, the tyrosine residue was not directly interacting with the different MHC molecule but was affecting the way the peptide was processed, which in turn affected MHC interaction.

Besides the mechanisms suggested previously, Gammon et al.²³⁹ and Sercarz et al.²⁴⁶ have proposed the possibility of competition between different MHC-binding structures ("agretopes") within the same processed fragment. If a partially unfolded fragment first binds to MHC by one such site already exposed, further processing may stop, and other potential binding sites for MHC may never become accessible for binding. Such competition could also occur between different MHC molecules on the same presenting cell.²³⁹ For instance, BALB/c mice, expressing both A^d and E^d, produce a response to hen lysozyme specific for 108 to 120, not for 13 to 35,²³⁹ and this response is restricted to E^d. However, B10.GD mice that express only A^d respond well to 13 to 35 when immunized with lysozyme. The BALB/c mice clearly express an A^d molecule, so the failure to present this 13 to 35 epitope may be

due to competition from E^d , which may preempt by binding the 108 to 120 site with higher affinity and preventing the 13 to 35 site from binding to A^d . Competition between different peptides binding to the same MHC molecule could also occur.

All these results, taken together, indicate that antigen processing not only facilitates interaction of the antigenic site with the MHC molecule and/or the TCR but also influences the specificity of these interactions and, in turn, the specificity of the elicited T-cell repertoire. The molecular mechanisms behind such effects are just now being elucidated, as described in the following sections.

Processing of Antigen for T Cells Restricted to Class II Major Histocompatibility Complex Molecules. It has long been known that T-cell responses such as delayed hypersensitivity in vivo or T-cell proliferation in vitro to exogenous proteins can be stimulated not only by the native protein but also by denatured protein¹⁷⁶ and fragments of native protein.²¹⁹ Indeed, this feature, along with the requirement for recognition in association with class II MHC molecules, distinguishes T- from B-cell responses. In a number of cases, the site recognized by cloned T cells has been located to a discrete synthetic peptide corresponding to a segment of the primary sequence of the protein. Examples include insulin,^{187,219} cyto-chrome c,¹⁸⁸ lysozyme,^{182,213} and myoglobin.^{178,185,189} In each case, the stimulatory peptide must contain all the information required for antigen presentation and T-cell stimulation. The lack of conformational specificity does not indicate a lack of TCR specificity. Rather, it results from antigen processing into peptide fragments that destroys conformational differences prior to binding the TCR. One way to accomplish this is via antigen processing, which involves the partial degradation of a protein antigen into peptide fragments (Fig. 23.6).

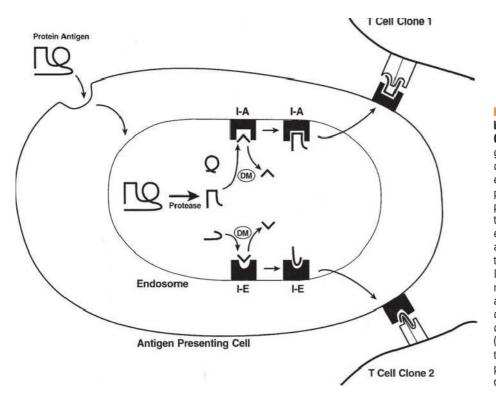

FIG. 23.6. Steps in Antigen Presentation by Class II Major Histocompatibility Complex (MHC) Molecules. Soluble antigen enters the presenting cell by phagocytosis, pinocytosis, or receptor-mediated endocytosis. It is partially degraded to peptide fragments by acid-dependent proteases in endosomes. Antigenic peptides associate with MHC class II molecules (I-A or I-E in the mouse) to form an antigenic complex that is transported to the cell surface. Before an MHC class Il molecule can bind the peptide, it must release the class II-associated invariant chain peptide fragment of invariant chain from the binding groove, which is catalyzed by human leukocyte antigen (HLA)-DM. Binding of T-cell receptors to the peptide-MHC complex triggers T-cell proliferation, resulting in clonal expansion of antigen-specific T cells.

Evidence of processing came from the fact that a single protein antigen could stimulate T cells to different epitopes, each specific for a different MHC antigen. For example, when a series of myoglobin-specific T-cell clones were tested for both antigen specificity and MHC restriction, six clones were specific for a site centering on amino acid Glu 109, and all six recognized the antigen in association with I-A^d. Nine additional T-cell clones were specific for a second epitope centered on Lys 140 and were restricted to a different MHC antigen, I-E^d. Thus, the antigen behaved as if it was split up into distinct epitopes, each with its own ability to bind MHC.²¹⁵

That T cells recognize processed antigen was demonstrated by the fact that inhibitors of processing can block antigen presentation. Early experiments by Ziegler and Unanue²⁴⁷ showed that processing depends on intracellular degradative endosomes, as drugs such as chloroquine and ammonium chloride (NH4 Cl), which raise endosomal pH and inhibit acid-dependent proteases, could block the process. However, prior degradation of proteins into peptide fragments allows them to trigger T cells even in the presence of these inhibitors of processing.²⁴⁸ For example, T-cell clone 14.5 recognizes the Lys 140 site of myoglobin equally well on the antigenic peptide (residues 132 to 153) as on the native protein (Fig. 23.7). The difference between these two forms of antigen is brought out by the presence of processing inhibitors. Leupeptin, for example, inhibits lysosomal proteases and blocks the T-cell responses to native myoglobin but not to peptide 132 to 153. Thus, native myoglobin cannot stimulate T cells without further processing, whereas the peptide requires little or no additional processing.²⁴⁹

Why is antigen processing necessary? For class II MHC molecules, experiments suggest that antigen processing may uncover functional sites that are buried in the native protein structure. For example, a form of intact myoglobin that has been partially unfolded through chemical modification can behave like a myoglobin peptide and can be presented by APC even in the presence of enough protease inhibitor or chloroquine to completely block the presentation of native myoglobin.²⁴⁹ Denatured lysozyme could also be presented without processing to one T-cell clone.¹⁸⁴ This result suggests that the requirement for processing may simply be a steric requirement, that is, to uncover the two sites needed to form the trimolecular complex between antigen and MHC and between antigen and TCR. Thus, unfolding may be sufficient without proteolysis, and proteolysis may simply accomplish an unfolding analogous to Alexander's approach to the Gordian knot.

The importance of antigen unfolding for T-cell recognition and the ability of unfolding to bypass the need for antigen processing apply to a range of polypeptide sizes from small peptides to extremely large proteins. At one extreme, Lee et al.²⁵⁰ found that even fibrinogen, of Mr 340,000, does not need to be processed if the epitope recognized is on the carboxy-terminal portion of the α chain, which is naturally unfolded in the native molecule. At the other extreme, even a small peptide of only 18 amino acid residues, apamin, requires processing unless the two disulfide bonds that hold it in the native conformation are cleaved artificially to allow

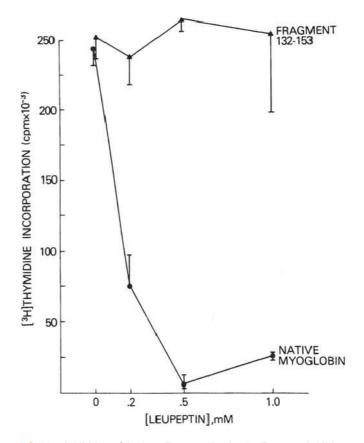

FIG. 23.7. Inhibition of Antigen Presentation by the Protease Inhibitor Leupeptin: Differential Effect on Presentation of the Same Epitope of Native Myoglobin or Peptide 132 to 153 to the Same Monoclonal T-Cell Population. Splenic cells from nonimmunized B10.D2 mice, as a source of antigen-presenting cells, were incubated with leupeptin at the concentration indicated for 15 minutes prior to and during exposure to 2 μ M native myoglobin or 1 μ M peptide fragment, washed, irradiated, and cultured at 400,000 cells per well with 10,000 T cells of clone 14.5; thymidine incorporation was measured after 4 days of culture.²⁴⁹

unfolding.²⁵¹ Therefore, large size does not mandate processing, and small size does not necessarily obviate the need for processing, at least for class II presentation. The common feature throughout the size range seems to be the need for unfolding. This evidence, taken together with the earlier data on unfolding of myoglobin and lysozyme, strongly supports the conclusion that unfolding, rather than size reduction, is the primary goal of antigen processing, and that either antigen presentation by MHC molecules or TCR recognition frequently requires exposure of residues not normally exposed on the surface of the native protein. This conclusion is supported by recent studies of peptides eluted from class II MHC molecules, and the crystal structures of class II MHC-peptide complexes, which show that longer peptides can bind with both ends extending beyond the two ends of the MHC groove^{252–254} (see "Antigen Interaction with MHC Molecules" section).

Besides proteolysis, unfolding may require the reduction of disulfide bonds between or within protein antigens. A gamma interferon–inducible lysosomal thiol reductase (GILT) is expressed in APCs and localizes to the late endosomal and lysosomal compartments where MHC class II peptide loading occurs.²⁵⁵ Unlike thioredoxin, this enzyme works at the acid pH of endosomes and uses Cys but not glutathione as a reducing agent. APCs from GILT knockout mice were tested for the ability to present hen egg lysozyme to hen egg lysozyme– specific T-cell lines.²⁵⁶ For two epitopes, the T-cell response was insensitive to the GILT defect, even though they involved a disulfide bond in the native protein. But for one epitope, located between disulfide bonds, the T-cell response was completely inhibited when the APCs lacked GILT reductase. In this case, reduction of disulfide bonds was an essential step for antigen presentation, presumably needed to generate free peptides for MHC class II binding.

Processing of Antigen for T Cells Restricted to Class I Major Histocompatibility Complex Molecules. Early studies on class I-restricted T cells, such as cytolytic T cells (CTLs) specific for virus-infected cells, assumed that they responded mainly to unprocessed viral glycoproteins expressed on the surface of infected cells. However, since the mid-1980s, it has been clear that CTLs, like other T cells, recognize processed antigens. For example, influenza NP was a major target antigen for influenza specific CTLs, even though NP remains in the nucleus of infected cells and none is detectable on the cell surface.²⁵⁷ Further support came from the finding that target cells that take up synthetic NP peptide 366 to 379 were lysed by NP-specific CTLs.²²⁸ This constitutes evidence that antigen presented in association with class I molecules requires processing into antigenic fragments. Also, the demonstration that synthetic peptides could sensitize targets for CTLs introduced a powerful tool for mapping and studying CTL epitopes.

Even for influenza hemagglutinin, which is expressed on the surface of infected cells, surface expression was not required for antigenicity, implying that it is the processed antigen that stimulates a T-cell response. Target cells expressing leader-negative hemagglutinin, which is not transported to the cell surface but remains in the cytosol, were lysed equally well as those with surface hemagglutinin.²²⁹ Similar conclusions were drawn from anchor-negative mutants.²⁵⁸ Indeed, studies of HIV-1 gp160 genes with or without a leader sequence suggest that removal of the leader sequence can increase the amount of protein that is retained in the cytosol and is available for processing and presentation through the class I MHC processing pathway.²⁵⁹ The explanation may be that the signal peptide results in cotranslational translocation of the growing peptide chain into the endoplasmic reticulum (ER), whereas proteins without a signal peptide remain in the cytosol, where they are accessible to the processing machinery of the class I pathway (see subsequent discussion). This cytosolic protein processing machinery consists pri-marily of the 26S proteasomes.^{260,261} The specificity of such proteasomes to cleave at certain positions in a protein sequence thus provides the first hurdle that a potential epitope must surmount to be presented by class I MHC molecules to be cut out correctly but not destroyed by the proteasome.

In the standard proteasome, 14 distinct subunits assemble to form a high-molecular weight complex of about 580 kD with three distinct protease activities located on different subunits. The proteasome is a barrel-shaped structure, with the protease activities arrayed on the inner surface, and unfolded proteins are believed to enter the barrel at one end, leaving as peptides at the other end. The different proteases cut preferentially after aromatic or branched chain amino acids (chymotryptic-like activity of the β 5 subunit), basic amino acids (trypsin-like activity of the β 2 subunit), or acidic residues (glutamate preferring of the β 1 subunit).^{262,263} Protease activity is increased against misfolded proteins, such as senescent proteins, which are tagged with ubiquitin and directed to the proteasome. In addition, viral proteins produced during infection and proteins synthesized with artificial amino acids are particularly susceptible to degradation by proteasomes. The products of protease digestion are peptides ranging from to 3 to 14 amino acids in length, including 9-mers, of just the right size for MHC binding. The chymotrypsin- and trypsin-like activities may be particularly important for antigenic peptides, as many peptides that naturally bind MHC end in hydrophobic or basic residues.²⁶⁴

The proteasome is the major processing machinery of the nonendosomal processing pathway. This is shown by the effect of proteasome inhibitors on MHC class I assembly and antigen presentation and by the effect of Large Multifunctional Peptidase (LMP-2) and LMP-7 mutations on antigen processing. A family of proteasome inhibitors have been described^{262,263,265} that consist of short peptides, three to four amino acids in length, ending in an aldehyde, such as Ac-Leu Leu norLeu-al, carbobenzoxy-Leu Leu nor-Val-al,²⁶³ or nonpeptides such as lactacystin.²⁶⁶ Although the peptides appear to be directed primarily at the chymotrypsin-like protease activity, as false substrates, in fact, they inhibit all three types of protease activity.

By inhibiting antigen processing, these inhibitors induce a phenotype of reduced expression of MHC class I and inability to present antigen to class I-restricted CTL.²⁶³ The MHC class I heavy chains remain in the ER, as shown by failure to become resistant to endoglycosidase H,²⁶⁷ which occurs in the Golgi. They are also unable to form stable complexes with β2microglobulin due to a lack of peptides. These effects are specific for the protease function because the inhibitors do not block presentation of synthetic peptides, which also rescue MHC class I expression, and because inhibition is reversible when inhibitor is removed. These results suggest that proteasomes are the primary supplier of antigenic peptides for class I, as other pathways are unable to compensate. However, it is also possible that the inhibitors could block other potential processing enzymes as well. An alternative processing pathway that bypasses the proteasome is provided by signal peptidase. As signal peptides are cleaved from proteins entering the ER, these hydrophobic peptides can bind MHC class I.²⁶⁸ Particularly for MHC molecules such human leukocyte antigen (HLA)-A2, which prefer hydrophobic sequences, this peptidase can be an alternative source of antigenic peptides that are independent of proteasomes and transporter associated with antigen presentation (TAP)-1/2 transport (see section on "Transport") because they are formed inside the ER.

The proteins destined for proteasomal processing include some normally short-lived proteins with a half-life of about 10 minutes, which constitute about 25% of the proteins in the cell. The rest arise from long-lived proteins, with a half-life of about 1 day, which may be synthesized incorrectly. These defective ribosomal products are ubiquitinated and marked for rapid degradation in proteasomes.^{269,270} In a normal cell, these can arise from errors in ribonucleic acid transcription, protein translation, assembly, folding, or targeting. But in a virally infected cell, misfolded viral proteins provide a ready supply of antigenic peptides for antigen presentation and T-cell recognition almost as soon as the virus starts to produce new viral proteins. Similarly, incorporation of amino acid analogues, such as canavavanine in place of arginine, creates misfolded proteins that are rapidly processed and more efficiently presented via the proteasomal pathway.²⁷¹

Interestingly, the MHC itself encodes, near the class II region, three proteins, known as LMP-2 and LMP-7 for "lowmolecular-weight protein," and MECL-1, for "multicatalytic endopeptidase complex-like 1," which contribute to the proteasome structure. The LMP-2, MECL-1, and LMP-7 subunits are upregulated by interferon- γ , and substitute for the subunits β 1, β 2, and β 5, respectively, forming what has been dubbed an "immunoproteasome," present in professional APCs. All complexes with LMPs contain proteasome proteins, but only 5% to 10% of proteasomes contain LMP-2 and LMP-7. The ones without LMPs are called constitutive proteasomes.

These MHC-encoded subunits of the immunoproteasome shift the preference of proteasomes for cleaving after certain sequences, resulting in the production of different peptide fragments.²⁷²⁻²⁷⁴ Proteasomes lacking LMP-2 through mutation or gene knockout have the same affinity, but decreased cleavage rate, for sequences ending in hydrophobic or basic amino acids. The effect is specific for these proteolytic sites, as the activity against sequences containing acidic amino acids actually increased.²⁷³ Despite the shift in specific peptides released, the overall level of MHC class I expression was reduced only slightly in LMP-7 knockouts²⁷⁴ and not at all in the LMP-2 knockouts. However, presentation of specific epitopes of the male H-Y antigen or of influenza NP was reduced by three-fold to five-fold in these knockouts. Toes et al.²⁷⁵ quantitatively compared the cleavage fragments produced by standard proteasomes and immunoproteasomes and defined the prevalence of different amino acids on each side of the cleavage site. Consistent with earlier studies, there is a strong preference for both to cleave after leucine and also to a lesser extent after other hydrophobic residues, both aliphatic and aromatic. However, the immunoproteasomes have a stronger tendency to cleave after such hydrophobic residues and a much reduced cleavage frequency after acidic residues, Asp and Glu, than standard or constitutive proteasomes. This shift in specificity is concordant with the observation that class I MHC molecules tend to bind peptides with C-terminal hydrophobic or basic residues, not acidic ones. Thus, the immunoproteasomes in professional APCs may be more effective at generating antigenic peptides that can be presented by MHC molecules.^{272,275} Protein degradation by proteasomes is processive, so the peptides released after 5% digestion are the same as the fragments released after 90% digestion. This suggests that intact proteins may enter the barrel, but they are not released at the other end until processing is complete.

Immunoproteasomes were shown to be essential for production of a hepatitis B virus core antigenic epitope²⁷⁶ and to increase production of epitopes from adenovirus²⁷⁷ and lymphocytic choriomeningitis virus.²⁷⁸ Similarly, certain epitopes of latent membrane protein 2 of Epstein-Barr virus depended on immunoproteasomes.²⁷⁹ In that case, the requirement for immunoproteasomes depended on the context of the peptide within the native protein. Incomplete protein synthesis due to puromycin or expression of the epitope surrounded by protein fragments with fewer membrane spanning domains allowed epitope generation by constitutive proteasomes.

On the other hand, some epitopes are generated more effectively by the constitutive proteasome than the immunoproteasome.^{275,280} When the repertoire of seven defined class I MHC-restricted epitopes was compared in an elegant quantitative study in LMP-2-deficient or wild-type C57BL/6 mice, it was found that responses to the two epitopes that are immunodominant in wild-type mice were greatly reduced in the LMP-2-deficient mice, which lack immunoproteasomes, and two normally subdominant epitopes became dominant.²⁸¹ However, from adoptive transfer experiments in both directions, it was found that the reduced response to one normally dominant epitope was due to decreased production without immunoproteasomes, but that to the other was due to an altered T-cell repertoire in the LMP-2-deficient mice, presumably due to alterations in the peptides presented in the thymus. Further, the increased response to one of the subdominant determinants was related to increased production of this peptide by the constitutive proteasomes compared to the immunoproteasomes. Thus, the immunoproteasome specificity plays a significant role in determining the repertoire of epitopes presented, and in selecting those that are immunodominant, as well as regulating the CD8⁺ T-cell repertoire generated in the thymus.

Another protein associated with proteasomes is the proteasome activator PA28, which assembles into 11s structures.²⁸² Like LMP-2 and LMP-7,²⁷² PA28 is inducible by interferon- γ , and its induction causes a shift in proteasome function that may lead to the production of greater amounts of and different repertoires of antigenic peptides. For example, synthetic substrates were designed to test the ability of proteasomes to generate authentic MHC-binding peptides. These substrates contained the MHC-binding ligand flanked by the natural sequence as found in the original protein.

To generate the MHC-binding ligand, the proteasome would have to cleave the substrate twice.²⁸³ By itself, the 20s proteasome was able to produce singly cleaved fragments, but with added PA28, doubly cut peptides were generated preferentially. Thus, PA28 favored the production of antigenic peptides, possibly by keeping the peptide in the proteasome until processing was complete. Alternatively, PA28 may coordinate the proteolytic activity of two adjacent sites to generate doubly cut peptides of just the right length (8- to 9-mers) to fit in the MHC groove. The distance between these nearby sites would determine the size of the peptides produced. The PA28 has been shown to increase generation of a dominant lymphocytic choriomeningitis virus epitope independently of the presence of the other interferon- γ -inducible components LMP-2, LMP-7, and MECL-1.²⁸⁴

The specificity of this proteasomal processing system determines the first step in winnowing the number of

protein segments that can become CTL epitopes, by selectively producing some peptide fragments in abundance and destroying others. Thus, it is probably not just coincidental that the C-terminal residues produced by proteasomal cleavage often serve as anchor residues for binding class I MHC molecules, or that the lengths of peptides produced are optimal for class I MHC binding.^{272,285} Better understanding of the specificity of proteasomes will contribute to the new methods to predict dominant CD8⁺ T-cell epitopes.²³²

An analysis of proteasomal target sites was based on the proteasomal degradation pattern of three proteins: beta-casein, enolase, and prions.²⁸⁶ The resulting peptides were analyzed by mass spectrometry, and the cleavage sites identified, including four amino acids on the amino end of each cleavage site and two amino acids on the carboxy end. The results are summarized in Figure 23.8. The three proteolytic activities of the proteasome were represented by favorable amino acids: Arg (trypsin-like), Tyr and Phe (chymotrypsin-like), and peptidylglutamylpeptide (Asp and Glu) at position P1. At this site, Pro was unfavored, as were Asn, Lys, and Ser. Additional negative effects were observed for Asp, Pro, and Ile at position P2. On the carboxy side of the cleavage site, at position P'1, the positive effect of Tyr was noted as well as negative effects of Ile, Phe, and Val.

Additional downstream processing steps, after the proteasome, are known to be important for generation of antigenic peptides. One of these occurs in the cytoplasm, prior to TAP transport, and others occur after transport into the ER. The proteasome creates a first draft of the peptides, which are then selected and trimmed to produce the final pool of antigenic peptides of optimal size and sequence for MHC binding while protecting the nascent peptides from degradation before they can bind MHC.

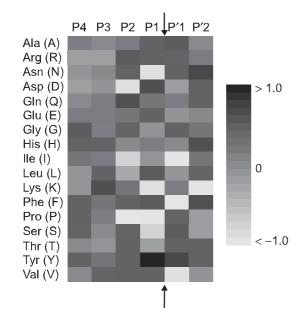

FIG. 23.8. The Effect of Specific Amino Acids on Proteasomal Cleavage between Positions P1 and P'1. Amino acids that favor cleavage are shown in *black*, whereas those that inhibit cleavage are shown in *white*. Reproduced from Donnes and Kohlbacher²⁸⁶ with permission.

Recent studies have revealed that most peptides are released from the proteasome when they still need further processing to become antigenic peptides.^{287,288} In the cytoplasm, the major proteolytic activity comes from an enzyme called tripeptidyl amino peptidase II (TPPII), which is located on a large particle. It has amino peptidase activity, which can remove 1 to 3 amino acids at a time and is useful for peptides of 15 amino acids or less. It also has endopeptidase activity that can cut in the middle of peptides larger than 15 amino acids, with the release of fragments of at least 9 amino acids. These are a significant source of 9-mers with new carboxyl ends, and this may be the only way to generate carboxyl ends other than the proteasome itself.

The importance of TPPII activity for antigen processing is shown by the fact that a specific inhibitor, butabindide, can prevent peptide loading of MHC, resulting in reduced surface expression. The most likely path for most protein antigens is to enter the proteasome and emerge as peptides of 15 amino acids or larger. These are then trimmed by TPPII, resulting in peptides ready for TAP transport. Longer peptides are trimmed internally by TPPII endoprotease, which may generate carboxyl ends needed for TAP binding. The resulting peptides are then transported by TAP into the ER, where they may be trimmed further to prepare them for MHC binding. An additional role of TPPII is shown by the generation of unique epitopes that are not produced by proteasomes. For example, an important T-cell epitope of the Nef protein of HIV requires TPPII processing. Proteasomal inhibitors have no effect on it, but butabindide prevents its processing and presentation to HLA-A3- or All-restricted T cells.²⁸⁹ This pathway seems particularly important for generating epitopes ending in lysine groups, which bind these two MHC types but are rarely generated by proteasomes alone. TPPII can act in parallel with proteasomes or in tandem with them to release this epitope from intact protein or its partially degraded fragments.

Transport into a Cellular Compartment Where Major Histocompatibility Complex Binding Can Occur

The second hurdle a potential epitope must surmount is to be transported into the cellular compartment for loading onto MHC molecules. These compartments are different for class I and II molecules, as noted previously.

Transport Pathways Leading to Major Histocompatibility Complex Class I Presentation. The second hurdle for peptide presentation by class I MHC molecules is to get from the cytosol, where the peptides are produced, to the ER, where the newly synthesized class I MHC molecules are assembled and loaded with peptide. The discovery of a specific active transporter suggested that specificity of transport could further restrict the repertoire of peptides available to load onto class I MHC molecules. Genetic analysis of mutant cell lines that failed to load endogenous peptides onto class I MHC molecules revealed homozygous deletions of part of the MHC class II region near the DR locus. Molecular cloning of DNA from this region revealed at least 12 new genes, of which 2, called TAP-1 and TAP-2 showed a typical sequence for ABC transporter proteins.^{290–292} Their function is to transport processed peptides from the cytosol to the ER. Once in this compartment, peptides are handed off by TAP to newly formed MHC class I molecules and stabilize a trimolecular complex with β 2-microglobulin. This complex is then transported to the cell surface, where antigen presentation occurs. Without the peptide transporters, empty dimers of MHC class I with β 2-microglobulin form, but these are unstable. Excess free peptide would rescue MHC class I by stabilizing the few short-lived empty complexes that reach the surface, as shown by Townsend et al.²⁹³ and Schumacher et al.²⁹⁴ Thus, MHC-linked genes coding for proteolysis, peptide transport, and presentation at the cell surface have been identified. In effect, the MHC now appears to encode a complex system of multiple elements devoted to the rapid display of foreign protein determinants on the surface of an infected cell. By continuously sampling the output of the protein synthesizing machinery, this system permits rapid identification and destruction of infected cells by CTL before infectious virus can be released.

In an infected cell, as soon as viral proteins are made, peptide fragments generated by the proteasome become available to the TAP-1 and TAP-2 transporter proteins (Fig. 23.9). These transport the peptide fragments into the ER for association with newly formed MHC class I molecules, which would carry them to the cell surface for antigen presentation, all within 30 minutes. Indeed, the finding of a physical association between TAP and the nascent class I heavy chain/ β 2-microglobulin complex suggests that the peptide may be directly handed off from TAP to the new MHC molecule without being free in solution.^{295,296} If TAP transport is highly selective, then some cytosolic peptides may fail to enter the ER for presentation with class I, but if it is promiscuous, then some peptides may be transported that were better off not presented, such as those leading to autoimmunity.

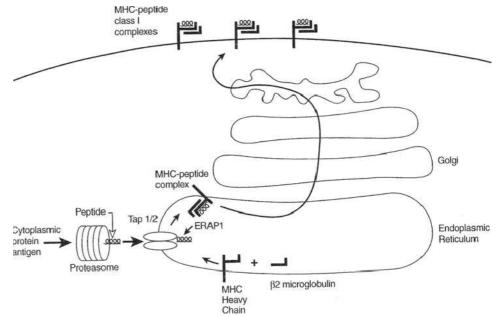

The idea that other proteins may control accessibility of MHC class I-binding sites for peptides originally came from

the observation that two rat strains with the same MHC type (RT1.A^a) were nevertheless not histocompatible, and CTL could recognize the difference between them.²⁹⁷ The difference, called a cim effect, for class I modification, occurred because different peptides were binding the same MHC in the two strains.^{298,299} The rat has two alleles for a peptide transporter supplying peptides to MHC. The one called TAP2A has peptide specificity matching that of RT1.A^a and delivers a broad set of peptides for MHC binding. The other transporter allele, called TAP-2B, supplies a different set of peptides that are discordant with RT1.A^a, so fewer types of peptides are bound. Although RT1.A^a would prefer to bind peptides with Arg at position 9, it has to settle for peptides with hydrophobic termini as provided by TAP-2B,³⁰⁰ thereby accounting for the apparent histocompatibility difference. Thus, the specificity of TAP transport was shown to provide a selective step in narrowing the potential repertoire of CTL epitopes.

To measure TAP specificity in other species, a transportable peptide bearing an N-linked glycosylation site was added to cells permeabilized by treatment with streptolysin. If the peptide was transported by TAP, it would enter the ER and cis Golgi, where it would be glycosylated.³⁰¹⁻³⁰³ The extent of glycosylation served as a measure of TAP function. When competitor peptides were added as well, TAP-mediated transport of the reporter peptide decreased, indicating saturation of peptide-binding sites. In this way, a series of related peptides could be tested for the ability to compete for TAP binding and transport in order to identify the requirements for TAP binding and transport.

TAP binding and transport depended strongly on peptide length.^{303,304} Mouse TAP was shown to have a strong preference for peptides of nine residues or longer.³⁰⁴ For human TAP, peptides shorter than seven amino acids long were not transported, regardless of sequence.³⁰³ Peptides 8 to 11 amino acids long were almost all transported, with some variation in binding affinities depending on sequence.

FIG. 23.9. Cytoplasmic Antigen-Processing Pathway leading to Major Histocompatibility Complex (MHC) Class I Presentation. Cytoplasmic antigen is degraded in the proteasome to fragments, which are transported into the endoplasmic reticulum by the transporter associated with antigen presentation (TAP) transporter. Peptide supplied by TAP forms a stable complex with MHC class I heavy chains and ß2-microglobulin, and the complex is transported through the Golgi, where it achieves mature glycosylation, and out to the cell surface for presentation to class I-restricted T cells. Additional processing options by tripeptidyl amino peptidase II in the cytoplasm and endoplasmic reticulum aminopeptidase I in the endoplasmic reticulum, before and after TAP transport, allow greater flexibility in meeting the requirements of binding both TAP and MHC molecules.

Peptides 14 to 21 amino acids in length were transported selectively, whereas those longer than 24 amino acids were almost never transported intact. Thus, human TAP transport selected against peptides <7 or >24 amino acids in length, regardless of sequence. Unlike the rat, human and mouse TAP do not show allelic differences in peptide transport.

Although TAP can and must transport a wide variety of peptides, it may still have preferences for which peptides are transported most efficiently and which MHC types are provided with the peptides they need. For example, a selfpeptide that naturally binds HLA-B27 was modified slightly to produce an N-linked glycosylation site, resulting in the sequence RRYQNSTEL.³⁰³ Using the glycosylation of this peptide to measure transport, saturation of TAP by homologous peptides occurred with a 50% inhibitory concentration of $<1 \mu$ M. Other peptides with unrelated sequences also inhibited, often with equally high affinity. Not only did natural HLA-binding peptides compete but also did peptide variants lacking the MHC-binding motif at positions 2 and 9 (see subsequent discussion). Clearly, peptides binding different MHC types were transported by the same TAP protein, and even peptides that bound mouse MHC were transported by human TAP. In another example, using rat TAP proteins, peptides with Pro at position 2, 6, or 9 were found to be poor competitors for transport of a reference peptide.³⁰²

In a different approach, using a baculovirus system overexpressing TAP proteins in microsomes, the affinity of TAP binding was determined for a wide variety of synthetic peptides, allowing mapping of the important residues.^{305,306} Binding, rather than transport, appears to be the major step determining TAP peptide selectivity.307 Indeed, artificial neural networks have been developed to predict peptide binding to human TAP.³⁰⁸ Using this scheme, it was found that peptides eluted from three different human class I molecules had higher predicted affinities for TAP than a control set of peptides with equal binding to those class I MHC molecules, supporting the hypothesis that TAP specificity contributes to the selection of the subset of peptides able to bind a class I molecule that actually bind in vivo.³⁰⁸ Unlike MHC class I, there were no anchor positions at which a specific amino acid was required. However, there were several positions where substituting the wrong amino acid caused a marked reduction in TAP binding. In a typical MHC class I binding 9-mer, the strongest substitution effects were observed at position 9 (P9), followed by substitutions at P2 and P3, followed by P1. At the carboxy-terminal P9, the preferred residues were Tyr and Phe (as well as Arg and Lys), whereas Glu was worst, causing a 3 log reduction in binding. Similarly, substituting Pro at P2 caused a 1.5 to 2 log reduction in binding, as compared to preferred residues Arg, Val, and Ile.

These binding studies were extended to 231 peptides, which were evaluated for binding to both mouse and human TAP proteins.³⁰⁹ Both TAP proteins showed strong positive selection favoring certain amino acids (Tyr and Phe) at position P9 and strong negative selection against others (Glu, Asp, and Ser) at P9. However, mouse TAP showed greater negative effects from basic amino acids (Arg or Lys) at P9. Both TAPs were sensitive to Pro at P1, P2, and P3, but

human TAP was also sensitive to negative effects of amino acids Asp, Glu, and Gly at these positions. In both cases, TAP binding was insensitive to amino acid substitutions at intermediate P4 through P8.

TAP preferences such as these would selectively transport some peptides more than others from cytoplasm to ER. Use of combinatorial peptide libraries independently confirmed that the critical residues influencing TAP transport were the first three N-terminal residues and the last C-terminal residue.³¹⁰

Interestingly, these preferred residues are many of the same ones forming the MHC class I-binding motifs (P2 and P9). However, as the MHC-binding motifs differ from each other, it is not possible for TAP preferences to match them all. For example, the TAP preference for Arg at P2 and Phe, Tyr, Leu, Arg, or Lys at P9 overlaps with the binding motif of HLA-B27 and may favor the transport of peptide ligands for this MHC type. Remarkably, the variant B*2709, which does not prefer Tyr or Phe at P9, is not associated with autoimmune disease as in the more common form of HLA-B27. In contrast, HLA-B7 requires a Pro at P2, which greatly decreases TAP binding. Similarly, some peptides binding HLA-A2 have hydrophobic residues unfavorable for TAP binding, suggesting suboptimal compatibility between TAP and the most common HLA class I allele. Measurements with a series of naturally presented peptides from HLA-A2 and HLA-B27 indicated a mean 300fold higher affinity of TAP for the HLA-B27 peptides than for those from HLA-A2, and some of the HLA-A2 peptides did not bind TAP at all.³⁰⁸ How are these low-affinity peptides delivered to MHC? One suggestion is that peptide ligands for HLA-A2 and HLA-B7 may be transported as a larger precursor peptide containing the correct amino acids, which are then trimmed off to fit the MHC groove.

A series of studies support this mechanism, showing that longer peptide precursors are trimmed at the N-terminus by aminopeptidases in the ER to form HLA-binding peptides.³¹¹ The ability to transport larger peptides, followed by trimming, could increase the range of permissible antigenic peptides, by facilitating transport of nonantigenic peptides, followed by trimming to the size and specificity needed for MHC binding. For example, following hepatitis B virus infection, certain peptide epitopes that are frequently recognized by CTL are nevertheless not bound or transported by TAP. By extending these peptides by one or two amino acids of the natural sequence at the amino end, their TAP binding was greatly enhanced, but at the expense of reduced MHC binding. When tested on permeabilized cells, the overall effect of the extended peptides was to increase MHC binding. Apparently, by improving TAP transport, these peptides were able to increase peptide delivery into the ER, where they were trimmed to produce peptides compatible with MHC binding.³¹²

Similarly, it is known that peptides with a Pro at P2, needed to bind to certain MHC molecules but poorly transported, are produced from longer precursors that are transported by N-terminal trimming in the ER by aminopeptidases.³¹³ In fact, the inability of the aminopeptidase to cleave beyond a residue preceding a Pro naturally leads to trimming of peptides to produce ones with a Pro at P2. Alternatively, some of these peptides may derive from signal peptides and enter the ER in a TAP-independent manner. As HLA-A2 tends to bind hydrophobic peptides, signal peptides, which are usually hydrophobic, may account for some HLA-A2-binding epitopes. The ER trimming enzyme has been identified as endoplasmic reticulum aminopeptidase I (ERAP I).^{314–316} This enzyme is a 106 kD zinc metalloproteinase, and it is the major ER protease with broad specificity. It is inducible by interferon- γ and inhibited by the aminopeptidase inhibitor leucinethiol. Downregulation of ERAP I with small interfering ribonucleic acid in decreased expression of MHC class I, indicating that ERAP I contributes to the supply of peptides. ERAP I prefers peptides of 9 or 10 amino acids or longer and ignores peptides of 8 amino acids or fewer, which may allow it to generate antigenic peptides for MHC binding without degrading them beyond recognition.

The aminopeptidase provides a way to relax the requirement for proteasomes to generate ends that can simultaneously bind TAP and MHC. In contrast, the fact that a comparable carboxypeptidase has not been identified suggests that carboxyl ends generated by proteasomal processing must be suitable for TAP transport and compatible with MHC binding. This requirement is quite stringent, as the carboxylterminal residue is the most important for TAP binding, and it is frequently an anchor residue for MHC as well.

The significance of selective peptide transport may be to limit immunity to self-peptides. If the match between HLA-B27 and TAP specificity is too good, it may contribute to the increased incidence of autoimmune disease associated with HLA-B27.³⁰⁵ An effect of human TAP specificity in loading of peptides in viral infection has confirmed the biologic significance of TAP specificity.³¹² TAP-binding specificity also limited the repertoire of alloantigenic peptides presented by HLA-B27.³¹⁷ Tapasin, which is involved in the TAP-binding process, may also contribute to selective MHC loading contributing to immunodominance by favoring binding of peptides with slow dissociation rates from MHC molecules.³¹⁸

By combining the selectivity of proteasomal processing, TAP transport and MHC binding, it has been possible to generate models that correlate with known antigenic peptides.^{319,320} These can be used to analyze the sequence of any given protein and to predict epitopes that may be recognized by T cells restricted to MHC class I. These may be important for analyzing the T-cell response to viral or neoplastic antigens and for generating synthetic vaccines capable of eliciting a T-cell response to these antigens.

The importance of TAP proteins to antiviral immunity is shown by the fact that herpesviruses have targeted TAP-1 function as a way to interfere with antigen presentation to CD8⁺ CTL. A herpes simplex virus immediate early viral protein called ICP47 binds to TAP and inhibits its function, causing reduced expression of new MHC class I molecules on the cell surface and inability to present viral or other antigens with MHC class I.^{321–323} As a way to evade immune surveillance, this strategy could contribute to viral persistence in chronic infection and viral activation in recurrent disease as frequently occurs with herpes simplex virus-1 and herpes simplex virus-2. These findings also raise the possibility of making a live-attenuated ICP47-defective herpes simplex virus vaccine that would be more immunogenic than natural infection. Transport Pathways Leading to Major Histocompatibility Complex Class II Presentation. Unlike the class I pathway, which delivers peptides to MHC, the MHC class II pathway transports MHC molecules to the endosomal compartment, where antigenic peptides are produced. During transport, the peptide-binding groove must be kept free of endogenous peptides. The cell uses one protein, called invariant chain (and its processed fragment CLIP), to block the binding site until needed, and another protein, HLA-DM, to facilitate release of CLIP peptides and their exchange for antigenic peptides as they become available.

MHC class II molecules assemble in the ER, where α and β chains form a complex with invariant chain.^{324–326} Invariant chain binds MHC and blocks the peptide-binding groove, so endogenous peptides transported into the ER, for example by TAP, cannot bind.^{325,327–332} The complex of α , β , and invariant chains, consisting of nine polypeptide chains in all,³³³ is transported via the Golgi and directed by signals on invariant chain into endosome-/lysosome-like vesicles called MHC class II compartments. The compartments contain acid-activated proteases capable of digesting foreign proteins into antigenic peptides. In addition, they degrade invariant chain to a fragment called CLIP, corresponding to amino acids 80 to 103. As long as CLIP remains in the binding groove, antigenic peptides cannot bind, so the rate of CLIP release limits the capacity of MHC to take up antigenic peptides.

Peptide loading can be measured by its effect on MHC structure. When an MHC class II molecule binds a peptide, it changes conformation, and certain monoclonal antibodies are specific for the peptide-bound conformation.³³⁴ Also, the α - β complex becomes more stable after peptide binding, which can be detected by running the MHC on an SDS gel without boiling. The peptide bound form runs on gels as a large α - β dimer while MHC without peptides (but still bound to CLIP) is unstable under these conditions and falls apart to give α and β chain monomers on SDS gels.³³⁵

Mutant cell lines have been generated with a deletion between HLA-DP and HLA-DQ genes on chromosome 6.^{334,336–338} These cells express normal levels of MHC class II structural proteins, HLA-DQ and HLA-DR, but fail to present protein antigens.³³⁸ Some of their class II MHC proteins appear on the cell surface but more are retained in the MHC class II compartments. Biochemically, they still contain CLIP peptides,³³⁹ rather than peptide antigens, and they have not achieved the conformation³³⁴ or SDS stability of peptide-binding MHC class II complexes.³⁴⁰ The defect was discovered to be due to loss of either of the two chains of a class II molecule, HLA-DM, and the phenotype can be corrected by adding back the missing gene.³⁴¹ In the presence of normal HLA-DM, MHC releases CLIP and binds antigenic peptides for presentation to T cells.

The importance of HLA-DM function for T-cell help in vivo was studied in H2-DM knockout mice.³⁴² These mice have reduced numbers of T cells, their class II MHC molecules reach the cell surface bearing high levels of CLIP peptide, and their B cells are unable to present certain antigens, such as ovalbumin, to T cells. When H2-DM knockout

mice were immunized with 4-hydroxy-5-nitrophenyl acetyl ovalbumin, specific IgG antibodies were reduced 20-fold, as compared to wild type. Germinal center formation and class switching were greatly reduced, and affinity maturation was not observed. The phenotype was more pronounced for some MHC types, such as I-A^b, than for others, such as I-A^k. Due to tighter binding of CLIP peptides, these MHC types may be more dependent on H2-DM to maintain empty class II molecules in a peptide receptive state.

In vitro studies with purified MHC class II molecules and biotin-labeled peptides have shown that HLA-DM can accelerate loading of exogenous peptides into HLA-DR-binding sites.^{343,344} For example, loading of myelin basic protein fragment 90 to 102 was accomplished in 9 minutes with HLA-DM versus 60 minutes without it (Table 23.5). Other peptides were also loaded at the same rate, suggesting that the rate limiting step was the same for each: removal of CLIP peptides to expose the peptide binding sites on HLA-DR. The kinetic effect was optimal between pH 4.5 and 5.8, which is typical of the endosomal/lysosomal compartment where HLA-DM operates. HLA-DM did not affect the affinity, as measured by half-maximal binding, but it had a marked effect on the kinetics of binding.

Conversely, when biotinylated peptides were allowed to saturate HLA-DR–binding sites overnight, and then free peptides were removed, the off rate could be measured over time.^{343,344} As shown in Table 23.5 (adapted from Sloan et al.³⁴³), the off rate for different peptides could be compared in the absence or presence of HLA-DM. The half-life for CLIP peptides was reduced from 11 hours to 20 minutes by add-ing HLA-DM. This could explain the enhanced loading of all other peptides, as they must wait for CLIP to come off. In the case of antigenic peptides, myelin basic protein 90 to 112 was released 80-fold faster in the presence of DM than in its absence. However, another peptide, influenza hemagglutinin

Effect of Human Leukocyte Antigen-DM on Peptide on Rates TABLE 23.5 and Off Rates for Binding to Human Leukocyte Antigen-DR1 **Half-Time** Half-life **Peptide HLA-DM** for **Binding** for Release CLIP (80-103) 60 min 11 hr +9 min 0.3 hr MBP (90-102) 62 min 86 hr _ 9 min 1 hr + HA (307-319) 67 min 144 hr + 10 min 144 hr

CLIP, class II–associated invariant chain peptide; HA, hemagglutinin; HLA, human leukocyte antigen; MBP, myelin basic protein.

The on (association) and off (dissociation) rates of biotinylated peptide from purified soluble HLA-DR1 were measured by fluorescence assay, in the presence or absence of HLA-DM. The on rates of all three peptides are increased similarly in the presence of HLA-DM and probably reflect the rate-limiting dissociation of the bound CLIP fragment of the invariant chain. In contrast, once the peptides are bound, the off rates differ as a result of differences in affinity. Thus, HLA-DM catalyzes release of more weakly binding peptides and allows stable binding of higher affinity peptides. In effect, this is an editing function of HLA-DM. Adapted from the data of Sloan et al.²³⁸ 307 to 319, was not affected at all. The differential effect on these antigenic peptides suggests that HLA-DM can serve a potential role in editing which peptides stay on MHC long enough to be presented and which are removed.³⁴³ By releasing myelin basic protein preferentially and not the hemagglutinin peptide, HLA-DM would favor the stable MHC binding and presentation of hemagglutinin peptides over myelin basic protein peptides. The affinity of each peptide is determined by the fit between peptide and MHC groove, not by HLA-DM. However, DM can amplify the impact of the difference in affinity (ie, signal to noise ratio) by facilitating release of low-affinity peptides and allowing the high-affinity ones to remain. This editing function could have an important effect on which peptides get presented and elicit a T-cell response. HLA-DM could contribute to immunodominance of a peptide binding MHC with high affinity by releasing its lower affinity competitors. Alternatively, HLA-DM could contribute to self-tolerance by releasing self-peptides of low affinity before they could stimulate self-reactive T cells either at the time of positive selection (so they would fail to be positively selected) or in the periphery (so they would fail to be activated). When HLA-DM was engineered to be expressed on the cell surface, it also facilitated loading of exogenous peptides onto class II MHC molecules and affected the activation of T cells of different fine specificity for the same epitope.³⁴⁵

Major Histocompatibility Complex Binding and Assembly of a Stable Peptide-Major Histocompatibility Complex Antigen Interaction with Major Histocompatibility Complex Molecules. Perhaps the most selective step a potential antigenic site must pass is to bind with sufficiently high affinity to an appropriate MHC molecule.

The response specificity of T cells to antigens on APCs or target cells provides a number of hints that antigen interacts directly with MHC molecules of the APCs to form an antigenic complex recognized by T cells. First, genes coding for immune responsiveness (Ir genes) to a specific antigen are tightly linked to genes for MHC-encoded cell surface molecules.^{127,171} Second, it became apparent that T-cell recognition of antigen is the step at which MHC restriction occurs.^{127,179,219,346} For example, in vitro T-cell responses to small protein and polypeptide antigens were found to parallel in vivo responses controlled by Ir genes, and T cells were exquisitely sensitive to differences in MHC antigens of the APCs in all their antigen recognition functions. This observation in vitro made it possible to separate the MHC of the T cell from that of the APC. The T-cell response to antigenic determinants on each chain of insulin depended on the MHC antigens of the APC. This was particularly apparent when T cells from an $(A \times B)F1$ animal responded to antigen presented by APCs of either the A or B parental MHC type.^{219,347} Neither parental APC stimulated an allogeneic response from $(A \times B)F1$ T cells, and the response to antigen was now limited by the MHC of the APCs. This ability of the APCs to limit what could be presented to the T cells was termed "determinant selection."^{219,347} It became obvious that even in a single $(A \times B)F1$ animal, distinct sets of antigen-specific T cells exist that respond to each antigenic determinant only in association with MHC type A or B.³⁴⁸

Experiments on the fine specificity of antigen-specific T-cell clones suggested that the MHC of the APCs could influence the T-cell response in more subtle ways than just allowing or inhibiting it. Determinant selection implied that a given processed peptide should contain both a site for MHC interaction and a distinct functional site for TCR binding. Thus, a protein with multiple determinants could be processed into different peptides, each with a different MHC restriction, consistent with the independent Ir gene control of the response to each antigenic determinant on the same protein.¹⁸¹ For example, T-cell clones specific for myoglobin responded to different antigenic determinants on different peptide fragments of myoglobin²¹⁵: Those specific for one of the epitopes were always restricted to I-A, whereas those specific for the other were always restricted to I-E. The simplest interpretation was that each antigenic peptide contained an MHC association site for interacting with I-A or I-E. At the level of Ir genes, mouse strains lacking a functional I-E molecule could respond to one of the sites only, and those with neither I-A nor I-E molecules capable of binding to any myoglobin peptide would be low responders to myoglobin.

Evidence for a discrete MHC association site on peptide antigens came from studies with pigeon cytochrome c. The murine T-cell response to pigeon cytochrome c and its carboxy-terminal peptide (81 to 104) depends on the I-E molecules of the APCs.¹⁷⁹ However, distinct structural sites on the synthetic peptide antigen appear to constitute two functional sites: an epitope site for binding to the TCR and an "agretope" (for "antigen restriction tope") site for interacting with the MHC molecule of the APC.^{179,196-198} Amino acid substitutions for Lys at position 99 on the peptide destroyed the ability to stimulate T-cell clones specific for the peptide, whereas the difference between Ala and a deletion at position 103 determined T-cell stimulation in association with some MHC antigens but not others, independent of the T-cell fine specificity. In addition, immunizing with the peptides substituted at position 99 elicited new T-cell clones that responded to the substituted peptide but not the original and showed the same pattern of genetic restriction, correlated with the residue at position 103, as the clones specific for the original peptide. These results implied that the substitutions at position 99 had not affected the MHC association site but independently altered the epitope site that interacts directly with the TCR. In contrast, position 103 was a likely subsite for MHC interaction, without altering the TCR-binding site.

It remained to be shown that MHC molecules without any other cell surface protein were sufficient for presentation of processed peptide antigens. This was demonstrated by Watts et al.,³⁴⁹ who showed that glass slides coated with lipid containing purified I-A molecules could present an ovalbumin peptide to an ovalbumin-specific T-cell hybridoma. This result meant that no other special steps were required other than antigen processing and MHC association. Likewise, Walden et al.³⁵⁰ specifically stimulated T-cell hybridomas with liposomes containing nothing but antigen and MHC molecules. Also, Norcross et al.³⁵¹ transformed mouse L cells with the genes for the I-A α and β chains and converted the fibroblasts (which do not express their own class II molecules) into I-A–expressing cells. These cells were able to present several antigens to I-A–restricted T-cell clones and hybridomas³⁵¹ and similar I-E transfectants presented to I-E–restricted T cells.²¹⁵ Thus, whatever processing enzymes are required are already present in fibroblasts, and the only additional requirement for antigen-presenting function is the expression of I-A or I-E antigens.

The planar membrane technique has been applied to determine the minimum number of MHC-antigen complexes per APC necessary to induce T-cell activation.352 After pulsing the presenting cells with antigen, the cells were studied for antigen-presenting activity, and some of the cells were lysed to produce a purified fraction containing MHC charged with antigenic peptides. These MHC-peptide complexes were used to reconstitute planar membranes, and their potency was compared to a reference MHC preparation pulsed with a high peptide concentration in vitro and presumed to be fully loaded. In this way, the relative peptide occupancy of MHC-binding sites corresponding to any level of antigen presentation could be determined. For B cells and macrophages, the threshold of antigen loading necessary for triggering T cells was 0.2% of I-E^d molecules occupied by peptide, corresponding to about 200 MHC-peptide complexes per presenting cell. For artificial presenting cells, such as L cells transfected with I-E^d, the threshold was 23 times greater or 4.6% of MHC occupied by peptide. Similarly, when MHC-peptide binding was measured directly, using radiolabeled peptide to determine the minimum level of MHC-peptide complexes required for T-cell triggering, B cells were capable of presenting antigen with as few as 200 to 300 MHC-peptide complexes per cell.³⁵³ A similar number of peptide-MHC class I molecule complexes was reported to be required on a cell for recognition by CD8⁺ cytotoxic T cells.³⁵⁴ These results explain how newly generated peptide antigens can bind enough MHC molecules to stimulate a T-cell response, even in the presence of competing cellular antigens, as a low level of MHC occupancy is sufficient. In addition, this threshold of presentation may explain how multivalent protein antigens, such as viral particles, with 100 to 200 protein copies each, can be over 10³-fold more immunogenic than the same weight of protein monomers.355-357 Studies on the number of TCRs needed for triggering, based on titrating peptide and recombinant soluble class I MHC molecules on plastic, suggested that interaction of three to five TCRs with MHC-peptide complexes was sufficient, consistent with several T cells interacting with one APC.^{358,359} Biochemical evidence for the direct association between processed peptide and MHC molecules was demonstrated by competition between peptides for antigen presentation^{225,360-363} and then more directly by equilibrium dialysis,³⁶⁴ molecular sieve chromatography,³⁶⁵ or affinity labeling.³⁶⁶ Equilibrium dialysis (see Chapter 7) was performed by incubating detergent-solubilized class II molecules with fluoresceinated or radioactive antigenic peptides, followed by dialysis against a large volume of buffer. Peptide can pass in or out of the dialysis bag, but the class II molecules are trapped inside. In the absence of binding by class II molecules, the labeled peptide would distribute itself equally between the inside and outside of the dialysis

chamber. However, when the appropriate class II molecules were added to the chamber, extra peptide molecules were retained inside it due to formation of a complex with MHC class II. In this way, direct binding of antigen and MHC was shown, and an affinity constant was determined.^{364,365}

A second approach was to form the antigen-MHC complex over 48 hours, followed by rapid passage over a Sephadex G50 sizing column (Sigma-Aldrich). The bound peptide came off the column early because it is the size of class II molecules (about 58 kD), while free peptide was usually included in the column and eluted later, as it is only approximately 2 kD.³⁶⁵ Peptide bound to specific and saturable sites on MHC. Competitive binding showed that different peptide antigens with the same MHC restriction bind to the same site on the MHC class II molecule.^{367,368} For example, Table 23.6 shows the results with peptide antigens that are known to be presented with I-A or I-E antigens of the D or K haplotype. We observe that Ova peptide 323 to 329, which is presented with I-A^d, also binds well to purified I-A^d, whereas nonradioactive peptide competes for the peptide-binding sites of the I-A^d molecule. Similarly, the other I-A^d-restricted peptide, myoglobin 106 to 118, competes with Ova 323 to 339 for the same site. However, myoglobin 132 to 153, which is not restricted to I-A^d, does not compete for it but does compete for its own restriction element, I-E^d. Similarly, pigeon cytochrome c competes best for its restriction element I-E^k rather than I-A^k or I-E^d, which do not present cytochrome. Conversely, recombinant $E\beta$ genes have been used to map separate sites on a class II MHC molecule for binding to peptide antigen and to the TCR.³⁶⁹

Using these two biochemical methods, it has been possible to explain major losses of peptide antigenicity resulting from amino acid substitutions in terms of their adverse effect on epitope or agretope function. For example, the response of each of two ovalbumin-specific T-cell clones was mapped to peptide 325 to 335 by using a nested set of synthetic peptides. Five substitutions were made for each amino acid in the peptide, and the resulting 55 different peptides were each tested for the ability to stimulate the clone.³⁷⁰ Presumably, those peptides that failed to stimulate could be defective at an epitope or an agretope functional site. In fact, only two amino acids (Val 327 and Ala 332) were essential for MHC interaction, and changes at either of these resulted in a loss of antigenicity for the clone. Seven other amino acids were critical for T-cell stimulation but did not affect MHC binding. Thus, these must be part of the functional epitope. Interestingly, certain substitutions for His 328, Ala 330, and Glu 333 had effects on MHC binding, whereas others had effects on T-cell stimulation without affecting MHC binding. These amino acids might participate in both agretope and epitope functional sites, or, alternatively, the substitutions may affect the conformation of the peptide as it binds, thus indirectly affecting T-cell recognition³⁷¹ (see following discussion). The fact that substitutions at 9 of 11 amino acids could be tolerated without affecting MHC binding is consistent with the determinant selection hypothesis in that multiple antigenic peptides are capable of interacting with the same antigen-binding site on the MHC molecule.

Similarly, by using a T-cell clone specific for peptide 52 to 61 of hen egg lysozyme, substitutions at each amino acid were analyzed for the ability to bind to I-A^k and stimulate the clone.³⁷² Four of eleven amino acid residues were silent, whereas substitutions at three positions resulted in reduced binding to I-A^k. Substitutions at the remaining three positions resulted in decreased T-cell stimulation without affecting MHC association. The epitope was very sensitive to substitutions, even conservative ones such as changing Leu 56 to Ile, norLeu, or Val. The results in both of these studies confirmed by competitive binding that the MHC molecule contains a single saturable site for peptide binding. This site must be capable of binding a broad range of antigenic peptides. In binding the MHC groove, antigenic peptides assume the extended conformation that exposes the epitope for recognition by the TCR.

Although a full set of general principles explaining the specificity of antigen presentation and T-cell recognition has not yet emerged, it is studies such as these, combined with complementary structural studies characterizing the antigen-interacting portions of MHC molecules^{214,253,254,369,373–380} (see Chapters 21 and 22) and of TCRs^{381–387} (see Chapter 11) that will ultimately lead to an understanding of these principles.

One observation that came out of this type of structurefunction study was that a single peptide can bind to a class II MHC molecule in more than one way, and thus be seen by different T cells in different orientations or conformations.^{371,388} The same conclusion can be reached from an entirely different type of study, in which mutations are introduced into the MHC molecule. Mutations in the floor of the peptide-binding groove, which cannot directly interact with the TCR, can differentially affect recognition of a peptide by one clone and not another.^{389–391} In a particularly thoroughly studied case, it was clear that the quantitative level of peptide binding was not affected by the mutation, but rather the change in the floor of the groove imposed an altered conformation on the peptide that differentially affected recognition by different T cells.³⁹¹ If indeed the TCR cannot detect the mutation in the MHC molecule except indirectly by its effect on the peptide conformation, then one is forced to conclude that different T cells have preferences for different conformations of the same peptide bound to (what appears to the T cell as) the same MHC molecule.

Another general observation to come from this type of study is that substitution of amino acids often affects presentation by MHC and recognition by T cells through introduction of dominant negative interactions or interfering groups, whereas only a few residues are actually essential for peptide binding.³⁹² Both for class II binding³⁹²⁻³⁹⁵ and for class I MHC binding,³⁹⁶ most residues can be replaced with Ala or sometimes Pro without losing MHC binding, as long as a few critical residues are retained. Of course, T-cell recognition may require retention of other residues. If many of the amino acid side chains are not necessary for binding to the MHC molecule, then one might expect side chains of noncritical amino acids to occasionally interfere with binding, either directly or through an effect on conformation. That is exactly what was observed for a helper epitope from the HIV-1 envelope protein when a heteroclitic peptidethat is, one that stimulated the T cells at much lower concentrations than did the wild-type peptide—was obtained by replacing a negatively charged Glu with Ala or with Gln, which has the same size but no charge.³⁹² An Asp, negatively charged but smaller, behaved like the Glu. Thus, this residue was not necessary for binding to the class II MHC molecule, but a negatively charged side chain interfered with binding to the MHC molecule as measured by competition studies. Information about residues that interfere with binding has allowed the refinement of sequence motifs for peptides binding to MHC molecules to permit more reliable prediction of binding³⁹⁷ (see following discussion).

This observation also provides a novel approach to make more potent vaccines by "epitope enhancement," the process of modifying the internal sequence of epitopes to make them more potent, for example, by increasing affinity for an MHC molecule or TCR, or able to induce more broadly cross-reactive T cells specific for multiple strains of a virus.^{398–401} Proof of principle that this approach can make more potent peptide vaccines has recently been obtained.⁴⁰¹ The modified "enhanced" helper T-cell epitope from the HIV-1 envelope protein described previously,³⁹² with Ala substituted for Glu, was shown to be immunogenic at 10to 100-fold lower doses for in vivo immunization than the wild-type HIV-1 peptide to induce a T-cell proliferative response specific for the wild-type peptide. Further, when a peptide vaccine construct using this helper epitope coupled to a CTL epitope^{402,403} was modified with the same Glu-to-Ala substitution, it was more potent at inducing CD8⁺ CTL specific for the CTL epitope than was the original vaccine construct, even though the CTL epitope was unchanged (Fig. 23.10).⁴⁰¹ The increased potency of the vaccine construct was shown to be due to improved class II MHCrestricted help by genetic mapping using congenic strains of mice expressing the same class I MHC molecule to present the CTL epitope and the same background genes but differing in class II MHC molecules.401 Thus, class II-restricted help makes an enormous difference in induction of class I-restricted CTL, and epitope enhancement can allow con-

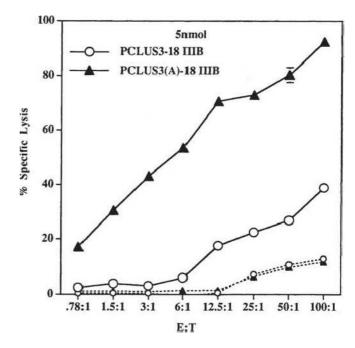

FIG. 23.10. Enhancement of Immunogenicity of a Peptide Vaccine for Induction of Class I Major Histocompatibility Complex (MHC)-**Restricted Cytotoxic T-Lymphocytes by Modification of the Class II** MHC-Binding Portion to Increase Cluster of Differentiation (CD)4+ T-Cell Help. Peptide vaccine PCLUS3-18 IIIB contains a class II MHC binding helper region, consisting of a cluster of overlapping determinants from the human immunodeficiency virsu-1 envelope protein gp160, and a class I MHC-binding cytolytic T cell (CTL) epitope, P18 IIIB. Modification of the helper epitope to remove an adverse negative charge by replacement of a Glu with an Ala residue was shown to increase binding to the class II MHC molecule.³⁹² Here, introduction of the same modification of the helper epitope, to produce PCLUS3(A)-18IIIB, is shown to greatly increase immunogenicity in vivo for induction of CTL to the class I-binding P18IIIB portion. Immunization of A.AL mice with 5 nmol of either vaccine construct subcutaneously in montanide ISA 51 adjuvant, and stimulation of resulting spleen cells with P18IIIB for 1 week in culture, resulted in 33-fold more lytic units for lysing targets coated with P18IIIB when mice were immunized with the modified second-generation vaccine than when they were immunized with the original construct with the natural sequence. Thus, class II-restricted CD4⁺ T-cell help has a major impact on induction of class I-restricted CTL, and this process of "epitope enhancement" can be used to make vaccines more potent than the natural viral antigens. Targets: BALB/c 3T3 fibroblasts with P18IIIB (solid lines) or no peptide (dashed lines). (Modified from Ahlers et al.⁴⁰¹ with permission.)

struction of more potent vaccines, providing greater protection against viral infection.⁴⁰⁴ Further, the improved help was found to be qualitatively, not just quantitatively, different, skewed more toward Th1 cytokines.⁴⁰⁴ The mechanism was found to involve greater induction of CD40 ligand on the helper T cells, resulting in greater interleukin 12 production by the antigen-presenting dendritic cells, which in turn polarized the helper cells toward Th1 phenotype.⁴⁰⁴ The dendritic cells conditioned with the helper T cells and the higher affinity peptide and then purified were also more effective at activating CD8⁺ CTL precursors in the absence of helper cells, supporting a mechanism of help mediated through activation of dendritic cells.^{405–407} This study showed also that such help was mediated primarily through upregulation of interleukin 12 production and CD80 and CD86 expression on the dendritic cell.⁴⁰⁴ A similar or overlapping HIV envelope epitope recognized by human CD4⁺ T cells when presented by HLA-DR13 has been mapped and has undergone epitope enhancement as well.⁴⁰⁸ Understanding this mechanism of epitope enhancement may contribute to the design of improved vaccines.

Similar epitope enhancement has been carried out for class I MHC–binding viral or tumor peptides as well,^{409–414} and in one case has been found to result in greater clinical efficacy of a melanoma vaccine used for human immunotherapy.⁴¹⁵ Cautions have also been raised about the use of enhanced epitopes (sometimes also called agonistic or heteroclitic epitopes), in that the amino acid sequence modifications that affect MHC binding can also alter the conformation of the MHC-bound peptide and affect the specificity of T cells elicited.^{416–419} The altered or enhanced peptides that elicit

the most T cells specific for the wild-type epitope are the most effective at clearing tumors.⁴²⁰ Thus, it is important in using epitope-enhanced peptides that the peptides still activate a large number of T cells that recognize the wild-type sequence. These results emphasize the importance of affinity for MHC molecules vaccine efficacy⁴²¹ and suggest that rational design of vaccines with higher affinity epitopes may produce more effective second-generation vaccines.^{422,423} To that end, the discovery of sequence motifs predicting MHC molecule binding and the development of bioinformatics strategies to predict peptide affinity have proven a great impetus to the field.⁴²⁴

In the case of class I MHC molecules, results defining sequence binding motifs generalize the conclusion that only a few critical "anchor" residues determine the specificity of binding to the MHC molecule (Table 23.7).^{264,396,425–429} These motifs were defined by a detailed study of one peptide-MHC system⁴²⁷ by sequencing the mixture of natural peptides eluted from a class I MHC molecule and finding that at

HLA, human leukocyte antigen; MHC, major histocompatibility complex.

Data from Goodman and Sercarz,²³⁴ Walden et al.,³⁵⁰ Sette et al.,³⁷⁰ Kurata and Berzofsky,³⁷¹ Allen et al.,³⁷² Brown et al.,³⁷³ and Bjorkman et al.,³⁷⁴

certain positions in the sequence, a single residue predominated within the pool of peptides,425 and by separating and sequencing individual natural peptides eluted from a class I molecule and finding a conserved residue at certain positions.⁴²⁶ The latter two studies also made the important observation that the natural peptides eluted from class I MHC molecules were all about the same length, eight or nine residues, and this was confirmed for a much larger collection of peptides eluted from HLA-A2 and analyzed by tandem mass spectrometry.⁴²⁸ This finding was consistent with other studies demonstrating that a minimal nonapeptide was many orders of magnitude more potent than longer peptides in presentation by class I molecules to T cells.430,431 This conservation of length was critical to the success of the approach of sequencing mixtures of peptides eluted from a class I molecule⁴²⁵ because such a method requires that the conserved anchor residues all be at the same distance from the N-terminus. The fact that Falk et al.⁴²⁵ could find a single amino acid at certain positions, such as a Tyr at position 2 in peptides eluted from K^d, implies not only that most or all of the peptides bound to K^d had a Tyr that could be aligned but also that the peptides were already aligned as bound to the MHC molecule, with each one having just one residue N-terminal to the Tyr. This result implies that the position of the N-terminal residue is fixed in the MHC molecule. It is this fact that has made the identification of motifs for binding to class I molecules much more straightforward than finding motifs for binding class II molecules.

This conclusion has not only been confirmed but also explained by x-ray crystallographic data on class I peptide-MHC complexes.^{376–378} It appears that both the N-terminal α -amino group and the C-terminal carboxyl group are fixed in pockets at either end of the MHC groove, independent of what amino acids are occupying those positions, and that the rest of the peptide spans these fixed points in a more or less extended conformation. The minimum length that can span the distance between these pockets is 8 residues, but 9 or 10 residues can be accommodated with a slight bulge or β turn in the middle of the peptide, explaining the narrow restriction on length. Between these ends, one or two pockets in the groove can accommodate the side chain of an amino acid, usually either at P2 binding in the B pocket or at P5 binding in the C pocket, depending on the particular MHC molecule. Additionally, the side chain of the C-terminal residue serves as an anchor in the F pocket at the end of the groove. These residues that fit into pockets correspond exactly to the "anchor" residues, at P2 or P5, and P8, P9, or P10, defined by the sequence motifs, and appear to be the primary determinants of specificity for peptide binding because the rest of the interactions are largely with peptide backbone atoms, including the α -amino and carboxyl groups, and therefore do not contribute to sequence specificity. This finding can explain both the breadth of peptides that can bind to a single MHC molecule because most of the binding involves only backbone atoms common to all peptides and also the exquisite specificity of binding is determined by the anchor residues that account for the Ir gene control of responsiveness.

In contrast, when natural self-peptides were eluted from class II MHC molecules,^{252,432} the lengths were much more variable, ranging from 13 to 18 residues, and several variants of the same peptide were found with different lengths of extra sequence at one end or the other ("ragged ends"). This finding suggested that both ends of the peptide-binding groove of class II MHC molecules are open, in contrast to class I, so that additional lengths of peptide can hang out either side, and trimming does not have to be precise. However, a corollary is that the peptides eluted from class II molecules would not be aligned in a motif starting from the exact amino terminus and that was indeed what was found. Although a moderately conserved motif was found in some of the peptides eluted from the murine class II molecule I-A^d, consistent with the motif defined based on known antigenic peptides binding to I-A^d,⁴³³ the motif was neither so clearly defined nor so highly conserved as in the class I case and required aligning of sequences to identify a core motif of about nine amino acid residues.432 Subsequently, a number of motifs for peptides binding to human class II MHC molecules have been defined.^{264,434–439} Unlike peptides eluted from MHC class I grooves, these class II-binding peptides may locate the core-binding motif at various distances from the amino or carboxyl end of the peptide.

The crystal structure of a peptide bound to a human class II MHC molecule, DR1, revealed that indeed the ends of the groove are open, and the peptide can extend beyond the groove in either direction.^{254,440} In addition, the more broadly defined class II motifs in Table 23.7 can be explained by less stringent requirements for amino acid side chains to interact with binding pockets in class II. In general, the MHC class II binding pockets are shallower than for class I, and a selected peptide derives less binding energy from each pocket. In fact, they form fewer H-bonds with the peptide side chains, and more H-bonds are directed at the peptide backbone, allowing a variety of different peptides to bind. Rather than requiring a specific amino acid at each position, the shallow binding pockets of MHC class II tend to exclude peptides based on unfavorable interactions, such as side chains too large to fit the binding pocket. Even one amino acid side chain that binds strongly to an MHC pocket is sufficient to anchor the peptide to MHC class II and set the frame for the interaction of the rest of the peptide with the MHC groove.

For example, binding of three peptides to the class II molecules I-A in mice or HLA-DQ in humans are shown in Figure 23.11. The first residue of the peptide motif is designated P1, the next is P2, and so on. The α -helical walls and β -sheet floor of the MHC class II groove (see Chapter 21) are peeled away to reveal the peptide backbone and side chains in relation to MHC-binding pockets. For the ovalbumin peptide Ova₃₂₃₋₃₂₉ binding to I-A^d, residues P1, P4, and P9 all point down into the binding pockets.⁴⁴¹ The best fit is between Val 327 and the P4 pocket, which creates mainly hydrophobic interactions with MHC and serves as the anchor residue. Residues P5 (His 328) and P8 (His 331) project upward for binding to the TCR. The shallow P4 pocket can tolerate only small hydrophobic side chains, such as Val, so it dictates which peptides can bind here. The other MHC

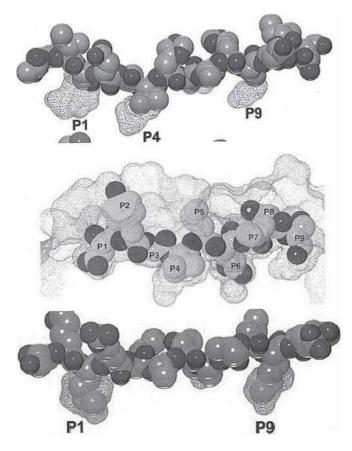

FIG. 23.11. Interaction of Peptides with the Binding Groove of Major Histocompatibility Complex Class II, as Determined by X-ray Crystallography. Anchor residue side chains fill binding pockets to a greater or lesser extent, supplemented by H-bonds to the peptide backbone. Examples include I-A^d with ovalbumin peptide 323 to 334 (*Top*),⁴⁴¹ I-A^k with hen egg lysozyme 52 to 60 (*Middle*),⁴⁴² and HLA-DR3 with invariant chain class II–associated invariant chain peptide (*Bottom*).⁴⁴³

pockets, P1 and P9, accommodate many different residues, so they have little effect on which peptides can be presented by I-A^d.

For hen egg lysozyme peptide₅₀₋₆₂ binding to I-A^k, interactions with MHC are observed for P1, P4, P6, and P9.⁴⁴² The P1 interaction is very different from I-A^d, as the P1 pocket is a perfect fit for Asp and has an arginine at the end of the tunnel to neutralize charge. This structure explains why nearly all peptides presented by I-A^k must have Asp at this position. In contrast, the P4 and P9 pockets are partially filled and will tolerate a number of different side chains at these positions. The P6 pocket requires a Glu or Gln here, even though the MHC residues deep in the pocket are acidic. It is presumed that one of the Glu residues must be protonated to allow Glu binding at this position. This arrangement of the peptide leaves P2, P5, and P8 exposed to solvent in the crystal structure and to the TCR during antigen presentation.

For the CLIP peptide binding to HLA-DR3, deep pockets at P1 and P9 are more fully occupied by the peptide side chains.⁴⁴³ The pH-dependent binding is important because CLIP must be stable at neutral pH and unstable at acid pH in the presence of HLA-DM in order to perform its function. Based on affinity for MHC, these interactions explain the peptide-binding motifs for MHC class II that select which peptides can be presented to T cells. In addition, these interactions orient the peptide in the MHC groove and determine which residues are accessible for recognition by the TCR.

T-Cell Receptor Recognition

The last hurdle that a potential antigenic determinant must surmount is recognition by a TCR within the repertoire of the individual responding. This repertoire may be limited by the availability of combinations of V, D, and J genes (see Chapter 11) in the genome that can combine to form an appropriate receptor, given the lack of somatic hypermutation in TCRs in contrast to antibodies,^{383,444} and then by self-tolerance, as mediated by thymic or peripheral negative selection, or by limits on the repertoire that is positively selected in the thymus on existing self-peptide-MHC complexes. The available repertoire may also be influenced by prior exposure to cross-reactive antigens. In general, however, it has been hard to find holes in the repertoire.445 Indeed, studies examining large panels of peptides binding to particular class I molecules for correlations between peptide affinity for MHC and T-cell responses have failed to find high-affinity peptides for which no T-cell response can be raised, whereas not all lower affinity peptides elicit a response.446,447 These results suggest that if the peptide can bind well enough to the MHC molecule, there is virtually always a T cell that can see the complex. However, the array of other MHC molecules present can influence the breadth of the T-cell repertoire.⁴⁴⁸ Furthermore, when TCR repertoires of mice and humans were compared for peptides presented by HLA-A2.1, they seemed to be capable of seeing the same spectrum of peptides.449 Eleven peptides from hepatitis C virus proteins, each of which had a motif for binding to HLA-A2.1, were tested for recognition by CTL from HLA-A2.1 transgenic mice and human HLA-A2.1 positive patients infected with hepatitis C virus. The same four peptides that were recognized by the T cells from the mice were the ones recognized by the human T cells, whereas the others were not recognized well by either murine or human T cells. The selection of which peptides were recognized seemed to be determined by binding to the HLA-A2.1 molecule rather than by the availability of T cells. Thus, despite the differences in TCR genes in mice and humans, the repertoires are plastic enough that if a peptide passes the other three hurdles of processing, transport, and binding to MHC molecules, T cells can be elicited to respond to it in either species.⁴⁴⁹ Likewise, no hole in the helper T-cell repertoire could be found to explain low responders to the recombinant hepatitis B vaccine.450

On the other hand, evidence exists that MHC binding is not the whole story. Schaeffer et al.⁴⁵¹ examined 14 overlapping peptides covering the sequence of staphylococcal nuclease with different class II MHC molecules, constituting 54 different peptide-MHC combinations. Clearly, MHC binding plays a major role because 12 out of 13 immunogenic peptides were high or intermediate binders to MHC molecules, whereas only 1 of 37 poor binders were immunogenic. Of high-affinity binders, five out of five peptides were immunogenic. However, for intermediate affinity MHC-binding peptides, only 7 out of 12 were immunogenic. Similar results were found for the class I MHC molecule HLA-B*0702, in which it was found that 7 of 7 high-affinity binders but only 9 out of 12 intermediate affinity binders, were immunogenic.⁴⁴⁷ Thus, MHC binding alone is not sufficient to ensure immunogenicity. The T-cell repertoire was one factor suggested that might limit the spectrum of immunogenic peptides.

Indeed, examples for selection at the level of the TCR repertoire exist. A particularly elegant example described by Moudgil et al.⁴⁵² is one in which a peptide (46 to 61) of mouse lysozyme presented by I-A^k is recognized T cells from CBA/J and B10.A mice, expressing I-A^k and I-E^k, but not by T cells from B10.A(4R) mice expressing only I-A^k, even though the APC from B10.A(4R) mice can present the peptide to T cells from the other strains. T cells from the B10.A(4R) mice can respond to variant 46 to 61 peptides in which the C-terminal Arg is replaced by Ala, Leu, Phe, Asn, or Lys, indicating that the C-terminal Arg is hindering recognition, but not binding by I-A^k, and in this case, not processing as the B10.A(4R) APC can present the peptide. It appears that the hindrance interferes with recognition by TCRs available in B10.A(4R) mice, but not TCRs available in B10.A or CBA/J mice, or in $(B10.A(4R) \times CBA/J)F1$ mice. Because the B10.A mice are congenic with the B10.A(4R) mice, the difference is not one of non-MHC-linked genes such as TCR structural genes or non-MHC self-antigens producing self-tolerance. Further, because the F1 mice respond, the difference is not due to a hole in the repertoire produced by a self-antigen of the B10.A(4R) mice. It was concluded that the CBA/J and B10.A mice contain an additional repertoire, positively selected on I-E^k or possibly an H-2D/L class I molecule, in which these strains differ, which can recognize the 46 to 61 peptide despite the hindering Arg at the C-terminus. An alternative related explanation is that strains that express $I-E^k$ or D^k or D^d/L^d have an additional repertoire of TCRs positively selected on I-A^kpresenting self-peptides from processing of these other MHC molecules in the thymus. This example illustrates a case in point that subtle differences in TCRs, presumably caused in this case by positive selection, can lead to responsiveness or nonresponsiveness to a determinant that has already passed all of the three earlier hurdles, processing, transport, and MHC binding. Of course, there are some holes related to selftolerance, primarily related to the loss of response to dominant determinants⁴⁵³ and especially loss of high-avidity T cells.^{454–457} Interestingly, not only is there no loss of response to cryptic determinants but also T cells recognizing cryptic determinants of mouse lysozyme can be positively selected on other nonmouse lysozyme self-ligands in a lysozyme knockout mouse.⁴⁵³ The selective loss of high-avidity T cells to immunodominant determinants has suggested a strategy to apply epitope enhancement to modify subdominant lower affinity tumor antigen peptides to increase their affinity for MHC molecules, and thereby make them more immunogenic in order by to take advantage of a repertoire not already crippled by loss of the high-avidity clones.⁴⁵⁸

Another elegant example of T-cell repertoire limitations on immunodominance comes from a study of mice deficient in LMP-2, and so unable to make immunoproteasomes. Reduced response to one normally immunodominant influenza epitope was found by T-cell adoptive transfer studies to be due to an alteration in the T-cell repertoire, presumably because of altered processing of self-peptides in the thymus.²⁸¹

A recent study found another mechanism by which the T-cell repertoire contributes to immunodominance. It was found that the relative immunodominance of a dominant determinant of the HIV envelope protein among different strains of H-2D mice all presenting the same peptide-H-2D^d complex correlated with the avidity of the T cells responding in those strains.⁴⁵⁹ The mechanism found was that highavidity T cells proliferate faster than low-avidity ones when exposed to antigen and therefore dominate the response. This mechanism differs from those at earlier steps that progressively constrain the response, and thereby narrow the repertoire to dominant epitopes, whereas this mechanism selectively expands the dominant repertoire. This mechanism may also explain other recent findings such as the higher affinity of dominant compared to subdominant TCRs specific for human cytomegalovirus.⁴⁶⁰ Because highavidity T cells are better able to clear virus infection, $4^{61,4\overline{62}}$ a recent study even suggests that the driving force for MHC polymorphism is to create a large enough repertoire to select for high-avidity T cells.463

Several critical parameters have been reported to be involved in more effective T-cell activation during TCRpeptide-MHC interaction. In some situations, TCR avidity for the peptide-MHC complex appears to play a more critical role than dissociation rate⁴⁶⁴ and a threshold for maximal activity may even be defined,⁴⁶⁵ whereas in other situations, the half-life of the TCR-peptide-MHC interaction seems most critical.^{466–468} Moreover, in situ in two-dimensional surface interactions, a rapid on-rate may compensate for a faster off-rate (shorter half-life) and allow effective TCRpeptide-MHC engagement, suggesting the total cumulative duration time (including multiple repeat engagements) may be most critical.^{469–472}

As more is understood about the molecular basis of TCR recognition, with crystallographic data now available,^{386,387,473} it becomes possible to apply epitope enhancement in a rational way to the affinity of the peptide-MHC complex to the TCR, as was described for the peptide affinity for MHC molecules. Sequence modifications in the peptide that increase the affinity for the TCR were shown to be more effective at expanding in vivo the T cells specific for tumor antigens.^{474–476} Most of these modifications were found empirically, but a systematic study of substitutions throughout a number of peptides revealed a pattern in which peptides with conservative substitutions at P3, P5, or P7 were most likely to yield increased TCR affinity, narrowing the candidate list of peptides that require empirical screening.⁴⁷⁷ This strategy provides a second type of epitope enhancement, derived from basic immunologic principles, to produce more effective vaccines.

The advent of DNA vaccines has made it possible to link a series T-cell epitopes in tandem and express them in the form of a multiepitope vaccine. These chimeric proteins have the

potential advantages of focusing the immune response on biologically important epitopes, combining T helper epitopes with CTL epitopes, using epitopes with high affinity for MHC, and linking the epitopes in any desired order to optimize immunogenicity. Ideally, antigen processing throughout the construct would produce multiple epitopes that could be presented independently. In the case of HIV, where antigenic variation is so common, these vaccines could be designed to overcome variation by including epitopes that are conserved within each geographical region (clades).

For example, Létourneau et al.478 expressed a string of HIV sequence fragments from the gag, pol, vif, and env genes that were highly conserved within their own clades. As they progressed from one fragment to the next, they alternated sequences from different HIV clades: Immunity to multiple epitopes would produce broad based immunity across clades. Fourteen fragments were linked in tandem. Each fragment contained multiple T-cell epitopes, for a total of 270 known epitopes recognized with human MHC. In addition, T cells from most patients infected with HIV responded to peptide pools from the vaccine, indicating that the epitopes were processed and presented to T cells. But when the multiepitope vaccine was given as a DNA vaccine followed by two viral vector boosts, it elicited relatively weak T-cell responses to two out of six peptide pools in HLA-A2 transgenic mice.

For these constructs to function as multiepitope vaccines, antigen processing between epitopes is required. In any given string, all of the epitopes are expressed equally, but different locations might be processed differently. In order to elicit T-cell immunity to multiple epitopes at the same time, there must be efficient processing and presenting of epitopes in all parts of the string. For example, Depla et al.⁴⁷⁹ created a vaccine with 30 epitopes from hepatitis B virus that were restricted to five different MHC class I types. The immune response to the combined antigen was compared to individual peptides as an indication of the effect of antigen processing on presentation of internal epitopes. For two MHC types, the same 5 out of 12 epitopes were immunogenic, regardless of whether they were presented as a string of epitopes or as free peptides. However, for three other MHC types, whereas 14 out of 18 epitopes were immunogenic as peptides, only 3 out of 18 were immunogenic in the multiepitope vaccine. This difference suggests inefficient antigen processing at multiple sites, either because of failure to process the epitopes correctly or due to excessive degradation.

One way to control processing was suggested by Livingston et al.^{480,481} These authors found that the first amino acid following each epitope is an important marker for antigen processing. They demonstrated that poor presentation of an internal epitope can be corrected by adding a spacer of as little as one amino acid between epitopes to improve the yield of processed peptides. The most favorable amino acid spacers were Lys, Arg, Asn, and Gln, followed by Cys, Gly, Ala, Thr, or Phe. The least active spacer residues were Asp, Val, Met, or Leu.^{480,481} For example, an epitope from hepatitis B virus core antigen was poorly immunogenic when it was located next to a Phe residue, but its immunogenicity was enhanced by four logs when Lys was substituted for Phe at this position. These amino acid preferences may reflect the major protease activities of proteasomes: The most targeted amino acids could improve the yield of intact epitopes.

This strategy was used to construct a multiepitope vaccine from HIV antigens.482 Twenty-one epitopes were identified, based on the T-cell response of infected humans, and these were linked together in a multiepitope DNA vaccine. Spacers of one to four amino acids were inserted between epitopes to optimize antigen processing. The DNA vaccine was used to immunize HLA transgenic mice, and the response to each epitope was compared to peptide vaccinated mice. For two HLA types, A2 and A3, the peptide and multiepitope vaccines were nearly equal, suggesting efficient processing. In addition, for HLA-A2, the potency of the T-cell response to different epitopes was largely independent of their position in the vaccine sequence, suggesting efficient antigen processing at various points throughout the chimeric protein. But for a third HLA type, B7, despite a normal peptide response, the multiepitope vaccine failed to elicit immunity to four out of seven epitopes tested, indicating that processing was limiting the response to these residues.

Design of an effective multiepitope vaccine depends on finding the optimal balance between antigen processing and epitope survival. Antigen processing between epitopes generates antigenic peptides, but processing within the epitope would destroy its antigenicity. Delamarre et al.483 have compared pairs of proteins with the same sequence but different conformations, resulting in different susceptibilities to lysosomal processing. Ribonuclease (RNAse) A was relatively stable to lysosomal extracts of dendritic cells, whereas RNAse S was degraded quickly. Of these two forms of the same protein, RNAse A was a far more potent immunogen, as measured by T-cell proliferation or Delayed Type Hypersensitivity (DTH). Similarly, horseradish peroxidase is stable to lysosomal proteases in the native form, but is quickly degraded in the apo form. Native horse radish peroxidase (HRP) was a much more potent immunogen than the unstable apo form. These results indicate the harmful effect of excessive processing on T-cell stimulation and immunogenicity.

Multiepitope immunogens have been designed to elicit CTLs by stimulating T helper cells and CTLs simultaneously. These immunogens have combined T helper and CTL epitopes in a variety of ways. Some vaccines contain at least one T helper epitope and one CTL epitope on each polypeptide chain.⁴⁸⁴ Others have expressed them separately: A polypeptide consisting of multiple T helper epitopes was coadministered with a DNA plasmid coding for multiple CTL epitopes.⁴⁸⁵ A third way would be to express alternating T helper and CTL epitopes in tandem in the same multiepitope vaccine, either as DNA or polypeptide. The T-cell response to paired T helper epitopes was generally weak,484 whereas the response to a string of multiple T helper epitopes was reportedly stronger, although it did not confer any improvement on the immune response to CTL epitopes expressed separately.485

As with T-cell help for B cells, a multiepitope vaccine for CTLs should combine T helper and CTL epitopes in the same construct.⁴⁰² It would deliver both epitopes into the same APC, to facilitate helper T cell effects on CTL induction. But the epitopes should target different cellular compartments, leading to the main processing pathways: T helper epitopes should travel to endosomes for processing and presentation with MHC class II. CTL epitopes should traffic to the cytoplasm for proteasomal processing and presentation with MHC class I.

Defining the Role of Individual Amino Acids and Effects of Altered Peptide Ligands

Once an antigenic peptide is identified, the next step is to map key amino acid residues by making a series of variant peptides, each of which differs from the native sequence by a single amino acid substitution, as previously described in the section on MHC binding. One approach, called an alanine scan, substitutes Ala for the natural amino acid at each position in the peptide or uses Ser or Gly to replace naturally occurring Ala. Ala is used because the side chain is only a methyl group, so it replaces whatever functional side chain is present with the smallest one other than that of Gly, which is not used because of its effects on conformation. Thus, one can ask whether loss of the naturally occurring side chain affects function, without the introduction of a new side chain that might itself affect function. Generally, each peptide will have several amino acids where Ala substitution destroys antigenicity. Some of these correspond to contact residues for the TCR, whereas others are contact residues for MHC. In many cases, the MHC-binding residues can be determined by testing the substituted peptides in a competitive MHC-binding assay (discussed previously). The amino acid substitutions that knockout T-cell proliferation but not MHC binding are presumed to be in the epitope recognized by the TCR directly, and these can be studied with additional substitutions. For example, this technique was used to compare the residues interacting with the MHC molecule or TCR when the same HIV-1 V3 loop peptide P18 (residues 308 to 322) was presented by three different MHC molecules, a human class I molecule, a mouse class I molecule, and a mouse class II molecule (Fig. 23.12).^{486,487} Interestingly, there was a striking concordance of function of several of the residues as presented by all three MHC molecules (see Fig. 23.12). For example, Pro and Phe interacted with the MHC in all three cases, and the same Val interacted with the TCR in all three cases. Also, the same Arg in the middle of the peptide interacted with both the mouse class I and II molecules, and the C-terminal Ile was an anchor residue for both human and murine class I molecules.486,487

In the case of autoimmune T cells, these techniques have been used to study the number and variety of epitopes recognized by self-reactive T cells. In the nonobese diabetic mouse, the β chain of insulin is a major target of T cells recovered from pancreatic islets.⁴⁸⁸ Alanine scanning of β chain peptide 9 to 23 revealed two patterns of T-cell recognition for the same peptide. Some T cells recognize peptide 9 to 16, whereas others respond to peptide 13 to 23. Each epitope appears to have distinct sites for MHC and TCR binding, even though they come from the same peptide chain. Similarly, in systemic lupus erythematosus, human T cells specific for the Sm antigen are narrowly restricted to a few epitopes that are found on a small group of proteins.⁴⁸⁹ On the Sm-B antigen, three epitopes were recognized. On Sm-D antigen, there were two. In each case, alanine scans showed that the same epitopes were recognized by distinct T-cell clones. These results are consistent with the hypotheses that the autoimmune response to insulin or to Sm antigen may be induced by abnormal exposure of a very few cryptic epitopes, or they may depend on selective loss of tolerance for a limited number of epitopes shared by a small subset of self-proteins.

TCRs may distinguish different chemical classes of amino acid side chains. An example of structural differences between amino acid side chains recognized by the TCR comes from an analysis of non-cross-reactive CTL that distinguishes homologous peptides from the V3 loop of different strains of HIV-1 envelope protein. The residue at P8 in the minimal determinant was identified as a key

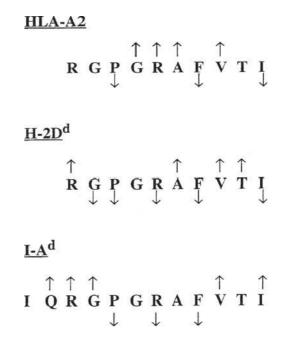

FIG. 23.12. Comparison of the Major Histocompatibility Complex (MHC)-Interacting ("Agretopic") and T-Cell Receptor (TCR)-Interacting ("Epitopic") Residues of the Same Human Immunodeficiency Virus (HIV)-1 Envelope V3 Loop Peptide as It Is Presented by Human Class I, Murine Class I, and Murine Class II MHC Molecules to Cluster of Differentiation (CD)8+ Cytolytic T Cell and CD4+ Helper T Cells. The sequence of the optimal binding portion of peptide P18 IIIB from the HIV-1 envelope protein V3 loop for each MHC molecule, in single letter amino acid code, is shown. Arrows pointing up indicate residues determined to interact with the TCR, and arrows pointing down indicate residues determined to interact with the MHC molecule. Mapping of residue function for binding to the human class I MHC molecule HLA-A2.1 was described in Alexander-Miller et al.,487 and binding to the murine class I molecule H-2D^d and the murine class II molecule I-A^d was described in Takeshita et al.⁴⁸⁶ Note the common use of the Pro and Phe for binding all three MHC molecules and the use of the key Val residue for binding all the TCRs. Also, the murine MHC molecules both use the central Arg residue as a contact residue, whereas both class I molecules use the C-terminal IIe residue as an anchor residue. Thus, there is a surprising degree of concordance.

"epitopic" TCR contact residue in both strain IIIB, which has a Val at this position, and strain MN, which has a Tyr at this position.^{486,490,491} CTLs specific for strain IIIB do not recognize the MN sequence but will recognize peptides identical to MN except for the substitution of any aliphatic amino acid at that position, such as Val, Leu, or Ile.⁴⁰⁰ In contrast, CTL specific for the MN strain do not recognize the IIIB sequence but will recognize the IIIB peptide if the Val at this position is replaced by a Tyr.⁴⁹⁰ Moreover, they will see any MN variant in which the Tyr is replaced by another aromatic amino acid, such as Phe, Trp, or His.400 Thus, the two noncross-reactive TCRs see similar peptides but discriminate strongly between peptides with amino acids with aliphatic versus aromatic side chains. On the other hand, they do not distinguish strongly among different aliphatic residues or among different aromatic residues. Interestingly, however, in each category, the least active is the bulkiest member of the category, Ile and Trp, respectively, suggesting that these residues must fit into a pocket of limited size in the TCR.

The interaction of peptide ligand with TCR can be studied by introducing single substitutions of conservative amino acids at these contact residues, such as Glu for Asp, Ser for Thr, or Gln for Asn. The TCR readily distinguishes among peptides with these minor differences at a single residue, and the results have been revealing. Depending on affinity for the TCR, closely related (altered) peptides can elicit very different responses in T cells. Thus, although a substituted peptide may be very weak or nonstimulatory by itself, it may still act as a partial agonist or even a strong antagonist of an ongoing T-cell response. Antagonistic peptides can be demonstrated by pulsing APCs with native peptide antigen first so that one is not measuring competition for binding to MHC molecules, followed by pulsing with a 10-fold or greater excess of the antagonist before adding T cells. In the case of influenza hemagglutinin peptide 307 to 319 presented with HLA-DR1, peptide analogues such as Gln substituted for Asn 313 inhibited the proliferation of a human T-cell clone, even though they did not stimulate the clone. Anergy was not induced, and the antagonist peptide had to be present throughout the culture to inhibit the response.^{492,493} Thus, lack of antagonist activity is another feature of the interaction between peptide (in complex with MHC molecule) and TCR that is required for the peptide to be a stimulatory antigenic determinant.

Partial agonists were first demonstrated using T-cell clones specific for an allelic form of mouse hemoglobin. These T cells were from CE/J mice, which express the Hb^s allele of mouse hemoglobin, after immunization with the Hb^d allele. The minimum antigenic peptide corresponds to amino acids 67 to 76 of the Hb^d sequence and differs from Hb^s at P72, P73, and P76.⁴⁹⁴ Peptides substituted at each residue from amino acid 69 to 76 were tested for T-cell proliferation and cytokine release. Some substitutions, such as Gln for Asn at P72, blocked T-cell stimulation completely in both assays. Other substituted peptides, such as Asp for Glu at P73, lost T-cell proliferation but still stimulated interleukin 4 release, and these are considered partial agonists (Fig. 23.13).⁴⁹⁵ Lack of stimulation was not due to failure to bind MHC, as both substituted peptides gave reasonable

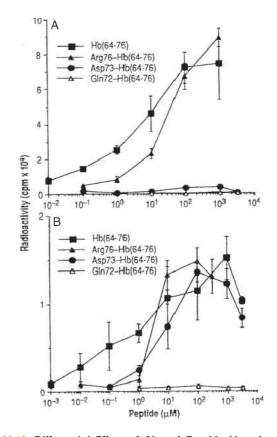

FIG. 23.13. Differential Effect of Altered Peptide Ligands on the Response to Peptide 64 to 76 from Hemoglobin. A: Proliferative response of a T-cell line incubated with antigen-presenting cells and the natural Hb (64-76) peptide or with peptides substituted at positions 72, 73, or 76. B: Interleukin 4 release by the T-cell line under the same conditions. The peptide substituted with Asp for Glu at position 73 is unable to induce T-cell proliferation, but it can still induce production of interleukin 4, so it is a partial agonist. In contrast, substitution of Gln for Asn at position 72 knocks out both responses equally. Modified from Evavold and Allen,⁴⁹⁵ with permission.

binding in a competitive-binding assay.⁴⁹⁶ Similar alteration of cytokine profile by altering the peptide ligand can be seen in other systems.^{493,497,498}

For one of the Hb 64 to 76 specific T-cell clones, PL.17, substitutions at amino acids 70, 72, 73, or 76 reduced antigenic potency by 1000-fold or more, even though conservative amino acids were substituted. Although substitution of Ser for Ala 70 prevented T-cell stimulation in both assays, there was clearly some response to this peptide, as it induced expression of the interleukin 2 receptor.⁴⁹⁹ In addition, once T cells were exposed to the Ser 70 peptide, they became unresponsive to subsequent exposure to the natural Hb^d peptide. This phenomenon closely resembled T-cell anergy and persisted for a week or more. The Ser 70 substitution alters a contact residue of the peptide for the TCR of clone PL.17 and affects its affinity. Other T-cell clones, however, can respond to this peptide presented on the same MHC molecule (I-E^k). Other Hb^d peptides substituted at this position, such as Met and Gly 70, also induced anergy but not proliferation, whereas nonconservative substitutions such as Phe, Asn, Asp, and His 70 induced neither.⁵⁰⁰

Another well-studied example is influenza hemagglutinin peptide 306 to 318 as presented on human HLA-DR1. Based on the known crystal structure of the peptide-MHC complex,²⁵³ amino acid substitutions could be targeted to contact residues for the TCR at P307, P309, P310, P312, P315, and P318.⁵⁰¹ At each position, nonconservative substitutions often rendered the peptide inactive, whereas conservative substitutions at several sites either gave full antigenicity or gave progressively lower stimulatory activity, down to 1000fold less than native peptide while retaining the ability to induce anergy. For example, substituting His or Gly for Lys 307 gave 1000-fold reduced stimulation of T-cell proliferation but full ability to induce tolerance. Similarly, substituting His for Lys 315 gave complete loss of stimulation but nearly full anergy inducing activity. As before, induction of the interleukin 2 receptor (CD25) was a sign of T-cell activation by these altered peptide ligands, even when they did not induce proliferation. Unlike these peptides, the antagonists do not induce interleukin receptors or secretion, and they do not cause long-lasting tolerance. Overall, a number of altered peptide ligands have now been identified that, in appropriate complexes with MHC molecules, induce anergy or act as antagonists of the TCR and block activation by agonist ligands by delivering an abortive signal.⁴⁹³

Several methods have been found to anergize T cells to a specific antigen for up to a week, and all have the common theme of delivering a partial signal via the TCR, resulting in tolerance rather than stimulation. The first method was to expose the T cells to peptide plus APCs treated with the carbodiimide cross-linker ECDI.⁵⁰² This treatment may prevent accessory molecules on the presenting cell from interacting with the TCR complex or costimulatory signals from contributing to T-cell activation. The second method was to present peptide on presenting cells with mutated I-E molecules.^{503,504} The third method was to use altered peptide ligands that act as TCR antagonists as described previously.^{493,500,501} The final method was to block CD4 function with a monoclonal antibody, which would delay the recruitment of CD4 to the engaged TCR.⁵⁰⁵ Because generation of a complete stimulatory signal requires the interaction of TCR and accessory molecules, modifications that affect either component can block signaling. An altered peptide ligand, with decreased affinity for the TCR, may form an unstable complex, which cannot stay together long enough to recruit accessory molecules and generate a complete signal.^{505,506} Altered peptide ligands with low affinity for the TCR can also act as partial agonists that can compete with optimal agonists and reduce T-cell stimulation based on a similar mechanism (short dwell time of peptide-MHC complex on the TCR).¹⁹⁹

Abnormal TCR signaling can be demonstrated by following the activity of protein kinases. Normal signaling produces phosphorylation of TCR subunits, such as ζ chain, as well as phosphorylation and activation of receptor-associated tyrosine kinases, such as ZAP-70. These kinases generate the downstream signal needed for T-cell activation. However, in each case studied, partial antigen signaling resulted in ζ chain phosphorylation without phosphorylation or activation of ZAP-70, ^{500,504,505} so downstream activation did not occur. This abnormal pattern occurred regardless of the method of anergy induction.

Partial signaling may be important for T-cell survival during negative selection in the thymus or in maintaining peripheral tolerance. By responding to self-antigens as if they were altered ligands presented in the thymus, T cells could use anergy induction as a successful strategy for avoiding clonal deletion. Similarly, peripheral tolerance may be an important mechanism for preventing autoimmune disease. Immunotherapy with altered peptide ligands could be envisioned as a way to block an ongoing response or induce tolerance to a specific antigen, such as the synovium in arthritis, or foreign MHC antigens in allograft rejection. However, a potential pitfall is that different T cells recognize the same peptide differently, so a peptide that is seen as an altered peptide ligand by some T-cell clones may be seen as a complete antigen by others. In addition, the choice of peptide would vary with MHC type. To be effective, an altered peptide ligand should antagonize or anergize polyclonal T cells and should work with each patient's MHC type.

A similar mechanism may be invoked to explain the generally weak immunogenicity of tumor antigens. According to this hypothesis, the only T cells capable of responding to self-antigens on tumors may have low-affinity receptors for them. In effect, the natural sequence is the altered ligand that induces tolerance. In some cases, this anergy can be overcome with modified peptides that have greater affinity for the TCR and induce a full stimulatory signal, resulting in an effective immune response to the tumor antigens,⁴⁷⁴ as previously described under epitope enhancement.

Prediction of T-Cell Epitopes

The fact that T cells recognize processed fragments of antigens presented by MHC molecules leads to the ironic situation that T-cell recognition of antigen, which is more complex than antibody recognition due to the ternary complex needed between TCR, antigen, and MHC molecule, may actually be focused on simpler structures of the antigen than those seen by most antibodies specific for native protein antigens. In contrast to the assembled topographic antigenic sites seen by many antibodies,^{50,51} T cells specific for processed antigens are limited to seeing short segments of continuous sequence.^{177,233} Therefore, the tertiary structure of the protein plays little if any role in the structure of the epitope recognized by T cells, except as it may influence processing. However, the structure of the T-cell antigenic site itself must be limited to primary (sequence) and secondary structure, the latter depending only on local rather than long-range interactions. This limitation greatly simplifies the problem of identifying structural properties important to T-cell recognition because one can deal with sequence information, which can now be obtained from DNA without having a purified protein, and with the secondary structure implicit therein without having to obtain an x-ray crystallographic three-dimensional structure of the native proteina much more difficult task.

Because the key feature necessary for a peptide to be recognized by T cells is its ability to bind to an MHC molecule, most approaches for predicting T-cell epitopes are based on predicting binding to MHC molecules. These approaches, which have been reviewed,^{424,507–510} can be divided into those that focus on specific individual MHC molecules one at a time, such as motif-based methods, and those that look for general structural properties of peptide sequences. We shall discuss first the methods based on general properties and then those directed to individual MHC molecules.

The first structural feature of amino acid sequences found associated with T-cell epitopes that remains in use today is helical amphipathicity,^{227,511–514} which is statistically significant independent of the tendency to form a helix per se.⁵¹² Because the x-ray crystallographic structures of both MHC class I^{376–378,515} and II molecules^{253,443} have consistently shown peptides to be bound in extended, not α -helical, conformation, helicity per se has been abandoned as an associated structural feature of T-cell epitopes. However, as discussed in the following text, other explanations of amphipathic structures have been discovered that do not require the peptide to be bound to the MHC molecule as an α helix. Amphipathicity is the property of having hydrophobic and hydrophilic regions separated in space. It was observed that the immunodominant T-cell epitopes of myoglobin and cytochrome c corresponded to amphipathic helices.^{185,189,516} DeLisi and Berzofsky⁵¹¹ developed an algorithm to search for segments of protein sequence that could fold as amphipathic helices based on the idea that the hydrophobicity of the amino acids in the sequence must oscillate as one goes around an amphipathic helix. For the hydrophobic residues to line up on one side and the hydrophilic residues on the other, the periodicity of this oscillation must be approximately the same as the structural periodicity of the helix, about 100 degrees per residue (360 degrees per 3.6 residues per turn) (Fig. 23.14).

A microcomputer program implementing this analysis was published.⁵¹⁴ Margalit et al.²²⁷ optimized the original approach,⁵¹¹ correctly identifying 18 of the 23 immunodominant helper T cell antigenic sites from the 12 proteins in

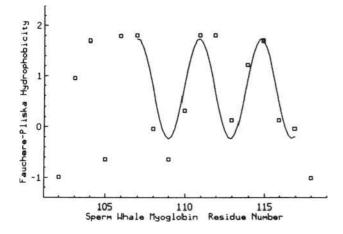

FIG 23.14. Plot of hydrophobicity of each amino acid in sperm whale myoglobin 102 to 118, according to the scale of Fauchère and Pliska,⁶⁰⁴ as a function of amino acid sequence, showing least-squares fit of a sinusoidal function to the sequence of hydrophobicities from 107 to 117. (From Berzofsky et al.,¹⁸⁰ with permission.)

an expanded database (p < .001)²²⁷ (see Table 23.4). Indeed, when the database was expanded to twice and then four times its original size, the correlation remained highly significant, and the fraction of sites predicted remained relatively stable (34/48 sites = 71%, p < .003; 61/92 sites = 66%, p < .001).^{517,518} A similar correlation was found for 65% of peptides presented by class I MHC molecules.⁵¹⁸ A primary sequence pattern found in a substantial number of T-cell epitopes by Rothbard and Taylor⁵¹⁹ was consistent with one turn of an amphipathic helix. Also, another approach, called the "strip-of-the-helix" algorithm, which searches for helices with a hydrophobic strip down one face, found a correlation between amphipathic helices and determinants presented by both class II and I MHC molecules.^{513,520}

Newer data suggest at least two explanations, not mutually exclusive, for this correlation in the absence of helical structure found in the peptides bound to MHC molecules.⁵²¹ First, crystal structures of peptides bound to class II MHC molecules have found that the peptides are bound in an extended conformation, but with a -130-degree twist like that of a type II polyproline helix,^{253,443} and can be quite amphipathic because of this twist.²⁵³ Although the -130-degree twist is distinct from that of an α helix, it gives a periodicity similar enough to be detected. Second, it was observed that spacing of the anchor residues in the motifs for peptides binding to class I and II MHC molecules was consistent with the spacing of turns of an α helix, for example, at P2 and P9 (seven residues apart like two turns of a helix) or at P5 and P9 (spaced like one turn of a helix).⁵²¹ Because the anchor residues are most often hydrophobic, this pattern resulted in an amphipathic periodicity pattern like that of an amphipathic α helix for just the anchor residues alone, seen in most motifs.⁵²¹ Thus, if the other residues have a random pattern, the anchor residue spacing alone, which is enforced by the spacing of the pockets in the MHC molecules that bind these anchor residues, will produce the amphipathic helical signal, even though the peptide is bound in an extended conformation. This amphipathic helical periodicity has held up as a correlate for peptides defined as T-cell epitopes⁵²¹ and has continued to be a useful predictive tool for identifying potential epitopes, successful in a number of studies, when one does not want to focus on individual MHC alleles or wants to find regions of high epitope density. Other structural properties such as coil content and exposure have been used as general predictors of MHC class II binding.522

Other approaches to predicting T-cell epitopes are generally based on sequences found to bind to specific MHC molecules.^{424,507–510,523–525} The simplest approach is to apply standard sequence search algorithms to known protein sequences to locate motifs for peptides binding to particular MHC molecules, using collections of motifs identified in the literature.²⁶⁴ This approach showed early success for epitopes in proteins from *Listeria monocytogenes*⁵²⁶ and malaria,⁵²⁷ but it also became apparent that only about 30% of sequences bearing motifs actually bound to the corresponding MHC molecules.^{526,528,529} This discrepancy may relate to adverse interactions created by nonanchor residues^{392,397,530} and could be overcome to some extent by generating extended motifs taking into account the role of each residue in the sequence.^{397,530}

To determine whether one could locate regions of proteins with high densities of motifs for binding multiple MHC molecules, Meister et al.⁵³¹ developed the algorithm Epimer, which determined the density of motifs per length of sequence. A surprising result was that the motifs were not uniformly distributed but clustered. This clustering may reflect the fact that many motifs are related, and that the same anchor residues are shared by several motifs, perhaps because MHC molecules are also related and their variable segments that define some of the binding pockets are sometimes exchanged by gene conversion events.⁵³² This hypothesis has now been confirmed and extended by studies showing that each anchor pocket can be grouped into families of MHC molecules sharing similar pockets and therefore anchor residues, but the families for the B, C, and F pockets do not coincide, so there is a reassortment between pockets.533,534 These observations allow prediction of motifs for additional MHC molecules. In the case of HIV, the densities of motifs for class I MHC binding were anomalous at both the low and high ends of the spectrum.⁵³⁵ Clustering at the high end may be due to anchor sharing and showed no correlation with conserved or variable regions of the sequence. However, at the low end, long stretches with low motif density occurred preferentially in variable regions, suggesting that the virus was mutating to escape the CTL immune system.535 This clustering may be useful in vaccine development because identification of sequences containing overlapping motifs for multiple MHC molecules may define promiscuously presented peptides that would elicit responses in a broad segment of the population.⁵³¹

Another type of MHC allele-specific approach is the use of matrices defining the positive or negative contribution of each amino acid possible at each position in the sequence toward binding to an MHC molecule. A positive or negative value is assigned to each of the 20 possible amino acids that can occur at each position in a peptide sequence, and these are summed to give the estimated potential of that peptide for binding. The values in the matrix are derived from either experimental binding studies using peptide panels with single positions substituted with each possible amino acid, 439,536-539 or from comparisons of peptides known to bind in a compilation of the literature, if the number known is sufficiently large.^{507,540} One improvement described is an amino acid similarity matrix that disfavors substitutions with opposite charge.⁵⁴¹ Davenport et al.^{542,543} also developed a motif method based on Edman degradation sequencing of pooled peptides eluted from MHC molecules. All of these methods have had some success in predicting peptides binding to particular MHC molecules,⁵⁰⁷ but they all require the assumption that each position in a peptide must be acting independently of its neighbors, which is a reasonable first approximation, but exceptions are known.544,545 The more experimental data that goes into generating the matrix, the more reliable the predictions. Therefore, the predictive success may be greater for some of the more common HLA molecules for which more data exists. This matrix approach has been used for both class I and II MHC molecules. Current predictive matrix algorithms, compared to experimental screening, have been found to detect the vast majority of CD8⁺ T-cell epitopes detected experimentally, for example, in vaccinia virus, in which the top-ranked 300 peptides using four different algorithms predicted 40 per 49 epitopes found.⁵⁴⁶

A potentially very useful observation is the finding that HLA class I molecules can be grouped into families (HLA supertypes) that share similar binding motifs.^{438,536,547,548} The broader motifs that encompass several MHC molecules have been called supermotifs. For example, HLA-A*0301, A*1101, A*3101, A*3401, A*6601, A*6801, and A*7401 all fall into the HLA-A3 superfamily.⁵⁴⁷ A peptide that carried this supermotif should be active in a broader range of individuals than one which was presented by a single HLA molecule. Moreover, as several HLA supertypes have been defined, it should be possible to design a vaccine effective in a large fraction of the population with only a limited number of well-selected antigenic determinants.⁵⁴⁹

Another approach for predicting peptides that bind to MHC molecules is based on free energy calculations of peptides docked into the groove of a known MHC structure, for which the crystallographic coordinates are known, or on structural modeling of the MHC molecule by homologous extension from another MHC molecule, when the crystal structure is not known, followed by peptide docking calculations.^{550–552} It is important to use free energy rather than energy, as the latter alone cannot find the most stable orientation of a side chain and cannot correctly rank order different side chains at the same position. This approach correctly predicts the structure of several known peptide-MHC complexes when starting with the crystal structure of a different complex, in each case to within 1.2 to 1.6 Å all-atom root-mean square deviation.⁵⁵¹ Using this structural modeling can allow one to extend motifs to nonanchor positions for cases where only anchor residue motifs are known and can allow one to predict new motifs for MHC molecules whose motifs have not yet been determined.

Another approach to predicting MHC-binding sequences uses a technique called threading that has been developed for predicting peptide secondary structure, based on threading a sequence through a series of known secondary structures, and calculating the energies of each structure. Altuvia et al.^{553,554} showed that threading could be applied to peptides in the groove of MHC molecules, because when several peptides that bind to the same MHC molecule are compared crystallographically, the conformation of the peptides is fairly similar, as for example in several peptides cyrstallized bound to HLA-A2.1.⁵¹⁵ In testing the threading approach, Altuvia et al.553,554 showed that known antigenic peptides are highly ranked among all peptides in a given protein sequence, and the rank order of peptides in competitive binding studies could be correctly predicted. The advantage of this approach is that it is independent of known binding motifs and can identify peptides that bind despite lack of the common motif for the MHC molecule in question. It can

also be used to rank a set of peptides all containing a known motif. For both class I and II MHC–binding peptides, a number of structure-based predictive approaches have been developed as well.^{522,555–558}

Finally, artificial neural networks can be trained on a set of peptides that bind to a given MHC molecule to recognize patterns present in binding peptides.^{559,560} When the predictions of the artificial neural networks are tested, the results can be used to further train the artificial neural networks to improve the predictive capability in an iterative fashion.

Recently, predictive algorithms for proteasomal cleavage sites^{561,562} and TAP-transported peptides^{319,563} have been developed. Combining these into approaches to predict epitopes based on all the steps a peptide must pass through, cleavage, transport, and MHC binding (except for TCR binding), has led to the most recent comprehensive algorithms for epitope prediction that can achieve up to 72% sensitivity.^{286,320,508,564-568}

As all these methods are further developed and refined, they promise to allow accurate prediction of peptides that will bind to different MHC molecules and thus allow the design of vaccines without empirical binding studies until the end of the process. In addition, empirical high throughput methods for epitope mapping have been developed to speed the latter.⁵⁶⁹ Further, localization of clusters of adjacent or overlapping binding sequences in a short segment of protein sequence can also be useful for selecting sequences that will be broadly recognized. Predictive algorithms for locating T-cell epitopes also have the potential use to reduce immunogenicity of therapeutic proteins (such as hormones, cytokines, and monoclonal antibodies) against which one would not want an immune response to develop.^{570,571} For this purpose and others, it is useful to be able to predict all the epitopes likely to be recognized not just with a single MHC allele but with all of a person's MHC molecules or even those of a larger population; such methods have also been developed.572

RELATIONSHIP BETWEEN HELPER T-CELL EPITOPES AND B-CELL EPITOPES ON A COMPLEX PROTEIN ANTIGEN

As we have seen, the factors that determine the location of antigenic sites for T and B cells, with the possible exception of self-tolerance, are largely different. Indeed, if B cells (with their surface antibody) bind sites that tend to be especially exposed or protruding-sites that are also more accessible and susceptible to proteolytic enzymes-then there is reason to think that T cells may have a lower probability of being able to recognize these same sites, which may be more likely to be destroyed during processing. Certainly, assembled topographic sites will be destroyed during processing. On the other hand, there are examples in which T cells and antibodies seem to see the same, or very closely overlapping, sites on a protein, 43,185,215,573-575 although fine specificity analysis usually indicates that the antibody and T cell fine specificities are not identical. The question dealt with here is whether there are any functional or regulatory factors in T cell–B cell cooperation that would produce a relationship

between helper T cell specificity and B cell specificity for the same protein antigen.

Early evidence that helper T cells might influence the specificity of the antibodies produced came from a number of studies showing that Ir genes, which appeared to act through effects of T-cell help, could influence the specificity of antibodies produced to a given antigen.^{181,576-583} It was hard to imagine how MHC-encoded Ir genes could determine which epitopes of a protein elicit antibodies, when such antibodies are generally not MHC restricted. One explanation suggested was that the Ir genes first select which helper T cells are activated, and these in turn influence which B cells, specific for particular epitopes, could be activated.¹³⁰ Because, for cognate help, the B cell has to present the antigen in association with an MHC molecule to the helper T cell, the Ir gene control of antibody specificity must operate at least partly at this step by selecting which helper T cell can be activated by and help a given B cell. Conversely, if the helper T cell selects a subset of B cells to be activated on the basis of their antibody specificity, then there is a reciprocal interaction between T and B cells influencing each other's specificity. Therefore this hypothesis was called "T-B reciprocity."130 Steric constraints on the epitopes that could be used by helper T cells to help a B cell specific for another particular epitope of the same protein were also proposed by Sercarz et al.584

The concept was first tested by limiting the fine specificity of helper T cells to one or a few epitopes and then determining the effect on the specificities of antibodies produced in response to the whole molecule. This was accomplished by inducing T-cell tolerance to certain epitopes⁵⁸⁵ or using T cells from animals immune to peptide fragments of the protein.^{128,586,587} In each case, the limitation on the helper T-cell specificity repertoire influenced the repertoire of antibodies produced.

One purpose of the B-cell surface Ig is to take up the specific antigen with high affinity, which is then internalized by receptor-mediated endocytosis and processed like any other antigen.⁵⁸⁸⁻⁵⁹⁵ Therefore, the explanation was proposed that the surface Ig, which acts as the receptor to mediate endocytosis, sterically influences the rate at which different parts of the antigen are processed because what the B cell is processing is not free antigen but a monoclonal antibody-antigen immune complex.¹³⁰ This concept presupposes that many antibody-antigen complexes are stable near pH 6 in the endosome, and that what matters is the kinetics of production of large fragments, rather than the products of complete digestion, when both the antigen and the antibody may be degraded to single amino acids. Such protection from proteolysis of antigen epitopes by bound antibody can be demonstrated at least in vitro.⁵⁷ More recently, the effect of antigen-specific B-cell surface Ig on the fragments produced by proteolytic processing of antigen was elegantly demonstrated by Davidson and Watts.⁵⁹⁶ They demonstrated that the pattern of fragmentation of tetanus toxoid, as measured by SDS-polyacrylamide gel electrophoresis, produced during processing by B-lymphoblastoid clones specific for tetanus toxoid varied among B-cell clones depending on their specificity for different epitopes within the antigen. Binding to the antibody may also influence which fragments are shuttled to the surface and which are shunted into true lysosomes for total degradation. Thus, different B cells bearing different surface Ig would preferentially process the antigen differently to put more of some potential fragments than others on their surface in contrast to nonspecific presenting cells that would process the antigen indifferently. By this mechanism, it is proposed that B-cell specificity leads to selective antigen presentation to helper T cells and, therefore, to selective help from T cells specific for some epitopes more than from T cells specific for others.¹³⁰

To test this hypothesis, Ozaki and Berzofsky¹²⁹ made populations of B cells effectively monoclonal for purposes of antigen presentation by coating polyclonal B cells with a conjugate of monoclonal antimyoglobin coupled to anti-IgM antibodies. B cells coated with one such conjugate presented myoglobin less well to one myoglobin-specific T-cell clone than to others. B cells coated with other conjugates presented myoglobin to this clone equally well as to other clones. Therefore, the limitation on myoglobin presentation by this B cell to this T-cell clone depended on the specificity of both the monoclonal antibody coating the B cell and the receptor of the T-cell clone. It happened in this case that both the monoclonal antibody and the T-cell clone were specific for the same or closely overlapping epitopes. Therefore, it appears that the site bound by the B-cell surface Ig is less well presented to T cells. This finding is also consistent with a recent study of chimeric proteins in which one or more copies of an ovalbumin helper T-cell determinant were inserted in different positions.⁵⁹⁷ Although the position of the ovalbumin determinants did not affect the antibody response to one epitope, the position did matter for antibody production to an epitope of the chimeric protein derived from insulin-like growth factor I. An ovalbumin determinant inserted distal to this epitope was much more effective in providing help than one inserted adjacent to the same epitope, when both constructs were used as immunogens, even though both constructs elicited similar levels of ovalbumin-specific T-cell proliferation in the presence of nonspecific presenting cells in vitro as a control for nonspecific effects of flanking residues on processing and presentation of the helper T-cell determinants. However, circumstantial evidence from the Ir gene studies mentioned previously suggests that T cells may preferentially help B cells that bind with some degree of proximity to the T-cell epitope, as there was a correlation between T cell and antibody specificity for large fragments of protein antigens under Ir gene control.^{127,130,181,579,580,583} Therefore, antibodies may have both positive and negative selective effects on processing. Further studies on presentation of β -galactosidase–monoclonal antibody complexes by nonspecific APCs suggest similar conclusions.^{598,599} Presumably, the conjugates are taken up via Ig fragment c (Fc) receptors on the presenting cells and processed differentially according to the site bound by the antibody so that they are presented differentially to different T-cell clones. Thus, non-B-presenting cells can be made to mimic specific B-presenting cells. This also suggests that circulating antibody may have a role in the selection of which T cells are activated in a subsequent exposure to antigen.

The issue of whether bound antibody enhanced or suppressed presentation of specific determinants to T cells was explored further by Watts et al.600 and Simitsek et al.601 They first found that a particular tetanus toxoid-specific Epstein-Barr virus-transformed human B-cell clone 11.3 failed to present the tetanus toxoid epitope 1174 to 1189 to specific T cells, whereas it presented another epitope as well as did other B cells, and another B-cell clone presented the 1174 to 1189 epitope well. Moreover, the free 11.3 antibody also inhibited presentation of this epitope to T cells at the same time that it enhanced presentation of other epitopes by Fc receptor facilitated uptake.⁶⁰⁰ They subsequently found that the same 11.3 B cell and antibody actually enhanced presentation of another epitope of tetanus toxoid, 1273 to 1284, by about 10-fold, even though both epitopes were within the footprint of the antibody as determined by protection from proteolytic digestion.⁶⁰¹ The enhancement could be mediated also by free antibody as well as Fab fragments thereof, indicating that the mechanism did not involve Fc receptor facilitated uptake. Furthermore, the 11.3 antibody had no effect on presentation of another determinant in the same tetanus toxoid C fragment, 947 to 967, which was not within the footprint of the antibody, and another antibody to the C fragment did not enhance presentation of 1273 to 1284. The authors concluded that the same antibody or surface Ig can protect two determinants from proteolysis but sterically hinder the binding of one to class II MHC molecules while facilitating the binding of the other.⁶⁰¹ The facilitation may involve protection from degradation. This antibody-mediated enhancement of presentation of selected epitopes to helper T cells can greatly lower the threshold for induction of a T-cell response and may thereby elicit responses to otherwise subdominant epitopes. It can also contribute to epitope spreading, for example, in autoimmune disease, in which an initial response to one dominant determinant leads to a subsequent response to other subdominant determinants, perhaps by helping for antibody production, which in turn facilitates presentation of the other determinants.

Taken together, these results support the concept of T–B reciprocity in which helper T cells and B cells each influence the specificity of the other's expressed repertoire.¹³⁰ This mechanism may also provide an explanation for some of the cases in which Ir genes have been found to control antibody idiotype.^{602,603} These relationships probably play a significant role in regulating the fine specificity of immune response of both arms of the immune system. Therefore, they will also be of importance in the design of synthetic or recombinant fragment vaccines that incorporate both T- and B-cell epitopes to elicit an antibody response.

CONCLUSION

Overall, antibodies and T cells recognize different structural features in different contexts or environments, and thus complement each other to detect the spectrum of foreign (or self-) antigens encountered. Antibodies recognize three-dimensional structures on the exposed surface of molecules either in solution or on a cell surface. Therefore, they are dependent on the conformation of the antigen and can recognize structures that are assembled on the surface of the antigen molecule by the way it folds but that are not contiguous in the primary sequence. However, they do not generally recognize structures buried within protein molecules or inside cells. In contrast, T cells are designed to recognize short segments of primary amino acid sequence of protein antigens, and thus are not dependent on the conformation of the original protein unless it affects processing. Furthermore, T cells particularly provide internal surveillance of proteins inside cells, recognizing peptide fragments of these presented by MHC molecules that carry these fragments to the cell surface. This surveillance of intracellular proteins requires a number of hurdles including proteolytic processing of the antigen into fragments, transport of these into the compartments where they are loaded onto MHC molecules, binding with appropriate specificity to the combining site of specific MHC molecules, and then finally recognition by an appropriate TCR. These hurdles limit the number of amino acid sequences that can be recognized and account in part for immunodominance. Furthermore, the two major subsets of T cells also complement each other by recognizing exogenous and endogenous proteins processed and transported through different pathways and presented by difference classes of MHC molecules. Thus, the two major classes of T cells complement the types of structures and the locales surveyed by antibodies. For example, in the case of viruses, antibodies can detect intact virions and shed viral proteins in solution as well as viral proteins expressed on the surface of infected cells; CD4⁺ T cells can recognize viral proteins taken up by APCs and processed in an endosomal pathway and CD8⁺ T cells can detect proteins synthesized within the infected cell, whether or not they are ever expressed intact on the cell surface or secreted. Together, they provide the immune system with a strategy to detect all forms of foreign invaders as well as to protect the host through different effector mechanisms.

Fc Receptors and Their Role in Immune Regulation and Inflammation

Jeffrey V. Ravetch • Falk Nimmerjahn

HISTORICAL BACKGROUND

CHAPTER

Cellular receptors for immunoglobulins (Igs) were anticipated by the description of cytophilic antibodies of the IgG class, identified by Boyden and Sorkin in 1960.¹ These antibodies conferred upon normal cells, like macrophages, the capacity to specifically absorb antigen. Using sheep red blood cells (RBCs) as the antigen resulted in rosette formation between the cytophilic antisheep RBC antibodies and macrophages and provided a convenient means of visualization of the binding of cytophilic antibodies with normal cells. Subsequent studies by Berken and Benacerraf² suggested that the crystallized fragment (Fc) of the cytophilic antibody interacted with a cell surface receptor on macrophages. Similar studies on B-lymphocytes extended the generality of these receptors and led to the term Fc receptor (FcR) to denote the surface molecules on lymphoid and myeloid cells that are capable of interacting with the Fc of immunoglobulin molecules.³ Studies on IgE, IgM, and IgA demonstrated the existence of distinct receptors for those isotypes as well on various immune cell types. Detailed biochemical characterization of Fc receptors was inaugurated by the studies of Kulczycki et al.⁴ on the high-affinity IgE FcR of mast cells, revealing a hetero-oligomeric $\alpha\beta\gamma_2$ subunit structure. A distinction between FcRs for the IgE and IgG isotypes emerged with the observation of the very high (10^{10} M^{-1}) binding affinity of IgE for its receptor in comparison with the low binding (10⁶ M⁻¹) of IgG1 to its receptor. This distinction led to the realization that the functional IgG1 ligand was exclusively in the form of an immune complex (IC), whereas IgE binding occurred through monomer interaction with its receptor. This difference in binding affinity had significant functional implications for the structures of these receptors and mechanisms by which each isotype activated its target cell. Determination of the structure of these receptors was facilitated by their molecular cloning, beginning with the IgG FcRs^{5,6} and followed by the IgE FcR.⁷ Two distinct types of IgG receptors, differing in their transmembrane and cytoplasmic sequences, were identified that offered a molecular explanation for the apparent contradictory activation and inhibitory activities attributed to IgG FcRs. The primary structure of the subunits of the high-affinity IgE FcR revealed homology in the ligand binding α subunit to its IgG counterparts. However, the extent of similarity between these receptors became apparent with the observation that the γ chain subunit was common to both IgG and IgE FcRs, providing both assembly and signaling functions to these activation receptors.^{8,9} This common structure suggested a functional

link between IC diseases and allergic reactions, a prediction that was confirmed through mouse knockout studies of IgG FcRs.^{10,11} The FcRs, through their dependence on the immunoreceptor tyrosine-based activation motif (ITAM) pathway of cellular activation, belonged to the family of immunoreceptors that included the antigen receptors on B and T cells. Three-dimensional crystal structures have been solved for the low-affinity IgG FcRs^{12,13} and the high-affinity IgE FcR,¹⁴ alone and in complex with their Ig ligands,^{15,16} further establishing the close structural link between these Ig receptors.

The functional roles of IgG FcRs were suggested by the distribution of these receptors on both lymphoid and myeloid cells.¹⁷ On myeloid cells, they were presumed to mediate effector cell activation, resulting in phagocytosis, antibody-dependent cellular cytotoxicity (ADCC), and release of inflammatory mediators. However, the well-known ability of the classical pathway of complement to generate activated fragments in response to ICs capable of inducing inflammatory responses by myeloid cells complicated the interpretation of the physiological role of IgG FcRs. Thus, the contribution of IgG FcRs to the mechanism of IC-mediated inflammation, as distinct from the role of complement, remained uncertain. Insight into this distinction was gained through the generation of mouse strains specifically deficient or blocked in either FcRs^{10,18-20} or components of the classical complement pathway.²¹ Studies on IC-mediated inflammatory responses in these animals, such as the Arthus reaction, led to the realization that IgG FcRs and not the classical pathway of complement activation were the functional mediators of inflammatory responses triggered by ICs.^{20,22,23} The situation for IgE was less confounding, and the identification and characterization of a high-affinity receptor for this isotype on mast cells offered a plausible explanation for many of the inflammatory features of allergic reactions,²⁴ validated later by mouse knockouts of this receptor. IgG ICs had also been observed to mediate suppression of B-cell responses; thus, the presence of an IgG FcR activity on B cells provided a possible, but uncharacterized, mechanism for this inhibitory activity. Molecular characterization of this inhibitory activity for the B-cell FcR, FcRIIB, resulted in the first detailed description of an inhibitory motif, now termed the immunoreceptor tyrosine-based inhibitory motif (ITIM),^{25,26} and the signaling pathway by which it abrogates ITAM-triggered activation. The ITIM mechanism is now recognized as ubiquitous and has resulted in the recognition of a large family of inhibitory receptors on immune cells that function to maintain proper

thresholds for activation and abrogate activation responses to terminate an immune reaction.²⁷

FcRs are now recognized as central mediators of antibody-triggered responses, coupling the innate and adaptive immune responses in effector cell activation.²⁸ In addition to these specialized roles, the IgG FcRs have served as an example of the emerging class of balanced immunoreceptors, in which activation and inhibition are tightly coupled in response to ligand binding. Perturbations in either arm of the response have been shown to lead to pathological consequences and have been taken as a paradigm of how these systems are likely to work for those paired immunoreceptors with unknown ligand-binding functions. The newly described roles for FcRs in maintaining peripheral tolerance, shaping the antibody repertoire, regulating antigen-presenting cell (APC) maturation, and promoting mast cell survival indicate the diversity of functions that these receptors possess and their central role in modulating both afferent and efferent responses in the immune response.

This chapter focuses primarily on the IgG and IgE FcRs, for which substantial data on their structure, function, regulation, and role in a variety of physiological and pathological conditions are now available. The similarity in structure and signaling between those receptors and other members of this family, such as the IgA FcR and the recently discovered Fc-receptor for mouse and human IgM (FcµR), is also discussed. These FcRs will be referred to as "canonical Fc receptors," reflecting their shared structural and functional properties. In contrast, lectins such as SIGN-R1 and DC-SIGN, which bind IgG Fc when sialylated, represent a novel class of FcRs with distinct structures and functions and will be discussed in detail in the following. Other Ig receptors with specialized functions in the transport of Igs, such as the FcRn²⁹ and the poly-Ig FcR,³⁰ will not be discussed here.

STRUCTURE AND EXPRESSION Molecular Genetics

Two general classes of canonical FcRs are now recognized: the activation receptors, characterized by the presence of a cytoplasmic ITAM sequence associated with the receptor, and the inhibitory receptor, characterized by the presence of an ITIM sequence. These two classes of receptors function in concert and are usually found coexpressed on the cell surface. Thus coengagement of both signaling pathways is the rule, setting thresholds for and ultimately determining the physiological outcome of effector cell responses. Among the factors that determine this threshold level are the actual affinities of the individual activating and inhibitory receptors for a specific IgG ligand and the expression level of the receptor pairs on immune effector cells. Importantly, the affinity of different antibody isotypes and subclasses for their respective activating and inhibitory FcRs varies significantly, thus explaining the differential activity of antibody isotypes in vivo.^{20,31,32} In addition, alleles of specific FcRs have been described that alter their affinity for individual subclasses thus accounting for the variable responses seen in a population to an antibody (see subsequent discussion). Noncanonical FcRs such as the IgM receptors

Fc μ R, Fca/ μ R, the poly-Ig receptor, and the sialylated IgG Fc receptors SIGN-R1 and DC-SIGN, contain neither ITAM nor ITIM motifs.

Subunit Composition

Canonical FcRs are typically type I integral membrane glycoproteins consisting of, at the least, a ligand recognition α subunit that confers isotype specificity for the receptor. α subunits for IgG, IgE, IgM, and IgA have been described.^{17,33-35} These subunits typically consist of two extracellular domains of the IgV type superfamily, a single transmembrane domain and a relatively short intracytoplasmic domain. In activation FcRs, a signaling subunit of the γ family is often found, resulting in an $\alpha \gamma_2$ complex. The inhibitory FcyRIIB molecule, in contrast, is expressed as a single-chain receptor. The α subunits have apparent molecular weights of between 40 and 75 kDa, and share significant amino acid sequence homology in their extracellular domains. Alternatively, spliced forms of Fc rRIIB modify the intracytoplasmic domain of this molecule. For example, the B2 form lacks sequences that inhibit internalization and thus demonstrates enhanced internalization of ICs, in comparison with $Fc\gamma$ RIIB1. However, all the splice variants contain the ITIM motif, a necessary and sufficient domain for mediating inhibitory signaling. The conservation of this sequence in mice and humans, its presence in all splice variants, and the hyperresponsive phenotypes generated in mice deficient in this receptor all support inhibition as the central function of Fc γ RIIB. The specific structures of the α subunits of the canonical FcRs are shown in Figure 24.1. The notable exceptions to the general structure just outlined are seen for the high-affinity $Fc\gamma RI\alpha$ subunit, which has three extracellular domains; the activation $Fc\gamma RIIA\alpha$ subunit, which does not require additional subunits for assembly or signaling; and the glycosylphosphatidyl-inositol (GPI)linked Fc γ RIIIB, which attaches to the cell surface through a GPI linkage, rather than through a transmembrane domain.

The γ subunit is found associated with activation IgG, IgE, and IgA FcRs, as well as with non-FcR molecules, such as paired Ig-like receptor A (PIR-A) and natural killer (NK) cell cytotoxicity receptors, but not with IgM receptors, nor the lectins SIGN-R1 and DC-SIGN.³⁶⁻³⁸ It is required for assembly of the α subunits of these receptors by protecting these subunits from degradation in the endoplasmic reticulum. The γ chain is found as a disulfide-linked homodimer, with a short extracellular domain containing the cysteine involved in dimerization, a transmembrane domain, and an intracytoplasmic domain containing the ITAM. An aspartic acid residue found in the transmembrane domain of the γ chain is often associated with a basic amino acid residue in the transmembrane domain of the α subunit. The γ subunit belongs to a gene family that includes the T-cell receptor-associated ζ chain and the NK receptor DAP-10- and DAP-12-associated molecules.³⁹ Fc γ RIIIA can associate with the ζ chain, resulting in the $\alpha \zeta_2$ complex found in human NK cells.

A third subunit is found associated with the activation FcRs Fc ϵ RI and Fc γ RIII, the β subunit. This 33-kDa subunit has four transmembrane-spanning domains and amino and carboxy intracytoplasmic domains, belonging to the cluster

FIG. 24.1. Summary of Fc Receptor Structures, Expression Patterns, and in Vivo Functions. The immunoreceptor tyrosine-based activation motif signaling motif is indicated by the *green rectangle*; the immunoreceptor tyrosine-based inhibitor motif is indicated as a *red rectangle*. Alleles of FcyRIIA and FcyRIIB and their binding properties are discussed in the text.

of differentiation (CD)20 family of tetraspan molecules.²⁴ An ITAM sequence is found in the intracytoplasmic carboxy domain. In mast cells and basophils, the β chain assembles into an $\alpha\beta\gamma$ complex with the α chain belonging to either Fc γ RIII or Fc ϵ RI. Its presence is required for assembly of Fc ϵ RI in rodents. In humans, however, $\alpha\gamma$ complexes of Fc ϵ RI are found in monocytes, Langerhans cells, and dendritic cells (DCs), in addition to the $\alpha\beta\gamma$ complexes found in mast cells and basophils. The ITAM motif found in the β subunit is not an autonomous activation sequence but functions as a signaling amplifier of the ITAM found in the γ subunits.⁴⁰

Gene Organization, Linkage, and Polymorphisms

All α subunits of canonical FcRs share a common gene organization, which indicates that the evolution of this family of receptors resulted from gene duplication from a common ancestor.⁴¹ Sequence divergence then resulted in the acquisition of distinctive specificities for these related sequences. Most of the genes belonging to the expanded FcR family, including the recently identified Fcµ-receptor, the Fcα/µR, the poly-Ig receptor, the group of FcR-homologous or -like (FCRL) proteins, the α chains of Fc γ RI, Fc γ RII, Fc γ RII, and Fc ε RI including the common FcR- γ chain (Fig. 24.2), are found on the long arm of chromosome 1.^{34,35,42–44} This region is syntenic with a comparable region on mouse chromosome 1; however, Fc γ RI α and several FCRLs are found on mouse chromosome 3. In humans, the α subunit of the IgA receptor is found on chromosome 19 as is the lectin DC-SIGN (CD209) and the β subunit is on chromosome 11. The Fc γ RII–Fc γ RIII locus on chromosome 1 is further linked to a variety of lupus susceptibility genes found in that region, including the *Sle1* cluster.⁴⁵ A locus linked to atopy has been identified at 11q12–13 and further delineated polymorphisms of the β chain (I181V and V183L) that are associated with a heightened risk of atopy. However, a direct functional association of these polymorphisms with the known biological activities of the β chain has not been found.⁴⁶

Polymorphisms in the α chains of the Fc γ Rs have been described, most notably in FcyRIIA and FcyRIIIA; these polymorphisms result in differences in binding affinity to specific IgG subclasses.⁴⁷ For example, a histidine at position 131 in FcyRIIA results in higher affinity binding to IgG2 and IgG3 than does an arginine at that position. Similarly, Fc PRIIIA with value at position 158 of the α chain has a higher binding affinity for IgG1 and 3 than does the polymorphic form with phenylalanine at that position. These polymorphisms translate into a more robust ADCC response for the FcyRIIIA val/val and the FcyRIIA his/his haplotype in vitro and has been positively correlated with a better clinical response to antitumor antibodies inclunding the CD20-specific antibody rituximab, the Her2/neu-specific antibody trastuzumab, and the epidermal growth factor receptor-specific antibody cetuximab in human lymphoma, metastatic breast cancer, and colorectal cancer patient cohorts, respectively.48-53 This data is consistent with previous results obtained with rituximab

and trastuzumab in mouse models, demonstrating an important role of cellular Fc γ Rs for the activity of these therapeutic antibodies in vivo.^{54,55} Four amino acids are polymorphic for Fc γ RIIIB at positions 18, 47, 64, and 88, which contribute to the neutrophil antigen polymorphisms for this receptor. Several studies have attempted to link specific FcR polymorphisms or copy number variations to autoimmune diseases, specifically to systemic lupus erythematosus (SLE).⁵⁶ Recent studies have reported associations in susceptibility to SLE in both murine and human populations with levels of $Fc\gamma$ RIB

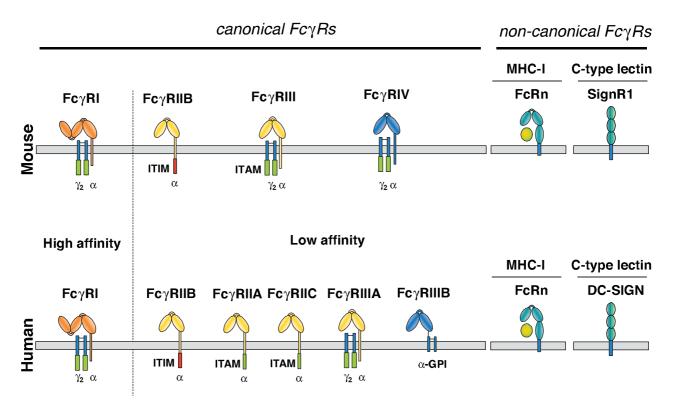

FIG. 24.3. Comparison of the Human and Mouse Canonical and Noncanonical Fc γ -Receptor Protein Family. In both species, canonical Fc γ Rs can be distinguished by their affinity for the antibody Fc-portion (high or low affinity) and by the signaling pathways they trigger (activating versus inhibitory). The noncanonical neonatal FcR belongs to the family of major histocompatibility class I proteins and regulates immunoglobulin (Ig)G half life. Mouse SIGNR1 or human DC-SIGN are C-type lectin proteins that can only bind to IgG glycoforms rich in terminal sialic acid residues and are involved in the anti-inflammatory activity of IgG.

expression or alleles of FcyRIIB.57 Reduced expression of FcyRIIB on activated B cells, such as memory cells, has been seen in patients with SLE and chronic inflammatory demyelinating polyneuropathy (CIDP), and is associated with a promoter polymorphism.^{58,59} In mouse strains that develop a spontaneous, lupus-like disease, restoring the level of FcyRIIB expression on their B cells to a wild-type level reverses disease.^{60,61} A higher incidence of an allele of FcyRIIB has been reported in several populations with autoimmune disease. This allele, found in the transmembrane domain of the receptor, is suggested to result in a hypomorphic phenotype, similar to the reduced expression observed.⁵⁷ Of note, despite increasing the risk for development of SLE, this FcyRIIB allele seems to decrease the likelihood of malaria infections and the severity of disease and can be found at increased frequencies in areas of the world where malaria is endemic.^{62,63}

Species Comparisons

Detailed comparisons between the canonical FcRs in mice and humans have revealed several notable differences in both structure and expression of these molecules (Figs. 24.1 to 24.3). Whereas IgG, IgM, and IgE FcRs are conserved in these species, IgA FcRs are not. To date, a murine homolog for the IgA FcR has not been identified. In general, murine and human IgG FcRs display comparable degrees of heterogeneity and complexity.^{41,64} Specific differences, however, have been noted. For example, $Fc\gamma RI$ is encoded by a single gene in the mouse, in comparison with three genes in the human.⁴³ Two genes for activation FcRs, FcyRIIA and C, are found in the human and not rodents, which is notable because of their unusual single-chain activation structure.⁶⁵ Both mice and human encode a gene referred to as FcyRIIIA, although recent studies have identified a novel mouse FcR with higher homology to the human FcyRIIIA called FcyRIV.^{31,64,66} As mentioned previously, FcyRIIIB is unique among FcRs in being expressed as a GPI-anchored protein (see Fig. 24.3). Its expression is limited to human neutrophils, in comparison with FcyRIIIA, which is expressed widely on cells of the myeloid lineage, such as macrophages, NK cells, mast cells, and DCs. Finally, both mice and humans have only a single gene encoding the inhibitory FcyRIIB molecule. Among the noncanonical FcRs, the lectin DC-SIGN is the functional homologue of the murine SIGN-R1 molecule with respect to its ability to bind sialylated IgG Fc and mediate an antiinflammatory response.^{67,68} While the overall structure of these proteins are similar (see Fig. 24.3), their patterns of expression are quite distinct. SIGN-R1 expression is restricted to marginal zone macrophages of the spleen and lymph node, whereas DC-SIGN expression is seen on myeloid DCs and macrophages in a variety of tissues, including spleen, bone marrow, and lymph node.⁶⁹

The genes for the IgE FcR are conserved in mice and humans. The difference that is observed relates to the requirement for the β chain to achieve surface expression in mice, precluding the expression of the $\alpha\gamma_2$ complex.²⁴ In humans, this form of the receptor is widely expressed on monocytes, Langerhans cells, and DCs, and is likely to be found on mast cells and basophils as well. This difference in Fc*e*RI subunit composition is likely to result in functional differences as well. Although these specific interspecies differences are important, the fundamental organization of the canonical FcR system, with activation and inhibitory signaling through a shared ligand specificity coupled to opposing signaling pathways, is well conserved, as is the role of the noncanonical FcRs in mediating the immunomodulatory functions of sialylated IgG. Thus, conclusions regarding the function of this expanded FcR system in immunity by the analysis of murine models are relevant to an understanding of the role of these receptors to human immunity as well.

Expression

Canonical FcRs are expressed widely on cells of the myeloid lineage, including monocytes, macrophages, DCs, mast cells, basophils, neutrophils, eosinophils, and NK cells.^{17,33} In addition, B cells and follicular DCs (FDCs) express the inhibitory FcyRIIB receptor, whereas T cells are generally negative for FcyR expression, but may express the Fc-receptor for IgM. Interestingly, the majority of FCRL proteins are expressed during varying stages of B-cell development. Despite their homology to the canonical FcRs, however, the FCRL proteins seem not to bind to Igs, rendering FcyRIIB the only IgG binding FcR on B cells. The specific expression pattern for each FcR varies, and these patterns are summarized in Figure 24.1. Because canonical FcRs represent a balanced system of activation and inhibition, the general rule of coexpression of FcRs of these classes is maintained. B cells use the B-cell antigen receptor as the activation coreceptor for FcyRIIB, whereas NK cells appear to utilize NK inhibitory receptors to modulate $Fc\gamma$ RIIIA activation. The decoy Fc γ R, Fc γ RIIIB, is expressed exclusively on human neutrophils, on which it functions to concentrate and focus ICs without directly triggering cell activation, perhaps also playing role in neutrophil recruitment.⁷⁰ The Fc yRIIA-Fc yRIIB pair functions on neutrophils to modulate IC activation. Fc ε RI can be modulated by Fc γ RIIB, as demonstrated both in vitro and in vivo; mice deficient in $Fc\gamma$ RIIB display enhanced IgE-triggered anaphylaxis⁷¹ by virtue of the ability of IgE to bind with high affinity to Fc ERI and with low affinity for $Fc\gamma RIIB$. Other mast cell inhibitory receptors, such as glycoprotein 49B1, modulate mast cell sensitivity to IgE: mice deficient in this molecule display enhanced anaphylactic responses to IgE stimulation.⁷² Expression of the common γ chain is broad: it has been found on all myeloid and lymphoid cells examined to date. In contrast, the β chain appears to be quite restricted in its expression: it has been found only on mast cells and basophils.

Regulation of canonical FcR expression can occur at several levels. In general, cytokines involved in activation of inflammatory responses induce expression of activation Fc γ Rs, whereas inhibitory cytokines downregulate these activation receptors. Transcriptional regulation of α chain levels has been documented for a variety of cytokines, including

interferon- γ interleukin (IL)-4, and transforming growth factor β .^{73,74} In addition, complement component C5a binding to its receptor, C5aR, results in the induction of expression of activation FcyRs.⁷⁵ Induction of Fc yRI, Fc yRIIA, and Fc γ RIIIA α and γ chains in myeloid cells occurs upon interferon- γ treatment: IL-4 generally inhibits expression of these activation receptors but induces expression of the inhibitory Fc yRIIB. Administration of intravenous gamma globulin, a widely used treatment for inflammatory diseases, has been shown to induce expression of the inhibitory FcyRIIB on effector macrophages and B cells in mice and humans.^{59,76-78} This induction is not direct but mediated through other, noncanonical FcR pathways including molecules such as SIGNR1 and its human orthologe DC-SIGN (see Fig. 24.7). Engagement of these receptors by sialylated IgG results in an intrinsic Th2 pathway, ultimately leading to the expression of IL-4, which induces FcRIIB expression on inflammatory macrophages.^{67,68,79,80} The situation in B cells is likely to be more complex, whereby regulation of Fc ?RIIB is critical for the maintenance of peripheral tolerance. Germinal center B cells downregulate Fc yRIIB, perhaps in response to IL-4 production by T cells. Regulation of FcR expression has also been documented to occur upon binding of ligand. IgE regulates the expression of Fc ERI by stabilizing the intracellular pool of receptor upon receptor engagement.⁸¹ Thus, high IgE levels result in the induction of surface expression of $Fc \in RI$. However, this same mechanism of regulation is not seen for $Fc\gamma Rs$: mice deficient in IgG have $Fc\gamma R$ levels comparable with those of wild-type animals. Competition for limiting subunits also contributes to regulation of receptor expression. In mast cells, it appears that the level of γ chain is limiting. Competition between α chains for the limiting concentration of γ chain has been documented in mouse knockouts, whereby levels of one receptor increase if the α chain of the other receptor is reduced.⁸² This type of reciprocal regulation has recently also been observed for FcyRs in neutrophils and is likely to be significant in the cross-regulation of FcRs by different isotypes of Ig.83

Three-Dimensional Structure

The crystal structures of Fc yRIIA, Fc yRIIB, Fc yRIIIA, and Fc ERI have been solved, as have the cocrystals of Fc PRIIIA-IgG1 Fc and Fc *E*RI–IgE Fc⁸⁴ (Fig. 24.4). These studies demonstrate that the receptors have a common structure in which the two extracellular Ig domains fold in a strongly bent overall structure, arranged into a heart-shaped domain structure. A 1:1 stoichiometry between the receptor and ligand is observed, with the receptor inserted into the cleft formed by the two chains of the Fc fragment (C γ 2 or $C\varepsilon$ 3). The binding region of the FcR to Fc fragments consists mainly of rather flexible loops that rearrange upon complex formation. Only domain 2 and the linker region connecting domains 1 and 2 interact in the complex with different regions of both chains of the Fc. Conserved tryptophans located on the FcRs interact with proline to form a "proline sandwich." A solvent-exposed hydrophobic residue at position 155 is conserved among all FcRs and represents a binding site for the important IgG1 residue Leu 235 (not

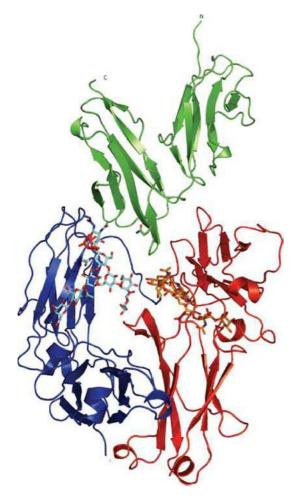

FIG. 24.4. Ribbon Diagram of Crystallizable Fragment (Fc) Receptor III–Immunoglobulin (IG)G1 Fc Structure. found in IgE). Specificity is generated among the receptorligand pairs in a variable region connecting the two extracellular domains that is in contact with the lower hinge region of the Fc fragment (residues 234 to 238), a region not conserved among the IgGs and IgE. The binding region of FcRs to their Ig ligands does not overlap with other Fc binding molecules such as protein A, protein G, and FcRn.

The structure of the FcR bound to its ligand reveal that the antigen-binding fragment (Fab) arms are quite sharply bent and may adopt a perpendicular orientation toward the Fc. This arrangement would give the Fab arms maximal flexibility to bind antigen when the Fc fragment is oriented parallel to the membrane of the FcR-expressing cell. The asymmetrical interaction of the two Fc chains with a single FcR prevents a single antibody molecule from triggering dimerization of receptors and initiating signaling. Instead, dimerization is initiated by the interaction of antigen with the Fab arms, thus linking adaptive responses to effector cell triggering. Of note, the majority of the IgG-Fc γ R cocrystals have been generated with

FcγRs produced in bacteria and therefore in an aglycosylated form. In general glycosylation at Asn 297 is critical for FcγR binding; modulation of FcγR binding by glycan modification has been observed for several classes of glycan modifications, including sialylation, fucosylation, and branching N-acetyl glucosamine.^{85,86} The first IgG-FcγR cocrystal structure with differentially glycosylated IgG variants demonstrated that carbohydrate-carbohydrate interactions between IgG and FcγR are essential for high-affinity recognition of afucosylated IgG glycovariants by FcγRIIIA.⁸⁷ In contrast, low-affinity binding of FcγRIIIA to fucosylated IgG is independent of these carbohydrate interactions. These novel insights may offer new ways of optimizing IgG-FcγR interactions for enhanced therapeutic activity of IgG.

IN VITRO ACTIVITY Binding Properties

As outlined in Figures 24.1 and 24.3, Ig binding to canonical FcRs falls into either high- or low-affinity binding classes. The high-affinity binding class is typified by $Fc \in RI$, with a binding affinity of 10¹⁰ M⁻¹ for IgE, which ensures a monomeric interaction between IgE and its receptor. Fc yRI binds with relatively high affinity for IgG1 and IgG3 (human) and IgG2a (mouse) with an affinity constant of 10⁸ M⁻¹. In contrast to these high-affinity FcRs, the low-affinity receptors, such as the human Fc yRIIA, Fc yRIIB, Fc yRIIIA, Fc yRIIIB, and FcoRI, and the mouse FcyRIIB, FcyRIII, and FcyRIV bind with affinities ranging from 5×10^5 M⁻¹ (Fc γ RIII) to 5×10^7 M⁻¹. This low-affinity binding ensures that these receptors interact with ICs and not monomeric ligands. As described subsequently, this dependence on high-avidity and low-affinity interactions ensures that these receptors are activated only by physiologically relevant ICs and not by circulating monomeric Ig, thus avoiding inappropriate activation of effector responses. In general, low-affinity $Fc\gamma Rs$ bind IgG1 and IgG3 preferentially; their binding to IgG2 and IgG4 is of even lower affinity. As mentioned previously, polymorphisms in FcyRIIA and FcyRIIIA affect binding to IgG2 and IgG1, respectively, which may have significance in vivo in predicting responses to specific cytotoxic antibodies (Table 24.1). The isolated consideration of the affinity of antibody isotypes to their activating FcyRs is not sufficient, however, to explain the differences in in vivo activity. More importantly, the ratio of the affinities of an antibody isotype to the activating FcyRs compared to the inhibitory FcyRIIB (termed A/I-ratio) predicts antibody activity more consistently.^{20,64} Thus, antibody isotypes with a high A/I-ratio, such as mouse IgG2a and IgG2b, will show a greater activity than counterparts with a lower ratio (see Table 24.1). The sugar moiety of the antibody Fc-portion is essential for FcR binding and the presence or absence of certain sugar residues can significantly impact on antibody-FcR binding.20,80,88,89 The absence of fucose, for example, will selectively increase the affinity of human IgG1 or mouse IgG2b for human FcyRIIIa or mouse FcyRIV, respectively. In contrast, the presence of terminal sialic acid on the N-linked Fc glycan reduces affinities for FcRs by an order of magnitude with a concomitant reduction in in vivo activity.⁸⁰ Subunit interactions have also

been reported to influence affinity for ligand, as demonstrated for the common γ chain associating with Fc γ RIIIA.⁹⁰ Its affinity for IgG1 is higher than the GPI-anchored form of this receptor, Fc γ RIIIB.

The crystal structures of IgG1-Fc PRIIIA and IgE-Fc RI reveal similarities in the binding properties of these two complexes. Of significance is the 1:1 stoichiometry of the complexes, which ensures that a single receptor binds to a single immunoglobulin molecule.^{15,16} This property in turn ensures that activation occurs upon cross-linking of receptor complexes by multivalent ligands. Two binding sites on the receptor interact asymmetrically with two sites on the Fc molecule. The FcR inserts into the cleft formed by the two chains of the Fc molecule, burying a binding surface of 895 Å for each binding site. Alterations in the Fc structure that reduce the cleft, such as deglycosylation of IgG, inhibit FcR binding. Four distinct regions have been defined in the Fc domains involved in FcR interactions. For IgE, this includes residues 334 to 336, 362 to 365, 393 to 396, and 424. The homologous regions for IgG are residues 234 to 239, 265 to 269, 297 to 299, and 327 to 332. Interactions of these residues occur with the carboxy-terminal domain 2 of the respective FcRs. In view of the similarities of these complexes and the homologies among the receptors and their ligands, an obvious question that arises concerns the molecular basis for specificity. Attempts to resolve that question have relied on mutagenesis studies of the ligands and domain exchanges between receptors. For example, exchange of the FG loop in domain 2 of $Fc \varepsilon$ to $Fc \gamma$ receptors confers detectable IgE binding; similarly, variation in this loop in Fc γ Rs may provide interactions that determine IgG specificity for these receptors. Mutagenesis of IgG1 revealed that a common set of residues is involved in binding to all Fc yRs, but Fc yRII and Fc yRIII also utilize distinct residues.⁹¹ Several IgG1 residues not found at the IgG–FcR interface by crystallographic determination had a profound effect on binding, which indicates the greater complexity of these interactions in solution.

The implications of these structural studies are that the Fc domain of IgG may be selectively mutated to direct its binding to specific Fc γ Rs. Fc mutants that selectively engage activation Fc γ Rs (IIIA and IIA) while minimally interacting with inhibitory and decoy Fc γ Rs (IIB and IIIB) would confer optimal cytotoxic potential for tumoricidal applications. Indications that such Fc engineering is possible are suggested by IgG mutants with selective binding to Fc γ RII.

Effector Cell Activation

The critical step in triggering effector cell response by canonical FcRs is mediated by the cross-linking of these receptors by Ig. This can occur either by interactions of low-affinity, high-avidity IgG ICs or of IgG opsonized cells with activation $Fc\gamma Rs$ or by the cross-linking of monomeric IgG or IgE bound to $Fc \gamma RI$ or $Fc \varepsilon R$, respectively, by multivalent antigens binding to the Fab of the antibody. Crosslinking of ITAM-bearing FcRs results in common cellular responses, determined by the cell type, rather than the FcR. Thus, for example, Fc ERI or Fc PRIII cross-linking of mast cells results in degranulation of these cells, whereas crosslinking of macrophage expressed $Fc \alpha RI$ or $Fc \gamma RIII$ by opsonized cells triggers phagocytosis. These functions underlie the functional similarity of activation FcRs in which crosslinking mediates cellular responses by ITAM-mediated tyrosine kinase cascades. In addition to degranulation and phagocytosis, activation FcR cross-linking has been demonstrated to induce ADCC, the oxidative burst, and the release of cytokines and other inflammatory cell mediators. A sustained calcium influx is associated with these functions, as is transcription of genes associated with the activated state.

Cellular activation initiated by ITAM-bearing activation FcRs can be enhanced by coengagement with integrin and complement receptors. Although the ability of these receptors to mediate phagocytosis, for example, are modest, synergistic interactions with FcRs result in sustained activation and enhancement. Synergistic interactions between activation FcRs and toll receptors, mannose receptors, and other pattern-recognition molecules have also been reported in vitro and suggest that interplay between the innate and adaptive effector mechanisms of an immune response are involved in mediating efficient protection from microbial pathogens.

In contrast to the activation of effector cell responses triggered by cross-linking of ITAM-bearing FcRs in vitro, cross-linking of an ITIM-bearing inhibitory receptor to an ITAM-bearing receptor results in the arrest of these effector responses. Homoaggregation of Fc γ RIIB by its crosslinking on effector cells by ICs does not result in cellular responses; rather, it is the coengagement of ITAM- and ITIM-bearing receptors that results in the functional generation of an inhibitory signal. In vitro, it is possible to ligate any ITAM-bearing receptor to any ITIM-bearing receptor with a resulting inhibitory response. This activity is used functionally to define putative ITIMs and has proved to be a useful device in dissecting the signaling pathways induced by ITAM-ITIM coligation.

B-Lymphocyte Suppression

B-cell stimulation through the B-cell antigen receptor can be arrested by the coligation of Fc rRIIB to the B-cell receptor (BCR). This occurs naturally when ICs, retained on FDCs in the germinal center, interact with both the BCR and Fc γ RIIB during the affinity maturation of an antibody response. In vitro suppression of B-cell activation has been demonstrated by coligation of BCR and Fc ?RIIB, resulting in arrest of calcium influx and proliferative responses triggered by the BCR,^{25,95} the result of recruitment of the SH2-containing inositol 5'-phosphatase (SHIP)-1.96 Calcium release from the endoplasmic reticulum is not affected, and there is thus an initial rise in intracellular calcium; however, this calcium flux is not sustained, because SHIP recruitment blocks calcium influx by uncoupling of the capacitance channel. Homoaggregation of Fc yRIIB by ICs can trigger apoptosis in B cells, as demonstrated in the DT40 B-cell line and in murine splenocyte preparations.⁹⁷ This activity is retained in ITIM mutants and is dependent on the transmembrane sequence of Fc PRIIB. Consistent with this, other studies showed that a SHIPindependent but BTK-, JNK1-, and cABL-dependent pathway is involved in induction of apoptosis upon FcyRIIB homoaggregation.⁹⁸ The potent inhibitory effect of FcyRIIB on B-cell activation has recently been used therapeutically to suppress autoantibody production by B cells. By engineering the Fcfragment of CD19-specific antibodies to have increased affinity to FcyRIIB, resulting in an enhanced coengagment of the inhibitory FcyRIIB with the BCR signaling complex, it was possible to suppress humoral immunity in mice and to shut down autoantibody production by B cells.94 In contrast to mature B cells, which coexpress the BCR and FcyRIIB, plasma cells responsible for high-level antibody production downregulate BCR expression but maintain FcyRIIB expression. It was suggested that crossliniking of FcyRIIB by ICs on bone marrow plasma cells might be involved in inducing apoptosis in a fraction of plasma cells thereby creating niches for newly generated plasma cells during exposure to a new antigenic stimulus.⁹⁹

SIGNALING

Immunoreceptor Tyrosine-Based Activation Motif Pathways

The general features of signal transduction through ITAM receptors are conserved among all members of this family, including T-cell receptors, BCRs, and various FcRs. The 19 amino acid-conserved ITAM is necessary and sufficient to generate an activation response, as demonstrated by the analysis of chimeric receptors. With a single exception, FcRs associate with accessory subunits that contain these signaling motifs. As described previously, the common γ chain contains an ITAM and is associated with $Fc \in RI$, $Fc \neq RI$, $Fc \neq RIII$, $Fc\gamma RIV$, and $Fc\alpha RI$. In addition, both $Fc\epsilon RI$ and $Fc\gamma RIII$ may associate with the β subunit in mast cells. The ITAM found in the β chain does not function as an autonomous activation cassette, as has been found for most other ITAMs. Rather, it functions to amplify the activation response generated by the γ chain ITAM by increasing the local concentration of Lyn available for activation upon aggregation of the receptor.⁴⁰ Fc γ RIIA contains an ITAM in the cytoplasmic domain of its ligand recognition α subunit and is thus able to activate in the absence of any associated subunit.

Upon sustained receptor aggregation, Src family kinases that may be associated with the receptor in an inactive form become activated and rapidly tyrosine-phosphorylate the ITAM sequences, creating SH2 sites for the docking and subsequent activation of Syk kinases. Ligands that rapidly dissociate from their receptors result in nonproductive signaling complexes that fail to couple to downstream events and behave as antagonists.¹⁰⁰ The specific Src kinase involved for each FcR depends on the receptor and cell type in which it is studied. Thus, Lyn is associated with the Fc ε RI pathway in mast cells, Lck is associated with FcyRIIIA in NK cells, and both of these kinases as well as Hck are associated with Fc yRI and Fc yRIIA in macrophages. After activation of the Src kinase, tyrosine phosphorylation of the ITAM motif rapidly ensues, leading to the recruitment and activation of Syk kinases. This two-step process is absolutely necessary to transduce the aggregation signal to a sustainable intracellular response. Once activated, Syk kinases lead to the phosphorylation or recruitment of a variety of intracellular substrates, including PI3K, Btk and other Tec family kinases, phospholipase C- γ (PLC γ), and adaptor proteins such as SLP-76 and BLNK. The Ras pathway is also activated through Sos bound to Grb2 that is recruited upon phosphorylation of Shc. Ras phosphorylates Raf, which in turn leads to MEK kinase and MAP kinase activation. A summary of these intracellular pathways is shown in Figure 24.5A. A crucial step in this sequential activation cascade occurs with the activation of PI3K by Syk. By generating phosphatidyl inositol polyphosphates, such as PIP₃, PI3K leads to the recruitment of pleckstrin homology (PH) domain-expressing proteins such as Btk and PLCy which in turn leads to the

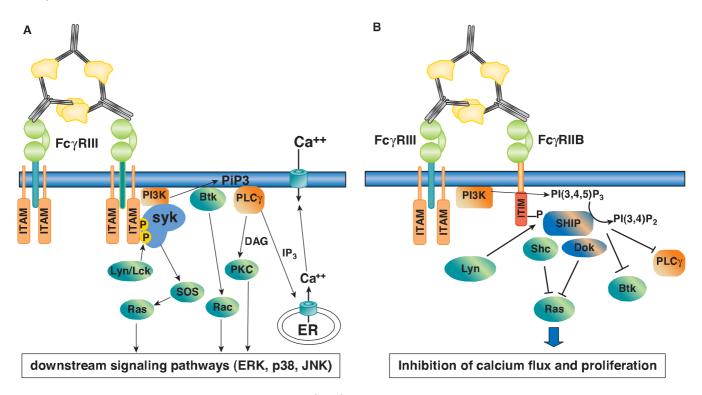

FIG. 24.5. Signaling by Activation and Inhibitory Fc Receptors (FcRs). A: FcγRIII signaling in natural killer cells is shown as an example of the activation class of FcRs. Cross-linking by an immune complex initiates the signaling cascade. The specific Src family kinase varies, depending on the cell type. B: FcR signaling in macrophages is shown as an example of simultaneous triggering of activation and inhibitory FcRs.

generation of inositol triphosphate and diacylglycerol, intermediates crucial to the mobilization of intracellular calcium and activation of protein kinase C, respectively.

Immunoreceptor Tyrosine-Based Inhibitory Motif Pathways

The inhibitory motif, embedded in the cytoplasmic domain of the single-chain $Fc\gamma$ RIIB molecule, was defined as a 13 amino acid sequence AENTITYSLLKHP, shown to be both necessary and sufficient to mediate the inhibition of BCR-generated calcium mobilization and cellular proliferation.^{25,26} Significantly, phosphorylation of the tyrosine of this motif was shown to occur upon BCR coligation and was required for its inhibitory activity. This modification generated an SH2 recognition domain that is the binding site for the inhibitory signaling molecule SHIP.96,101 In addition to its expression on B cells, where it is the only IgG FcR, Fc γ RIIB is widely expressed on macrophages, neutrophils, mast cells, DCs, and FDCs, absent only from T and NK cells. Studies on $Fc \gamma RIIB$ provided the impetus to identify similar sequences in other surface molecules that mediated cellular inhibition and resulted in the description of the ITIM, a general feature of inhibitory receptors.

Fc γ RIIB displays multiple inhibitory activities. Coengagement of Fc γ RIIB to an ITAM-containing receptor leads to tyrosine phosphorylation of the ITIM by the Lyn kinase, recruitment of SHIP, and the inhibition of ITAMtriggered calcium mobilization and cellular proliferation (see Fig. 24.5B).^{96,102,103} These two activities result from

different signaling pathways; calcium inhibition requires the phosphatase activity of SHIP to hydrolyze PIP₃ and the ensuing dissociation of PH domain-containing proteins such as Btk and PLC χ^{104} The net effect is to block calcium influx and prevent sustained calcium signaling. Calciumdependent processes such as degranulation, phagocytosis, ADCC, cytokine release, and proinflammatory activation are all blocked. Arrest of proliferation in B cells is also dependent on the ITIM pathway, through the activation of the adaptor protein Dok and subsequent inactivation of MAP kinases.^{105,106} The role of SHIP in this process has not been fully defined, inasmuch as it can affect proliferation in several ways. SHIP, through its catalytic phosphatase domain, can prevent activation of the PH domain survival factor Akt by hydrolysis of PIP₃.^{107,108} SHIP also contains phosphotyrosine-binding domains that could act to recruit Dok to the membrane and provide access to the Lyn kinase that is involved in its activation. Dok-deficient B cells are unable to mediate FcyRIIB-triggered arrest of BCR-induced proliferation, while retaining their ability to inhibit a calcium influx, which demonstrates the dissociation of these two ITIM-dependent pathways.

Another inhibitory activity displayed by $Fc\gamma RIIB$ is independent of the ITIM sequence and is displayed upon homoaggregation of the receptor. Under these conditions of $Fc\gamma RIIB$ clustering, a proapoptotic signal is generated through the transmembrane sequence. This proapoptotic signal is blocked by recruitment of SHIP, which occurs upon coligation of $Fc\gamma RIIB$ to the BCR, because of the Btk requirement for this apoptotic pathway.⁹⁷ This novel activity has been reported only in B cells and has been proposed to act as a means of maintaining peripheral tolerance for B cells that have undergone somatic hypermutation. The in vivo relevance of this pathway remains to be proven.

IN VIVO FUNCTIONS

Fc γ Receptors in the Afferent Response

The ability of IgG ICs to influence the afferent response has been known since the 1950s and can be either enhancing or suppressive, depending on the precise combination of antibody and antigen and the mode of administration.¹⁰⁹ Investigators have attempted to define the molecular mechanisms behind these activities with the availability of defined mouse strains with mutations in activation or inhibitory FcRs and through the use of specific blocking antibodies to individual receptors. Direct effects on B cells stem from the ability of the inhibitory $Fc\gamma$ RIIB molecule to influence the state of B-cell activation and survival. Because antigen is retained in the form of ICs on FDCs, it can interact with B cells by coengaging Fc γ RIIB with BCR, modulating the activation state of the cell. Mice deficient in this inhibitory receptor develop anti-deoxyribonucleic acid (DNA) and antichromatin antibodies and die of a fatal, autoimmune glomerulonephritis at 8 months of age. The phenotype is strain dependent and is not seen in BALB/c or 129 strains of mice.¹¹⁰ Combining Fc PRIIB deficiency with defects in other inhibitory receptor pathways, such as PD-1, results in autoantibodies with different specifities and distinct pathological presentation. Thus, PD-1-deficient Balb/c mice develop cardiomyopathy resulting from anticardiac myosin antibodies. PD-1/FcyRIIB double deficient BALB/c mice develop antiuroepithelial antibodies and hydronephrosis.¹¹¹ FcyRIIB thus acts as a modifier of autoimmune disease, a conclusion further supported by studies that determined the contribution of the C57BL/6 background to the spontaneous lupus-like disease observed in those mice. The B6 background, by virtue of an incomplete light chain editing pathway, provides a source of autoreactive B cells in the periphery, which, when combined with defects in the inhibitory $Fc\gamma$ RIIB pathway, leads to the accumulation of autoantibodies, pathogenic ICs, and disease.¹¹² Further support for this conclusion is provided by the observations that autoimmune disease-prone strains of mice, such as New Zealand black (NZB), BXSB, SB/Le, MRL, and nonobese diabetic, have reduced surface expression of Fc yRIIB on activated B cells, attributed to DNA polymorphisms in the promoter region of the gene encoding this receptor.^{113,114} This reduced expression of Fc γ RIIB is thus suggested to contribute to the increased susceptibility of these animals to the development of autoantibodies and autoimmune disease. Direct evidence that this is indeed the case comes from studies where FcyRIIB expression levels have been restored by retrovirus-mediated gene transfer in BXSB, NZM, and FcyRIIB knockout animals. These mice had dramatically reduced levels of autoreactive antibodies and were protected from the development of fatal autoimmune disease.⁶⁰ Consistent with these results obtained in mouse model systems, human patients with SLE and CIDP were demonstrated to have a reduced FcyRIIB expression level on B cells.58,59

Moreover, if Fc yRIIB indeed functions in vivo to maintain peripheral tolerance, then its loss should allow for the emergence of autoantibodies when otherwise resistant animals are challenged with potentially crossreactive antigens. This hypothesis has been validated in models of collagen-induced arthritis and Goodpasture syndrome. Fc γ RIIB-deficient mice, with the nonpermissive H-2^b haplotype, develop arthritis when immunized with bovine type II collagen.¹¹⁵ The loss of $Fc \gamma RIIB$ thus bypasses the requirement for the specific H-2^q and H-2^r alleles previously demonstrated to be necessary in this model by allowing Fc yRIIB-deficient autoreactive B-cell clones to expand and produce pathogenic autoantibodies. When the permissive DBA/1 strain (H-2^q) is made deficient in Fc γ RIIB, autoantibody development is augmented and disease is greatly enhanced. In a similar manner, immunization of H-2^b mice deficient in Fc₂RIIB with bovine type IV collagen results in crossreactive autoantibodies to murine type IV collagen, with dramatic pathogenic effects.^{115,116} These mice develop hemorrhagic lung disease and glomerulonephritis with a "ribbon deposition" pattern of ICs in the glomeruli. These characteristics are indicative of Goodpasture syndrome, a human disease not previously modeled in an animal species.

Expression of the inhibitory $Fc\gamma RIIB$ on B cells thus provides a mechanism for the suppressive effects of ICs on antibody production. Although $Fc\gamma RIIB$ is expressed throughout peripheral B-cell development, recent data suggest that it represents a late checkpoint controlling the expansion of autoreactive IgG-positive plasma cells. In contrast, deficiency of the inhibitory receptor did not impact the generation of autoreactive IgM antibodies.¹¹² Taking the considerably higher pathogenic potential of IgG compared to IgM antibodies into account, this late stage of $Fc\gamma RIIB$ -mediated regulation seems to be sufficient to prevent severe autoreactive processes.

The enhancing property of ICs on the afferent response is likely to arise from the expression of FcRs on APCs, such as DCs.^{117–119} DCs express all three classes of IgG FcRs as well as $Fc \in RI$. Although in vitro studies have suggested that triggering of activation FcRs can induce DC maturation, the in vivo significance of this pathway has not been established.¹²⁰ The ability of FcRs, particularly $Fc\gamma RI$, to internalize ICs could provide a mechanism for enhanced presentation and augmented antibody responses, whereas the presence of the inhibitory $Fc \gamma RIIB$ molecule appears to reduce the enhancing effect. Mice deficient in Fc ?RIIB display enhanced antibody responses to soluble antibody-antigen complexes, in some cases dramatically so, which is likely to result from enhanced presentation.^{121,122} In addition, in vitro studies suggest that internalization through specific FcRs on APCs may influence the epitopes presented and T-cell response generated as a result. At present, a growing body of data suggests that FcRs are indeed involved in enhancement of the afferent response, by influencing antigen presentation and cognate T-cell interactions. FcyRIIB-deficient DCs pulsed ex vivo with antigen in the form of ICs induce a strong and protective cytotoxic immune response after transfer into naïve mice.¹²³ In contrast, wild-type DCs induce a much smaller and nonprotective response, indicating that the threshold set by co-crosslinking of the inhibitory and activating FcRs prevents complete DC maturation. Moreover, blocking of IC binding to FcyRIIB on human DCs with an FcyRIIB-specific antibody resulted in spontaneous maturation of the cells by ICs present in low amounts in human serum.^{124,125} Taken together, these data indicate that the inhibitory receptor is an important regulator of DC activation. As the DC maturation state will determine whether an activating or a tolerogenic signal will be delivered to T cells, FcRs might be important factors for the maintenance of peripheral tolerance in the cellular immune system. Transiently blocking FcyRIIB activity with monoclonal antibodies in vivo might thus be an interesting strategy to optimize immunotherapeutic and vaccination approaches. Further defining the precise role of each FcR expressed on APCs will require conditional knockouts of these molecules on specific DC populations to resolve the contribution of these systems to the generation of an appropriate antibody response.

Fc γ Receptors in the Efferent Response

The first canonical FcR knockout to be described was for the common activation subunit, the γ chain, which resulted in the loss of surface assembly and signaling of $Fc\gamma RI$, Fc γ RIII and Fc γ RIV as well as Fc ϵ RI (10). Mice deficient in the common γ chain were systematically studied in diverse models of inflammation and found to be unable to mediate IgG-triggered inflammatory responses for cytotoxic or IC reaction; attributed to low-affinity activation receptors, the high-affinity $Fc \gamma RI$ played a minimal role in the in vivo inflammatory response triggered by IgG.^{22,126–128} The results were further confirmed by comparisons of mice deficient or blocked for either FcyRI, FcyRIII, or FcyRIV.^{19,20,32,129} The loss of Fc ERI ablated IgE-mediated anaphylaxis; this was demonstrated independently by gene disruption in the α subunit of that receptor.¹¹ Subsequent studies on mice deficient in the inhibitory Fc ?RIIB molecule established the opposing action of this receptor, in which mice deficient in that receptor displayed enhanced B-cell responses, autoimmunity, and augmented IgG-mediated inflammation in a subclass and effector cell–dependent manner. 18,20,32,55,128 The general finding, which is discussed in detail subsequently, illustrates that IgGs initiate their effector responses in vivo through coengagement of activating and inhibitory FcRs. The physiological response is thus the net of the opposing activation and inhibitory signaling pathways that each receptor triggers and is determined by the level of expression of each receptor and the selective avidity of the IgG ligand (see Table 24.1). This also explains the longstanding observation that different IgG isotypes have a differential activity in vivo (Fig. 24.6A). The absence of a murine homolog for Fc α RI has precluded similar studies for that receptor. Studies on mice bearing a human transgene of $Fc \alpha RI$ suggest that this receptor is involved in IgA nephropathy (Berger disease).¹³⁰

Type I: Immediate Hypersensitivity

Both cutaneous and systemic models of passive anaphylaxis, induced by IgE, were studied in $FcR\gamma$ chain-deficient mice and were found to be absent, a finding fully consistent

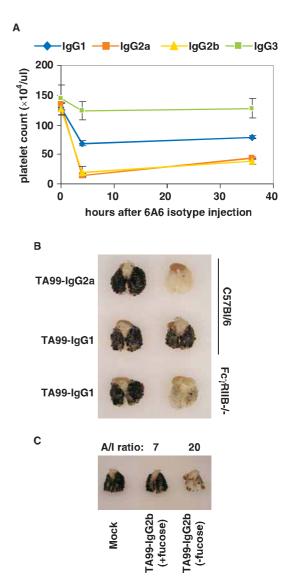

FIG. 24.6. Antibody Activity is Determined by Activating and Inhibitory Fc Receptors (FcRs). A: Mice were injected with the same amount of different 6A6 antibody isotypes, which recognize an integrin on mouse platelets and lead to FcR-dependent clearance of platelets from the blood as observed by the drop in platelet count after antibody injection. B: Wild-type or Fc γ RIIB knockout mice were injected intravenously with B16 melanoma cells on day 0 and with IgG1 and IgG2a isotype switch variants of the monoclonal antibody TA99 on alternate days. C: Mice were injected with antitumor antibodies containing or lacking branching fucose residues, thereby enhancing binding to activating FcRs and changing the A/I ratio (see text for details). Lungs were harvested on day 14. Adapted from Nimmerjahn and Ravetch,²⁰ with permission.

with the observations obtained in Fc ε RI-deficient mice and confirming the role of the high-affinity IgE receptor in mediating IgE-induced anaphylactic responses.^{10,11,40,131} Fc γ RIIB-deficient mice, challenged in this model, displayed an unexpected enhancement of IgE-mediated anaphylaxis, which suggests a physiological interaction between this inhibitory receptor and Fc ε RI.⁷¹ The molecular basis for this modulation of Fc ε RI signaling by Fc γ RIIB has not been determined, although previous studies have indicated that IgE can bind with low affinity to $Fc \gamma RII/Fc \gamma III$, which suggests that there exists a mechanism for coengagement of these receptors. Deletion of the mast cell inhibitory receptor glycoprotein 49B1 also results in enhanced IgE-induced anaphylaxis.⁷² In addition to $Fc \in RI$, mast cells also express the IgG FcyRIIB and FcyRIII, but not FcyRIV. Passive systemic anaphylaxis induced by IgG was attenuated in FcR γ chain-deficient and FcyRIII-deficient mice, which indicates the capacity of IgG and Fc γ RIII to mediate mast cell activation in vivo. Fc yRIIB-deficient mice displayed enhanced IgG-induced anaphylaxis. Active anaphylaxis, induced by immunization with antigen in alum, was enhanced in Fc ε RI-, Fc γ RIIB-, and glycoprotein 49B1–deficient mice and attenuated in FcR γ and Fc γ RIII-deficient mice. All these animals displayed antigen-specific antibodies for IgE and IgGs, which indicates that the active anaphylaxis seen was attributed primarily to IgG antibodies. The reason for the enhancement of anaphylactic responses in Fc ε RI-deficient animals resulted from the increased expression of $Fc\gamma RIII$ on mast cells in these mice, normally limited by competition of α chains for the available pool of the common γ chain.⁸² In the absence of Fc ε RI α chain, FcR γ chain is available to associate with Fc γ RIII α chain and assemble on the cell surface as a functional signaling receptor. A similar type of regulation was also described for expression of FcyRIII and FcyRIV on mouse neutrophils, where deletion of one receptor resulted in enhanced expression of the other γ-chain–dependent molecule.⁸³ These studies indicated the importance of the γ chain in regulating the level of surface expression of $Fc \in RI$ and $Fc \neq RIII$. Because γ chain is also associated with other members of the activation/inhibition paired receptors expressed on mast cells, such as PIR-A/PIR-B, the intracellular competition between these diverse α subunits and the common γ chain determines the level of surface expression of individual receptors and thus their ability to respond to specific biological stimuli. The absolute level of surface expression of FcRs on mast cells is clearly of therapeutic significance in both IgE- and IgG-mediated inflammatory responses; modulation of γ chain expression could thus represent a new therapeutic avenue for intervention in diseases such as anaphylaxis and asthma.

Type II Inflammation: Cytotoxic Immunoglobulin G

Cytotoxic IgGs are found in a variety of autoimmune disorders and have been developed for therapeutic indications in the treatment of infectious and neoplastic diseases. The mechanisms by which these antibodies trigger cytotoxicity in vivo have been investigated in FcR knockout mice. Anti-RBC antibodies trigger erythrophagocytosis of IgGopsonized RBCs in an FcR-dependent manner; γ chain– deficient mice were protected from the pathogenic effect of these antibodies, whereas complement C3–deficient mice were indistinguishable from wild-type animals in their ability to clear the targeted RBCs.^{132,133} Fc γ RIII plays the exclusive role in this process for the mouse IgG1 isotype. Murine IgG2a anti-RBC antibodies utilize primarily the Fc γ RIV receptor pathway despite the singular ability of murine IgG2a antibodies to bind as monomers to $Fc\gamma RI$. These and other studies suggest that the role of the high-affinity $Fc\gamma RI$ in IgG-mediated inflammation is likely to be restricted to augmenting the effector response (determined by $Fc\gamma RIII$ and IV) in situations that involve high concentrations of murine IgG2a antibodies which are found at localized inflammatory sites where $Fc\gamma RI$ expression is induced on recruited macrophages.

Experimental models of immune thrombocytopenic purpura (ITP) in which murine IgG1 antiplatelet antibodies trigger thrombocytopenia and yielded results similar to those of the anti-RBC studies cited previously. The specific FcyR involved depended on the subclass of antibody used. IgG1 antibodies mediated their activity exclusively through Fc γ RIII, while IgG2a and 2b were Fc γ RIV dependent. In contrast, FcyRI- or C3-deficient mice were fully susceptible to antibody-induced thrombocytopenia.^{20,31} Fc yRIIBdeficient mice showed an isotype-specific enhancement of antibody-mediated platelet depletion, with the strongest impact on IgG1 and much smaller increases for IgG2a and IgG2b isotypes. This is consistent with the affinities of these isotypes for their specific activating and the inhibitory receptor, which will determine antibody activity in vivo (see Table 24.1). In a passive protection model of Cryptococcus neoformans-induced disease, passive immunization with mouse IgG1, IgG2a, and IgG2b antibodies resulted in protection in wild-type animals but not in FcRychain-deficient animals.134

IgG antibodies raised to murine glomerular basement membrane preparations induce acute glomerulonephritis in a model of Goodpasture disease in wild-type but not FcR γ or Fc γ RIV-deficient animals.^{77,135,136} Fc γ RIIB-deficient animals displayed enhanced disease in this model, which indicates that the effector cells involved were constitutively expressing significant levels of Fc γ RIIB. Similar results were obtained when DBA/1 animals were immunized with bovine type II collagen to induce arthritis. Deficiency of FcR γ chain protected these mice from the pathogenic effects of the anticollagen antibodies that were generated.¹³⁷ As mentioned previously, deficiency of Fc γ RIIB in the DBA/1 collagen-induced arthritis model resulted in enhanced disease, through increased autoantibody production and elevated effector responses.

A dramatic example of the importance of these pathways in determining the in vivo activity of cytotoxic antibodies was obtained in models of antitumor antibody response. In a syngenic murine model of metastatic melanoma, a murine IgG2a antimelanocyte antibody was able to reduce tumor metastasis in wild-type animals but was ineffective in FcR γ or FcyRIV-deficient mice.^{20,83,138} In the absence of FcyRIIB, the activity of an IgG1 antibody, matched in its antigen binding domain, was enhanced, which indicates that the in vivo cytotoxic activity of the antibody was the net of activation and inhibitory receptor engagement^{20,55} (see Fig. 24.6B). These studies, together with similar studies performed with antiplatelet antibodies or defucosylated antibodies, demonstrated that the in vivo activity of a cytotoxic antibody could be predicted by a simple equilibrium binding model in which the ratio of the monomeric affinity constants for the activation and inhibitory Fc receptors (A/I ratio) are the dominant parameters, as demonstrated for T-cell receptormajor histocompability complex interactions.¹³⁹ An example for the enhanced cytotoxic activity of an antitumor antibody due to increased affinity for activating FcRs is shown in Figure 24.6C. The generation of an afucosylated antitumor antibody resulted in an increase of the A/I ratio of 7 to 20 for this IgG subclass, resulting in enhanced antitumor activity in vivo. Xenograft models of human tumors transplated into nude mice demonstrated, for a variety of tumors and cytotoxic antibodies, the requirement for FcR effector activity. For example, human breast carcinoma or lymphoma lines transplanted into nude mice and treated with either the humanized IgG1 or chimerized IgG1 antibodies (trastuzumab and rituximab), respectively, revealed that the ability of these antibodies to modulate tumor growth was abrogated in FcRy chain-deficient mice. A point mutation that eliminated FcR binding of the anti-Her2/neu murine IgG1 antibody 4D5 abolished the in vivo cytotoxic activity of the antibody against a human xenograft but did not affect the in vitro growth inhibitory activity; this again illustrates the difference between in vivo and in vitro mechanisms. Similar results were obtained for T-cell lymphoma xenograft models and anti-CD2 antibodies, among others.140,141 The general conclusions that can be drawn from these studies support a dominant role for the low-affinity activating Fc γ Rs in mediating cytotoxicity by IgG antibodies. Fc γ RIIB restricts the effector response for those antibodies with low A/I ratios and in situations in which the effector cell expresses this inhibitory molecule.

The relevance of these murine in vivo studies to the treatment of human populations with antitumor cytotoxic antibodies has been demonstrated in two studies that investigated the differential responses of patients treated with anti-CD20 (rituximab) for lymphoma.^{48,52} Both studies demonstrated a highly significant correlation between patient response, as measured by the time to relapse, and alleles of Fc γ RIIIA. In patients with an allele of this low-affinity activation receptor (158V) that confers higher binding affinity for human IgG1 Fc, improved outcome was observed, as compared to those with a lower binding allele of this receptor (158F). In addition, lymphoma patients with the high affinity allele showed a significantly better clinical response after receiving antiidiotype vaccination.⁵¹

Type III Responses: Immune Complex–Mediated Inflammation

The classic example of this reaction, the Arthus reaction, has been studied in a variety of FcR- and complement-deficient animals. The initial studies were performed by using the cutaneous reverse passive Arthus reaction, in which antibody was injected intradermally and antigen was given intravenously. An inflammatory response, characterized by edema, hemorrhage, and neutrophil infiltration, developed within 2 hours. This reaction was elicited in a variety of complement- and FcR-deficient animals. The results from several independent studies confirmed the initial observations: that IgG ICs triggered cutaneous inflammatory reactions even in the absence of complement but displayed an absolute

requirement for $Fc\gamma R$ activation.²² $Fc\gamma RIIB$ modulated the magnitude of the response, with enhanced Arthus reactions observed in Fc ?RIIB-deficient strains.18 The effector cell in the cutaneous reaction was determined to be the mast cell, as demonstrated by the use of mast cell-deficient strains and by mast cell reconstitution studies.¹³¹ The generality of this result was demonstrated in similar reactions performed in the lung, illustrating the FcR dependence and relative complement independence of this response.¹¹⁶ Thus, all studies have demonstrated an absolute dependence on FcR expression in the Arthus reaction. One model for IC-induced arthritis, the KRN/nonobese diabetic model, in which IgG1 anti-GPI antibodies are responsible for IC deposition in the synovium,¹⁴² has been shown to depend on both FcyRIII and C3 but not on components of the classical complement pathway, such as C1q and C4; transfer of serum to animals deleted for FcyRIII or C3 prevented the development of disease.^{143,144} Deficiency in the late components of complement, such as C5a or its receptor, have also been reported to result in a partial reduction in the magnitude of the response in IC-induced lung inflammation¹⁴⁵ and to result in a complete block in the KRN/nonobese diabetic arthritis model. The likely mechanism by which C5a exerts its effects is through upregulation of activating FcyRs, resulting in an amplification loop.⁷⁵ C5a is generated in this system as a result of FcR activation of effector cells and is independent of the classical, alternative, and mannan-binding protein pathways. Binding of C5a to the C5aR results in upregulation of activation receptors on these effector macrophages, thus augmenting the inflammatory response triggered by FcRs. These studies have led to a revision of the hypotheses about the mechanism of IC-mediated inflammation, typified by the Arthus reaction, in which there is an absolute requirement for activating Fc γ Rs in initiating mast cell activation by ICs. Fc γ R activation is, in turn, modulated by the inhibitory receptor Fc PRIIB. The A/I value of a specific IgG antibody and the densities of these opposing signaling receptors determines the concentration threshold for IC activation and the magnitude of the effector response that can be obtained. The classical pathway of complement activation is not required; however, C5a activation, through the FcyR pathway, may enhance the response under some circumstances through an amplifying loop. The release of inflammatory mediators such as vasoactive amines, chemokines, and cytokines leads to the hallmarks of this reaction: edema, hemorrhage, and neutrophil infiltration at the site of IC deposition.

The significance of the FcR pathway in initiating IC inflammation in autoimmune disease was further established by investigating a spontaneous murine model of lupus, the B/W F1 mouse. The Arthus reaction results predicted the absolute requirement of activation Fc γ R in initiating inflammation and tissue damage in IC diseases such as lupus. The FcR γ chain deletion was backcrossed onto the NZB and New Zealand white strains for eight generations, and the intercrossed progeny were segregated into B/W FcR γ -/– and FcR γ +/–. Anti-DNA antibodies and circulating ICs developed in all animals; IC and complement C3 deposition was similarly observed in all animals. However, mice deficient in the common γ chain showed no evidence of glomerulonephritis and had normal life expectancy, despite comparable levels of circulating ICs and glomerular deposition of these complexes along with complement C3. Mice heterozygous for the γ chain mutation were indistinguishable from B/W F1 animals with wild-type γ chains in developing glomerulonephritis and displaying reduced viability.¹²⁷ This spontaneous model supports the conclusions stated previously about the absolute requirement for FcyRIII in the activation of inflammatory disease by ICs: in the absence of this receptor, deposited ICs and C3 are not sufficient to trigger effector cell activation, which indicates that it is possible to uncouple pathogenic ICs from inflammatory disease by removing activating FcR engagement. Similar conclusions were reached in a murine model of Goodpasture disease where IC deposition, composed of mouse IgG2b antibodies, resulted in a fulminant glomerulonephritis.⁷⁷ Blocking the relevant activation FcR, FcyRIV, with a monoclonal antibody, protected the animals from fatal disease. These results further indicate that intervention in the effector stage of IC diseases, such as lupus and rheumatoid arthritis, would be accomplished by blocking activation $Fc\gamma Rs$ to prevent initiation of effector cell responses.

Immunoglobulin G–Dependent Neutralization and Induction of Agonistic Signaling

In contrast to these FcR-dependent activities, IgG molecules, by virtue of their exquisite specifity for discrete antigens, are expected to mediate FcyR-independent effects, such as neutralization of bacterial toxins or viruses. Here, IgG molecules would prevent the toxin or microorganism from binding to its cellular receptor, thereby protecting the host from the pathogenic effects of the infecting microbe. This picture changed, however, as it was demonstrated that both IgG-mediated toxin and virus neutralization can be dependent on cellular FcRs in vivo. Thus, neutralization of the anthrax toxin (called protective antigen component) by anti-protective antigen antibodies required FcR expression in vivo and anti-protective antigen antibodies that differed only by their Fc subclasses showed a hierarchy of protection with IgG2a and IgG2b antibodies affording a better protection than IgG1 antibodies, consistent with previous observation for cytotoxic IgG.^{146,147} Similar results were obtained for the mechanism of activity of neutralizing antibodies protecting from influenza or human immunodeficiency virus infection.^{148,149} These results suggest that current in vitro assays using only the pathogen-specific antibody, a target cell line might miss an important component required for antibody activity in vivo, and that novel assays including the FcR-dependent component might provide a better predictability of IgG activity.150

Beyond the central function of IgG in host defense, agonistic antibodies triggering signaling pathways in target cells are being evaluated for their therapeutic potential. For example, agonistic antibodies for tumor necrosis factor receptor family members such as anti-CD40 or anti-DR5 (drozitumab) are under evaluation for their ability to enhance tumor cell clearance by both direct and indirect mechanisms. Interestingly, the apoptosis inducing activity of anti-DR5 agonistic antibodies was found to be dependent on FcRs in vivo.¹⁵¹ A similar dependence on FcRs for in vivo activity was demonstrated for agonistic anti-Fas antibodies.¹⁵² A variety of CD40-specific agonistic antibodies have been used to deliver costimulatory signals to augment and sustain T-cell responses to result in tumor clearance.¹⁵¹ Recent studies showed that the inhibitory $Fc\gamma RIIB$ was essential for this agonistic activity and could not be replaced by activation $Fc\gamma Rs$.^{153,154} Although the exact mechanism of these FcR-dependent pathways remain to be established, these findings open the path toward generating improved agonistic anti-tumor necrosis factor receptor antibodies by Fc engineering. Consistent with this notion, a recent study showed that generating anti-CD40 antibodies with enhanced $Fc\gamma RIIB$ binding considerably augmented their in vivo adjuvant activity.¹⁵⁴

DISEASE ASSOCIATIONS Autoimmunity and Tolerance

In view of their functional capacity to link autoantibodies to effector cells, FcRs have naturally been considered to have a pathogenic role in the development of autoimmune diseases. Several studies have attempted to correlate specific polymorphisms in FcyRIIA, FcyRIIIA, or FcyRIIIB with incidence or severity of lupus or rheumatoid arthritis.¹⁵⁵ In view of the heterogeneity of these diseases, it is perhaps not surprising that inconsistent results have been obtained. Alleles that increase the ability of FcyRIIA to bind IgG2 or FcyRIIIA to bind IgG1 might be expected to correlate with disease severity in some populations. Indeed, these types of associations have been reported in some studies but not in others.¹⁵⁶ These variable results have often been explained as an indication that other genes may be in linkage disequilibrium with the FcR alleles under investigation. This is a plausible explanation when viewed in light of the autoimmunity susceptibility genes mapping in or near the region of the FcR genes, chromosome 1q21-24.157 This region of chromosome 1 has been implicated in a variety of human and murine linkage studies. For example, the Sle1 alleles derived from NZB flank the FcyRIIB gene and form a linkage group with the ability to break tolerance to nuclear antigens, resulting in production of antichromatin antibodies. Epistatic interactions between FcyRIIB and lupus susceptibility genes have been demonstrated in the murine lupus model of B6.RIIB. Crossing the yaa gene to this strain accelerates the development of disease; 50% survival is decreased from 8 months to 4 months, with 100% fatality by 8 months. This increase in severity correlates with a change in the specificity of the autoantibodies, from diffuse antinuclear antibodies to antibodies that stain with a punctate, nucleolar pattern on antinuclear antibody staining. Recently, it has been shown that the yaa susceptibility locus contains a duplication of the toll-like receptor 7 gene in the pseudoautosomal region of the y-chromosome (158). Moreover, toll-like receptor 7 and toll-like receptor 9 with their ability to recognize potential self-antigens such as ribonucleic acid or DNA, respectively, were shown to be important components in the generation of pathogenic autoreactive antibodies.^{159,160} Compared to other Yaa-independent SLE susceptibility loci, FcyRIIB may be a dominant factor for the development of autoantibodies

and the systemic activation of the immune system as demonstrated by a study using NZB/BXSB F1 animals congenic for the wild-type *fcgr2b* gene. In these mice, a dramatic reduction in the production of autoantibodies and immune cell activation was noted compared to mice with impaired $Fc\gamma$ RIIB expression.¹⁶¹ These data are consistent with studies that overexpressed $Fc\gamma$ RIIB in autoimmune-prone mouse strains resulting in suppression of autoantibody production.^{60,61}

Two types of polymorphisms in the Fc γ RIIB gene have been associated with SLE. Promoter polymorphisms have been described resulting in reduced expression of Fc γ RIIB on activated B cells in both mouse and human SLE and CIDP populations.^{59,113,162} In addition, a polymorphism in the transmembrane domain of Fc γ RIIB has been identified that is associated with susceptibility to SLE in Japanese populations. This polymorphism results in an Fc γ RIIB protein with reduced ability to enter lipid rafts and thus behaves as a hypomorphic allele for inhibitory function.¹⁶³

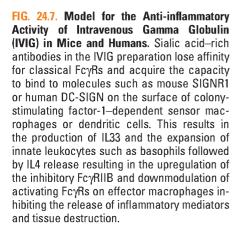

Together, these studies point to $Fc\gamma RIIB$ as a susceptibility factor in the development of autoimmunity with the ability to interact with other susceptibility factors to modify both the afferent and efferent limbs of the autoimmune response.

Inflammation

Antibody-mediated inflammatory diseases have been clearly demonstrated to involve the coupling of pathogenic autoantibodies or ICs to cellular FcRs. Therapeutics targeted to disrupt these interactions are in development, beginning with a monoclonal antibody to human IgE that functions to reduce IgE binding to its high-affinity receptor and thereby prevent allergic and anaphylactic reactions.¹⁶⁴ Because IgE is required for the survival of mast cells as well as in the regulation of Fc ERI expression, reduction in IgE has synergistic effects on the ligand, receptor, and effector cell. The success of this approach will undoubtedly lead to other approaches that target the receptor or its signaling pathway. Blocking $Fc \gamma RIIIA$ or IIA is expected to mimic the phenotype of FcRgamma-deficient animals in models of IgG-induced disease. Early attempts to use this approach in ITP were promising but limited by the crossreactivity to receptors on neutrophils, which led to neutropenia and the development of immune response to the murine antibody.¹⁶⁵ Development of second-generation anti-FcyRIIIA antibodies with greater specificity and reduced toxicity now appears to be a viable approach for the treatment of autoimmune diseases. Moreover, using small molecules to inhibit signaling molecules such as Syk seems to have promising effects in preventing autoantibody dependent platelet depletion in mice and humans.166

An alternative approach to limiting the activation of FcRs is to utilize the endogenous inhibitory pathway to abrogate IgE or IgG activation of their cognate receptors through coligation to Fc γ RIIB. This mechanism has been proposed to explain the ability to induce desensitization for the treatment of allergic diseases.^{33,167} Inducing production of IgG antibodies to an allergen may facilitate cross-linking of Fc γ RIIB to Fc ϵ RI. A similar approach involving anti-CD19 antibodies containing an engineered Fc-fragment with enhanced binding to FcyRIIB has been successfully used to shut down autoantibody production by human B cells in a xenograft mouse model system.¹⁶⁸ The ability to exploit the inhibitory pathway to reduce the activity of activation $Fc\gamma Rs$ has been demonstrated to account for some of the antiinflammatory activity associated with high-dose intravenous gamma globulin (IVIG), which consists of the pooled IgG fraction of serum from thousands of donors.⁷⁶ The use of IVIG for the treatment of ITP and other autoimmune diseases is well established, although the mechanism of action has been elusive. In murine models of ITP, arthritis, and nephritis, it has been demonstrated that protection by IVIG is dependent on the presence of FcyRIIB; deletion of FcyRIIB or blocking FcyRIIB by a monoclonal antibody eliminates the ability of IVIG to protect the animal against an inflammatory response.^{76,78,80} IVIG was demonstrated to lead to the in vivo induction of FcyRIIB on splenic effector macrophages, which would raise the threshold required for platelet clearance by activating FcyRs on these cells.^{20,31,78,83} A similar upregulation of the human inhibitory FcyRIIB was demonstrated in patients with CIDP receiving IVIG treatment as a first-line therapy.⁵⁹ Recently, it has become clear that the sialic acid-rich fraction of IgG antibodies in the IVIG preparation is responsible for the anti-inflammatory activity and FcyRIIB upregulation, enabling for the first time the generation of a recombinant IVIG replacement consisting of a sialic acid–rich IgG Fc fragment.^{79,80} Human and mouse sialic acid-rich IgG has a reduced affinity for classical FcRs and acquires the capacity to bind to SIGNR1 strongly expressed on mouse splenic marginal zone macrophages.^{68,80} By using SIGNR1-deficient mice expressing human DC-SIGN, it was demonstrated that human DC-SIGN expressed on macrophages or DCs can substitute for mouse SIGNR1 affording a candidate molecule essential for the anti-inflammatory activity of IVIG in humans.⁶⁷ Both molecules belong to the C-type lectin family and have been implicated in recognition of pathogenic microorganisms including human immunodeficiency virus and Mycobacterium tuberculosis.¹⁶⁹ Therefore, SIGNR1 and human DC-SIGN can be considered as noncanonical FcRs recognizing specific IgG glycovariants and, together with the family of toll-like receptors, provide a prime example for the dual usage of one molecule in the recognition of self- and non-self-ligands. Moreover, infusion of sialic acid-rich IgG resulted in an IL33-dependent expansion of basophils and IL4 production. IL4 is one of the interleukins known to upregulate FcyRIIB on innate immune effector cells, consistent with the upregulation of FcyRIIB noted in mouse model systems and humans. Together with previous data on the dependence of FcyRIIB upregulation on colony-stimulating factor-1-dependent macrophages, so called sensor macrophages, this suggests the following model for the anti-inflammatory activity of IVIG (Fig. 24.7). In this model, sialic acid-rich IVIG binds to mouse SIGNR1 or human DC-SIGN on sensor macrophages or DCs, which results in the production of IL33 that in turn leads to IL4 production by basophils, inducing the upregulation of FcyRIIB on effector macrophages, thereby raising the threshold for activation.⁶⁷ There is evidence that this

anti-inflammatory pathway triggered by IgG glycovariants rich in terminal sialic acid residues is of general importance for maintaining immune homeostasis. Thus, patients with rheumatoid arthritis and autoimmune-prone mouse strains have reduced levels of serum IgG-rich containing terminal sialic acid and galactose residues during active phases of the disease.^{170,171} A similar reduction of this anti-inflammatory IgG variant is observed during aging, consistent with an increased probability to develop autoimmune disease.¹⁷² This downmodulation of sialic acid-rich IgG was also observed during normal immunization conditions in mice, suggesting the general importance of this phenomenon during proinflammatory conditions.⁸⁰ The opposite type of regulation is seen in women with rheumatoid arthritis during pregnancy.¹⁷³ Parallelling the decreased frequency of arthritic flares an increased level of IgG glycoforms rich in terminal galactose and sialic acid residues was observed. In addition, inducing expression of FcyRIIB might be a clinically feasible approach and could be effective at modulating pathogenic autoantibodies from activation effector cell responses through activating FcRs.

Studies on the Fc α RI receptor have demonstrated a role for this molecule in the pathogenesis of IgA nephropathy, in which circulating macromolecular complexes are deposited in the mesangium, resulting in hematuria and eventually leading to renal failure. Soluble Fc α RI is found in the circulating IgA complexes, which suggests a role for the receptor in the formation of these pathogenic complexes. A transgenic mouse expressing Fc α RI spontaneously develops IgA nephropathy resulting from the interaction of polymeric mouse IgA and the human $Fc \alpha RI$ receptor to release soluble receptor–IgA complexes, which leads to deposition in the mesangium and the sequelae of IgA neuropathy.

CONCLUSION

Receptors for the Fc of immunoglobulins provide an essential link between the humoral and adaptive response, translating the specificity of antibody diversity into cellular responses. The canonical FcRs mediate their biological responses through the coupling of Fc recognition to ITAM-/ ITIM-based signaling motifs. A diverse array of biological responses depends on the FcR system, influencing both the afferent and efferent limbs of the immune response. Detailed biochemical, structural, and molecular biological data have provided a detailed understanding of how these receptors are regulated, are assembled, bind their ligand, and transduce specific cellular signals. FcRs play a significant role in vivo in maintaining peripheral tolerance by limiting the accumulation of autoreactive B cells that escape central tolerance checkpoints, such as light chain editing or potentially arise during somatic hypermutation in germinal centers, in modulating T-cell responses by regulating both antigen presentation and maturation by DCs, and in mediating the coupling of antigen recognition to effector-cell activation. They are the primary pathways by which pathogenic IgG and IgE antibodies trigger inflammatory responses in vivo. Allergic reactions, cytotoxic IgG responses, and IC-mediated inflammation are all critically dependent on FcR cross-linking and have resulted in a fundamental revision of the mechanisms underlying such classic immunological responses as the Arthus reaction. Blocking of these receptors uncouples the pathogenic potential of autoantibodies and represents an important new therapeutic target for the development of anti-inflammatory therapeutic agents. Central to the correct functioning of these responses is the balance that is maintained through the pairing of activation and inhibitory receptors that coengage the IgG ligand; perturbations in either component can result in pathological responses. The study of FcRs defined the ubiquitous inhibitory motif, the ITIM, and has provided a paradigm for how these pathways modulate ITAM-based activation responses. Studies in mice deficient in individual FcRs have provided the necessary insights for defining comparable activities in human autoimmune diseases and suggest ways in which manipulation of the IgG-FcR interaction may lead to new classes of therapeutics for the treatment of these diseases. Modulation of the inhibitory response, a novel activity associated with IVIG to account for some of its anti-inflammatory activity in vivo, represents a novel approach to the regulation of Igmediated inflammation and suggests that therapeutic agents based on those pathways are likely to be effective. It seems clear that this anti-inflammatory pathway is of general

importance for maintaining immune homeostasis, suggesting that IgG glycoforms rich in terminal sialic acid residues might be considered as a molecular switch either keeping the immune system in a resting state or, during infection or autoimmune responses, loosening the brakes thereby allowing full blown inflammation. In this pathway, noncanonical FcRs including SignR1 and human DC-SIGN recognizing specific IgG glycoforms are of central importance. Conversely, engineering of therapeutic antibodies targeted to eliminate infectious or neoplastic disease will probably benefit from optimization of their Fc domains for interaction with specific canonical FcRs.

Type I Cytokines and Interferons, and Their Receptors

Warren J. Leonard

OVERVIEW AND ISSUES OF NOMENCLATURE

CHAPTER

Cytokines are proteins that are secreted by cells and transduce signals via specific cell surface receptors on either the cytokine-producing cell (autocrine actions) or on other target cells (paracrine actions). From this operational type of description, it is clear that the distinction between cytokines, growth factors, and hormones may be imprecise. In general, cytokines and growth factors are similar, except that the term cytokine most often refers to molecules involved in host defense that have actions on leukocytes, whereas the term growth factor more often refers to molecules acting on other somatic cell types. Cytokines most often act locally. For example, in the interaction between a T cell and an antigen-presenting cell, cytokines are produced and usually exert potent actions locally, with rather limited biologic halflives in the circulation. In contrast, hormones are released and then disseminated via the bloodstream throughout the body, with actions on distal target organs. Nevertheless, this distinction between cytokines and hormones is not absolute, with certain cytokines acting at longer distances as well.

In the immune system, terms such as monokines and lymphokines were originally devised to identify the cellular source for cytokines.¹ Specifically, monokines included molecules such as interleukin (IL)-1, which was first recognized to be produced by monocytes, and lymphokines included molecules such as IL-2, which was first described as a T-cell growth factor produced by T lymphocytes. The monokine/ lymphokine nomenclature can be problematic; however, when a cytokine is synthesized by more than one type of cell. This resulted in the adoption of the term cytokine, as proposed by Stanley Cohen in 1974.^{2,3} The term cytokine refers to a protein made by a cell ("cyto") that acts ("kine") on target cells. Cytokines can have very broad ranges of actions, including on cell development, differentiation, growth, cytolytic activity of effector cells, survival, apoptosis, and chemotaxis.

Many cytokines are referred to as *interleukins* to indicate molecules that are produced by one leukocyte and act on another.⁴ However, this term is also problematic as some interleukins (eg, IL-1 and IL-6) are additionally produced by cells other than leukocytes and/or exert actions on cell types beyond the immune system. For example, IL-7 is produced by stromal and epithelial cells rather than by typical leukocytes. Furthermore, nomenclature can be inconsistent. For example, IL-7 is highly related to another cytokine that is denoted as thymic stromal lymphopoietin (TSLP) rather than as an interleukin (see section on IL-7 and Thymic Stromal Lymphopoietin), even though both can be produced by stromal and epithelial cells and share a receptor component as well as select actions on lymphocytes. The more descriptive name of TSLP correctly describes its production by thymic stroma but obscures its production by skin epithelial cells, and that major target cells include dendritic cells (DCs) and cluster of differentiation (CD)4+ T cells.

Among the many classes of cytokines, the "type I" cytokines are distinctive in their sharing a similar four α helical bundle structure, as detailed in the section on Type I Cytokines-Structural Considerations, and correspondingly, their receptors share characteristic features that have led to their description as the cytokine receptor superfamily, hematopoietin receptors, or type I cytokine receptors.⁵⁻⁸ Although many interleukins are type I cytokines, some are not. For example, two of the major "proinflammatory cytokines," IL-1 and IL-6, are interleukins, but IL-6 is a type I cytokine, whereas IL-1 is not. One interleukin, IL-8, is a CXC family chemokine, an entirely different type of molecule involved in chemotaxis. Moreover, IL-10, IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29 are more similar to interferons (IFNs) and are denoted as type II cytokines.

In summary, the term interleukin indicates a relationship to leukocytes, whereas the identification of a cytokine as a type I or type II cytokine indicates general properties of its three-dimensional structure. Knowing that a molecule is a type I cytokine is instructive as it indicates a likely general structure for the cytokine receptor as well as the mechanism of signal transduction. In contrast, the identification of a molecule as an interleukin provides little information other than that it often, but not always, is a type I or type II cytokine of immunologic interest.

In addition to molecules of primarily immunologic interest, other important proteins, such as growth hormone, prolactin, erythropoietin (Epo), thrombopoietin, and leptin, are type I cytokines and their receptors are type I cytokine receptors. Despite having their major actions outside the immune system, these cytokines nevertheless share important signal transduction pathways with type I cytokines of immunologic interest. By focusing on type I cytokines and IFNs and their receptors, this chapter necessarily focuses on cytokines that are evolutionarily related and share common signaling pathways, instead of focusing on common functions per se. For example, although IL-6 has overlapping actions with IL-1 and tumor necrosis factor (TNF)- α , these latter proinflammatory cytokines are not discussed in this chapter because they are not type I cytokines, and the signaling pathways they use are distinct from those used by IL-6. This illustrates the important concept that similar end functions can be mediated via more than one type of signaling pathway. This is not to minimize the observation that many type I cytokines in fact do have similar/overlapping functions, as detailed in the section on "cytokine redundancy."

The field of IFN research is older than the cytokine field, but both fields more recently have developed in parallel. In fact, one can consider the IFNs to be the first cytokines that were identified. IFN was discovered as an antiviral activity in 1957. This turned out to be type I IFN (IFN α/β). Type II IFN (IFN γ) was discovered in 1965. Over time, it was recognized that type I cytokines and IFNs/type II cytokines share a number of common features, including signaling pathways.

An unfortunate nomenclature issue exists that should be noted. There are specialized popuplations of T cells that include T helper 1 (Th1) and T helper 2 (Th2) cells (see following discussion), which produced specialized sets of cytokines, such as IFN γ by Th1 and IL-4 by Th2 cells. These are sometimes called type 1 and type 2 cytokines (for Th1 and Th2 cytokines); unfortunately, this jargon can result in confusion as IL-4 is a type I (ie, four α -helical bundle) cytokine that is functionally a type 2 cytokine (in that it is produced by Th2 cells), where IFN γ is a type II structure cytokine produced by Th1 cells.

TYPE I CYTOKINES AND THEIR RECEPTORS Type I Cytokines—Structural Considerations

Type I cytokines typically share only limited amino acid sequence identity, but strikingly, all type I cytokines whose structures have been solved by nuclear magnetic resonance and/or x-ray crystallographic methods achieve similar three-dimensional structures,^{5–9} and those whose structures have not yet been solved are believed to share similar three-dimensional structures. Type I cytokines contain four α helices and thus are designated as four α -helical bundle cytokines (Fig. 25.1). Within their structures, the first two and last two α helices are each connected by long overhand loops, resulting in an "up-up-down-down" topologic structure, as the first two helices (A and B) can be oriented in an "up" orientation and the last two helices (C and D) can be oriented in a "down" orientation, as viewed from the N- to C-terminal direction. As shown in Figure 25.1, the N- and C-termini of the cytokines are positioned on the same part of the molecule.

Type I cytokines are either "short chain" or "long chain" four α -helical bundle cytokines based on the lengths of the α helices.⁸ Some of the short-chain cytokines include IL-2,

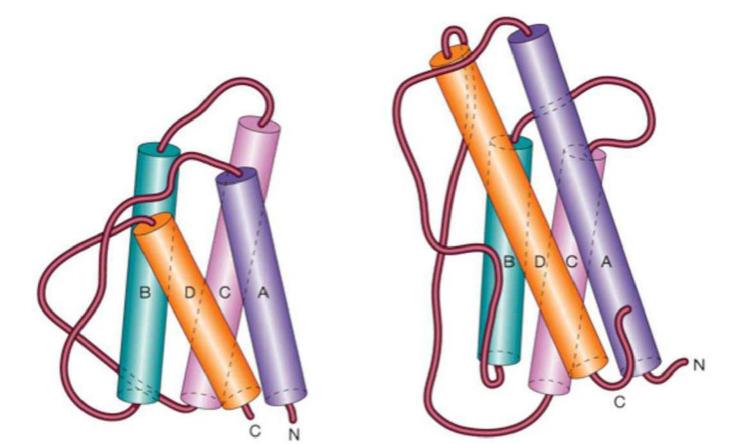

FIG. 25.1. Schematic of Four α -Helical Bundle Cytokines. Schematic drawing showing typical short-chain and long-chain four helical bundle cytokines. Although these both exhibit an "up-up-down-down" topology to their four α helices, note that in the short-chain cytokines, the AB loop is in behind the CD loop, whereas in the long-chain cytokines the situation is reversed. See text. The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

TABLE 25.1 Four	25.1 Four Helical Bundle Cytokines		
Short-Chain Cytokines	Long-Chain Cytokines		
IL-2	IL-6		
IL-4	IL-11		
IL-7	Oncostatin M		
IL-9	Leukemia inhibitory factor		
IL-13	CNTF		
IL-15	Cardiotropin-1		
IL-21	NNT-1/BSF-3		
TSLP			
IL-3	Growth hormone		
IL-5 ^a	Prolactin		
GM-CSF	Erythropoietin		
	Thrombopoietin		
M-CSF ^{a,b}	Leptin		
SCF ^b	G-CSF		

BSF-3, B cell-stimulating factor-3; CNTF, ciliary neurotrophic factor; G-CSF, granulocytecolony stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor; IL, interleukin; M-CSF, macrophage-colony stimulating factor; NNT-1, novel neurotrophin-1; SCF, stem cell factor; TSLP, thymic stromal lymphopoietin.
* Dimers.

^b Different from the other four helical bundle cytokines in that the M-CSF and SCF receptors (CSF-1R and c-kit, respectively) have intrinsic tyrosine kinase activity and are not type I cytokine receptors.

IL-3, IL-4, IL-5, granulocyte macrophage-colony stimulating factor (GM-CSF), IL-7, IL-9, IL-13, IL-15, IL-21, macrophagecolony stimulating factor (M-CSF), stem cell factor (SCF), and TSLP, whereas long-chain cytokines include growth hormone, prolactin, Epo, thrombopoietin, leptin, IL-6, IL-11, leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), novel neurotrophin-1 (NNT-1)/B cell-stimulating factor-3 (BSF-3)/cardiotrophin-like factor (CLC), and granulocytecolony stimulating factor (G-CSF) (Table 25.1).^{8,10,11} The α helices are approximately 15 amino acids long in short-chain helical cytokines and 25 amino acids long in long-chain cytokines. Additional differences include differences in the angles between the pairs of helices, and the AB loop is "under" the CD loop in the short cytokines but "over" the CD loop in the long cytokines (see Fig. 25.1).^{7,8,12} Moreover, short-chain cytokines have β structures in the AB and CD loops, whereas long-chain cytokines do not.

The division of type I cytokines into short-chain and longchain cytokines has evolutionary considerations and correlates with grouping of their receptor chains for these two subfamilies of type I cytokines. An analysis of short-chain cytokines has revealed that 61 residues comprise the family framework, including most of the 31 residues that contribute to the buried inner core. The similarities and differences in the structures of IL-2, IL-4, and GM-CSF have been analyzed.⁵ Among these cytokines, there is considerable variation in the intrachain disulfide bonds that stabilize the structures. For example, IL-4 has three intrachain disulfide bonds, GM-CSF has two, and IL-2 has only one. In IL-4, the first disulfide bond (between Cys 24 and Cys 65) connects loop AB to BC, the second disulfide bond (between Cys 46 and Cys 99) connects helix B and loop CD, and the third disulfide bond (between Cys 3 and Cys 127) connects the residue preceding helix B with helix D. In GM-CSF, the N-terminus of helix B and the N-terminus of β strand CD are connected by one disulfide bond, whereas the other disulfide bond connects the C-terminus of helix C and a strand following helix D. In IL-2, a single essential disulfide bond between Cys 58 and Cys 105 connects helix B to strand CD. Thus, each cytokine has evolved distinctive disulfide bonds to stabilize its structure, although it is typical that helix B is connected to the loop between helices C and D. The structures formed by helices A and D are more conserved than those formed by helices B and C, primarily due to the interhelical angles; helix D and the connecting region are the most highly conserved elements among the three cytokines.⁵ This is of particular interest, as the regions of type I cytokines that are most important for cytokine receptor interactions (based on analogy to the growth hormone receptor structure, see subsequent discussion) include helices A and D and residues in the AB and CD loops, whereas helices B and C do not form direct contacts.⁵

Variations on these typical four α -helical bundle structures can occur. For example, IL-5 is unusual in that it is a dimer, wherein the ends containing the N- and C-termini are juxtaposed, and helix D is "exchanged" between the two covalently attached monomers so that helix D of each molecule actually forms part of the four helix bundle of the other.¹³ M-CSF is also a dimer, but no exchange of helix D occurs.¹²

The IFNs form related albeit distinctive structures from type I cytokines and are designated as type II cytokines.⁸ IFN β has an extra helix that is positioned in place of the CD strand.¹⁴ IFN γ is a dimer, each of which consists of six α helices¹⁵ (Fig. 25.2). Two of these helices are interchanged, including one from each four α -helical bundle.^{12,15} IL-10, which is closely related to IFN γ , has a similar structure,¹⁶ as

FIG. 25.2. Structure of the Interferon γ Receptor (IFN γ R). Shown are ribbon diagrams of the structures of the IFN γ /IFN γ R complex as an example of a type II cytokine/cytokine receptor. In the IFN γ R, only IFNGR-1 complexed to the IFN γ dimer is shown, as the full structure with IFNGR-2 is not available. See text for discussion of the structure. The IFN γ -IFNGR-1 structure is from Walter et al.⁴⁰¹ The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

presumably do the more recently identified IL-10–like molecules, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29. Interestingly, although not universally the case, most four α -helical bundle cytokines have four exons, with helix A in exon 1, helices B and C in exon 3, and helix D in exon 4.⁷ A related organization is found for IFN γ , as well as for the long-chain helical cytokines, growth hormone, and G-CSF. However, there are exceptions, for example, IL-15 is divided into nine exons, whereas the IFN α s and IFN β are encoded by single exons.

Receptors for Type I Cytokines

The first report suggesting that type I cytokines interacted with receptors with similar features identified similarities in the sequences of the erythropoietin receptor and the IL-2 receptor β chain,¹⁷ and subsequent analysis of a large number of type I cytokine receptors established these receptors as a superfamily.¹⁸ Type I cytokine receptors are generally type I membrane-spanning glycoproteins (N-terminus extracellular, C-terminus intracellular). The only exceptions are proteins such as the CNTF receptor α chain (see the following discussion), which lacks a cytoplasmic domain and instead has a glycosylphosphatidylinositol (GPI) anchor; however, the orientation of this protein is otherwise similar to that of a type I membrane protein. In their extracellular domains, a number of conserved features have been noted (Table 25.2). These include four conserved cysteine residues that are involved in intrachain disulfide bonding, and a tryptophan residue, located two amino acids C-terminal to the second conserved cysteine. In addition, a membrane proximal WSXWS (Trp-Ser-X-Trp-Ser) motif is generally conserved, although again exceptions exist, for example, in the growth hormone receptor, the motif is a substantially different YGEFS (Tyr-Gly-Glu-Phe-Ser) sequence, and in the IL-23R, it is WQPWS (Trp-Gln-Pro-Trp-Ser). In some cases, such as the common cytokine receptor β chain, β_c , shared by the IL-3, IL-5, and GM-CSF receptors (see subsequent discussion), the extracellular domain is extended, with a duplication of the domains containing the four conserved cysteines and the WSXWS motif. Another shared feature of type I cytokine receptors is the presence of fibronectin type III domains.

The two pairs of conserved cysteine residues are typically encoded in two adjacent exons, and the exon containing the

Cytoplasmic domain

 Box 1/Box 2 regions—The Box 1 region is a proline-rich region that is involved in the interaction of Janus family tyrosine kinases. WSXWS motif is typically just 5' to the exon encoding the transmembrane domain. Although serines can be encoded by six different codons (ie, sixfold degeneracy in codon usage), only two of these (AGC and AGT) dominate as the codons used for the serines in WSXWS. All of these features indicate a common ancestral type I cytokine receptor.

Overall, analogous to limited sequence identity between type I cytokines, there is only limited sequence identity among type I receptor molecules. Nevertheless, they appear to form similar structures, based on the known structures for the receptors for growth hormone, prolactin, erythropoietin, IL-4, IL-13, IL-6, and IL-2^{9,19–25} as well as the modeling of other cytokine receptor molecules based on the known structures. The cytokines and their receptors have presumably coevolved, with the differences in amino acid sequences between different cytokines allowing for their distinctive interactions with their cognate receptor chains. Despite amino acid differences, there are also several sets of cytokines that coevolved to interact with shared receptor chains, which form type I cytokine and cytokine receptor subfamilies.^{8,11}

In addition to these noted similarities in the extracellular domains, there are sequence similarities that are conserved in the cytoplasmic domain of cytokine receptors. In particular, membrane proximal "Box 1/Box 2" regions are conserved (see Table 25.2), with the proline-rich Box 1 region being the most conserved.²⁶ This will be discussed in greater detail related to its role in the binding of JAK kinases.

Type I Cytokine Receptors Are Homodimers, Heterodimers, or Higher Order Receptor Oligomers

The first cytokine receptor structure solved was that for growth hormone (Fig. 25.3).¹⁹ Prior to x-ray crystallographic analysis, it was believed that growth hormone bound to its

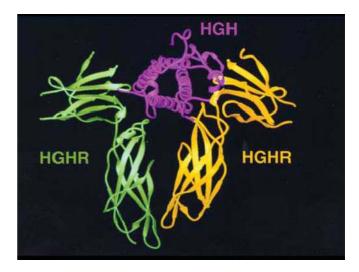

FIG. 25.3. Structure of the Growth Hormone Receptor. Shown are ribbon diagrams of the structure of the growth hormone receptor as an example of a type I cytokine receptor. For growth hormone, both growth hormone receptor monomers are shown. See text for discussion of the structures. The growth hormone/growth hormone receptor structure is from de Vos et al.¹⁹ The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

receptor with a stoichiometry of 1:1, but x-ray crystal solution structure revealed that a single growth hormone molecule interacts with a dimer of the growth hormone receptor, in which each receptor monomer contributes a total of seven β strands. Perhaps the most striking finding is that totally different parts of growth hormone interact with the same general region of each receptor monomer. The three-dimensional structure for the growth hormone/growth hormone receptor complex is shown in Figure 25.3. Solving the structure also clarified the basis for the assembly of the growth hormone receptor complex.¹⁹ Growth hormone first interacts with one receptor monomer via a relatively large and high-affinity interaction surface (site I), spanning ~1230 Å². A second receptor monomer then interacts with the growth hormone/growth hormone receptor complex via two contact points: one on growth hormone (spanning ~ 900 Å²) (site II) and the other on the first receptor monomer (spanning $\sim 500 \text{ Å}^2$) (site III), located much more proximal to the cell membrane. Thus, three extracellular interactions are responsible for the formation and stabilization of the growth hormone/growth hormone receptor complex. Mutations in critical residues in site I should prevent growth hormone binding to its receptor, whereas inactivating mutations in site II can be predicted to prevent dimerization and signal transduction, suggesting a basis by which different classes of antagonists might be identified.

The growth hormone/growth hormone receptor structure revealed that the growth hormone receptor extracellular domain is composed of two fibronectin type III modules, each of which is approximately 100 amino acids long and contains seven β strands, resulting in the formation of an immunoglobulin (Ig)-like structure. The contact surface between ligand and receptor occurs in the hinge region that separates these two fibronectin type III modules. Analysis of a growth hormone–prolactin receptor complex revealed a similar structure for the prolactin receptor.²⁰

The growth hormone/growth hormone receptor structure served as a paradigm for the structures of other type I cytokine receptors. As a receptor homodimer, it immediately served as a model for other homodimers, such as the Epo receptor, whose structure was solved²¹ using a small protein mimetic (20 amino acid long peptide) of Epo.²⁷ The Epo receptor structure is similar to that of the growth hormone receptor, although the "site III" stem region interaction surface in the Epo receptor is much smaller than that in the growth hormone receptor, comprising only 75 Å².²¹

In addition to the structural similarities for the growth hormone and Epo receptors and perhaps other homodimeric type I cytokine receptors, a similar structure was achieved by the heterodimeric growth hormone/growth hormone receptor/prolactin receptor structure,²⁰ in which one of the growth hormone receptor monomers is replaced by a prolactin receptor molecule. Thus, the two surfaces of growth hormone interact either with two identical monomers of growth hormone receptor or with two nonidentical monomers in the case of the growth hormone receptor/prolactin receptor heterodimer.

It seems reasonable that cytokine-receptor systems with a homodimeric receptor are evolutionarily older than those with heterodimeric receptors, and that the coordination of two different receptor chains in heterodimeric receptors would have evolved in order to allow higher levels of specialization. In this regard, it is interesting that growth hormone and Epo, whose actions are vital for growth and erythropoiesis, bind to receptor homodimers, whereas the heterodimeric structures that typify the immune system are perhaps more "specialized" functions that arose later in evolution.

Interestingly, all type I cytokines known to interact with homodimers (growth hormone, prolactin, Epo, and G-CSF) are long-chain helical cytokines, although other long-chain helical cytokines (eg, cytokines whose receptors contain gp130; see following discussion) interact with heteromeric receptors. The short-chain cytokines that signal through homodimers are SCF and M-CSF, but in these cases, the receptors (c-kit and CSF-1R, respectively) are different from type I cytokine receptors in that they contain intrinsic tyrosine kinase domains. Thus, SCF and M-CSF are not typical type I cytokines and all other short-chain cytokines signal through heterodimers or more complex receptor structures (eg, IL-2 and IL-15 receptors have three components).

Heterodimeric receptors are involved when site II on a cytokine has evolved to a point where it interacts with a different receptor molecule than site I does. This latter situation is the case for many cytokines, including all short-chain type I cytokines except for SCF and M-CSF. Overall, several sets of type I cytokines fall into distinct groups, wherein each group shares at least one common receptor component. This phenomenon is observed for certain sets of both short-chain and long-chain four α -helical bundle cytokines, and depending on the set of cytokines, the shared chain interacts either with site I or site II.

The structures of the low- and high-affinity forms of the IL-2 receptor have now been solved^{9,23,28}; these are the first complete structures for a short-chain cytokine/receptor complex.²⁹ Moreover, they are of added interest in that the low-affinity receptor involves the interaction of IL-2 with IL-2R α , which is not a type I cytokine receptor protein but instead is a distinctive sushi-domain containing protein, whereas the high-affinity receptor includes not only IL-2R α but also IL-2R β and γ_c , which are both type I cytokine receptor proteins that are shared either with IL-15 (IL-2R β) or with IL-4, IL-7, IL-9, IL-15, and IL-21 (γ_c) ,³⁰ as discussed in the following text. In the structure of IL-2 bound to its high-affinity receptor (Fig. 25.4), there is a long peptide connecting the IL-2Ra globular head and transmembrane segment, allowing the binding site on this protein to extend relatively far from the cell surface in order to bind the dorsal surface of IL-2. Both the IL-2/IL-2R α and IL-2/IL-2R β contacts are independent, and IL-2R α does not appear to contact either IL-2R β or γ_c ; however, IL-2/IL-2R β forms a composite surface with γ_c , somewhat analogous to the composite surface formed by growth hormone and one growth hormone receptor monomer for binding to a second monomer. As anticipated, the surface interaction between IL-2 and γ_c is smaller than that between IL-2 and either of the other chains. In addition to the heterodimeric IL-2 receptor structure, 23 the IL-6 31,32 and LIF 33 receptor complexes,

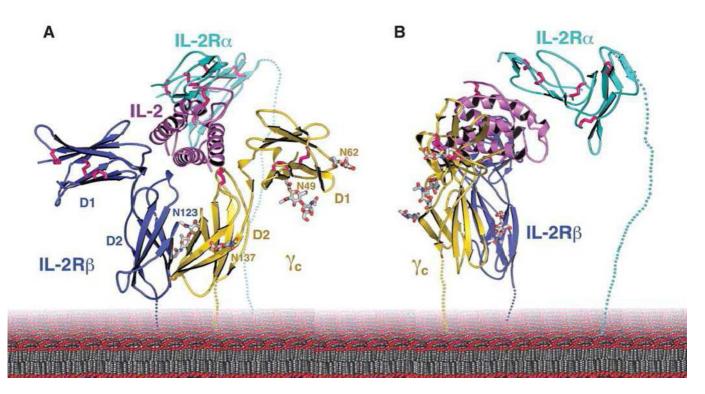

FIG. 25.4. Structure of the High-Affinity Interleukin (IL)-2 Receptor. This is the first structure for a short-chain type I cytokine complexed to its complete receptor. It is particularly interesting in that it includes the sushi-domain containing IL-2Rα chain as well. Reprinted from Wang et al.,²³ with permission of Dr. Garcia and *Science* magazine.

the IL-4/IL-13 receptor³⁴ complexes, and GM-CSF receptor structure³⁵ have been solved.

TYPE I CYTOKINE RECEPTOR FAMILIES AND THEIR RELATIONS

Cytokines that Share the Common Cytokine Receptor γ Chain (Interleukin-2, Interleukin-4, Interleukin-7, Interleukin-9, Interleukin-15, and Interleukin-21)

The receptors for six different immunologically important cytokines, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21, share the common cytokine receptor γ chain, γ_c (CD132).^{11,30,36–45} These cytokines are all short-chain four α -helical bundle cytokines; basic features of these cytokines are summarized in Table 25.3. The properties of these cytokines and their distinctive receptor chains are summarized in the following text, followed by a discussion of the discovery that they share a common receptor component and the implications thereof.

IL-2 is important not only for its function but also historically, as it was the first type I cytokine that was cloned,⁴⁶ the first type I cytokine for which a receptor component was cloned,^{47,48} and the first short-chain type I cytokine whose receptor structure was solved.²³ Many general principles have derived from studies of this cytokine, including its being the first cytokine that was demonstrated to act in a growth factor–like fashion through specific high-affinity receptors, analogous to the growth factors being studied by endocrinologists and biochemists.^{49,50}

Mature IL-2 is a 133 amino acid long peptide that can act as a major T-cell growth factor, in keeping with its original discovery as a T-cell growth factor.⁵¹ Although IL-2 is not produced by resting T cells, it is rapidly and potently induced following antigen encounter with resting CD4+ T cells, and transcription and synthesis of IL-2 are often used as indicators of T-cell receptor (TCR)-mediated cellular activation. Although the antigen determines the specificity of the T-cell immune response, the interaction of IL-2 with high-affinity IL-2 receptors regulates the magnitude and duration of the subsequent response, based on the amount of IL-2 produced, the levels of high-affinity receptors expressed, and the duration of IL-2 production and receptor expression. IL-2 can act in either an autocrine or paracrine fashion, depending on whether the producing cell is also the responding cell or whether the responding cell is a nonproducing cell. The gene encoding IL-2 is located on chromosome 4,⁵² and like many other helical cytokines, its gene consists of four exons.7 IL-2 binds to three different classes of receptors. These are formed by different combinations of three different chains, IL-2Rα,^{47,48,53} IL-2Rβ,⁵⁴⁻⁵⁷ and a protein initially called IL-2R γ^{36} but now known as the common cytokine receptor γ chain, $\gamma_c^{,11,30,37}$ These different classes of IL-2 receptors are discussed in the following text.

In addition to its being a T-cell growth factor, IL-2 has other important actions as well (see Table 25.3).²⁹ For example, it can increase Ig synthesis and J chain transcription in B cells,^{50,58,59} potently augment the cytolytic activity of

CD, cluster of differentiation; Ig, immunoglobulin; IL, interleukin; LAK, lymphokine activated killer; MHC, major histocompatibility complex; NK, natural killer; Tfh, T follicular helper; Th, T helper; Treg, regulatory T.

*h and m refer to human and mouse, respectively. The number of amino acids refers to the length of the open reading frame/length of signal peptide. The number of amino acids in the mature protein is therefore the difference between these numbers. Note that for IL-15, residues 1 to 29 have been identified as a signal peptide and 30 to 48 as a propeptide.

^bMore IL-15 messenger ribonucleic acid is produced in skeletal muscle, kidney, placenta, and lung than in thymus or spleen. It is important to note, however, that IL-15 messenger ribonucleic acid is widely expressed without concomitant production of IL-15 protein so that the source of biologically meaningful IL-15 may be more limited.

607

natural killer (NK) cells,^{60–62} induce the cytolytic activity of lymphokine activated killer cells, promote the elimination of autoreactive cells in a process known as antigen-induced (or activation-induced) cell death,^{29,50,63} and promote the differentiation of regulatory T (T_{reg}) cells,^{64,65} cells that suppress inappropriate responses and are important for immunologic tolerance. Low-dose IL-2 is sufficient to promote T_{reg}-cell survival, and thereby, for example, can protect mice from developing autoimmune diabetes.⁶⁶ Interestingly, IL-2 can also prime CD8+ T cells during a primary response to undergo enhanced proliferation in vivo during a secondary response,^{67,68} and autocrine IL-2 is believed to be required for secondary expansion of CD8+ memory T cells.⁶⁹ There appears to be a complex interplay between IL-2 and inflammatory signals to regulate effector and memory cytolytic T-lymphocytes generation in lymphocytic choriomeningitis virus infection, with persistent IL-2 promoting effector rather than memory cytotoxic T-lymphocyte development.^{70,71} In Listeria monocytogenesis infection, Th1 effector memory cells highly express the transcription factor T-Bet and IL-2Ra, and IL-2Ra appears to be critical for the development of these cells.⁷² Presumably because of its critical role in T_{reg} development, the absence of IL-2, IL-2R α , or IL-2R β leads to autoimmunity. Interestingly, the production of IL-2 by mast cells has been reported to contribute to the suppression of chronic allergic dermatitis by its increasing the relative number of T_{reg} cells at the site of inflammation.⁷³

IL-2 is also important in inducing or inhibiting Th differentiation. It is required for efficient Th174 and Th2 differentiation,^{75–78} which are populations of T helper cells first described based on patterns of cytokine production by mouse T cells.⁷⁹ This theme was then extended to human cells as well,80-84 although there are some variations in humans and mice in terms of the degree of how tightly restricted cytokine expression is. IFN γ is the cytokine most reliably produced by Th1 cells; IL-2 is also produced by these cells, although without as rigorous an association. In contrast, IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 are produced by Th2 cells. In both species, certain type I cytokines (eg, IL-3 and GM-CSF) are produced by both Th1 and Th2 cells. IL-12 and the transcription factors signal transducer and activator of transcription (STAT)4 and T-Bet are the major transcription factors promoting Th1 differentiation, whereas IL-4 and the transcription factor STAT6 drive Th2 differentiation. For Th1 cells, IL-2 acts by STAT5-dependent induction and expression of IL-12R\beta1/IL-12R\beta2 and T-Bet,⁷⁴ whereas for Th2 differentiation, IL-2 via STAT5 promotes IL-4^{75,76} and IL-4Rα⁷⁷ expression. In addition, IL-2 also affects chromatin remodeling at the Ifng locus during Th1 differentiation.⁸⁵ IL-2 also inhibits Th17 differentiation,⁸⁶ in part via downregulation of IL-6R α /gp130 expression⁷⁴ and by inducing T-bet,74,87 which prevents Runx1-mediated activation of RORyt, a transcription factor that drives Th17 differentiation.87

Like IL-2, IL-4 is produced primarily by activated CD4+ T cells.^{88,89} IL-4 is also produced by CD4+NK1.1+ "natural" T cells, denoted as natural killer T (NKT) cells,⁹⁰ and by mast cells and basophils.⁸⁸ IL-4 is the major B-cell growth factor, and it promotes Ig class switch, enhancing the production and secretion of mouse IgG1 (human IgG4) and being essential for the production of IgE.⁸⁸ IL-4 is involved in the physiologic response to parasites, including helminths, and for allergen sensitization. IL-4 induces expression of class II major histocompatibility complex molecules and increases cell surface expression of the CD23 (the low-affinity IgE receptor) on B cells. In addition to its actions on B cells, IL-4 can also act as a T-cell growth factor, inducing proliferation in both human and mouse T cells, and is critical for normal differentiation of Th2 cells.⁸⁹ Moreover, when IL-4 and transforming growth factor (TGF)- β are combined, cells that produce IL-9 (Th9) cells are induced (see following discussion). When combined with phorbol 2-myristate 3-acetate, IL-4 is also a potent comitogen for thymocytes. Importantly, IL-4 can inhibit certain responses of cells to IL-2.91 Moreover, IL-4 can exert actions on macrophages, hematopoietic precursor cells, stromal cells, and fibroblasts.⁹² The gene encoding IL-4 is located on human chromosome 5 (5q23.3–31.2) and mouse chromosome 11,^{92,93} in the same region as IL-3, IL-5, IL-13, and GM-CSF. The type I IL-4 receptor is expressed on T cells and other hematopoietic cells consists of the 140 kDa IL-4R α protein^{88,94–96} and γ_c .^{38,39} Expression of IL-4R α tends to be quite low, and cells that potently respond to IL-4 often express only a few hundred receptors per cell. In addition to the type I IL-4 receptor, an alternate form of the receptor (the type II IL-4 receptor), containing IL-4Ra and IL-13Ra1, although not expressed on mature T cells, is expressed on many other cell types and can transduce IL-4 signals into these cells. For example, IL-13R α 1 is expressed on neonatal Th1 cells and the type II IL-4 receptor has been implicated as mediating apoptosis of these cells.97

IL-7 is not produced by lymphocytes but instead is a 152 amino acid long cytokine that is produced by stromal cells and certain other cells.98-100 Based on the analysis of patients with X-linked severe combined immunodeficiency (SCID), JAK3-deficient SCID, and IL-7Ra-deficient SCID, IL-7 receptor-dependent signaling is essential for T-cell development in humans (discussed subsequently). The major role of IL-7 is to enhance thymocyte survival, growth, and differentiation¹⁰¹⁻¹⁰⁵ as well as low-affinity peptide-induced proliferation, and thus it promotes homeostatic proliferation of naive and memory CD8+ T cells.^{100,105-107} Additionally, IL-7 can regulate the homeostasis of CD4+ memory T cells^{108,109} and also can stimulate the growth of mature T cells.^{30,105,110,111} Although IL-7, as noted previously, is believed to primarily be a stromal factor, IL-7 has also been noted to be produced by the liver and kidney but not spleen or lymph nodes after toll-like receptor (TLR) signaling. Although basal liver production is low, after TLR signaling, hepatic IL-7 can promote CD4 and CD8 T-cell survival and promotes antigenspecific T-cell responses.¹¹² In addition, in the mouse, IL-7 is vital for the growth of mouse pre-B cells,^{96,98,103,104,111} and transient IL-7 signaling can inhibit Ig heavy chain gene rearrangements.¹¹³ IL-7 via STAT5 has also been shown to inhibit Ig-κ recombination in pro-B cells.¹¹⁴ In contrast to its requirement for B-cell development in the mouse, there is normal B-cell development in patients with defective IL-7 signaling, as is found in patients with X-linked SCID, JAK3-deficient

SCID, and IL-7Rα-deficient SCID (see following discussion). Thus, human B cells can develop normally in the absence of IL-7 responsiveness, demonstrating that in humans, IL-7 is not vital for the growth of human pre-B cells,^{30,115} and it remains unknown whether IL-7 plays important roles in human B-cell biology. Interestingly, IL-7 also acts on DCs, and this appears to limit the homeostatic proliferation of T cells under lymphopenic conditions.^{100,116} Clinically, IL-7 has been of interest in terms of its ability to induce T-cell proliferation and to thereby increase T-cell numbers, with a greater effect on CD8+ than on CD4+ T cells, as well as to augment the diversity of the TCR repertoire¹¹⁷; IL-7 also can increase antigen-specific responses following vaccination¹⁰⁰ and can promote antiviral immunity, apparently in part due to its induction of IL-22 and repression of SOCS3.¹¹⁸ The gene encoding IL-7 is located on human chromosome 8q12 to 8q13¹¹⁹ and mouse chromosome 3. The functional IL-7 receptor contains the 75 kDa IL-7R α^{120} and γ_c .^{37,40} Interestingly, signaling via the TCR, IL-2 or IL-7 can downregulate IL-7R α expression,121,122 with PI 3-kinase/AKT and GFI1B being implicated in its downregulation in T cells.¹²²⁻¹²⁴ The downregulation of IL-7Rα not only can both decrease responsiveness of cells but can also increase the availability of the cytokine for other cells that are poised to respond.¹¹ Induction of IL-7Rα requires PU.1 in B cells¹²⁵ and another Ets family protein, GABP, in T cells.¹²³

IL-9 was originally described as a mouse T-cell growth factor¹²⁶ that is produced by activated T cells and can support the growth of T-helper clones but not of cytolytic clones.¹²⁷ In contrast to IL-2, its production is delayed, suggesting its involvement in later, perhaps secondary signals. In the mouse, IL-9 can exert proliferative effects on erythroid progenitors, B cells, B-1 cells, mast cells, and fetal thymocytes. IL-9 is identical to mast cell growth-enhancing activity, a factor present in conditioned medium from splenocytes,¹²⁸ and synergizes with IL-3 for maximal mast cell proliferation. IL-9 is highly expressed in the lung of patients with asthma,¹²⁹ and overexpression leads to airway inflammation and Th2 cytokine production.¹³⁰ Interestingly, IL-9 is substantially made in the lung by innate lymphoid cells, and in these cells neutralizing antibodies to IL-9 lowered expression of IL-13 and IL-5, supporting a link between IL-9 and the regulation of the Th2 response.¹³¹ Consistent with the action of IL-9 on thymocytes in vitro, IL-9 transgenic mice develop thymic lymphomas, and IL-9 is a major antiapoptotic factor for such tumors.¹³² Nevertheless, IL-9 knockout mice have normal T-cell development¹³³; instead, they exhibit a defect in pulmonary goblet cell hyperplasia and mastocytosis following challenge with Schistosoma mansoni eggs, a synchronous pulmonary granuloma formation model. However, there was no defect in eosinophilia or granuloma formation.¹³³ Mice expressing an IL-9 transgene in the lung exhibit airway inflammation and bronchial hyperresponsiveness; nevertheless, IL-9-/- mice exhibit normal eosinophilia and airway hyperreactivity in an ovalbumin-induced inflammatory model.^{134–136} Thus, although IL-9 can contribute to allergic/pulmonary responses, there are compensatory cytokines that substitute for IL-9 in at least certain settings. IL-9 can be produced by the Th9 populations of cells,

which can be induced by IL-4 plus TGF- β in a fashion that is dependent on PU.1 and interferon regulatory factor (IRF)-4.¹³⁷ Interestingly, the addition of IL-25 further enhances the production of IL-9.138 IL-9-producing cells are typically IL-9+IL-10+Foxp3- effector T cells and can be derived from Th2 cells.^{139,140} Overall, IL-9 is believed to play a key role in allergic responses; additionally, given the ability of both Th17 and T_{reg} cells to produce IL-9 during autoimmunity and transplantation, it will be interesting to further clarify the role of IL-9 in autoimmunity.¹⁴¹ Currently, there is some confusion, as one study showed that antibody blockade of IL-9 or IL-9Ra blocks experimental autoimmune encephalomyelitis (EAE) disease progression,¹⁴² whereas another study showed that IL-9Ra knockout mice develop more severe EAE.¹³⁸ While mouse IL-9 is active on human cells, human IL-9 is not biologically active on mouse cells (the opposite situation from that for IL-2). Human IL-9 is located on chromosome 5q31 to 5q35,¹⁴³ which is also the location for the genes encoding IL-3, IL-4, IL-5, IL-13, and GM-CSF. In contrast, mouse IL-9 is "isolated" on chromosome 13, while IL-3, IL-4, IL-5, IL-13, and GM-CSF are clustered on chromosome 11. IL-9 binds to the 64 kDa IL-9Ra binding protein, which is similar in size to γ_c ,¹⁴⁴ and the functional IL-9 receptor consists of IL-9R α plus γ_c .^{30,41,42}

IL-15 was identified as a T-cell growth factor that also unexpectedly was expressed in the supernatant of a human T-lymphotropic virus type I (HTLV-I)-transformed T-cell line.^{145,146} Although IL-15 messenger ribonucleic acid (RNA) is produced by a range of nonlymphocytic cell types, it is difficult to detect physiologic levels of IL-15 protein.¹⁴⁷ Its main site of synthesis appears to be DCs and monocytes, and unlike IL-2, IL-15 is not produced by activated T cells.¹⁴⁸ IL-15 receptors are widely expressed; although IL-15 is perhaps most important for the development of NK cells¹⁴⁹⁻¹⁵¹ and CD8+ memory T cells,^{150,151} it also has both paracrine and autocrine actions on DCs, including promoting the survival of these cells.¹¹ Interestingly, it also regulates the TCR repertoire of $\gamma\delta$ intraepithelial lymphocytes¹⁵² and cross talk between different types of DCs.¹⁵³ The receptor for IL-15 on T cells contains IL-2R β ,^{43,147,154} γ _c,⁴³ and an IL-15–specific protein, IL-15Ra. IL-15Ra shares a number of structural similarities with IL-2Ra, including that it is a sushi domaincontaining protein (IL-2R α has two sushi domains, whereas IL-15R α has one),¹⁵⁵ and the IL2RA and IL15RA genes are closely positioned on human chromosome 10p14.156 A distinctive feature of IL-15 signaling is that it signals substantially by a process called transpresentation, wherein IL-15Ra on the surface of dendritic cells or monocytes will transpresent IL-15 to responding cells such as CD8+ T cells or NK cells that express IL-2R β + γ_c .^{148,157} IL-15R α has a longer cytoplasmic domain than IL-2R α and appears to be critical for IL-15Rα function, although potentially not for transpresentation.¹⁵⁸ Interestingly, transpresentation can be utilized by IL-2 as well.¹⁵⁹ The very high affinity of IL-15Rα for IL-15 is explained by a large number of ionic interactions mediated by the sushi domain.¹⁶⁰ Note that these responding cells can also express IL-15R α . In contrast to IL-2, which is a growth factor as well as a mediator of antigen-induced (or activationinduced) cell death and promoter of T_{reg} differentiation, the role of IL-15 appears to be more focused on growth of CD8+ T cells,¹⁶¹ maintaining long-lasting, high-avidity T-cell responses to foreign pathogens (ie, CD8+ T-cell memory).^{148,162} This ability has suggested it could have potential as a vaccine adjuvant.¹⁶³ Overall, the fact that IL-15 promotes the proliferation and differentiation of B, T, and NK cells; the cytolytic activity of CD8 T cells; and the maturation of dendritic cells, yet, unlike IL-2, fails to stimulate immunosuppressive T_{reg} cells indicates that it has an array of properties that make it potentially promising as an anticancer therapeutic agent; as a result, a number of ongoing clinical trials are now in progress.¹⁶⁴

IL-21 is the most recently identified member of the IL-2 family of cytokines. IL-21 can bind to specific receptors and exert actions on T, B, NK cells, DCs, and macrophages.¹⁶⁵ It augments T-cell proliferation as a comitogen,¹⁶⁶ can cooperate with IL-7 or IL-15 to drive the expansion of freshly isolated mouse CD8+ T cells, and it can augment the antitumor activity of CD8+ T cells.¹⁶⁷ IL-21 promotes the differentiation of Th17 cells^{168,169} as well as the generation of T follicular helper cells.¹⁷⁰ In the case of Th17 differentiation, IL-21 is part of an IL-6 to IL-21 to IL-23 signaling cascade^{169,171,172} to drive the differentiation of these cells in an RORγ-dependent manner.¹⁷³ Polarization of Th17 cells is dependent on TCR stimulation, TGF-β, and IL-6 but is independent of IL-23, which instead may be required for maintaining/expanding these cells.^{174–177}

The actions of IL-21 on B cells are particularly complex. It augments B-cell proliferation when combined with anti-CD40 or lipopolysaccharide (LPS) but inhibits proliferation in response to anti-IgM + IL-4¹⁶⁶; this inhibition is reversed if anti-CD40 is additionally provided. It induces apoptosis of incompletely activated B cells, perhaps serving a role analogous to that of IL-2 in activation-induced cell death of T cells to eliminate incompletely activated cells.¹⁶⁵ In contrast, IL-21 drives terminal differentiation to plasma cells of more fully activated cells. Strikingly, IL-21 can drive plasma cell differentiation of both peripheral memory B cells and cord blood B cells, at least in part explained by its ability to induce expression of BLIMP1.^{178,179} Strikingly, IL-21 regulates not only BLIMP-1 but also a broad range of genes via a functional cooperation between STAT3 and IRF4.¹⁸⁰ In IL-21R knockout mice, following immunization, IgG1 is diminished related to a role for IL-21 in class switching to IgG1 and IgG3, whereas IgE is elevated, related to the ability of IL-21 to inhibit CE transcription¹⁸¹ and/or to its ability to augment the apoptosis of IgE-producing B cells. Analysis of IL-21R/IL-4 double knockout mice has revealed that IL-21 cooperates with IL-4 to globally regulate Ig production in that these mice exhibit a panhypogammaglobulinemia, mimicking the T-cell phenotype in humans with X-linked SCID.¹⁸² IL-21 can also cooperate with IL-15 and Flt-3 ligand to increase development of NK cells¹⁶⁶ and augment antitumor activity¹⁸³; however, it was also reported to oppose the actions of IL-15¹⁸⁴ and can also direct NK cell apoptosis. Interestingly, IL-21 exerts potent antitumor effects, including against large established solid tumors.^{11,165} In the pMEL-1 CD8 TCR transgenic system, the effector cells recognize a melanoma antigen. When cells are adoptively

transferred into tumor-bearing mice and animals are vaccinated with the cognate antigen, the addition of IL-21 or IL-21 plus IL-15 has potent antitumor effects.¹⁶⁷ Moreover, treatment of cells with IL-21 in vitro prior to adoptive transfer results in markedly enhanced antitumor effects in vivo, conferring a distinctive differentiation program from that conferred by IL-2.¹⁸⁵ IL-21 is now in phase II clinical trials for cancer. In addition to its anticancer activity, IL-21 can also promote autoimmunity. Elevated IL-21 levels have been reported in the BXSB-Yaa mouse model of systemic lupus erythematosus,¹⁷⁸ and elevated IL-21 levels have been found in a subset of humans with systemic lupus erythematosus (P. Lipsky, personal communication). Elevated IL-21 has also been associated with other autoimmune processes, including in the non-obese diabetic (NOD) mouse.¹⁸¹ More importantly, in mouse models of type 1 diabetes, lupus, and experimental allergic uveitis, no autoimmune disease develops on an IL-21R knockout background.¹⁸⁶⁻¹⁸⁸ IL-21 unexpectedly can also be immunosuppressive via its induction of IL-10.189,190 Consistent with this, an IL-21/IL-10/STAT3 pathway is required for normal development of memory CD8+ T cells after lymphocytic choriomeningitis virus (LCMV) infection¹⁹¹; similarly, STAT3, presumably by an overlapping mechanism is important for human T-cell memory development, as evidenced by studies in patients with autosomal dominant hyper-IgE syndrome, which is caused by dominant negative mutations in STAT3.¹⁹² IL-21 has complex roles in viral responses. For LCMV, IL-21 is required to control chronic infection,¹⁹³ whereas IL-21 mediates the pathogenic response after infection with pneumonia virus of mice.¹⁹⁴ Interestingly, for hepatitis B virus, IL-21 appears to be critical in determining the age-dependent effectiveness of immune responses, wherein decreased IL-21 production in younger individuals hinders the generation of critical lymphoid responses to the virus, whereas more robust IL-21 production in adults is associated with viral clearance that occurs in 95% of patients.195

The receptor for IL-21 consists of IL-21R plus γ_c .^{30,44} IL-21R is most related to IL-2R β , and like IL-2R β , its expression is induced following cellular stimulation with anti-CD3 or phytohemagglutinin, and in addition, its expression is augmented in T cells following transformation with HTLV-I.¹⁹⁶ Both human and mouse IL-21 can act on cells of the other species. IL-21 is on human chromosome 4q26 to 4q27, while its receptor is on chromosome 16p11, immediately downstream of the *IL4R* gene.

Thus, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 collectively exhibit partially overlapping roles related to T cells, NK cells, B cells, and mast cells, and together would be expected to play vital roles for normal development and/or function of these cellular lineages. As discussed in the following, IL-2, IL-7, IL-9, and IL-15 utilize primarily STAT5A and STAT5B; IL-4 activates primarily STAT6; and IL-21 activates STAT1, STAT3, STAT5A, and STAT5B, with STAT3 being the dominant STAT for this cytokine.¹¹ The fact that these six cytokines share γ_c is of particular interest, especially as the gene encoding γ_c is mutated in patients with the most common form of severe combined immunodeficiency in humans.

X-Linked Severe Combined Immunodeficiency Disease Results from Mutations in the Gene Encoding $\gamma_{\rm c}$

The γ chain was originally identified as a third component of the IL-2 receptor³⁶ after it became clear that IL-2 receptor α and β chains alone were not sufficient to transduce an IL-2 signal. The hypothesis that the γ chain was a shared component of receptors for cytokines in addition to IL-2 was motivated from a comparison of the clinical phenotypes in humans that result from defective expression of IL-2 versus. the γ chain. In 1993, it was discovered that mutations in the gene encoding the γ chain resulted in X-linked SCID (the disease is also designated as SCIDX1).^{30,197} X-linked SCID is characterized by profoundly diminished numbers of T cells and NK cells^{30,45,197–201} (Table 25.4). Although the B cells are normal in number, they are nonfunctional, apparently due to a lack of T-cell help as well as an intrinsic B-cell defect.^{45,200,202} In contrast to the profoundly decreased number of T cells in patients with X-linked SCID, IL-2-deficient patients^{203,204} and mice²⁰⁵ have normal numbers of T cells (the phenotypes of mice deficient in type I and type II cytokines and their receptor, JAK kinases, and STAT proteins are summarized in Table 25.15). This observation indicated that defective IL-2 signaling was unlikely to be responsible for X-linked SCID, making the finding that the gene encoding the γ chain was mutated in X-linked SCID all the more unexpected. Thus, the conundrum was why a defect in a component of a receptor would cause a more severe than a defect in the corresponding cytokine. This led to the hypothesis that the γ chain was critical for other cytokine receptors as well.¹⁹⁷ In this model, defective IL-2 signaling either did not contribute to the defects in X-linked SCID or these defects were explained by the simultaneous inactivation of multiple signaling pathways.^{45,197} Indeed, it was found that the γ chain was also an essential component of both the IL-4 and IL-7 receptors on T cells,³⁷⁻⁴⁰ leading to it being renamed as the common cytokine receptor γ chain, γ_c .^{37,38} IL-9, IL-15, and IL-21 were subsequently also shown to share γ_c^{30} (Fig. 25.5).

The sharing of γ_c by six different cytokine receptors revealed that X-linked SCID is a disease of defective cytokine signaling. The major deficiencies in X-linked SCID can be attributed to defects related to different cytokines. Based

TABLE 25.4

Features of X-Linked Severe Combined Immunodeficiency

- 1. Absent or profoundly diminished numbers of T cells and mitogen responses
- 2. Absence of NK cells
- 3. Normal numbers of B cells, but defective B-cell responses
- 4. IgM can be normal but greatly diminished Igs of other classes
- XSCID carrier females exhibit nonrandom X-inactivation patterns in their T cells and NK cells; the X-inactivation pattern is random in surface IgM-positive B cells but nonrandom in more terminally differentiated B cells.

lg, immunoglobulin; NK, natural killer; XSCID, X-linked severe combined immunodeficiency.

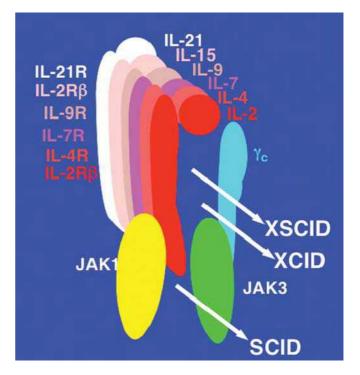

FIG. 25.5. Schematic of the Receptors for Interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21, Showing Interactions with JAK1 and JAK3. The figure shows that IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all share γ_c . IL-2R α and IL-15R α are not shown. Whereas the distinctive chains associate with JAK1, γ_c associates with JAK3. Mutations in γ_c cause X-linked severe combined immunodeficiency or more moderate forms of X-linked immunodeficiency. Mutations in JAK3 cause an autosomal recessive form of severe combined immunodeficiency (see text).

on the dramatically diminished T-cell development not only in IL-7–deficient¹⁰⁴ or IL-7R α –deficient¹⁰³ mice but also in *IL-7R*-deficient humans with T–B+NK+ SCID,^{206,207} yet normal T-cell development in mice deficient in IL-2,²⁰⁵ IL-4,^{208,209} both IL-2 and IL-4,²¹⁰ IL-9,¹³³ IL-15,¹⁵¹ IL-15R α ,¹⁵⁰ IL-21R,^{182,184} and most if not all of the defect in T-cell development in patients with X-linked SCID can be attributed to defective IL-7 signaling.³⁰ In addition to profoundly diminished numbers of T cells, humans with X-linked SCID lack NK cells. As discussed previously, NK-cell development is defective in IL-15– and IL-15R α –deficient mice, indicating that it is defective IL-15 signaling that is responsible for the defective NK-cell development in X-linked SCID.³⁰

In contrast to the greatly diminished number of T cells and absent NK cells in patients with X-linked SCID, B-cell numbers are normal. This is in contrast to the greatly diminished numbers of B cells in γ_c -deficient mice^{211,212} as well as mice deficient in either IL-7 or IL-7R α , indicating that IL-7 is not required for pre-B-cell development in humans and underscoring a major difference for IL-7 in human versus mouse biology. Indeed, patients with *IL-7R*-deficient SCID have a T–B+NK+ form of SCID.^{206,207} Although B cells develop in patients with X-linked SCID, they are nonfunctional. This is due in part to a lack of T-cell help (given the near absence of T cells in X-linked SCID), but a variety of data indicate an intrinsic B-cell defect as well.³⁰ As discussed previously, analysis of IL-4/IL-21R double knockout mice indicate that defective signaling by IL-4 and IL-21 appear to explain the intrinsic B-cell defect in X-linked SCID.¹⁸²

Rationale for the Sharing of γ_c

Why should there have been evolutionary pressure to maintain the sharing of γ_c , given the obvious increased risk associated with sharing a receptor component when it is mutated? There are at least two different types of models.^{45,213} First, the sharing of γ_c could be a basis for shared actions. For example, given that IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 can each act as T-cell growth factors, at least in vitro, it is possible that γ_c might couple to signal transducing molecule(s) that promote T-cell growth. Second, the sharing of γ_c might represent a means by which one cytokine using γ_c can modulate the signals of the others. To understand this model, it is important to recognize that, in contrast to antigen receptor complexes, cytokine receptor components individually are targeted to the cell surface, and the formation/stability of receptor complexes is promoted or stabilized by ligand binding, as noted in the discussion of growth hormone, wherein the second receptor monomer recognizes the combined surface of growth hormone and the first growth hormone receptor monomer¹⁹ or for the IL-2 receptor where γ_c "sees" a combined IL-2/IL-2RB surface.²³ This latter finding is consistent with γ_c originally having been coprecipitated with IL- $2R\beta$ in the presence but not in the absence of IL-2,²¹⁴ and dimerization of IL-2R β and γ_c is known to be required for efficient signaling.^{215,216} Thus, receptor heterodimerization at a minimum is stabilized by the cytokine and physiologically may be absolutely dependent on the presence of the cytokine. In the absence of stable preformed cytokine receptor complexes between γ_c and the other receptor chains, one can envision that γ_c might be differentially recruited to different receptors based on the relative amount of a cytokine or its binding efficiency. In a situation where γ_c is limiting, a cytokine might then not only induce its own action but could also simultaneously inhibit the action of another cytokine that was less efficient at recruiting γ_c to its cognate receptor complex.

An analysis of mice deficient in IL-2,²⁰⁵ IL-2R α ,²¹⁷ IL-2R β ,²¹⁸ and $\gamma_c^{211,212}$ provides the interesting observation that although the mice lacking γ_c have defective signaling in six

different cytokine pathways, mice deficient in IL-2, IL-2R α , and IL-2R β appear to be less healthy than the γ_c -knockout mice with more markedly activated T cells and autoimmunity that is not evident in γ_c -deficient mice. This is at least in part explained by the fact that IL-2–deficient mice lack Treg cells and thus develop autoimmune disease,⁶⁵ whereas γ_c -deficient mice lack T cells due to defective IL-7 signaling and thus lack effector T cells. These and other data indicate that γ_c plays a major role in regulating lymphoid homeostasis, as originally indicated.²¹⁹

Cytokines whose Receptors Share the Common β Chain, β_c (Interleukin-3, Interleukin-5, and Granulocyte Macrophage-Colony Stimulating Factor)

The hematopoietic cytokines, IL-3, IL-5, and GM-CSF (Table 25.5) are all synthesized by T cells and exert effects on cells of hematopoietic lineage.²²⁰⁻²²² These cytokines are vital for proliferation as well as differentiation of myeloid precursor cells. Of these three cytokines, IL-3 is the most pluripotent²²¹ and historically was also called multi-CSF, reflecting the large number of lineages on which it can act. It can act to promote proliferation, survival, and development of multipotent hematopoietic progenitor cells and of cells that have become dedicated to a range of different lineages, including granulocyte, macrophage, eosinophil, mast cell, basophil, megakaryocyte, and erythroid lineages. It induces a range of effects, including, for example, inducing the production off IL-4 by basophils.²²³ IL-3 also can exert end-function effects, such as enhancing phagocytosis and cytotoxicity. GM-CSF is mainly restricted to the granulocyte and monocyte/macrophage lineages, but its actions are nevertheless still quite broad.²²⁰ It is both a growth and survival factor. In addition, it can expand the number of antigen-presenting cells, such as DCs, and thereby may greatly expand the ability of the host to respond to antigen. IL-23 and RORyt can augment GM-CSF production in Th cells, whereas IL-12, IFNy, and IL-27 negatively regulate its expression, and GM-CSF is now known to be required for the initiation of autoimmune neuroinflammation in experimental autoimmune encephalitis. Collectively, these results suggest that GM-CSF is important for encephalitogenic actions of both Th1 and Th17 cells.^{224,225} GM-CSF mediates autoimmune effects at least in part by enhancing IL-6-

TABLE 2	25.5 Features of Cy	tokines whose Rece	ptors Share the Commor	η β Chain, $β_c$

GM-CSF, granulocyte macrophage-colony stimulating factor; IL, interleukin.

dependent Th17 cell development and survival.²²⁶ Whereas IL-3 and GM-CSF can act on eosinophils, they act at much earlier stages than IL-5, presumably expanding the number of eosinophil-committed precursors cells. IL-5 stimulates the eosinophilic lineage and eosinophil release from the bone marrow and is essential for expanding eosinophils after helminth infections,^{227,228} and can mediate the killing of S. mansoni. IL-5 can also induce Ig production in B cells activated by contact with activated Th cells in mouse systems, and IL-5 and IL-5Ra knockout mice have diminished CD5+ B1 cells and decreased thymocytes until approximately 6 weeks of age.^{227,228} Interestingly, the production of IL-5 by memory Th2 cells is driven by GATA3 but downregulated by expression of eomesodermin, which interacts with GATA3. Most memory Th2 cells produce the transcription factor Eomes, but the CD62¹⁰CXCR3¹⁰ population has decreased Eomes and is the population of cells that produces IL-5.²²⁹

On cells that express receptors for more than one of these cytokines, such as eosinophilic progenitors that express receptors for IL-3, IL-5, and GM-CSF, or on mouse pre-B cells, which express receptors for IL-3 and IL-5, the signals induced are indistinguishable.^{221,222} Thus, the differential lineage specificities of these cytokines are determined by the cellular distribution of their receptors rather than by fundamental differences in the signals that are induced by each cytokine. These observations are explained by studies demonstrating that each of these three cytokines has its own unique 60 to 80 kDa α chain (ie, IL-3Rα, IL-5Rα, and GM-CSFRα),²³⁰⁻²³⁶ but that they share a common 120 to 130 kDa β chain, β_{c} .^{222,237–239} The α chains are the principal binding proteins for the cytokines, whereas the shared β_c subunit augments binding affinity but does not exhibit binding activity in the absence of the proper α chain. The α chains have relatively short cytoplasmic domains (approximately 55 amino acids long for IL-3R α , IL-5R α , and GM-CSFR α) and are not believed to play major roles in signaling function, whereas β_c , with its cytoplasmic domain of 432 amino acids, is the primary determinant of the signal. As a result, there is a relative compartmentalization of binding and signaling function for these cytokines, although the cytoplasmic domains of the GM-CSFRa and IL-5Ra chains (and by analogy, perhaps the IL-3R α chain), as well as β_c , appear to be capable of at least modulating the growth signals in transfected cells.^{222,240-242} In any case, the sharing of β_c helps to explain why the signals induced by IL-3, IL-5, and GM-CSF are similar on cells that can respond to more than one of these cytokines. The situation for the β_c family of cytokines is therefore quite different from the receptors for γ_c family cytokines, wherein the chains with the largest cytoplasmic domains (IL-2R β , IL-4R α , IL-7R α , IL-9R α , and IL-21R) not only contribute most to signaling specificity but also are the proteins principally involved in ligand binding (note that for IL-2 and IL-15, IL-2Ra and IL-15Ra, respectively, serve important roles as well). The shared chain, γ_c , serves a vital accessory function (hence the development of X-linked SCID when the IL2RG gene is mutated), but it contributes less to cytokine binding and does not provide an obvious basis for signaling specificity (see subsequent discussion).

An interesting feature of the β_c family of hematopoietic cytokines is that there appears to be considerable redundancy

of function so that knockout mice that lack the ability to respond to all three cytokines (GM-CSF, IL-3, and IL-5) due to deletion of β_c as well as the mouse IL-3–specific β_c -like protein (discussed in the following text) nevertheless exhibit relatively normal hematopoiesis. These observations do not minimize the potency of these particular cytokines but instead underscore a substantial redundancy for a particularly important set of functions.^{221,222,243} It is also noteworthy that β_c -deficient mice exhibit defective host responses to infectious challenge, suggesting that these hematopoietic cytokines play a vital role in promoting immune function.

Cytokines whose Receptors Share gp130 (Interleukin-6, Interleukin-11, Oncostatin M, Ciliary Neurotropic Factor, Leukemia Inhibitory Factor, Cardiotrophin-1, Novel Neurotrophin-1/B Cell-Stimulating Factor-3/ Cardiotrophin-Like Factor, and Interleukin-27)

There are now eight cytokines that are known to utilize gp130 as a signal transducing molecule.^{244–255} Some of the properties of these cytokines are summarized in Table 25.6. This family is often referred to as the IL-6 family of cytokines and includes IL-6, IL-11, OSM, LIF, CNTF, CT-1, NNT/BSF-3/CLC, and IL-27. This group of cytokines comprises molecules with a diverse range of actions, ranging beyond the hematopoietic and

TABLE 25.6	Cytokines whose Receptors Share gp130 ^ª
Cytokine	Chromosome Location (h/m)
IL-6	7p21/5
IL-11	19q13.3–13.4/7

^aMost of the data in this table are derived from Yin et al.²⁴⁸

Note that NNT-1 can support survival of chicken embryonic and sympathetic neurons, can induce amyloid A, and analogous to IL-6 can induce B-cell hyperplasia. immune systems to the central nervous and cardiovascular systems, making them even more "multifunctional" than the γ_c and β_c families of cytokines, whose actions are more restricted to the lymphoid and hematopoietic systems.

IL-6 was originally identified and then cloned as a B-cell differentiation factor that stimulated terminal differentiation/maturation of B cells into antibody-producing plasma cells.²⁵⁶⁻²⁵⁸ However, IL-6 also can exert effects for T-cell growth and differentiation (and thus is a thymocyte "comitogen"), induce myeloid differentiation into macrophages, induce acute-phase protein synthesis of hepatocytes, and exert actions on keratinocytes, mesangial cells, hematopoietic stem cells, the development of osteoclasts, and neural differentiation of PC12 cells.²⁵⁰ IL-6 is also a mediator of amplified lymphocyte trafficking during febrile inflammatory responses, which is dependent on IL-6-mediated activation of L-selectin.²⁵⁹ IL-6 binds to an 80 kDa IL-6 binding protein, denoted IL-6Ra, which has a comparatively short 82 amino acid long cytoplasmic domain.^{257,260} This IL-6-IL-6Rα complex then interacts with and recruits the 130 kDa signal transducing molecule, gp130, which together with IL-6Rα can form a functional IL-6 receptor.²⁵⁰ From a structural perspective, gp130 contains a total of six fibronectin type III modules, with the four conserved cysteine residues and the WSXWS motif being located in the second and third of these modules, starting from the N-terminus. As such, these regions are topologically positioned at greater distance external to the cell membrane than is the case for the other type I cytokine receptors discussed previously.

The IL-6 system illustrates a novel twist related to the properties of their principal binding proteins: The cytoplasmic domain of IL-6R α is superfluous for signaling; a soluble form of the IL-6R α extracellular domain is in fact sufficient for ligand binding and coordination with gp130, a process termed *IL*-6 *transsignaling*.²⁶¹ Thus, in the presence of soluble IL-6R α and IL-6, many cell types that express gp130 but not IL-6R α are capable of signaling in response to IL-6. It was observed that IL-6 signaling requires the dimerization of gp130 and that the overall complex containing two molecules each of IL-6, IL-6R α , and gp130 (a dimer of a trimer or a hexamer),^{32,262–265} providing a possible paradigm for the stoichiometry of subunits for other members of the IL-6 family of cytokines.²⁴

IL-11 was identified as a factor produced by a stromal cell line in response to stimulation with IL-1.266,267 It has a number of effects on hematopoiesis, particularly in combination with IL-3 and SCF. Because IL-11 exhibited "IL-6-like activities," a complementary deoxyribonucleic acid (DNA) was isolated based on the presence of IL-6-like activity in the presence of antibodies to IL-6.268 Other actions of IL-11 include the ability to stimulate the proliferation of lymphoid and hematopoietic progenitor cells, stimulate megakaryocytic progenitors and megakaryocyte maturation, and stimulate erythroid progenitors (an action not shared by IL-6).^{266,267} Overall, it acts on T cells, B cells, hematopoietic cells, epithelium, endothelial cells, and osteoclasts.²⁶⁹ Like IL-6, IL-11 induces acute-phase proteins and augments antigen-specific B-cell responses, but it does not stimulate human myeloma cells.266-268,270 Subsequently, adipogenesis inhibitory factor was cloned and found to be identical to IL-11,²⁷¹ revealing another action of

IL-11. IL-11 is also produced by lung eosinophils and various structural cells in the lung and is expressed in patients with modest-to-severe asthma.²⁷² IL-11 signals via a receptor complex containing both IL-11Ra²⁷³ and gp130.²⁴⁴ Interestingly, IL-11Ra messenger RNA can be alternatively spliced to yield a form lacking the cytoplasmic domain, and like IL-6R α , a soluble form of IL-11R α can coordinate with IL-11 to transsignal in cells expressing gp130.274 Studies on the stoichiometry of the IL-11 receptor complex failed to reveal dimerization of gp130 to itself or LIFR β . Thus, assuming that it forms a hexameric receptor complex, only five of the members are known: two molecules of IL-11 and IL-11Rα, respectively, and one of gp130, suggesting that another component may still be found.²⁷⁵ IL-11 and STAT3 are expressed in gastrointestinal cancers associated with inflammation, suggesting a possible link to cancer.²⁶⁹

LIF is another multifunctional cytokine originally cloned based on the activity associated with its name.²⁷⁶ LIF can suppress the differentiation of pluripotent embryonic stem cells, inhibit adipogenesis (like IL-11), and induce monocyte differentiation of the M1 murine leukemia cell line, thus mimicking a number of the actions of IL-6.277 In addition, it exerts a number of actions in the central nervous system, and LIF was shown to be identical to cholinergic neural differentiation factor.²⁷⁸ and can induce acetylcholine synthesis while simultaneously suppressing catecholamine production, thereby inducing cholinergic function while suppressing noradrenergic function.²⁷⁸ LIF has been shown to be essential for embryo implantation.²⁷⁹ LIF binds to a receptor (LIFR β) that is structurally related to gp130,²⁸⁰ but the functional LIF receptor (LIFR) receptor requires the heterodimerization of LIFR β and gp130 as well.²⁴⁶ Interestingly, whereas IL-6 promotes Th17 differentiation, this is inhibited by LIF, apparently based on LIF's ability to activate ERKs and to augment the expression of SOCS-3, which can inhibit STAT3 activation.²⁸¹ Interestingly, LIF can also promote the differentiation of T_{reg} cells and may exhibit therapeutic potential in multiple sclerosis.²⁸² LIF maintains mouse embryonic stem cells, but LIF is not capable of maintaining human embryonic stem cells or mouse epiblast stem cells in the pluripotent state.²⁸³

CNTF was discovered based on its ability to promote neuronal survival.^{284,285} CNTF signals through a receptor comprising LIFRB and gp130 but requires a specific binding protein,^{286,287} now denoted CNTF receptor (CNTFR)α. Interestingly, CNTFRa lacks transmembrane and cytoplasmic domains and instead is a GPI-linked receptor molecule. CNTFRa appears to provide a receptor-cytokine surface with which gp130 and LIFR β can interact. Thus, CNTF is like IL-6 in that each requires initial binding to a receptor component (CNTFR α or IL-6R α) that does not require its own cytoplasmic domain for signaling. Whereas IL-6 signaling involves homodimerization of gp130, CNTF signaling involves the heterodimerization of LIFR β and gp130. In fact, the functional CNTFR appears to be a hexameric structure containing two molecules of CNTF, two of CNTFRα, and one each of gp130 and LIFRβ.²⁸⁸ The receptor is expressed largely within the nervous system and in skeletal muscle, accounting for largely restricted actions of CNTF.²⁸⁶

OSM is a growth regulator that was originally identified based on its ability to inhibit the growth of A375 human melanoma cells.^{289,290} OSM is a potent growth factor for Kaposi sarcoma in patients with acquired immunodeficiency syndrome.^{291,292} Not only OSM can bind directly to gp130 and signals through a receptor combination of gp130 and LIFR β^{246} but also has an alternative receptor comprising a specific OSM receptor subunit (OSMR β) and gp130.²⁹³ These are now known as the type I and type II OSM receptors (OSMRs), respectively. OSM can enhance the development of both endothelial cells and hematopoietic cells, possibly by increasing hamangioblasts, a common precursor for endothelial and hematopoietic cells.²⁵¹

CT-1 was initially isolated based on its actions on cardiac muscle cells.²⁹⁴ However, it is now clear that it is a multifunctional cytokine with hematopoietic, neuronal, and developmental effects, in addition to its effects on cardiac development and hypertrophy.^{295,296} Like OSM and LIF, CT-1 can also signal through a heterodimer of LIFR β and gp130.²⁴⁹ Interestingly, the CT-1 receptor on motor neurons may involve a third receptor component, possibly GPI linked.^{297,298}

NNT-1/BSF-3, like CNTF, can also support the survival of chicken embryonic sympathetic and motor neurons.²⁵³ Interestingly, in mice, NNT-1/BSF-3 can augment the effects of IL-1 and IL-6 and is a B-cell–stimulating factor (hence the term BSF-3). The NNT-1 receptor contains LIFRβ and gp130.²⁵³ NNT-1 is also known as CLC, and this forms a complex with a soluble receptor protein known as cytokine-like factor-1. Together, this complex is a second ligand for CNTFR.²⁹⁹ It appears that CLC can also interact directly with soluble CNTFR to form a related cytokine.²⁵⁴

IL-27 is an IL-6-related cytokine³⁰⁰ that represents a dimer of the p28 protein (also known as IL-30) and EB13 (Epstein-Barr virus-induced gene 3) (also known as IL-27B), which can induce proliferation of naive CD4+ T cells. p28 can exist by itself independently of EB13 and is capable of antagonizing gp130-mediated signaling by IL-6, and indeed, overexpression of p28 in transgenic mice prevents normal development of germinal centers and antibody production.³⁰¹ Together with IL-12, IL-23, CLC/cytokine-like factor-1, and CLC/soluble CNTFR, this is one of five cytokines that represent dimers including a type I cytokine and a soluble receptor-like protein. IL-27 signals via gp130 and the WSX-1/TCCR receptor,³⁰⁰ which is discussed in the section on diseases of cytokine receptors and related molecules. IL-27 has proinflammatory and anti-inflammatory effects. Although it was suggested to promote Th1 responses, it is clear that it can also antagonize such responses, and IL-27 can promote effector responses of both CD4+ and CD8+ T cells, of NK cells, and it additionally stimulates mast cells. The anti-inflammatory effects of IL-27 are indicated by the absence of WSX-1 resulting in increased mast cell and macrophage responses.^{302,303}

Thus, eight cytokines (IL-6, IL-11, LIF, CNTF, OSM, CT-1, NNT-1/BSF-3, and IL-27) all have receptors that are dependent on gp130.³⁰⁴ These can be divided into two sets of cytokines: those known to not require LIFR β (IL-6, IL-11, and IL-27) and those that use both gp130 and LIFR β (LIF, CT-1, OSM, CNTF, and NNT-1/BSF-3) (Table 25.7), with OSM having two forms of receptors, each of which contains gp130

TABLE 25.7	Composition of Receptors for the Interleukin-6 Family of Cytokines

BSF-3, B cell-stimulating factor-3; CLC, cardiotrophin-like factor; CLF-1, cytokinelike factor-1; CNTF, ciliary neurotrophic factor; CNTFR, CNTF receptor; CT-1, cardiotrophin-1; IL, interleukin; LIF, leukemia inhibitory factor; NNT-1, novel neurotrophin-1; OSM, oncostatin M.

Note that the sharing of CNTFR α by CNTF and the dimeric NNT-1/BSF-3/CLC – CLF-1 ligand helps to explain why the phenotype in CNTF–/– mice is less severe than that found in CNTFR α –/– mice.

but only one of which contains LIFR β . When cytokines share essentially the same receptor, one can hypothesize that two cytokines might exert identical actions on cells that can respond to both cytokines. It is clear that the presence of IL-6R α , IL-11R α , and CNTFR α (either on the cell surface or as a soluble receptor form, discussed subsequently) determines whether a cell can respond to IL-6, IL-11, and CNTF. This raises the interesting question as to whether functional homologues of these proteins will also exist for LIF, OSM, CT-1, NNT-1/BSF-3, and IL-27.

Significance of the Sharing of Receptor Chains

Interestingly, γ_c , β_c , and gp130 all contribute to signaling, but none of these shared cytokine receptor proteins has primary binding activity for any known cytokine. Instead, they each increase binding affinity in the context of the primary binding protein for each cytokine. Consequently, the capacity of a cell to respond to a given cytokine is determined by the unique binding chain(s), but signaling pathways can be shared.

Other Receptors with Similarities to gp130 (Granulocyte-Colony Stimulating Factor Receptor, OB-R, Interleukin-12R β 1, Interleukin-12R β 2, and Interleukin-31R)

As noted previously, LIFR β and OSMR β bear some similarities to gp130.²⁹³ In addition, the G-CSF receptor, the leptin receptor (also denoted OB-R, for obesity receptor), IL-12/IL-23 receptor components, and IL-31R all resemble gp130. The amino acid identity among these different receptors, compared pairwise, ranges from 18% to 32%, with LIFR β and OSMR β being the most similar. Although G-CSF is granulocyte-colony stimulating factor, it may have

a broader role. For example, G-CSF has been shown to stimulate myoblast proliferation and thereby to affect skeletal muscle formation,³⁰⁵ indicating broad pleiotropic actions by this cytokine.

Leptin

Leptin is the product of the obesity (ob) gene, an adipose tissue–derived cytokine that plays a role in body weight homeostasis.^{306–308} Additionally, leptin affects thymic homeostasis, increasing thymocyte number and having antiapoptotic effects in the thymus and periphery. It is proinflammatory, promoting Th1 differentiation, and augmenting the production of TNF- α , IL-1, and IL-6 by monocytes/macrophages.³⁰⁸ The leptin receptor, OB-R, was cloned and found to be most closely related to the gp130 signal transducer, G-CSF receptor, and LIFR β .³⁰⁹ Interestingly, this receptor is encoded by the "diabetes gene," which is mutated in db/db mice.³¹⁰

Interleukin-12, IL-23, and IL-35

As noted previously, IL-12 is the major inducer of Th1 cells. IL-12 is primarily produced by phagocytic cells in response to bacterial and intracellular parasites, such as Toxoplasma gondii, but it is also produced by other antigen-presenting cells, such as B cells.³¹¹ IL-12 potently induces the production of IFNy by NK cells and T cells and is also a growth factor for preactivated but not resting NK and T cells. IL-12 was originally discovered as NK cell stimulatory factor.³¹² IL-12 can also induce the production of IL-2, IL-3, GM-CSF, IL-9, TNF- α , and M-CSF, although inducing IFN γ is perhaps its most important known action.^{311,313,314} As is discussed in the section on immunodeficiency diseases, IL-12 is essential for the proper clearing of mycobacterial infections. It is interesting that Th2 cells do not respond to IL-12; the lack of responsiveness of these cells to IL-12 results from their loss of expression of the IL-12Rβ2 subunit of the IL-12 receptor.³¹⁵ Apparently, IL-4 inhibits IL-12R β 2 expression, whereas IL-2⁷⁴ and IFN γ^{315} induce its expression. The abilities of mice to survive infections is critically linked to the Th patterns of cytokines. For example, the ability to survive T. gondii infection is dependent on IFNy/IL-12 production (a Th1 pattern).⁸³

IL-12 can be thought of as having vital roles in both innate immunity and acquired immune responses. It is rapidly produced by NK cells and then T cells in response to antigens or foreign pathogens. This rapid response facilitates the activation of first-line defense against infections. In addition, however, IL-12 is also required for the subsequent differentiation of specialized T-cell populations, including its STAT4-dependent priming of Th1 cells for optimal production of IFNy and IL-2. IL-12 can act synergistically with hematopoietic growth factors, such as IL-3 and SCF, to support the proliferation and survival of hematpoietic stem cells.³¹¹ Structurally, IL-12 is a covalently linked dimer of 35 (IL-12A) and 40 (IL-12B) kDa peptides³¹¹; thus, successful production of IL-12 requires that a cell transcribe both the p35 and p40 genes.³¹⁶ Interestingly, whereas p35 bears sequence similarity to IL-6 and G-CSF, p40 is homologous to the extracellular domains of IL-6Ra, CNTFRa, and G-CSF

receptor and bears some of the features typical of type I receptors, including four conserved cysteines, a conserved tryptophan, and a WSEWAS motif, which has similarity to the typical WSXWS motif.³¹¹ Moreover, as both IL-12 receptor (IL-12R β 1 and IL-12R β 2) chains bear some similarity to gp130,^{312,316,317} one can think of p40 as a functional homologue of the soluble p80 IL-6R α chain. Thus, for this cytokine, part of the "receptor" has become part of the cytokine. Interestingly, all cells that produce IL-12 synthesize much more p40 than p35, suggesting that the careful control of signaling is at the level of the "primordial" p35 cytokine part of IL-12. p40 is on human chromosome 5q31 to 5q33 while p35 is on 3p12 tp 3p13.2.³¹¹ As noted previously, it is interesting that IL-2R β 2.

IL-23 is similar to IL-12 in that it also contains p40.³¹⁸ However, rather than also containing p35, IL-23 is a dimer of a p40 and p19 (IL-23A). IL-23 signals via a receptor that contains IL-12RB1 but not IL-12RB2.319 Instead, another receptor chain, denoted IL-23R, is the second component of the IL-23R³²⁰; both IL-12R β 2 and IL-23R are located on chromosome 1 within 150 kb of each other.³²⁰ Both IL-12 and IL-23 activate JAK2 and TYK2. IL-12 and IL-23 can activate STAT1, STAT3, STAT4, and STAT5. STAT4 is the dominant STAT protein activated by IL-12.320 Interestingly, as compared to human IL-23R, mouse IL-23R contains a 20 amino acid duplicated region that spans the WQPWS motif. IL-23 appears to play a vital role in the maintenance, rather than in the initial differentiation of Th17 cells (IL-17-producing cells), and IL-23 is essential for resistance to certain diseases, such as EAE, which were originally believed to be Th1-mediated diseases, as elimination of IL-23 by eliminating either the p40 subunit shared by IL-12 and IL-23 or by eliminating p19 confers resistance to EAE.^{175,321} Whereas IL-23 promotes Th17 cell numbers, IL-27 can negatively regulate their development.³²¹ In the CD40-mediated model of inflammatory bowel disease, IL-12 p35 secretion controlled wasting disease and serum cytokine production but did not affect mucosal pathology, which instead was associated with IL-23/p19.322 Interestingly, IL-23R has been identified as an inflammatory bowel disease gene,³²³ and IL-23 can drive intestinal inflammation via direct actions on T cells.³²⁴ Separate from Th17 cells, a population of innate lymphoid cells that produce IL-17, IL-22, and IFNy in response to IL-23 have been identified as the mediators of inflammatory bowel disease.³²⁵ IL-23 and its receptor are nevertheless critical for the terminal differentiation of Th17 cells.^{169,326} IL-27 is a related cytokine (discussed previously), but it can act as an inhibitor of Th1 responses associated with intracellular infections such as T. gondii. Whereas host defense to T. gondii is dependent on IL-12 and IFNy, IL-27-deficient mice control the parasite replication but develop a lethal inflammatory disease that is dependent on CD4+ T cells. Additionally, IL-27 can inhibit Th2 actions.³⁰³

IL-35 is produced by T_{reg} cells and plays a role in immunosuppression. It is a heterodimer of IL-12A (p35) and IL-27B (EBI3).³²⁷ IL-35 treatment of naive mouse or human T cells induces regulatory cells that have been called iTR35 cells³²⁸ and promote tolerance and tumor progression.

Interleukin-31

IL-31 is a four α -helical bundle cytokine that fits into the greater IL-6 extended family in that its receptor consists of IL-31RA and the OSMR β .³²⁹ IL-31R is a gp130-like type 1 receptor, with four splice variants. IL-31 is produced primarily by activated T cells and when overexpressed results in pruritis, alopecia, and skin lesions, indicating a potential role in dermatitis.^{329,330}

Other Examples of Shared Receptor Molecules Interleukin-7 and Thymic Stromal Lymphopoietin Share Interleukin-7 Receptor α Chain

In addition to IL-7, a second stromal factor, TSLP has been identified that shares at least some actions with IL-7.11,331-333 The TSLP receptor is a heterodimer of TSLPR and IL-7R $\!\alpha.^{_{334,335}}$ Interestingly, TSLPR is 24% identical to γ_c , making it the cytokine receptor most like γ_c .³³⁴ Human and mouse TSLP share only 43% amino acid identity, and human and mouse TSLP receptors share only 39% identity.336 This is very low for human and mouse orthologues of cytokine receptors, for example, human and mouse γ_c are 70% identical.³³⁷ In addition to their wide sequence divergence, mouse and human TSLP were originally suggested to substantially differ in their actions. Mouse TSLP was first reported to be a B-cell differentiation factor that is important for the development of IgM+ immature B cells from pre-B cells and to also be a weak thymic comitogen. In contrast, human TSLP appeared not to exert effects on these lineages but was found to be an epithelial-derived cytokine that potently activated DCs related to Th2 allergic responses, an action not then known to be shared by mouse TSLP.^{338–340} However, it is now clear that mouse TSLP can also activate DCs and that it plays a critical role in both atopic disease and asthma in mouse models, and that these effects of TSLP are mediated via actions on both DCs and CD4+ T cells.³⁴¹⁻³⁴⁷ TSLP can also promote immunity to helminth parasites,³³³ and TSLP is also important for mucosal healing in the dextran sulfate sodium-induced colitis model.³⁴⁸ Interestingly, human TSLP is expressed by Hassall corpuscles³⁴⁹ and was suggested to promote selection of T_{reg} cells in human thymus, thus contributing to central tolerance.³⁵⁰ It is striking, however, that mice lacking TSLP receptor have normal numbers of T_{reg} cells, indicating that TSLP is not absolutely essential for this function, and that other molecules can at least substitute for TSLP. Indeed, IL-7 is such a molecule.^{350a} TSLP is now known to be produced by a range of cell types, including epithelial cells, fibroblasts, keratinocytes, stromal cells, basophils, mast cells, and DCs,¹¹ and to in turn act on multiple lineages, including DCs, CD4+ and CD8+ T cells, mast cells, NKT cells, eosinophils, and B cells.^{11,333,351} Interestingly, TSLP promotes Th2 differentiation and has been shown to promote metastasis in breast cancer and pancreatic cancer.^{352–354} From a signaling perspective, whereas IL-7 activates JAK1 and JAK3, TSLP activates JAK1 and JAK2, making it the only type 1 cytokine to use this combination of JAK kinases to activate STAT5.³⁴⁷ Although IFNy also uses JAK1 and JAK2, it instead activates STAT1.355

Two Types of Interleukin-4 Receptors, One of which also Responds to Interleukin-13

As detailed previously, on T cells, IL-4 acts through a receptor comprising IL-4R α and γ_c (the type I IL-4 receptor)^{38,39}; however, IL-4 can also signal through type II IL-4 receptors comprising IL-4R α and IL-13R α 1 but not γ_c .³⁵⁶ IL-13 is another cytokine that shares some actions with IL-4 and was originally described as a T-cell-derived cytokine capable of inhibiting inflammation,³⁵⁷ although it is now clear that other cells such as NK cells and mast cells can also produce IL-13. IL-13 can induce identical signals to IL-4 on non-T cells that respond to IL-4 but lacks effects on mature T cells, as these cells do not bind IL-13.^{358,359} The shared actions of IL-4 and IL-13 include the ability to 1) decrease expression of inflammatory cytokines, 2) induce major histocompatibility complex class II expression, 3) induce CD23 expression and IgE production by B cells in humans, 4) inhibit IL-2-induced proliferation of chronic lymphocytic leukemia cells of B-cell origin, and 5) costimulate with anti-CD40 antibodies. This is explained by the observation that the type II IL-4 receptor consists of IL-4Ra plus IL-13Ra1,^{360,361} with both IL-4 and IL-13 inducing indistinguishable signals on cells expressing this receptor. Interestingly, IL-4 binds primarily to IL- $4R\alpha$ and IL-13 binds primarily to IL-13R α 1. This situation may be analogous to the situation for LIF, CT-1, and OSM, which can all act through receptors containing LIFRB and gp130 but differ in their abilities to directly interact with each of these receptor proteins. An additional IL-13 binding protein, IL- $13R\alpha 2$, has much higher binding affinity for IL-13 than does IL-13R α 1.³⁶² IL-13R α 2 is nonfunctional in terms of signaling and instead acts as a "decoy" receptor.

Although IL-13 was originally believed to be substantially redundant with IL-4, it has important distinctive actions as well. IL-13 may be vital in asthma, as blocking IL-13 can inhibit pathophysiologic changes of asthma.^{363,364} It also is clear that IL-13 regulates eosinophilic infiltration, airway hyperresponsiveness, and mucus secretion, and that it is a potent mediator of fibrosis.³⁵⁷ Moreover, IL-13 that is produced by innate natural helper cells in the lung contributes to asthma.³⁶⁵ The phenotype of IL-13 knockout mice suggested a role for IL-13 the ability to expel helminths,³⁶⁶ and it is clear that IL-13 specifically can modulate resistance to intracellular organisms, including *Leishmania major* and *Listeria monocytogenes*.³⁵⁷ IL-13 has also been identified as a factor that is secreted by and can stimulate the growth of Hodgkin and Reed-Sternberg cells.³⁶⁷

Although IL-4 and IL-13 are both critical for host defense to helminths, the use of reporter mice revealed that Th2 cells produce both cytokines. Tfh cells in lymph nodes as well as basophils make IL-4, whereas innate helper type 2 cells secrete IL-13. Thus, although both are produced during helminth infection, there are distinctive sites of production, correlating with distinctive roles.³⁶⁸

An Example of Multiple Affinities of Binding for a Single Cytokine: Three Classes of Interleukin-2 Receptors

Although cytokines typically signal via a single class of highaffinity cell surface receptor, more complex situations exist.

TABLE 25.8	Classes of Interleuk	kin-2 Receptors		
Affinity	K _d	Where Expressed	Composition	Functional
Low Intermediate High	10 ^{−8} M 10 ^{−9} M 10 ^{−11} M	Activated cells Resting cells Activated cells	IL-2R α IL-2R β and $\gamma_{\rm c}$ IL-2R β , and $\gamma_{\rm c}$ IL-2R α , IL-2R β , and $\gamma_{\rm c}$	No Yes Yes

IL, interleukin

The IL-2 system provides the very interesting illustration of a system with three classes of affinities of receptors (Table 25.8). In addition to the high-affinity receptor (IL-2R α + IL-2R β + $\gamma_c, K_d \approx 10^{-11}$ M), there are both low-affinity (IL-2R alone, K_d $\approx 10^{-8}$ M) and intermediate-affinity (IL-2R β + γ_c , K_d $\approx 10^{-9}$ M) receptors.^{29,50} Low- and high-affinity receptors are expressed on activated lymphocytes, whereas intermediate-affinity receptors are found on resting lymphocytes, particularly on NK cells. Both intermediate- and high-affinity receptors can signal, suggesting that IL-2R β and γ_c are necessary and sufficient for signaling, in keeping with the theme of dimerization indicated previously. Given that the intermediateaffinity form is functional, what then is the rationale for having a high-affinity IL-2 receptor that also contains IL- $2R\alpha$? This is a particularly important question in view of the fact IL-2R α has an extremely short cytoplasmic domain that does not appear to play a role in signaling. The importance of IL-2R α is clearly demonstrated by the severely abnormal phenotype of IL-2Ra-deficient mice, which exhibit autoimmunity, inflammatory bowel disease, and premature death,²¹⁷ and by the observation that IL-2R α mutations can cause an autoimmune syndrome in humans as well.³⁶⁹ A clue to the importance of IL-2Rα comes from the kinetics of association of IL-2 with each chain. Although the IL-2Ra appears to lack a direct signaling function, it has a very fast on-rate for IL-2 binding.³⁷⁰ Thus, the combination of this rapid onrate with the slow off-rate from IL-2R β/γ_c dimers results in high-affinity binding that is vital for responding to the very low concentrations of IL-2 that are physiologically present in vivo. Moreover, as activated T cells express approximately 10 times as many low-affinity than high-affinity receptors, IL-2Ra may serve as an efficient means of recruitment and concentration of IL-2 on the cell surface, allowing more efficient formation of IL-2/IL-2R β/γ_c signaling complexes.

As noted previously, IL-2R α is not a type I cytokine receptor and in fact has homology to the recognition domain of complement factor B.³⁷¹ Subsequently, the IL-15 receptor α chain was shown to also have a similar structure to IL-2R α ,¹⁵⁵ with both IL-2R α and IL-15R α having what are called "sushi" domains, which contribute to ligand binding. The fact that IL-2 and IL-15 both have related α chains is consistent with the close relationship between IL-2 and IL-15, and that the receptors for both IL-2R α and IL-15 contain both IL-2R β and γ_c .

As IL-2R α cannot transduce a signal by itself, the detection of IL-2R α on the cell surface does not necessarily reflect IL-2 responsiveness. Because IL-2R α was discovered before IL-2R β and γ_c , many papers in the literature have evaluated IL-2 receptor expression based on IL-2R α expression alone, and this may not reflect IL-2 responsiveness. IL-2R α is also expressed on a subpopulation of double negative thymocytes, but it remains unclear if IL-2 physiologically acts on these cells. Each of the components of the IL-2 receptor is located on a different chromosome: Human IL-2R α is located on chromosome 10p14 to 10p15,³⁷² IL-2R β is at 22q,^{373,374} and γ_c is at Xq13.1,¹⁹⁷ while the mouse homologues are located at chromosomes 2, 15, and X.

Erythropoietin, Thrombopoietin, and Stem Cell Factor

Epo was the first cytokine that was biochemically purified and is vital for erythropoiesis, whereas thrombopoietin is critical for thrombopoiesis. These cytokines each bind to receptors that are homodimers.^{21,375} Interestingly, Epo signaling may depend in part on the functional cooperation of the Epo receptor and c-kit, the receptor for SCF.376 This latter receptor has intrinsic tyrosine kinase activity and is not a type I cytokine receptor. Epo was the first cytokine with demonstrated clinical efficacy, for example, in renal insufficiency. Although it is dominantly associated with erythrocyte production, Epo receptors have been found more broadly on immune cells. Recently, Epo has been shown to have effects on a number of cell types, blocking NF-KB p65 and resulting in inhibition of the induction of TNF- α and inducible nitric oxide synthase in activated macrophages, with diminished control of Salmonella infection, whereas in a model of chemical-induced colitis, such inhibition of NF-KB-dependent immune modulators limits tissue damage and disease severity.³⁷⁷ It will therefore be important to determine the full scope of immunologic actions that are mediated by Epo.

CYTOKINE AND CYTOKINE RECEPTOR PLEIOTROPY AND REDUNDANCY

It is well recognized that many cytokines exhibit the phenomena of cytokine "pleiotropy" and "redundancy."304 Cytokine pleiotropy refers to the ability of a cytokine to exert many different types of responses, often on different cell types, whereas cytokine redundancy refers to the fact that many different cytokines can induce similar actions. One set of cytokines that exhibit cytokine pleiotropy is the γ_c family of cytokines. For example, IL-2 can induce T-cell growth, augment B-cell Ig synthesis, increase the cytolytic activity of lymphokineactivated killer and NK cells, and play an essential role in mediating activation-induced cell death; IL-4 can induce B-cell growth and Ig class switch; and IL-7 not only plays a major role in thymocyte development but also can stimulate mature T cells, and at least in the mouse, can act as a pre-B-cell growth factor. The gp130 family cytokines also exhibit broad actions. For example, IL-6 exerts effects ranging from that of a comitogen for thymocyte activation to that of a mediator of the acute-phase response in liver. Regarding cytokine redundancy, it has already been highlighted that IL-2, IL-4, IL-7, and IL-15 receptors contain γ_c can act as T-cell growth factors, and that IL-3 has actions that overlap with IL-5 and GM-CSF.

The recognition that cytokines not only have overlapping actions but also share receptor components, led to the concepts of "cytokine receptor pleiotropy" and "cytokine receptor redundancy."³⁰⁴ The first of these terms can be defined by the ability of a single cytokine receptor subunit to function in more than one receptor. Thus, examples include the sharing of γ_c , β_c , gp130, IL-4R α , LIFR β , and OSMR β , as summarized previously, as well as the sharing of IL-2R β by IL-2 and IL-15 receptors, the sharing of IL-4R α and IL-13R α in type II IL-4 receptors and IL-13 receptors, and the sharing of IL-7R α by the IL-7 and TSLP receptors. Another way of viewing receptor pleiotropy is that certain receptor chains are useful "modules" that function in more than one context.

The final term, cytokine receptor subunit redundancy, is the one with fewest examples. There is one well-documented example in mice but not in humans. IL-3 signals through IL- $3R\alpha$ plus either β_c or an alternative unique IL-3R β that shares 91% amino acid identity with β_c and appears to be a completely functionally redundant protein for IL-3 signaling, but IL-3R β cannot substitute for β_c in the context of IL-5 or GM-CSF signaling.²³⁹ Other potential examples exist. For example, in type I and type II IL-4 receptors, IL-4Ra coordinates with either γ_c or IL-13R α 1, respectively, and there are two types of OSM receptors, both of which contain gp130, but one of which contains a specific OSM receptor while the other contains LIFR β . What remains unknown, however, is whether the signals mediated by these different types of receptors are truly identical so that there is redundancy, or whether there are distinctive features to the signals that IL-4 and OSM induce via the different receptors. Indeed, mice lacking IL-13Ral have exacerbated Th2 responses and is essential for allergen-induced airway hyperreactivity, suggesting that type 2 IL-4 receptor signaling (either via IL-4 or IL-13) is not identical to that mediated by the type 1 IL-4 receptor (via IL-4).³⁷⁸

In addition to these examples related to type I cytokines, the IL-10 subfamily of type II cytokines is interesting in that IL-10R β (IL-10R1), IL-20R α (IL-10R1), IL-20R β (IL-20R2), and IL-22R α (IL-22R) are each shared receptor components, collectively affecting signaling in response to IL-10, IL-19, IL-20, IL-22, and IL-24.^{304,379} Specifically, IL-10 signals via a receptor containing IL-10R1 and IL-10R2, IL-19 signals via a receptor containing IL-20R1 and IL-20R2, IL-20 signals via a receptors containing IL-20R2 and either IL-20R1 or IL-22R, IL-22 signals via receptors containing IL-22R and IL-10R2, and IL-24 signals through receptors containing IL-20R2 plus either IL-20R1 or IL-22R. Two other IL-10 family members, IL-28 and IL-29, both signal via IL-28R + IL-10R2.³⁸⁰ Interestingly, IL-10 is believed to be a dimer; IL-26 may also be a dimer, but the other family members are monomers.³⁷⁹

SOLUBLE RECEPTORS

Soluble forms of many cytokine receptors have been identified, including those for IL-1, IL-2, IL-4, IL-5, IL-6, IL-7, IL-13Rα2, GM-CSF, type I and type II IFNs, IL-22, and TNF.^{381–383} As is clear from this list of cytokines, soluble receptors are not restricted to receptors for type I cytokines, and in the case of IL-2, the principal soluble receptor protein is IL-2R α , which is not a type I cytokine receptor. Soluble receptors can be created by alternative splicing that truncates the protein N-terminal to the transmembrane domain, resulting in a secreted protein rather than a membrane-anchored membrane in the case of IL-4Ra, IL-5Ra, IL-6Ra, IL-7Rα, IFNAR-2, and GM-CSFRα. Alternatively, they can be created by proteolytic cleavage of the membrane receptor as is found for the receptors for IL-2R α and TNFRI and TNFRII³⁸² (Table 25.9). Although it is conceivable that a distinct gene might encode the soluble forms of a receptor, no examples have been reported. In the cases where proteolytic cleavage occurs, the identity of the proteases has not been identified. The major questions related to these soluble receptors are as follows: 1) Do they have physiologic or pathophysiologic functions? 2) How do their affinities compare to the corresponding cell surface receptor? 3) Do they have diagnostic, prognostic, and therapeutic applications?

Unfortunately, there is little information available on the in vivo role of soluble receptors. In general, when analyzed using in vitro studies, soluble receptors can compete with their corresponding cell surface receptors, thereby serving negative regulatory roles. For example, this appears to be the case for the IL-22 soluble receptor. However, soluble IL-6R α exerts an agonistic role because, as summarized previously, IL-6 signaling occurs equally well via gp130 when the soluble rather than transmembrane form of IL-6Ra interacts with IL-6. Nevertheless, a mutated form of IL-6R α that cannot interact with gp130 but still binds IL-6 can effectively inhibit the actions of IL-6.³⁸⁴ In the case of IL-2R α , there is no reported physiologic function for soluble IL-2R α , as the affinity of the released receptor is, as expected, similar to that of the low-affinity receptor ($K_d \approx 10^{-8}$ M), making it unlikely to effectively compete with the high-affinity cell surface receptor ($K_d \approx 10^{-11}$ M). However, this and other soluble receptors could serve as cytokine carrier proteins and potentially could increase stability of a cytokine by protecting it from proteolysis.³⁸² This theoretically could be similar to the role of IL-2/anti-IL-2 conjugates in exhibiting higher activity.³⁸⁵ Moreover, there are potential diagnostic and prognostic uses for measuring the level of shed receptors (Table 25.10).

Infectious mononucleosis	

Other diseases

End-stage renal disease Rheumatoid arthritis Systemic lupus erythematosus Scleroderma Sarcoidosis

After transplantation

After interleukin-2 administration

In adults, the mean sIL-2R α levels are 280 \pm 161 units/mL (levels tend to be higher in pediatric populations). The situations where the levels exceed 5000 units/mL are adult T-cell leukemia, hairy cell leukemia, chronic myelogenous leukemia, and after interleukin-2 administration. The situations where levels are between 1000 and 5000 units/mL include acute myelogenous leukemia, chronic lymphocytic leukemia, non-Hodgkin lymphomas, acquired immunodeficiency syndrome associated with Kaposi sarcoma, tuberculosis, rubeola, and end-stage renal disease. Data are from Kurman et al.³⁸¹ and Fernandex-Botran et al.³⁸²

INTERFERONS (TYPE II CYTOKINES) AND THEIR RECEPTORS

IFNs represent an evolutionarily conserved family (Table 25.11) of cytokines that are related to the IL-10 family of type II cytokines. IFNs were discovered in 1957 on the basis of their antiviral activity and were the first cytokines that were discovered.³⁸⁶ IFNs are known as either type I or type II IFNs,^{387–396} where type I interferons include IFN α (originally known as leukocyte IFN) and IFN β (originally known as fibroblast IFN), and IFN ϵ , IFN κ , IFN ω , IFN δ , and IFN τ . IFN δ and IFN τ are absent in humans. IFN ω is closely related to the IFN α s and was for-

IFN, interferon; IL, interleukin.

merly designated as an IFN α . There are multiple (at least 12) IFN α s in mice and humans. In contrast, the other type I IFNs, IFN β and IFN ω , are each encoded by single human and mouse genes near the IFN α cluster, and in addition, there are multiple pseudogenes most closely related to IFN α and IFN ω . The type I IFNs are clustered on human chromosome 9 and mouse chromosome 4. Type II interferon is IFN γ ³¹⁴ which is encoded by a single gene on human chromosome 12 and mouse chromosome 10. IFN α/β is produced after viral infection in many cell types, although plasmacytoid DCs appear to be the largest producers of IFN α/β . These type I IFNs inhibit viral replication and induce the apoptosis of virally infected cells. In addition, IFN α/β mediate the activation of macrophages and NK cells, and they additionally affect the proliferation and survival of CD8+T cells.

The grouping of the IFN α s and IFN β together as type I IFNs is logical not only because of the similar amino acid sequences and structures of these IFNs but also based on the fact that they share the same receptor and induce essentially the same signals.^{397,398} Although DNA array analysis does show some differences in the genes induced by IFN α and IFN β , the basis for these differences are unclear.³⁹⁹ These signals include not only antiproliferative and antiviral activities but also the ability to stimulate cytolytic activity in lymphoyctes, NK cells, and macrophages. In contrast, IFNy has a distinct receptor. Type I and type II IFN receptors share a sufficient degree of similarity to each other so as to form a family.⁴⁰⁰ The structure of the IFNy receptor⁴⁰¹ is shown in Figure 25.2. IFN receptors are referred to as type II cytokine receptors, and there are substantial differences between these receptors and the type I cytokine receptors.8 Because both type I and type II IFNs bind to type II cytokine receptors, IFNs are occasionally referred to as type II cytokines but more generally are referred to as IFNs. Based on the similarity of the

IL-10 receptor to the IFNγ receptors,⁸ IL-10 was designated as a type II cytokine, and indeed when its x-ray crystal was determined, IL-10 was found to be topologically related to IFNγ.¹⁶ As noted previously, more recently a series of IL-10– related cytokines has been identified, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29, and these are also designated as type II cytokines, with IL-28A, IL28B, and IL-29 also known as IFNλs. Among type II cytokines, IFNγ has helices similar to those of the type I short-chain helical cytokines, but its short helices that occupy the AB and CD loops positions exhibit the long-chain cytokine-like AB over CD topology. IL-10 and IFNαβ have long-chain structures.⁸ Thus, the theme of short-chain and long-chain type I cytokines also extends to the IFNs and the IL-10 family of type II cytokines.

Type I IFNs signal through a receptor known as the type I IFN receptor.^{388,392,394,396,397} The receptor consists of at least two chains. $^{402-405}$ In contrast to the α and β chain nomenclature typical for type I cytokine receptors, IFN receptor chains are officially denoted as IFNAR-1 (previously also denoted IFN- α R1, IFNAR1, and IFN-R α) and IFNAR-2 (previously also known as IFN α/β receptor, IFN α R2, IFNAR2, and IFNR β).⁴⁰⁶ IFNAR-2 has both short and long forms as well as a soluble form.⁴⁰⁷ The long form has a much larger cytoplasmic domain and serves a more important role in signal transduction. Whereas IFNAR-1 cannot bind IFN α , IFNAR-2 binds with low affinity, and the combination of both chains results in high-affinity binding⁴⁰⁷ and function. As detailed in the following, IFNAR-1 binds the Janus family tyrosine kinase TYK2, whereas IFNAR-2 binds JAK1. In addition to these cellular receptors, it is interesting that vaccinia virus and other orthopoxviruses encode a soluble form of type I IFN receptor that is related to the IL-1 receptors and that is capable of binding IFN α , IFN β , and IFN ω .^{408,409} This form of IFN receptor is therefore not a member of the type II cytokine family but instead is an Ig superfamily protein. IFN α s are typically species specific, although IFN α 8 is a human type I IFN that can bind to the mouse receptor. IFNAR-1 confers species specificity of binding. As noted previously, type I IFNs are induced by viral infection. Infection with viruses results in the generation of nonself RNAs in the cell, which are recognized by retinoic acid inducible gene-I (RIG-I)-like receptors, which include RIG-I, MDA5, and LGP2, each of which contains a helicase domain. Retinoic acid inducible gene-I-like receptors are essential for the production of tpe I interferons as well as IL-6, and cells lacking both RIG-I and MDA5 are completely defective in the production of type I IFNs.410

IFN γ was first recognized in 1965 as immune IFN, named as IFN γ in 1980, cloned in 1982, and then confirmed to be the same as primary macrophage activating factor.^{388,397,411–413} In addition to its antiviral activity, IFN γ also has a range of actions on proinflammatory and anti-inflammatory host responses.³⁹³ For example, IFN γ can prime macrophages to manifest antimicrobial and antitumor effects. Moreover, following IL-12–mediated differentiation of Th1 cells, IFN γ is a major secreted product. This production is critical for host response to a range of infectious pathogens, including, for example, *T. gondii*. IFN γ inhibits the generation of Th2 cells as well as Th17 cells. IFN γ is produced by a range of cells, including T_{reg} cells and in this context appears to result in apoptosis of naive cells and Th2 effector T cells. It is produced by NK cells and can mediate NK-dependent lysis of tumor cells, augment IgG2a isotype switching of B cells, and activate DCs. Moreover, IFN γ can either contribute to disease protection or can be protective, depending on the context.⁴¹³ Finally, IFN γ - or anti-IFN γ -based therapy are being tried in a range of conditions.³¹⁴

IFN γ is encoded by four exons on chromosome 12. IFN γ forms a functional homodimer with an apparent molecular weight of 34 kDa, whereas little of the monomeric form can be detected and it is not biologically active. Each IFNy monomer has six α helices, four of which resemble the shortchain helical cytokines, and there is no β sheet structure. The subunits interact in an antiparallel fashion. In contrast to the ability of many different cells to produce IFN α , IFNy is more restricted, with it being produced primarily by NK cells, CD8+ T cells, and the Th1 subclass of CD4+ T cells.³⁸⁸ Many signals, including antigen stimulation, IL-12, and IL-18, can induce the production of IFNy. IFNy exerts its effects through specific receptors that are expressed on all types of cells except erythrocytes. Interestingly, even platelets express IFNy receptors, raising the possibility that they can serve a function in transporting IFN γ in the circulation.³⁸⁸ The functional human receptor consists of two chains⁴¹⁴: IFNGR-1, formerly also denoted IFNyR1 or IFN $\gamma R\alpha^{406,415}$ a 90 kDa protein whose gene is located on human chromosome 6q16 to 6q22 and mouse chromosome 10,⁴¹² and IFNGR-2, also denoted as IFNγRβ,^{416,417} located on human chromosome 21g22.1 and mouse chromosome 16.412 IFNGR-1 is required for ligand binding, whereas IFNGR-2 plays a role in signaling. JAK1 associates with the Leu-Pro-Lys-Ser sequence in the membrane proximal region of the cytoplasmic domain of IFNGR-1,418 whereas JAK2 binds to IFNGR-2.⁴¹⁹ The fact that IFNy is a homodimer explains how its binding induces the homodimerization of IFNGR-1, which then allows the recruitment of IFNGR-2. Thus, the functional IFNy receptor is believed to contain two molecules each of IFNGR-1 and IFNGR-2. Normal IFNy production is dependent on IL-12, and defective IFNy signaling is associated with failure to appropriately clear mycobacterial and other infections (discussed subsequently).

Both type I and type II IFNs are important for cancer immunoediting, a process in which neoplastic growth is suppressed by the immune system and tumor immunogenicity is shaped. IFN γ can suppress tumor development, but type I IFNs are required to initiate the antitumor response, at least in part via actions on DCs.⁴²⁰

Interleukin-10, a Type II Cytokine, and the Related Cytokines Interleukin-19, Interleukin-20, Interleukin-22, Interleukin-24, Interleukin-26, Interleukin-28A, Interleukin-28B, and Interleukin-29

IL-10 is a type II cytokine that originally was identified as cytokine synthesis inhibitory factor, 380,421,422 produced by Th2 cells. However, it then was observed to be produced by T_{reg} cells as well, and it is now clear that IL-10 is much

more broadly expressed, including by Th1, Th17 cells, B cells, macrophages, NKT, NK, T_{reg}, monocytes, and myeloid DCs but not plasmacytoid DCs, keratinocytes, as well as mast cells and eosinophils.^{423,424} IL-10 production by T_{reg} cells helps to explain their suppressive effects, and IL-10 production by T_{reg} cells is required for their suppression of Th17-mediated inflammation.425 The IL-10 gene contains five exons and is located on chromosome 1 in both mice and humans.⁴²² IL-10 has an open reading frame of 178 amino acids, including the signal peptide, and the mature protein is 18 kDa. Human IL-10 receptor maps to 11q23.3. IL-10 can inhibit the production of a number of cytokines, including IL-2, IL-3, IFNγ, GM-CSF, and TNF-α. Production of IL-10 is substantially dependent on the transcription factor E4BP4 (also called NFIL-3).426 IL-10 production is induced by pathogen-derived products, with TLR2 signaling being critical for its induction by antigen-presenting cells and macrophages, although TLR-independent induction of IL-10 has also been observed.⁴²³ Interestingly, IL-21 has been shown to be a potent inducer of IL-10 and to mediate IL-27 and part of the IL-6-mediated induction of IL-10 as well.^{189,190} IL-10 inhibits monocyte/macrophage/DC-dependent T-cell proliferation, in part, by markedly decreasing synthesis of a variety of cytokines, expression of costimulatory molecules, and chemokines, to name just some of its inhibitory effects.³⁸⁰ In addition to these indirect effects on T cells, IL-10 can exert direct stimulatory effects on thymocytes and T cells in vitro and promote the development of B1 cells and activity of NK cells. IL-10-deficient mice develop a form of inflammatory bowel disease that is similar to Crohn disease.422,427 Interestingly, the BCRF1 protein that is encoded by Epstein-Barr virus is very similar to IL-10 and shares many of its biologic properties as a macrophage "deactivating" factor and as a costimulator of proliferation of B cells.⁴²⁸ The Epstein-Barr virus IL-10 homologue is a selective agonist, although its binding to the IL-10 receptor is somewhat impaired.⁴²⁸ IL-10 is a major inhibitor of Th1 functions.⁴²² Although it was originally suggested that IL-10 might also favor Th2 development, IL-4 is the major mediator of Th2 cell development, and IL-10 instead plays a major role in limiting and terminating inflammatory responses.422

The IL-10 receptor is most closely related to IFN receptors, making it a type II cytokine receptor^{429,430} and corresponding to the close structural relationship of IL-10 to IFN γ . The receptor for IL-10 consists of an IL-10R1 chain and IL-10R2⁴²²; this latter protein is the same as CRF2-4, which was first identified as an "orphan" IFN receptor family member that is located on chromosome 21 within 35 kb of IFNGR-2.^{431,432} The major STAT protein used by IL-10 is STAT3.⁴²³

A series of IL-10–related cytokines have been identified, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29.^{379,424,433–437} IL-19 was discovered as a gene that was induced in LPS-stimulated monocytes. IL-19 has been suggested to potentially be involved in the pathogenesis of chronic inflammatory diseases, such as psoriasis. Like IL-19, IL-20 is produced by myeloid cells; it was also found to be produced by epidermal cells, with overexpression resulting in aberrant epidermal differentiation. IL-20 is believed to have a role in psoriasis, and in psoriatic skin, expression of IL-20 is primarily detected in DCs.^{379,438} IL-20 also appears to contribute to rheumatoid arthritis, atherosclerosis, and stroke; recently, IL-20 has been implicated in bone loss, with elevated IL-20 in patients with osteopenia and osteoporosis in in ovariectomized mice. Moreover, IL-20R1–deficient mice have increased bone density as did treatment with anti–IL-20.⁴³⁹

IL-22 was found as an IL-9-induced cytokine that can in turn induce acute-phase reactant production by hepatocytes and accordingly that it might be involved in inflammatory responses. It was first observed to be produced by activated Th1 cells but was subsequently noted to be more broadly produced by CD4+ and CD8+ T cells, NK cells, lymphoid tissueinducer cells and mucosal RORyt+NKp46+ cells in humans and mice,⁴⁴⁰⁻⁴⁴² and to be produced by Th17 cells. IL-22 is often coexpressed with IL-10, and STAT3, the Notch pathway, and the aryl hydrocarbon receptor promoter production of these cytokines; in contrast, TGF-B, ICOS, and IL-27 augment IL-10 production yet inhibit IL-22.424 IL-22 mediates cross talk between leukocytes and tissue epithelia, with target cells primarily in the digestive and respiratory systems, but it also can act on keratinocytes, can promote innate immunity,443 and can cooperate with IL-17A to effect epithelial and healing responses. In particular, IL-22 can contribute to epithelial resistance to injury after microbial infection of the gut or lungs, and thereby may play a role in host defense and tissue repair.⁴⁴² Interestingly, the transcription factor c-Maf mediates suppression of IL-22 production by TGF-B.444

IL-24 was originally discovered as melanoma differentiation-associated antigen 7. IL-24 is induced in peripheral blood mononuclear cells by mitogen stimulation and is produced not only by Th2 cells but also by myeloid cells. Overexpression of IL-24 can induce apoptosis in a wide range of tumor cells, including, for example, melanoma and malignant gliomas, and infection with adenoviral-drive melanoma differentiation-associated antigen 7 can sensitize tumors to ionizing radiation.³⁸⁰ Like IL-19, IL-20, and IL-22, IL-24 is expressed in psoriatic but not normal skin and like these other cytokines, functional receptors are highly expressed on keratinocytes. IL-10, IL-19, IL-20, IL-22, and IL-24 are all increased in synovial fluid cells in rheumatoid arthritis and thus are potential mediators of this autoimmune disease. IL-20 and IL-22 in particular may be associated with lupus.³⁷⁹

IL-26 was originally discovered as AK155. Relatively little is known regarding the function of IL-26.

IL-28A and IL-28B (IFNλ1 and IFNλ2) and IL-29 (IFNλ3) are also called type III IFNs and are induced in plasmacytoid DCs by viral infection and exhibit antiviral activity, analogous to type I IFNs; nevertheless, they bind to a receptor consisting of IL-10R2 and IL-28R⁴⁴⁵ and differ in terms of potency and kinetics from IFNα.³⁷⁹ IL-28A, IL-28B, and IL-29 induce relatively weak antiviral responses, and the IL-28R chain is relatively restricted in its expression, as compared to the IFNα receptor. IL-28A appears to enhance antiviral activity induced by TLR3 and TLR9 and to be important for host defense to influenza A.³⁷⁹ Interestingly, the genes encoding IL-10, IL-19, IL-20, and IL-24 colocalize at human chromosome 1q32, whereas those encoding IL-22

and IL-26 are at 12q14 to 12q15 near the *IFNG* gene, and IL-28 and IL-29 are at 19q13.^{380,446} Thus, these type II cytokines can be subdivided into three different groups based at least in part on chromosome localization.

Overall, IL-10 family cytokines are diverse and can be subdivided into the IL-19, IL-20, IL-22, IL-24, and IL-26 sub-family that acts on tissue epithelial cells and in the case of IL-20 in wound healing, whereas IL-28A, IL-28A, and IL-29 exhibit antiviral activity and are more IFN-like in their biology.³⁷⁹

SPECIES SPECIFICITY OF CYTOKINES

There are no general rules for the species specificity of human and mouse cytokines, and how the cytokines and their receptor chains have coevolved. To provide illustrative examples of each situation, human IL-2 can stimulate both human and mouse cells, whereas mouse IL-2 exhibits little action on human cells.⁵⁹ Conversely, human IL-12 does not work on mouse cells, whereas mouse IL-12 is biologically active on both mouse and human cells.³¹¹ This selective property of IL-12 is dependent on the species origin of p35. Finally, IL-4 exhibits rather strict specificity so that human and mouse IL-4 only induce responses on human and mouse cells, respectively.^{92,93} As noted previously, IFNαs are generally specifies specific, although IFN08 is not. In addition to these examples, varying degrees of relative species specificity have been demonstrated, depending on the cytokine. Thus, a cytokine may or may not be restricted in its specificity to its own species, and if it does occur, cross-species activity may have attenuated potency.

SIGNALING THROUGH INTERFERON AND CYTOKINE RECEPTORS

Our understanding of signaling through IFN and cytokine receptors has tremendously increased in the past few years. Multiple signaling pathways/molecules have been observed for various cytokines. Collectively, these include the JAK-STAT pathway, IRF family proteins, Ras/ mitogen-activated protein (MAP) kinase pathway, Src and Zap70 and related proteins, PI 3-kinase, IRS-1 and IRS-2, and phosphatases. Each of these pathways will be discussed in turn. The JAK-STAT pathways are important for both type I and IFNs/type II cytokines, while the IRF proteins play central functions more so for the IFNs than type I cytokines.

OVERVIEW OF JAKS AND STATS

The JAK-STAT pathway^{30,355,397,447–449} is particularly exciting in that it serves as a rapid mechanism by which signals can be transduced from the membrane to the nucleus. JAK kinases are known as Janus family tyrosine kinases, and the acronym "STAT" denotes signal transducer and activator of transcription. STAT proteins are substrates for JAK kinases. A tremendous amount of information is now available on JAKs and STATs that demonstrate their importance related to development, differentiation, proliferation, cellular transformation, and tumorigenesis.

JAKs

The JAK kinases are 116 to 140 kDa, and comprise approximately 1150 amino acids.^{355,397} The seven regions of conserved sequences in JAK kinases, denoted JH1 to JH7, are depicted in Figure 25.6. One of the hallmark features of these kinases is that in addition to the presence of a catalytic tyrosine kinase domain (JH1), there is also a pseudokinase region (JH2). The name Janus kinase reflects the two faces of the mythological Roman god, with one face representing the true kinase and the other the pseudokinase. Although the JH nomenclature was used historically, it has obvious limitations in that except for the JH1 catalytic and JH2 pseudokinase domains, and it remains unclear whether or not the other JH regions correspond to discrete domains. Modeling has indicated five important regions, including an N-terminal domain, a FERM (4.1, ezrin, radixin, moesin) domain, and SH2, kinase-like (which spans two of the JH domains), and kinase domains.⁴⁵⁰

There are four mammalian JAK kinases, JAK1,⁴⁵¹ JAK2,⁴⁵² JAK3,^{453,454} and TYK2,⁴⁵⁵ each of which was identified as part

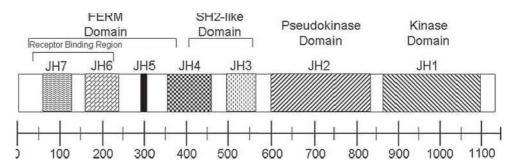

FIG. 25.6. Schematic of JAK Kinases. Shown are the locations of the seven JH domains. JH1 is the catalytic domain. JH2 is the pseudokinase domain, the presence of which prompted the naming of this family as Janus family tyrosine kinases. As noted in the text, the JH nomenclature has limitations and in fact masks the presence of an SH2 domain that spans parts of the JH4 and JH3 domains. Also shown is the conserved tyrosine (Y1007 in JAK2) whose phosphorylation is required for maximal catalytic activity.

of a study intended to identify new kinases.³⁵⁵ At least one JAK kinase is activated by every IFN and cytokine, and some cytokines activate two or three JAK kinases.^{355,397,447,448} Table 25.12 lists a number of features of each JAK kinase, whereas Table 25.13 summarizes the JAK kinases that are activated by a variety of cytokines.

Because JAK1, JAK2, and TYK2 are ubiquitously expressed, each cell type expresses either three or in some cases all four JAK kinases (eg, lymphoid cells that also express JAK3). The JAK kinases that are activated by a specific cytokine are those that can bind to its receptor's cytoplasmic domain. JAK kinases physically bind to the membrane proximal Box 1/Box 2 region of the cytoplasmic domains,^{454–459} and the N-terminal region of the JAK is required for this function.^{460–462} In cytokine receptors, the Box 1 region is proline rich,²⁶ suggesting that JAK kinases may have SH3-like domains in their N-terminal regions to mediate these interactions. As each cytokine or IFN receptor is a homodimer, heterodimer, or higher order oligomer, it is

IL-6, IL-11, CNTF, LIF, OSM, CT-1	JAK1, JAK2, TYK2
TSLP	JAK1, JAK2

CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin-1; G-CSF, granulocyte-colony stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor; IFN, interferon; IL, interleukin; LIF, leukemia inhibitory factor; OSM, oncostatin M; TSLP, thymic stromal lymphopoietin.

*Note that IL-4 activates JAK1 and JAK3 when it acts through the type I IL-4 receptor (IL-4Rα + γ_c, found for example on T cells). However, JAK3 is not activated when IL-4 signals through the type II IL-4 receptors (IL-4Rα + IL-13Rα1, a form of receptor that is expressed on a number of non-T cells, including fibroblasts).

reasonable to assume that at least two JAK molecules (either two molecules of one JAK or one molecule each of two different JAKs) will be activated, as one JAK will be associated with each receptor chain. In accord with their ubiquitous expression, JAK1, JAK2, and TYK2 are activated by a variety of different sets of cytokines (see Tables 25.12 and 25.13). For example, JAK1 is activated not only by type I and II IFNs but also by the γ_c family of cytokines (eg, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21), whereas JAK2 is activated not only by IFNy but also by growth hormone, Epo, prolactin, and the hematopoietic cytokines, IL-3, IL-5, and GM-CSF.355,447 TYK2 is somewhat more restricted in that it is activated by IFN α/β and IL-12/IL-23; the significance of its activation by gp130 family cytokines is less clear. Interestingly, JAK1, JAK2, and TYK2 are recruited by each of the cytokine receptors that share gp130 as a signal transducing molecule, raising the question as to whether these cytokines require all three JAK kinases for optimal function or whether any one or two is/are sufficient. At least for IL-6, JAK1 is vital, 463,464 whereas the importance of JAK2 and TYK2 is less clear.

JAK3 is different from the other JAK kinases in that it is much more inducible. Moreover, JAK3 is only activated by cytokines whose receptors contain γ_c .^{30,45} Interestingly, each cytokine whose receptor contains γ_c activates not only JAK3 but also JAK1. The basis for the activation of both JAK1 and JAK3 by IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 is that JAK1 associates with each of the distinctive signaling chains (IL-2R β , IL-4R α , IL-7R α , IL-9R α , and IL-21R), whereas JAK3 associates with γ_c .^{30,45} Although this could be a coincidental result of coevolution of these cytokine systems, these observations raise the possibility that JAK1 is the JAK kinase that most efficiently functionally cooperates with JAK3.

Given the wide range of cytokines that activate any particular JAK kinase and that in some cases multiple cytokines can activate the same set of JAKs, it is clear that the JAK kinases by themselves do not determine signaling specificity. For example, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all activate JAK1 and JAK3 but induce a range of actions. Moreover, JAK2 is the only JAK kinase that is activated by growth hormone and erythropoietin, cytokines with different target cells and biologic functions. Interestingly, JAK2 is the JAK that interacts with all cytokine receptors that form homodimers. Given that homodimeric receptors are likely the oldest cytokine receptors in evolution, this suggests that JAK2 might be the "primordial" JAK kinase from which others evolved.

Importance of JAK Kinases in Signaling

In addition to the activation of JAK kinases by multiples cytokines and IFNs, a variety of other data indicate their importance for signaling. One of the vital series of experiments that led to the establishment of the critical role of JAK kinases in IFN signaling involved a group of mutant cell lines that were defective for IFN signaling, but wherein signaling could be rescued by genetic complementation.³⁹⁷ Defective signaling in response to IFN α and IFN β was found in a mutant fibroblast cell line (U1 cells) lacking TYK2; defective signaling in response to IFN α ,

IFN β , and IFN γ was found in a mutant cell line lacking JAK1 (U4 cells), and defective IFN_γ signaling was found in cells lacking JAK2.397 A variety of other data have indicated the importance of JAK kinases in cytokine signaling pathways. First, dominant negative JAK2 inhibits signaling by erythropoietin and growth hormone,465,466 while a dominant negative JAK3 inhibits signaling in response to IL-2⁴⁶⁷; as noted previoulsy, JAK1 is vital for IL-6 signaling. Second, humans^{468,469} and mice^{470–472} deficient in JAK3 exhibit developmental and signaling defects. Third, humans with an activating mutation in JAK2 develop polycythemia vera,⁴⁷³ and a JAK2 inhibitor inhibited the growth of acute lymphoblastic leukemia cells in vitro.474 Fourth, a patient with mutation in TYK2 developed a form of immunodeficiency.⁴⁷⁵ Fifth, in Drosophila, the hopscotch gene encodes a JAK kinase, wherein loss-of-function alleles result in lethality and decreased proliferation, whereas a gain-offunction allele, hopscotch Tumorous-lethal results in melanotic tumors and hypertrophy of the hematopoietic organs.476,477 Sixth, in zebrafish, JAK1 is vital for normal cell migration and anterior specification.⁴⁷⁸ Seventh, as discussed in the following, JAK kinases are constitutively activated in many cell lines infected with a number of viruses, including HTLV-I, v-Abl, spleen focus-forming virus, and with v-Src.⁴⁷⁹⁻⁴⁸² These data together underscore the vital roles of JAKs in cytokine signaling. Depending on the function of the particular cytokine (eg, development, differentiation, or proliferation), the particular JAK kinases potentially may be involved in a variety of processes, and when dysregulated, in at least certain settings, they appear to contribute to cellular transformation.

JAK3 Mutations Result in an Autosomal Recessive Form of Severe Combined Immunodeficiency that is Indistinguishable from X-Linked Severe Combined Immunodeficiency

A very large number of different mutations in γ_c have been observed in X-linked SCID. As might be expected, in cases where it has been examined, amino acid substitutions in the extracellular domain result in defective cytokine binding. In contrast, mutations or truncations in the γ_c cytoplasmic domain result in defective signaling. Analysis of a family in which a number of males exhibit a moderate form of X-linked combined immunodeficiency revealed that this disease also resulted from a mutation in γ_c^{41} (Leu $271 \rightarrow Gln$) that resulted in a decrease, but not total loss of JAK3 association, in contrast to the loss of JAK3 interaction seen with mutations in the γ_c cytoplasmic domain that cause X-linked SCID. Thus, the severity of the immunodeficiency inversely correlated with the degree of JAK3 activation.^{30,45} Moreover, it was predicted that JAK3 was required for T-cell and NK-cell development, and that mutations in JAK3 might result in a clinical phenotype indistinguishable from that in X-linked SCID.⁴¹ Indeed, this is the case in humans.468,469 As one would hypothesize, many mutations in JAK3 have been identified.³⁵⁵ Presumably, any mutation that interferes with its ability to interact with γ_{c} , with its catalytic activity, or with recruitment of substrates

could result in clinical disease, ranging from moderate-tosevere immunodeficiency.

Analogous to the similarity of X-linked SCID and JAK3deficient SCID, mice deficient in either γ_c or JAK3 also have indistinguishable phenotypes.^{211,212,470-472} These in vivo data underscore the vital role of JAK3 in mediating γ_c -dependent functions and suggested that JAK3 is essential for most, if not all, γ_c functions. Some in vitro data indicate that γ_c may do more than to recruit JAK3,467,483 and interestingly, γ_c can interact with calpain,⁴⁸⁴ but the recruitment of JAK3 is clearly essential, and the defects in T-cell and NK-cell development associated with γ_c or JAK3 deficiency are indistinguishable. Because JAK3 deficiency is not clinically or phenotypically more severe than γ_c deficiency in humans and mice, it seems likely that γ_c is the major, if not only, protein with which JAK3 associates. Moreover, as had been predicted based on the association of γ_c with JAK3,⁴¹ JAK3 inhibitors are immunosuppressive, and one JAK inhibitor has now been approved by the FDA.485 Although JAK3 was suggested to associate with CD40,486 a functional role for JAK3 in CD40 signaling has been questioned.⁴⁸⁷ The phenotypes of mice lacking each of the four JAK kinases are summarized in Table 25.14.

JAK2 Mutations and Translocations

The JAK2V617F mutations has now been identified in most of patients with polycythemia vera,^{473,488} some of whom have homozygous and some have heterozygous mutations. The homozygous patients had duplications of the mutated allele. This mutation results in a constitutively activated kinase and presumably confers factor-independent growth, something that has been demonstrated in transfected cell lines. Moreover, patients with polycythemia exhibit erythropoietin-independent BFU-E. Furthermore, the *JAK2* locus is involved in a chromosomal translocation to create the TEL-JAK2 protein that is causally related to a human leukemia,⁴⁸⁹ further underscoring the relationship of JAK2 to the growth of hematopoietic cells.

TYK2 Mutations and Human Immunodeficiency

A mutation in TYK2 has now been identified in a patient with primary immunodeficiency.⁴⁷⁵ The patient had clinical defects more severe than anticipated from TYK2-deficient mice, with increased susceptibility to viral infections and atypical mycobacterial infections and defective signaling in response to IL-23, IL-6, and IL-10. Additionally, the patient had hyper-IgE production, which perhaps corresponds to enhanced Th2 cell–mediated allergic inflammation in TYK2–/– mice.⁴⁹⁰ Because this was a single patient, it remains to be determined if other individuals with TYK2 deficiency will have this full range of clinical problems.

ACTIVATION OF JAKS AND THE JAK-STAT PARADIGM

The paradigm of JAK-STAT activation is shown in Figure 25.7, which also shows activation of other pathways, such as the Ras-MAP kinase and PI 3-kinase/AKT/p70 S6

Phenotypes of Mice Deficient in Type I and Type II Cytokines, Their Receptors, JAKs and STATs

TABLE 25.14

Type I Cytokines and Their R	eceptors
γ. family	
IL-2 ^{205,692,693}	Normal thymic and peripheral T-cell development. Decreased polyclonal T-cell responses in vitro, but more normal in vivo responses to pathogenic challenges. Autoimmunity with marked changes in levels of serum immunoglobulin isotypes. Ulcerative colitis–like inflammatory bowel disease.
L-4 ^{208,209}	Defective Th2 cytokine responses and class switch; defective IgG1 and IgE production.
IL-2/IL-4 ²¹⁰	Some features of both IL-2 and IL-4 knockout mice. No gross abnormalities of T-cell development.
IL-7 ¹⁰⁴	Greatly diminished thymic and peripheral T-cell development and B lymphopoiesis, resulting in pro-
	found lymphopenia.
IL-9 ^{133,135}	No T-cell defect. Defect in pulmonary goblet cell hyperplasia and mastocytosis following challenge with <i>Schistoma mansoni</i> eggs. No defect in eosinophilia or granuloma formation.
IL-15 ¹⁵¹	Defective NK-cell development. Defect in CD8 memory T-cell homeostasis.
IL-2Rα ²¹⁷	Normal initial lymphoid development, but massive enlargement of peripheral lymphoid organs, poly- clonal T- and B-cell expansions, and activated T cells, with impaired activation-induced cell death. Autoimmunity with increasing age, including hemolytic anemia and inflammatory bowel disease.
IL-2Rβ ²¹⁸	Severe autoimmunity including autoimmune hemolytic anemia. Death within approximately 3 months. Deregulated T-cell activation. Dysregulated B-cell differentiation and altered Ig profile.
γc ^{211,212}	Greatly diminished thymic development but double negative, double positives, and single positives all represented. Age-dependent accumulation of peripheral CD4+ T cells with an activated memory phenotype. Greatly diminished numbers of conventional B cells, although B1 cells are present. No NK cells or γδ cells. Absent gut-associated lymphoid tissue, including Peyer patches.
IL-4R α^{694}	Like IL-4—/— mice, they have defective Th2 cytokine responses and class switch; defective IgG1 and IgE production. In addition, they cannot expel <i>Nippostrongylus brasiliensis</i> , presumably because of defective IL-13 signaling.
IL-7Rα ¹⁰³	Greatly diminished thymic and peripheral T-cell development and B lymphopoiesis, resulting in pro- found lymphopenia.
IL -15 $R\alpha^{150}$	Defective NK cell development. Defect in CD8 memory T-cell homeostasis.
IL-13 ^{366,695}	Defective Th2 cell development and the ability to expel helminths. Impaired diarrhea to OVA.
IL-4/IL-13 DK0695	Produce almost no IgE, highly resistant to OVA-induced diarrhea.
IL-13Rα1 ^{378,695}	Exacerbated Th2 responses, with diminished mortality after infection with <i>S. mansoni</i> and greater susceptibility to <i>N. brasiliensis</i> . However, partially impaired allergic diarrhea to OVA.
IL-21R ^{182,184}	Decreased IgG1, elevated IgE.
IL-21R/IL-4 DK0 ¹⁸²	Panhypogammaglobulinemia (mimicks the B-cell phenotype in humans with XSCID).
0.4	
β _₀ family IL-5 ²²⁷	Decreased basal level of eosinophils and defective induction of eosinophils following infectious challenge. Developmental defect in CD5+ B1 cells. Normal antibody and cytotoxic T-cell responses.
GM-CSF ^{696,697}	Normal basal hematopoiesis. Unexpected abnormalities of the lung; abnormal pulmonary homeostasis.
IL-3Rβ ⁶⁹⁸	No defects (due to redundant function of β_c).
β _c ^{243,698}	Defective responses to IL-5 and GM-CSF but normal responses to IL-3 (due to redundant function of IL-3Rβ). Diminished eosinophils: both basal levels and in responses to infectious challenge. Unexpected abnormalities of the lung characterized by pulmonary proteinosis and reduced phago-cytosis by alveolar macrophages. In other words, the defects are a combination of those found in the IL-5– and GM-CSF–deficient mice.
$\text{IL-3R}\beta + \beta_{\text{c}} \text{ DK0}^{698}$	Same phenotype as eta_c -deficient mice, except that they cannot respond to IL-3.
gp130 family	
IL-6 ⁶⁹⁹	Impaired acute-phase responses following infection or tissue damage. Decreased numbers of hematopoietic progenitor cells.
gp130 ^{700,701}	Embryonic lethal. Extreme hypoplastic development of the myocardium; although the ventricular wall was very thin, trabeculation within the ventricle chamber was normal. Hematologic abnormalities characterized by greatly reduced CFU-S and somewhat reduced CFU-Gm and BFU-E. Markedly diminished size of thymus and numbers of thymocytes. Reduced primordial germ cells in embryonic gonads. Diminished size of placenta.
LIF ⁷⁰²⁻⁷⁰⁴	Decreased hematopoietic progenitor cells. Normal sympathetic neurons but deficient neurotransmitter switch in vitro. Defective blastocyst implantation.
$LIFR\beta^{705,706}$	Postnatal lethality. Normal hematopoietic and germ cell compartments but multiple neurologic, skeletal, placental, and metabolic defects. The greater severity than found in LIF-deficient mice re- flects that LIFRβ is shared by several cytokines, including CNTF, LIF, OSM, and CT-1.
CNTF ⁷⁰⁷	Progressive atrophy and loss of motor neurons.

TABLE 25.14	Phenotypes of Mice Deficient in Type I and Type II Cytokines, Their Receptors, JAKs and STATs (Cont.)
CNTFR α^{708}	Severe motor neuron deficient resulting in perinatal mortality. The more severe phenotype than in
IL-11Rα ⁷⁰⁹	CNTF-deficient mice was unexpected and suggests another cytokine may utilize CNTFRα. Blastocysts can implant but decidualization cannot occur, associated with failure of pregnancy. Fetal lethal phenotype.
IL-12 p40 ⁷¹⁰	Impaired but not completely lacking in their ability to produce IFNγ and to mount a Th1 response in vivo. Elevated secretion of IL-4; normal production of IL-2 and IL-10. Substantially decreased CTL responses. Resistant to infection with intracellular pathogens.
IL-12Rβ1 ⁷¹¹	Defective IL-12 signaling. IL-2 but not IL-12 could augment NK activity. Defective IFNγ production in response to ConA or anti-CD3. Severe defect in Th1 differentiation.
IL-12 p35 ^{175,712} IL-12Rβ2 ⁷¹³ IL-23 p19 ^{175,714}	Selective loss of IL-12 function without loss of IL-23. Less resistant to infection than p40 and IL-12Rβ1 KO. Selective loss of IL-12 function without loss of IL-23. Less resistant to infection than p40 and IL-12Rβ1 KO. Complete resistance to EAE, defective DTH response.
EBI3 ⁷¹⁵	Increased pathologic features of colitis and shorter survival than in p28 KO mice, indicating that IL-35 rather IL-27 is protective.
IL-27 p28 ⁷¹⁵	Decreased pathologic features of colitis and longer survival than in EBI3 KO mice, indicating that IL-35 rather than IL-27 is protective.
Epo, Tpo, G-CSF, and	M-CSF
Epo ⁷¹⁶	Embryonic lethal. Complete block of fetal liver erythropoiesis, resulting in severe anemia, yet normal development of BFU-E and CFU-E progenitor cells.
EpoR ⁷¹⁷	Same as Epo-deficient mice.
TpoR ⁷¹⁸	Decreased megakaryocytes and platelets, but other hematopoietic cells are present in normal numbers.
G-CSF ⁷¹⁹	Neutropenia and impaired neutrophil mobility. Diminished granulocytes and macrophage precursors.
M-CSF ^{720,721}	Osteopetrosis, absence of teeth. Females are infertile, suggesting an unexpected role for M-CSF.
M-CSF + GM-CS	F ⁷²¹ A combination of defects of both M-CSF and GM-CSF, with osteopetrosis and alveolar proteinosis. Early death of pneumonia.
Type II cytokines and th	
IFNAR1 ⁷²²⁻⁷²⁴	Normal development. Defective immune defense against most viral infections tested, including lymphocytic choriomeningitis virus, Semliki Forest virus, Theiler virus, vesicular stomatitis virus. Normal resistance to <i>Listeria monocytogenes, Leishmania major, Mycobacterium bovis,</i> and <i>Mycobacterium avium</i> .
IFNγ ⁷²⁵⁻⁷²⁷	Normal lymphoid development. Impaired resistance to <i>Listeria monocytogenes, Leishmania major, M. bovis,</i> and <i>M. avium.</i> Can mount curative responses to a number of viruses. CD4+ effector cells default to the Th2 pathway after infection with <i>Leishmania</i> . Succumb to infection with <i>Toxoplasmosis gondii.</i>
IFNGR1 ^{723,724,728}	Normal lymphoid development. Impaired resistance to <i>Listeria monocytogenes, Leishmania major,</i> <i>M. bovis,</i> and <i>M. avium</i> Can mount curative responses to a number of viruses.
IL-10 ^{422,427}	Normal lymphocyte development and antibody responses. Chronic enterocolitis, anemia, and growth retardation. Augmented inflammatory responses.
IL-19 ⁷²⁹	Increased susceptibility to dextran sulfate sodium–induced colitis, increased accumulation of macrophages, and production of proinflammatory cytokines and IFNγ.
IL-20R1 ³⁹	Increased bone density with defective osteoclast differentiation.
IL-20R2 ⁷³⁰	Anti-TCR stimulation results in elevated IL-2 and IFNγ production, with increased antigen-specific CD4 and CD8 cells that produce IFNγ, but diminished IL-10.
IL-22 ⁷³¹	Increased susceptibility to infection with <i>Citrobacter rodentium</i> , with augmented bacterial burden, in- testinal epithelial damage, and mortality.
IL-28A ⁷³²	Normal clearance of a range of viruses but diminished antiviral activity in response to TLR3 and TLR9 agonists. Expression of IL-28 and nonhematopoietic cells appears to be the most critical.
STATs and JAKs	
STAT1557,558	Defective responses to both type I and type II IFNs. Defective response to certain viruses and bacterial antigens.
STAT2559	Defective signaling in response to type I IFNs; interestingly, the defect in not as severe in STAT2- deficient macrophages as it is in STAT2-deficient fibroblasts.
STAT3 ^{560–564}	Embryonic lethal. Embryos implant but cannot grow. The fact that this phenotype is even more severe than that seen with gp130 suggests a role for STAT3 via a gp130-independent cytokine. By Cre-lox methodol- ogy, <i>STAT3</i> was also selectively targeted in T cells, which exhibit defective IL-2–induced proliferation that correlates with a defect in IL-2–induced IL-2Rα expression; as expected, T cells also exhibit defective signaling in response to IL-6. <i>STAT3</i> -deficient neutrophils and macrophages show defective IL-10 signal- ing. STAT3 is also essential for normal involution of the mammary epithelium, for wound healing, and for normal hair cycle processes. <i>STAT3</i> -deficient DCs exhibit defective Flt3L-dependent expansion of DCs.

TABLE 25.14 Pheno	otypes of Mice Deficient in Type I and Type II Cytokines, Their Receptors, JAKs and STATs (Cont.)
STAT4 ^{566,567}	Defective Th1 development. Essentially, the same phenotype as in IL-12–deficient mice, including de-
STAT5A ^{511,571}	fective IL-12–mediated boosting of NK cell cytolytic activity. Defective lobuloalveolar development in the mammary gland, a syndrome resulting from defective pro- lactin signaling. Defective IL-2–induced IL-2Rα expression and associated defects in IL-2–induced T-cell proliferation. Defective superantigen-induced expansion of Vβ8 T cells. Defective antigen- induced recruitment of eosinophils into the lung as well as antigen-induced IgG1 production.
STAT5B ^{512,572}	Defective growth analogous to Laron dwarfism, a disease of defective growth hormone signaling. Defective IL-2–induced IL-2Rα expression. More severe defects in IL-2–induced T-cell proliferation and NK-cell proliferation. Defective antigen-induced recruitment of eosinophils into the lung as well as antigen-induced IgG1 production. Defective NK cytolytic activity.
Partial STAT5A/ STAT5B ^{513,514}	Defective signaling in response to prolactin and growth hormone. Absent NK-cell development. Major defect in T-cell proliferation and TCR signaling. Anemia.
Complete STAT5A/ STAT5B ⁵⁷³	Fetal lethality; absent T-cell development.
STAT6 ⁵⁶⁸⁻⁵⁷⁰	Defective Th2 development. Essentially, the same phenotype as IL-4–deficient mice. Defective B-cell proliferation.
JAK1 ⁴⁶³	Perinatal lethality, with defective signaling by gp130-dependent cytokines (IL-6, IL-11, CNTF, OSM, LIF, CT-1, and NNT-1/BSF-3). Defective signaling by γ _c -dependent cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21; of these, IL-2 and IL-7 were formally evaluated).
JAK2 ^{733,734}	Fetal lethality with profound anemia due to defective signaling in response to Epo.
JAK3 ⁴⁷⁰⁻⁴⁷²	Very similar and possibly identical to γ _c -deficient mice. Defective signaling in response to γ _c -dependent cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21). Greatly diminished T cells in thymus and spleen, but then age-dependent peripheral expansion of CD4+ T cells. Unlike humans with JAK3 mutations, Jak3-deficient mice have greatly diminished B-cell numbers as well.
TYK2 ^{735–737}	Mice lacking TYK2 exhibit diminished signaling in response to IFNα/β and IL-12, but it is not abrogated. Primarily STAT3 activation is diminished, even though STAT1/STAT2 and STAT4, respectively, are the STAT proteins that are primarily activated by IFNα/β and IL-12. Additionally, there are dimin- ished responses to IFNγ and IL-18.

BFU, burst forming unit; BSF-3, B cell-stimulating factor-3; CD, cluster of differentiation; CFU, colony forming unit; CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin-1; CTL, cytotoxic T lymphocyte; DC, dendritic cell; DKO, double knockout; DTH, delayed type hypersensitivity; EAE, experimental autoimmune encephalomyelitis; Epo, erythropoietin; G-CSF, granulocytecolony stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor; IFN, interferon; Ig, immunoglobulin; IL, interleukin; KO, knockout; LIF, leukemia inhibitory factor; M-CSF, macrophage-colony stimulating factor; NK, natural killer; NNT-1, novel neurotrophin-1; OSM, oncostatin M; STAT, signal transducer and activator of transcription; TCR, T-cell receptor; Th, T helper; Tpo, thrombopoietin; XSCID, X-linked severe combined immunodeficiency.

kinase pathways. Following IFN or cytokine engagement, dimerization or higher order oligomerization of receptor complexes is induced. This in turn allows the juxtapositioning of JAK kinases, facilitating transphosphorylation and activation. In receptors with only two chains, the direct transphosphorylation of one JAK by the other seems likely to occur. In more complex receptors, such as the IFNy system, because the receptor is a heterotetramer with two IFNGR-1 chains that each bind IAK1 and two IFNGR-2 chains that each bind JAK2, it is not clear if JAK1 and JAK2 transactivate each other or if one of the JAK kinases plays a dominant role. Indeed, one study suggests that JAK2 may phosphorylate both itself and JAK1, thereby increasing the catalytic activities of both kinases.491 JAK1 in turn then phosphorylates IFNGR-1, allowing the recruitment of STAT1. In this model, it is additionally suggested that JAK2 phosphorylates STAT1.491 Interestingly, a kinase-dead mutant of JAK1 was able to mediate the induction of certain IFNy-induced genes, indicating a potential "structural" role for JAK1, but catalytically active JAK1 was essential for the establishment of the antiviral state,⁴⁹¹ emphasizing the essential role of both JAK1 and JAK2 for normal IFNy function.

The previous discussion assumes that transphosphorylation of JAK kinases is a mechanism for the amplification of catalytic activity. Unless other kinases are involved, however, implicit to this idea is that the JAK kinases themselves must exhibit some basal activity that is amplified to a higher level by autophosphorylation or transphosphorylation. It is reasonable to speculate that both models may be operative, depending on the system. Consistent with JAK kinases being activated by phosphorylation, mutagenesis of a critical tyrosine in TYK2⁴⁹² or JAK2⁴⁹³ (eg, tyrosine 1007 in the case of JAK2) in the activation loop of the kinase domain inhibits activity. It is also conceivable that phosphorylation of other tyrosines on the JAKs may create appropriate motifs for the recruitment of additional signaling molecules.

The function of the pseudokinase domain remains unclear. No other metazoan protein tyrosine kinases contain such a domain. The JH2 lacks the third glycine in the critical Gly-X-Gly-X-X-Gly motif, is missing an aspartic acid that serves as the proton acceptor that is typically conserved in the catalytic loop of both tyrosine and serine kinases, and is missing the conserved phenylalanine in the Asp-Phe-Glu motif that binds adenosine triphosphate³⁵⁵ together, pre-

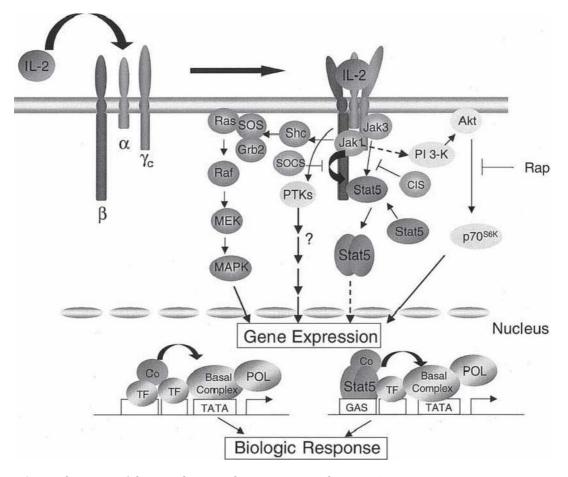

FIG. 25.7. Schematic of Cytokine Signaling Showing Multiple Signaling Pathways Activated by Interleukin (IL)-2. Shown is the association of JAK1 and JAK3 with different chains of the receptor. Activation of JAK kinases results in tyrosine phosphorylation of IL-2Rβ. This allows the docking of STAT5 proteins via their SH2 domain. The STATs themselves are tyrosine phosphorylated, dimerize, and translocate to the nucleus where they modulate expression of target genes. The schematic also indicates that another phosphotyrosine mediates recruitment of SHC, which then can couple to the Ras/Raf/MEK/mitogen-activated protein kinase pathway. Also shown is the important phosphatidyl inositol 3-kinase pathway. These and other pathways are activated by many type I cytokines.

sumably explaining the lack of catalytic function of the JH2 pseudokinase domain.⁴⁵² Despite the lack of catalytic activity, there are data in support of vital functions for this region. While the kinase domain alone can act as an active kinase, it is interesting that a mutation in the JAK kinase JH2 domain can hyperactivate the Drosophila (*hop*^{Tum-1}/DSTAT) JAK-STAT pathway, and that the corresponding Glu695 to Lys mutation in mouse JAK2 also resulted in increased autophosphorylation of JAK2 and phosphorylation of STAT5 in transfected cells.⁴⁹⁴ Moreover, the JH2 domain may play an important role in mediating the interaction of JAKs with STAT proteins.⁴⁹⁵

Given that JAK kinases are associated with a wide range of IFN and cytokine receptors, it was predicted that JAKs would mediate signals involved in multiple processes. These include important roles in development (as demonstrated by the lack of T-cell and NK-cell development associated with JAK3 deficiency, a defect at least partially due to defective signaling in response to IL-7 and IL-15), signaling in response to cytokines that are mitogenic growth factors (eg, IL-2, IL-3, etc.), and in the antiviral response (IFNs). Studies in zebrafish revealed not only a role for JAK1 in early vertebrate development but also revealed that during early development JAK1 kinase was exclusively of maternal origin.⁴⁷⁸ These developmental roles for JAK1 in zebrafish are consistent with the importance of a JAK kinase in early Drosophila development as well.⁴⁹⁶

SIGNAL TRANSDUCER AND ACTIVATOR OF TRANSCRIPTION PROTEINS ARE SUBSTRATES FOR JAKS THAT AT LEAST IN PART HELP DETERMINE SPECIFICITY

Given that there are only four JAK kinases but scores of cytokines, it is clear that JAKs by themselves cannot fully determine specificity. Indeed, different cytokines with different actions activate the same JAKs. One level of specificity comes from the same JAKs having different substrates, depending on the receptor. The best characterized substrates for JAKs are the STAT proteins,^{355,447,448} and these appear to provide some, but not all of the specificity, particularly given that there are only seven STAT proteins. Among the mutant cell lines with defects in IFN signaling, in addition to the ones with defects in JAKs noted previously, others were defective in STAT proteins, providing perhaps the earliest data proving a vital role for STAT proteins in signaling in response to IFNs.

STAT proteins are classically considered to be latent transcription factors that initially exist in the cytosol but then must be activated by phosphorylation, with subsequent translocation to the nucleus. STATs were first discovered as factors that bound to the promoters of interferon-inducible genes. The seven mammalian STAT proteins are STAT1,⁴⁹⁷ STAT2,⁴⁹⁸ STAT3,^{499,500} STAT4,^{501,502} STAT5A,⁵⁰³⁻⁵⁰⁷ STAT5B,^{505,507,508} and STAT6.⁵⁰⁹ Table 25.15 summarizes the cytokines that activate each of the STATs. Additionally, some STATs (eg, STAT3) are known to have more than one isoform with distinct functions.⁵¹⁰ Although the STATs conserve a reasonable level of homology, STAT5A and STAT5B are unusually closely related, being 91% identical at the amino acid level.⁵⁰⁵⁻⁵⁰⁸ It is interesting that mouse and human STAT5A are more related

TABLE	25.15	Cytokines and the Signal Transducer and Activator of Transcriptions They Activate

gp130 family IL-6, IL-11, Leptin		F, OSM, CT-1 STAT3 STAT3

CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin-1; G-CSF, granulocyte-colony stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor; IFN, interferon; IL, interleukin; LIF, leukemia inhibitory factor; STAT, signal transducer and activator of transcription; TSLP, thymic stromal lymphopoietin.

Note that for IL-2, IL-7, IL-9, and IL-15, STAT5A and STAT5B appear to be the major STATs that are activated, although STAT3 in particular and STAT1 to a lesser degree can also be activated. For IL-21, STAT3 is the dominant STAT protein activated, followed by STAT1 and STAT5A/STAT5B.^{44,885} than STAT5A and STAT5B within a single species. The same is true for mouse and human STAT5B, suggesting that there has been evolutionary pressure to maintain the difference between STAT5A and STAT5B and that these two proteins might have certain distinctive functions. In this regard, STAT5A and STAT5B knockout mice exhibit both similarities as well as some differences in their phenotypes^{511–514}; however, given different levels of each STAT5 protein in certain tissues, it remains to be determined if the different phenotypes result from different intrinsic actions of STAT5A and STAT5B versus differences in the total level of STAT5.

As active STAT proteins exist as dimers, the ability of at least some STATs to form heterodimers (eg, STAT1 with STAT2 or STAT3⁴⁴⁸) increases the number of different complexes that can form. In addition, further complexity can be generated by the ability of at least some of the STATs to exist in alternatively spliced forms, ^{508,515} some of which are inactive.

A schematic of STAT proteins is shown in Figure 25.8. The STATs can be divided into two basic groups: those that are longer (STAT2 and STAT6, approximately 850 amino acids) and those that are shorter (STAT1, STAT3, STAT4, STAT5A, and STAT5B, between 750 and 800 amino acids). The STAT genes cluster in three locations. Mouse STAT2 and STAT6 are both located on chromosome 10; STAT1 and STAT5B are located on chromosome 11.⁵¹⁶ Correspondingly, human STAT5A and STAT5B are closely positioned on chromosome 17q.⁵⁰⁸

The classic model is that in order for STATs to be "activated" and to be able to function as transcriptional activators, a number of cellular events must occur. They first bind to phosphorylated tyrosines on cytokine receptors, are tyrosine phosphorylated, dissociate, dimerize, translocate from the cytosol to the nucleus, bind to target DNA sequences, and activate gene expression. A number of conserved structural features common to all STATs help to explain these functions. These include an SH2 domain, a conserved tyrosine residue, a DNA-binding domain, and a C-terminal transactivation domain, and an N-terminal STAT tetramerization region (Fig. 25.8). In addition, there is now evidence for the biologic function of nuclear STATs that are not phosphorylated, as discussed subsequently.

Docking of Signal Transducer and Activator of Transcription on Receptors or Other Molecules, their Tyrosine Phosphorylation, and Dimerization

Each STAT protein has an SH2 domain that plays two important roles: 1) for receptor docking, as for example, has been shown for STAT1 docking on IFNGR-1,⁵¹⁷ STAT2 docking on IFNAR-1,⁵¹⁸ STAT3 docking on gp130,⁵¹⁹ STAT5A and STAT5B docking on IL-2R β and IL-7R α ,^{356,520} and STAT6 docking on IL-4R α ⁵²¹; and 2) for STAT dimerization that is mediated by the SH2 of one STAT interacting with the conserved phosphorylated tyrosine of another STAT protein. In the case of the IFN α receptor, no STAT1 docking site on IFNAR-1 or IFNAR-2 has been identified, and it is believed that STAT1 may interact with STAT2 after STAT2 is itself tyrosine phosphorylated.³⁵⁵ It is also possible that STATs can dock on JAKs, given the ability to directly coprecipitate JAKs and STATs.^{480,495} After

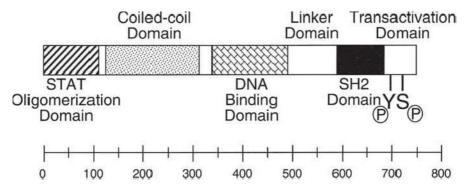

FIG. 25.8. Architecture of a Typical Signal Transducer and Activator of Transcription (STAT) Protein. Shown are the locations of the following important regions: 1) The N-terminal region has been shown to mediate the interaction of STAT dimers bound to adjacent gamma activated sites (known to be important for STAT1 but presumably true for all STATs), 2) the DNAbinding domain, 3) the SH2 domain that mediates STAT docking on receptors and STAT homodimerization/heterodimerization following tyrosine phosphorylation, and 4) the location of the conserved tyrosine whose phosphorylation allows the SH2-mediated dimerization. At least in STAT1 and STAT3, Serine 727, which is C-terminal to the conserved tyrosine, is an important site for phosphorylation. In the case of STAT1, p48 interacts downstream of the STAT dimerization domain. CBP/p300 interacts with two sites at both the N-terminus and C-terminus. Although it has been suggested that the region between the DNA-binding domains and the SH2 domain is an SH3 domain, this remains unproven, and no interactions with proline-rich regions have been reported; as a result, the labeling of this region as an SH3 domain has been omitted. Note that this structure is typical of that for STAT1, STAT3, STAT4, STAT5A, and STAT5B. The main features are conserved in STAT2 and STAT6, but these are approximately 50 to 100 amino acids longer.

docking has occurred, a conserved tyrosine (tyrosine 701 in STAT1, tyrosine 694 in STAT5A, etc.) can be phosphorylated. This phosphorylation is required for SH2 domain-mediated STAT dimerization, and the phosphorylation likely occurs while the STAT is docked on the receptor in physical proximity to receptor-associated JAK kinases. Following STAT phosphorylation, the STAT protein dissociates from the receptor, and its dimerization with itself or another STAT is presumably then favored over its reassociation with the cytokine receptor chain given that STAT dimerization, whereas docking on a receptor involves only one interaction. Thus, efficient activation of STATs requires the presence in STATs of a conserved SH2 domain and a critical tyrosine.

Whereas some receptor proteins such as IFNGR-1⁵¹⁷ and IL-7R α^{356} have a single STAT docking site (for STAT1 and STAT5, respectively), a number of receptor molecules, including IL-2R β ,^{356,520} IL-4R α ,⁵²¹ gp130,⁵¹⁹ Epo receptor (EpoR),⁵²² and IL-10R1,⁵²³ have more than one docking site for their respective STATs. The presence of more than one site not only provides functional redundancy but also potentially could allow the simultaneous activation of two STAT molecules, providing a high local concentration of phosphorylated STATs to facilitate their dimerization.

Signal Transducer and Activator of Transcription Nuclear Translocation and Deoxyribonucleic Acid Binding

Following dimerization, the STATs translocate into the nucleus where they can bind to DNA as transcription factors.

The mechanism for nuclear translocation was originally mysterious given the absence of an obvious nuclear localization signal.⁵²⁴ However, it was shown that tyrosinephosphorylated STAT1 dimers can directly interact with importin- α 5, allowing internalization. This suggested that there indeed was a nuclear localization signal that is normally masked, and mutation of Leu407 does not interfere with tyrosine phosphorylation, dimerization, or DNA binding but prevents nuclear localization.⁵²⁴ Following its dephosphorylation, nuclear STAT1 is exported to the cytosol by a process that is dependent on the chromosome region maintenance 1 (CRM1) export reporter.⁵²⁵ Thus, both import and export of STAT1 appear to be regulated processes.⁵²⁶

Whereas most STAT dimers directly bind to DNA, in the case of IFN- α/β , STAT1-STAT2 heterodimers are formed, and these bind DNA in conjunction with a 48 kDa DNAbinding protein known as IRF9; the STAT1-STAT2-IRF9 complex is known as IFN-stimulated gene factor 3 (ISGF3).⁴⁴⁸ In the case of other STAT dimers, accessory proteins are not required for DNA binding. The motif recognized by ISGF3 complexes is AGTTTNCNTTTCC (known as an ISRE, for IFN-stimulated response element), whereas the other STAT complexes bind more semipalindromic TTCNmGAA motifs that are generally denoted as gamma-activated site (GAS) motifs for IFN γ -activated sequences, reflecting their original discovery in the context of IFN γ .^{355,397,447}

A series of chimeric STAT proteins were used to delineate a DNA-binding domain of approximately 180 amino acids, with two conserved subdomains. Although multiple STATs bind to the same motifs, their relative efficiencies vary, indicating fine specificities conferred by the different

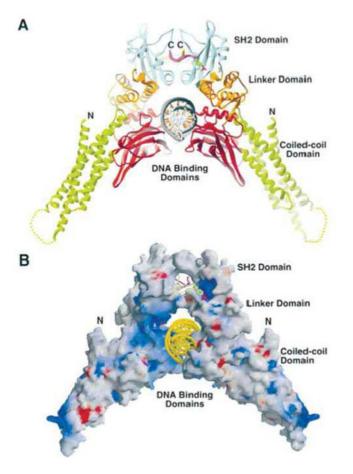

FIG. 25.9. Three-Dimensional Structure of a Signal Transducer and Activator of Transcription 1 Dimer Bound to Deoxyribonucleic Acid. Reproduced from Chen et al.⁵²⁷ and Becker et al.,⁵²⁸ with permission of Dr. Kuryian and Cell Press.

DNA-binding domains. For example, whereas STAT1 homodimers favor a TTCN3GAA motif, STAT6 prefers a TTCN4GAA motif.⁵²¹ These differences partially explain why different STATs modulate the expression of nonidentical sets of target genes. The structures of STAT1 and STAT3 β bound to DNA^{527,528} (Fig. 25.9) almost resembles that of a vertebral column, wherein the DNA represents the spinal cord. The N-terminal and coiled-coil domains are spatially the furthest from the DNA, whereas the DNA-binding domain, linker, and SH2 domain surround the DNA, with the stability apparently being provided by the SH2-phosphotyrosine interaction between the STAT monomers and each STAT monomer–DNA interaction with the DNA, presumably via a "half GAS site,"⁵²⁹ as discussed under STAT tetramerization.

N-terminal regions mediate cooperative DNA binding of STAT proteins when multiple STAT-binding sites occur in close proximity,^{530,531} for example, in the IFN γ gene.⁵³⁰ In the IL-2R α gene, IL-2 response elements have been described in both the 5' regulatory region and the first intron, each of which has tandem GAS motifs that functionally cooperate to mediate IL-2 $\mathbf{R}\alpha$ transcription.^{532–535}

STAT proteins were the first transcription factors that were identified as targets for tyrosine phosphoryla-

tion. Previously, tyrosine phosphorylation was primarily associated with membrane proximal events, but the tyrosine phosphorylation of STATs is associated with a membrane proximal event, as the STATs dock on cell surface receptors. This phosphorylation then allows the rapid dimerization that facilitates nuclear localization and DNA binding. STATs can interact directly with JAK kinases (first shown for STAT5 and JAK3),⁴⁸⁰ suggesting that STATs may at times dock on JAKs rather than on receptors.

Nonphosphorylated Signal Transducer and Activator of Transcription Proteins Can Be Nuclear

In addition to the classical tyrosine phosphorylation–mediated dimerization and nuclear translocation, it is now clear that STAT proteins can exist in the nucleus even without being tyrosine phosphorylated and in that context can modulate gene expression.^{536–538} Moreover, nonphosphorylaed STATs (eg, STAT4) can form N-domain–mediated dimers.⁵³⁹

Optimal Binding Sites for Signal Transducer and Activator of Transcription Proteins

The optimal binding motifs for several STAT proteins have been determined. For STAT1, STAT3, and STAT4, a TTCCSGGAA motif was defined,448,530 while STAT5A and STAT5B optimally bind a TTCYNRGAA motif⁵²⁹ and STAT6 binds a TTCNTNGGAA motif (where Y is C or T and R is G or A).^{521,529} Whereas dimeric STAT protein binding strongly preferred canonical motifs, the range of sequences recognized by STAT5 tetramers is broader, often occurring to two imperfect motifs or with one canonical motif with an associated "TTC" or "GAA" half GAS motif. The optimal inter-GAS motif spacing is 11-12 bp, with relative secondary peaks of 6-7 bp and 16 bp as well.^{529a} The presence of suboptimal GAS motifs spaced at appropriate distances to allow tetrameric binding may allow greater specificity via cooperative binding of STAT oligomers. A subset of genes bind STAT5 tetramers and STAT5 tetramers are critical for cytokine responses and normal immune function.

Transcriptional Activation by Signal Transducer and Activator of Transcription

In addition to tyrosine phosphorylation, some STATs can be phosphorylated on serine, and STAT1 and STAT3 phosphorylation at Serine 727 in the C-terminal transactivation domain is required for full activity.^{540–542} The Serine 727 region resembles a MAP kinase recognition site, and one study indicated that MAP kinase activity is required for IFN α/β -induced gene expression.⁵⁴³ Serine 727 mediates the interaction of STAT1 with MCM5, a member of the minichromosome maintenance family of proteins; this interaction presumably is important for maximal transcriptional activation.⁵⁴⁴ In contrast, STAT2 is not serine phosphorylated.⁴⁴⁸ STAT5A and STAT5B are serine phosphorylated,⁵⁴⁵ and this phosphorylation may be important in cellular transformation.^{546,547}

In addition to this regulated modification of the STAT proteins, STATs can also interact with other factors. For

example, as noted previously, STAT1-STAT2 heterodimers bind DNA only after interacting with IRF9 to form ISGF3.448 STAT1 interacts with and synergizes with Sp1 for transcriptional activation in the ICAM-1 gene⁵⁴⁸ and with TRADD to influence IFNy signaling.⁵⁴⁹ An alternatively spliced shorter form of STAT3, denoted STAT3β, associates with c-Jun to enhance transcriptional activity, 550 and full-length STAT3 can also associate with c-Jun. 551 Moreover, certain STATs can interact with the potent transcriptional coactivators CBP/p300.⁵⁵²⁻⁵⁵⁴ In the case of STAT1, this is mediated by interactions involving both the N- and C-terminal regions of STAT1 and the CREB and E1A binding regions of CBP, respectively.⁵⁵³ STAT5A has been shown to associate with the glucocorticoid receptor.⁵⁵⁵ Additionally, the IL-2-response element in the IL-2Ra gene requires not only STAT5 binding but also the binding of Elf-1, an Ets family transcription factor, to a nearby site.⁵³² Thus, active STAT complexes appear to involve the coordination of STAT proteins with other factors. The corepressor silencing mediator for retinoic acid receptor and thyroid hormone receptor was identified as a potential STAT5-binding partner that binds to both STAT5A and STAT5B and potentially plays a negative regulatory role.556

Specificity of Signal Transducer and Activator of Transcription Proteins

Analogous to the JAKs, the same STATs are activated by multiple cytokines. The phenotypes of mice lacking expression of each of the seven STAT proteins are known, and these knockout models have helped to clarify which cytokines critically depend on a given STAT protein. STAT1 knockout mice exhibit defects that are very selective for the actions of type I and type II IFNs,^{557,558} suggesting that STAT1 is only vital for the actions of IFNs, even though a variety of other cytokines have been reported to activate STAT1. Although it is possible that STAT1 plays an important but redundant role for at least some of these other cytokines, the phenotype of STAT1-deficient mice indicates a need for caution in the interpretation of in vitro experiments that use high concentrations of cytokines or cell lines. STAT2-deficient mice exhibit defects consistent with selective inactivation of IFN α/β signaling.⁵⁵⁹ STAT3-deficient mice exhibit fetal lethality; the embryos implant, but they exhibit defective development and growth.⁵⁶⁰ Deletion of STAT3 within specific lineages has revealed that mice lacking STAT3 in T cells⁵⁶¹ have normal lymphoid development but exhibit a defect in IL-2-induced IL-2R α expression, somewhat analogous to what is seen in STAT5A- and STAT5B-deficient mice (see the following discussion). They also exhibit defective Th17 differentiation due to defective signaling by IL-6 and IL-21.169 Neutrophils and macrophages lacking STAT3 exhibit defective signaling to IL-10, and it is known that STAT3 is important for the normal involution of the mammary epithelium, for wound healing, and for normal hair cycle.^{562,563} DCs lacking STAT3 exhibit a defect in Flt3L-dependent differentiation,⁵⁶⁴ and antigen-presenting cells that are deficient in STAT3 exhibit disruption of priming of antigen-specific CD4+ T cells.⁵⁶⁵ STAT4-deficient mice exhibit a phenotype

similar to that of IL-12-deficient mice (ie, defective Th1 development), consistent with the observation that STAT4 is activated by IL-12. 566,567 Analogously, STAT6-deficient mice exhibit a phenotype similar to that of IL-4-deficient mice (ie, defective Th2 development),^{568–570} in keeping with the observation that STAT6 is only activated by IL-4 and the closely related cytokine, IL-13. Interestingly, mice lacking STAT5A exhibit a defect in prolactin-mediated effects, including defective lobuloalveloar proliferation,⁵⁷¹ whereas mice lacking STAT5B have defective growth similar to that found in Laron dwarfism.⁵⁷² Thus, although STAT5A and STAT5B appear to always be coordinately induced, each of these STATs is important in vivo. In addition to these defects, both STAT5A- and STAT5B-deficient mice have defects in T-cell development and signaling.^{511,512} STAT5A-deficient mice have diminished numbers of splenocytes and exhibit a defect in IL-2–induced IL-2Rα expression.⁵¹¹ STAT5B-deficient mice have similar defects but also have diminished thymocytes.⁵¹² Most dramatically, these mice have a major defect in the proliferation of freshly isolated splenocytes⁵¹² and defective NK-cell development.⁵¹² Mice lacking both STAT5A and STAT5B in lymphoid cells exhibit a dramatic defect in T-cell development,⁵⁷³ and even hypomorphic expression of both STAT5A and STAT5B is sufficient to result in a lack of NK-cell development.⁵¹³ Presumably, the lack of T-cell development relates to defective IL-7 signaling, whereas the lack of NK-cell development relates to defective IL-15-dependent STAT5 activation. STAT5A/STAT5B double knockout mice exhibit lethality that is associated with severe anemia that develops in these mice.574

Signal Transducer and Activator of Transcription Proteins are Evolutionarily Old

Just as Drosophila has a JAK kinase, there is a Drosophila STAT, denoted as either DSTAT or STAT92E.^{575,576} The existence of JAK kinases and STAT proteins in lower organisms suggest that the system is evolutionarily old. A STAT has been identified in *Dictyostelium* that recognizes the sequence TTGA,⁵⁷⁷ has highest sequence similarity to STAT5B, and can bind mammalian IFN-stimulated response elements.⁵⁷⁷ Interestingly, *Saccharomyces cerevisiae* do not appear to have STATs as no SH2 domains have been identified in the entire *S. cerevisiae* genome.

What Types of Functions Are Mediated by Signal Transducer and Activator of Transcriptions?

First and foremost, STAT proteins can translocate to the nucleus and bind to regulatory regions of target genes and influence transcription. Although STATs are generally activators of transcription, they can repress. For example, STAT1 can function as a transcriptional repressor of the c-myc gene.⁵⁷⁸

STAT proteins were discovered based on the study of IFNinducible genes as part of studies intended to understand the cellular differentiation events that lead to development of the antiviral state. In addition to roles in differentiation, STAT proteins can contribute, directly or indirectly, to survival and/or mitogenic/proliferative responses that typify hematopoietic and immunologic cytokines, such as IL-3, IL-5, GM-CSF, IL-2, and IL-4.355 First, a number of in vitro systems have demonstrated that viruses or viral oncogenes are associated with activated JAK-STAT pathways, suggesting a role for STATs in cellular transformation. Indeed, STAT3 and STAT5 have been implicated as oncogenes, with compelling data for transformation capability of STAT3 in cell lines, persistently tyrosine-phosphorylated STATs in several types of leukemia and lymphoma, and the development of T-lymphoblastic lymphomas in STAT5 transgenic mice.⁵⁷⁹ The role of STAT3 in the tumor microenvironment makes it an attractive target for cancer immunotherapy.⁵⁸⁰ Second, there is diminished proliferation in a number of the STAT knockout mice that have been analyzed. For example, STAT4-deficient cells exhibit diminished cellular proliferation to IL-12566,567; STAT6deficient cells exhibit diminished proliferation to IL-4568,569; and STAT5-deficient mice have diminished T-cell proliferation to IL-2.^{511,512} Some of these effects are indirect, based on modulation of receptor expression. For example, STAT6deficient mice exhibit decreased IL-4Ra expression. Similarly, the absence of STAT5 results in decreased IL-2-induced IL- $2R\alpha$ expression as well as decreased proliferation.^{511,512} Thus, in at least some cases, decreased proliferation results at least in part from decreased expression of receptor components. STAT5A and STAT5B regulate BCL-XL induction, indicating their ability to affect cell survival.⁵⁷⁴ Finally, STAT1 has been linked to cell growth arrest and induction of the cdk inhibitor p21^{WAF1/CIP1, 581} and activation of STAT1 occurs in thanatophoric dysplasia type II dwarfism as the result of a mutant fibroblast growth factor receptor.⁵⁸² In this chondrodysplasia, the mutant fibroblast growth factor receptor induces nuclear translocation of STAT1, expression of $p21^{WAF1/CIP1}$, and growth arrest, suggesting a possible relationship to the disease. Thus, different STATs may potentially mediate either growth expansion or growth arrest. Moreover, STATs may potentially play other types of roles, as well. For example, STAT3 has been reported to serve as an adapter to couple PI 3-kinase to the IFNAR-1 component of type I IFN receptors.⁵⁸³

A more complete understanding of the actions of the different STAT proteins may be facilitated with a compilation of the genes that are regulated by each STAT. Progress in this area has been made for a number of cytokines by microarray or RNA-Seq analysis (eg, for the IFNs³⁹⁹). It is also important to recognize that not all cytokine signals are dependent on STATs, as illustrated, for example, by STAT1independent IFN signals,⁵⁸⁴ STAT5-independent IL-2 signals,⁵²⁰ and STAT1/STAT3-independent IL-21 signals.⁵⁸⁵

Do Other Proteins Bind to GAS Motifs?

At least one non-STAT protein can bind to GAS motifs. The *BCL6* gene is often mutated or has undergone translocations in diffuse large cell B-cell lymphomas. Interestingly, BCL6 binds to GAS motifs capable of binding STAT6 and specifically can inhibit IL-4 action.⁵⁸⁶ Mice lacking BCL6 expression exhibit defective germinal center formation, suggesting that formation of germinal centers may be at least partially dependent on BCL6 regulated (presumably negative) control of certain STAT-responsive genes.⁵⁸⁶

OTHER LATENT TRANSCRIPTION FACTORS AS EXAMPLES OF CYTOPLASMIC TO NUCLEAR SIGNALING (NF-κB, NFAT, AND SMADS)

An exciting feature of STAT proteins is that they exist in an inactive form in the cytosol and then are rapidly translocated to the nucleus. The rapid activation within minutes of signals from cell membrane to nuclear DNA binding makes the STAT acronym apt, analogous to the urgency associated with "STAT" emergency physician orders in clinical medicine. The rapid activation of STAT proteins is somewhat analogous to several other transcription factors.587 NF-KB also undergoes rapid nuclear translocation but by a completely different mechanism from STATs. In contrast to STAT proteins where the tyrosine phosphorylation of the STATs is an initiator of nuclear translocation, for NF-KB, it is the serine phosphorylation and/or uguitination of IkB that results in its dissociation and/or destruction, allowing the release and translocation of NF-κB. There is the classical NF-κB pathway used by many cytokines, which involves the IKK α / IKKβ/IKKγ-dependent phosphorylation of IκB, resulting in the activation of NFkB1 (p50)/Rel-A (p65) heterodimers as well as the alternative pathway in which a homodimer of IKKα mediates the activation of NFκB2 (p52)/Rel-B heterodimers.^{588–594} A third example of cytosolic to nuclear translocation occurs with nuclear factor of activated T-cell (NFAT) family proteins,⁵⁹⁵⁻⁵⁹⁷ which are vital for regulating transcription of a number of cytokines, including for example IL-2, IL-4, and GM-CSF. NFAT is translocated to the nucleus where it associates with activator protein 1 (AP-1) family proteins to form a functional complex. It is the activation of calcineurin and dephosphorylation of NFAT that allows its nuclear translocation. A fourth example of cytosolic to nuclear translocation occurs with the SMAD proteins that mediate TGF- β signaling, which contributes to Th17 differentiation (discussed subsequently). For SMADs, the phosphorylation is on serine and the kinase is intrinsic to the receptor, but like STATs, activation of these latent transcription factors is rapid and initiated by the binding of a growth factor. Thus, several mechanisms, each involving phosphorylation or dephosphorylation, have evolved to allow cytoplasmic to nuclear translocation of latent transcription factors.

OTHER SUBSTRATES FOR JAKS

As JAKs are potent cytosolic tyrosine kinases, it is evident that the JAKs may do more than just phosphorylate tyrosine residues on receptors where STAT proteins dock as well as phosphorylating the STATs. In vitro data indicate that JAK kinases also can phosphorylate receptor tyrosines other than the docking sites for STATs. For example, in the case of IL-2R β , JAK1 can phosphorylate not only tyrosines 392 and 510, which are STAT docking sites, but also tyrosine 338, which is a docking site for SHC,⁵²⁰ all of which are required for maximal proliferation. JAK kinases are known to autophosphorylate themselves or transphosphorylate other JAKs. Other molecules are potentially phosphorylated by JAK kinases, including the STAM adapter molecule⁵⁹⁸ and the p85 subunit of PI 3-kinase.⁵⁹⁹

Interferon Regulatory Factor Family Proteins

IRFs form a family of nine proteins that are regulated by type I IFNs.^{395,600,601} They each have a well-conserved N-terminal DNA-binding domain that forms a helix-loop-helix structure as well as a C-terminal interaction domain. IRFs are critical for a number of actions, including type I IFN–dependent gene transcription.³⁹⁵ Select IRFs play critical roles in TLR-mediated IFN induction. IRFs can have negative as well as positive effects. For example, IFNγ-mediated repression of IL-4 is mediated by IRF protein(s).⁶⁰²

OTHER SIGNALING MOLECULES IMPORTANT FOR CYTOKINES

Other Tyrosine Kinases besides JAKS

In addition to their activation of JAK kinases, a number of cytokines can activate Src family kinases. For example, IL-2 can activate p56lck^{603,604} in T cells and p59fyn and p53/p56lyn in B-cell lines.^{605,606} The activation of some of these kinases has been reported to be mediated by associating with the "A" region of IL-2RB. Another tyrosine kinase, Syk, has been reported to associate with the S region of IL-2R^β.⁶⁰⁷ However, the significance of these interactions is less clear than that for JAK kinases. First, cells lacking Lck can vigorously proliferate in response to IL-2.608,609 Second, when the A region is deleted, proliferation still occurs, albeit at a lower level than seen with wild-type IL-2R^β.⁶¹⁰ However, Y338, which is required for the recruitment of SHC, is in the A region and is required for normal proliferation.⁵²⁰ Thus, it is possible that the decrease in proliferation associated with deletion of the A region relates more to the loss of Y338 than it does to the loss of association of Lck. Moreover, in Il2rb-/- mice reconstituted with an IL-2RB A-region mutant, proliferation is increased rather than decreased.⁶¹¹ Additional investigation is required to clarify the role of activation of Src family kinases by IL-2 and other cytokines as well as the significance of the Syk interaction with IL-2R β . As Syk and JAK1 both associate with the S region of IL-2R β , mutations that delete the S region simultaneous prevent both associations, making it hard to determine the specific role of Syk. Syk-deficient mice exhibit normal IL-2 proliferation,612 further suggesting that Syk may not play an important role in IL-2-induced proliferation. The G-CSF receptor also can form a complex with Lyn and Syk,⁶¹³ but again Syk-deficient mice do not exhibit a defect in G-CSF signaling. 612 β_{c} has also been reported to interact with Src family kinases⁶¹⁴; gp130 has been reported to associate with a number of other kinases, including Btk, Tec, and Fes⁶¹⁵⁻⁶¹⁷; and IL-4R α has been shown to interact with Fes.⁶¹⁸ However, relatively little is known about the significance of tyrosine kinases besides JAKs in cytokine signaling. Additionally, PI 3-kinase, p38, ERK, and JNK can each become activated, leading to activation of many downstream transcription factors, including NF-KB, AP1, PU.1, IRF1, IRF4, and IRF8, to mediate a program of gene expression.

IRS Proteins

IRS-1 was discovered as a tyrosine phosphorylated substrate of the insulin receptor.⁶¹⁹ IRS proteins have a large num-

ber of phosphotyrosine docking sites, particularly for the p85 subunit of PI 3-kinase, and they presumably serve to recruit important accessory molecules. Interestingly, both insulin and IL-4 could induce tyrosine phosphorylation of an IRS-1–like molecule in hematopoietic cells. The 32D myeloid progenitor cells lack IRS-1 and could only signal in response to insulin or IL-4 when they were transfected with IRS-1.⁶²⁰ Both the insulin receptor and IL-4R α proteins contain NPXY sequences that are important for IRS-1 or IRS-2 binding; in IL-4R α , this is contained within a sequence denoted as the I4R motif.⁶²¹

Other cytokines have subsequently been shown to activate IRS-1 and/or IRS-2. For example, growth hormone can induce phosphorylation of IRS-1⁶²² and IRS-2⁶²³; IFN γ and LIF induce phosphorylation of IRS-2⁶²³; and the γ_c -dependent cytokines IL-2, IL-7, and IL-15 can induce tyrosine phosphorylation of IRS-1 and IRS-2 in T cells.⁶²⁴ The significance of these findings remain unclear, as 32D cells reconstituted with a complete IL-2 receptor can proliferative vigorously in response to IL-2,⁶⁰⁸ whereas as noted previously, in these same cells, IL-4 responsiveness requires coexpression of both IL-4R α and IRS-1, indicative of differing roles for IRS proteins for different cytokines.

Phosphatidylinositol 3-Kinase

PI 3-kinase is a lipid kinase that consists of an 85 kDa regulatory subunit and a 110 kDa catalytic subunit.⁶²⁵ PI 3-kinase phosphorylation and activation can be induced by a number of cytokines,^{626–629} and the use of inhibitors, such a wortmannin or LY294002, have demonstrated its importance in signaling for at least certain cytokines. IRS-1 has multiple docking sites for PI 3-kinase (YXXM motifs) and thus for some cytokines, such as IL-4, the association of IRS-1 might be the mechanism by which PI 3-kinase can be recruited.

The Ras/Mitogen-Activated Protein Kinase Pathway

Another major signaling pathway for a number of cytokines is the Ras/MAP kinase pathway.⁶³⁰ This pathway presumably is used by cytokines whose receptors recruit the SHC adaptor molecule, which in turn mediates the recruitment of Grb2 and Sos, eventually leading to the activation of Ras. In turn, Ras couples to the MAP kinase pathway through a welldefined signaling cascade. Certain cytokines, such as IL-2 and IL-3, appear to use this pathway, whereas others, such as IL-4, do not, indicating that this pathway is differentially important depending on the cytokine that is being used.

DOWNMODULATION OF CYTOKINE SIGNALS

Much of the previous discussion has centered on the mechanisms by which cytokines induce signals. However, the mechanisms by which cytokine signals can be terminated are also extremely important. There are multiple levels at which negative regulation can occur. These include 1) regulating a balance between the production (transcriptional and translational control) of the cytokine, its receptor, and/ or downstream signaling molecules and the degradation of these same molecules; and 2) regulation of the activation state of the receptor and downstream signaling molecules. For example, these can be mediated by transcriptional repressors or molecules that either inhibit cytokine signaling (eg, SOCS proteins) or reverse activated states (eg, phosphatases).

Transcriptional control of cytokine production is a widely used mechanism. Many T-cell–derived cytokines such as IL-2, IL-3, and IL-4 are only produced by activated T cells, and their production is lost with the loss of activation. IL-15 provides an example where translation of the protein is carefully regulated, in part by the existence of multiple upstream antithymocyte globulins.¹⁴⁷ Most cytokine receptor chains are constitutively expressed, but some like IL-21R and IL-2R β are regulated in part by signals that act through the TCR. The most regulated receptor chain may be IL-2R α , whose expression is absent on resting lymphocytes but strongly induced following stimulation with antigens, mitogens, and certain cytokines, but the transcriptional/translational control of most cytokine receptors is poorly studied.

Because phosphorylation events are vital for the creation of phosphotyrosine docking sites, dephosphorylation is an obvious mechanism of control. Indeed, two tyrosine phosphatases, Shp-1 (formerly also known as SHP, HCP, SH-PTP1, and PTP1C) and Shp-2 (formerly also known as Syp and PTP1D) have been shown to play roles related to cytokine signaling.^{631,632} Shp-1 mutations cause the motheaten (me) and viable motheaten (mev) phenotypes in mice.^{633,634} The viable motheaten mouse had a less severe phenotype that is associated with increased numbers of erythroid progenitor cells and hyperresponsiveness to Epo,635 suggesting that Shp-1 might normally diminish responsiveness to Epo. Indeed, it was demonstrated that Shp-1 binds directly to the EpoR when Y429 is phosphorylated.⁶³⁶ This tyrosine is located in a "negative" regulatory region of the EpoR, and when mutated, Epo-responsive cells can grow in lower concentrations of Epo. Following Shp-1 binding to Y429, dephosphorylation and inactivation of JAK2 is facilitated.⁶³⁶ Thus, the negative regulation of Epo signaling appears to be at the level of a receptor-dependent inactivation of a JAK kinase. Shp-1 has also been shown to interact with β_c and to mediate diminished IL-3-induced signaling637 and to be able to associate with both TYK2638 and JAK2.639

Shp-2 has generally been considered primarily an "activating" phosphatase; it is therefore interesting that it can also interact with JAK1, JAK2, and TYK2.⁶⁴⁰ In addition to the presumed dephosphorylation of JAK kinases by phosphatases, STAT proteins also appear to be regulated at the level of tyrosine dephosphorylation,⁶⁴¹ and interestingly, it has been shown that dephosphorylation of phosphotyrosine on STAT1 dimers requires extensive spatial reorientation of the two monomers within the dimer, something that is facilitated by the N-terminal domain that is involved in tetramerization.⁶⁴² Finally, another type of phosphatase, namely the lipid phosphatases, known as SHIP and SHIP2, can act as negative regulators of cytokine signals.⁶⁴³

In addition to Shp-1 and Shp-2, CD45, PTP1B, and T-cell PTP (TCPTP) have been reported to regulate JAK kinases. CD45 appears to play roles related to Epo and IFN signal-

ing. PTP1B has been reported to dephosphorylate JAK2 and TYK2, and TCPTP has been reported to dephosphorylate JAK1 and JAK3.⁴⁴⁹ In the cytosol, Shp-2 and PTP1B have also been reported to dephosphorylate cytosolic STAT5 and nuclear STAT1 and STAT3, whereas TCPTP has been reported to dephosphorylate STAT1 and STAT3 in both cytosol and nucleus, but additional work is needed to determine whether these events are occurring physiologically in vivo.⁴⁴⁹

In addition to dephosphorylation, another mode of negative regulation is by degradation. In addition to the degradation of receptor molecules, STAT1 itself is a target of the ubiquitin-proteasome pathway.⁶⁴⁴ Finally, it is possible that regulation also can occur at the level of alternative splicing. In this regard, alternatively spliced versions of some of the STATs^{448,508,515} have been reported.

THE CIS/SOCS/JAB/SSI FAMILY OF INHIBITORY ADAPTER PROTEINS

In 1995, the protoype molecule for an interesting class of proteins was discovered. The prototype molecule was named CIS, for cytokine inducible, SH2-containing protein, and it was shown to negatively regulate the actions of a set of cytokines.^{645,646} CIS is rapidly induced by a variety of cytokines, including IL-2, IL-3, GM-CSF, and Epo, to physically associate with both the β_c and Epo receptors.^{645,646} Subsequently, a related protein, variably denoted SOCS-1, JAB (JAK-binding protein), and SSI-1 (STAT-induced STAT inhibitor-1) was identified that could negatively regulate the activity of other cytokines, including IL-6647-649 and IL-2, among others. Interestingly, this protein could associate with JAK family kinases, whereas this function has not been reported for CIS. A total of eight CIS/SOCS/JAB/SSI family members have been identified that collectively regulate signals in response to multiple cytokines.⁶⁵⁰⁻⁶⁵⁴ These proteins are now generally known as SOCS proteins and share a central SH2 domain and a region known as a C-terminal region known as a SOCS box. Additional SOCS box-containing proteins lack SH2 domains and include proteins known as ASBs (ankyrin repeat-containing proteins with a SOCS box), SSBs (SPRY domain-containing proteins with a SOCS box), and WSBs (WD40 repeat-containing proteins with a SOCS box). SOCS proteins tend to be expressed at very low levels in nonactivated cells and to be induced by cytokines and pathogens. Following their induction, they negatively influence cytokine signaling, serving as negative feedback regulators. Their actions can extend beyond type I cytokines, for example, SOCS-1 can negatively regulate LPS responses.655

Knockout mice for a number of the SOCS proteins have been prepared, alone and in combination. CIS knockout mice are relatively normal, but CIS transgenic mice exhibit low body weight, failure of lactation, and diminished numbers of NK and NKT cells as well as altered TCRmediated responses, presumably related to its ability to inhibit STAT5-dependent responses including those related to growth hormone, prolactin, IL-15, and IL-2, as well as others. SOCS-1 knockout exhibit multiorgan inflammation and neonatal lethality as the result of augmented re-

sponsiveness to IFN γ , and this lethality can be prevented if the mice are crossed to IFNy-deficient mice. Interestingly, SOCS-1-/- mice also indicate an essential role for SOCS-1 in thymocyte differentiation, and there are diminished numbers of maturing B cells. Deletion of SOCS-1 within thymocytes/T cells/NKT cells results in multiple lymphoid abnormalites with increased CD8+ T cells due to increased sensitivity to γ_c -dependent cytokines, including IL-7.⁶⁵⁶ SOCS-2 knockout mice exhibit gigantism, ostensible due to dysregulated growth hormone signaling. SOCS-2 knockout T cells exhibit enhanced Th2 differentiation, and knockout mice exhibit elevated Th2 responses after helminth infection.⁶⁵⁷ SOCS-3 knockout mice exhibit embryonic lethality due to placental insufficiency and dysregulated responses to LIF and IL-6 as well as hematopoietic defects. Conditional SOCS-3 knockout mice have revealed a physiologic role for SOCS-3 in regulating G-CSF signaling in myeloid cells and for "emergency" granulopoiesis⁶⁵⁸ as well as for IL-6/ gp130 signaling.^{659,660} SOCS-6 knockout have mild growth retardation.^{449,652,661} Additional SOCS knockout mice and various combinations continue to be generated, adding additional information to this important area of negative regulation of STAT-dependent signaling.

PROTEIN INHIBITORS OF ACTIVATED SIGNAL TRANSDUCER AND ACTIVATOR OF TRANSCRIPTION PROTEINS

Protein inhibitors of activated STAT (PIAS) proteins are other negative regulators of cytokine actions, 449,662-666 with PIAS-1 being an inhibitor of STAT1-binding activity and PIAS-3 being a similar inhibitor of STAT3-binding activity. These PIAS proteins block the DNA-binding activity of STAT dimers. Two other members, PIASx (which has both α and β splice variants) and PIASy, have also been described, with PIASx inhibiting STAT4 and PIASY inhibiting STAT1. They appear to act at least in part as transcriptional corepressors by recruiting other proteins such as histone deacetylase. In addition, PIASx and PIASy have added actions not restricted to the context of STAT inhibition. For example, PIASy is a nuclear matrix-associated SUMO E3 ligase (a ubiquitin-related protein) that can repress the activitity of the Wnt-responsive transcription factor, LEF1.665 PIASy coexpression results in the covalent modification of LEF1 by SUMO. Thus, as a class, PIAS proteins have more than one type of action.449,667

DISEASES OF CYTOKINE RECEPTORS AND RELATED MOLECULES A Range of Cytokine-Related Causes of Severe Combined Immunodeficiency

As detailed previously, mutations in the γ_c cause X-linked SCID, and mutations in JAK3 cause a similar T–B+NK–SCID. Given that γ_c -dependent cytokines activate primarily STAT5A and STAT5B as signaling molecules downstream of the JAKs, it remains an open question as to whether mutations in these STAT proteins also cause human disease. Although one could hypothesize that mutations in either

STAT5A or STAT5B alone might not cause a phenotype due to potential redundancy, mice lacking STAT5A or STAT5B exhibit defects in T- and NK-cell numbers as well as T-cell proliferation and NK cytolytic activity,^{511,512} and mice lacking both STAT5A and STAT5B have an even more profound defect, with absent T-cell⁵⁷³ and NK-cell development.⁵¹³ Moreover, STATB mutations have been found and cause growth hormone insensitivity, IGF-1 deficiency, and immune dysfunction.^{573a,573b}

It can be predicted that human immunodeficiencies might also result from mutations in some of the cytokines whose receptors contain γ_c or from mutations in other components of the receptors for these cytokines. Indeed, as noted previously, patients with IL-2 deficiency exhibit a SCID-like syndrome, due to inadequate function of their T cells, and recently, an unusual immunodeficiency has been found to result from a mutation in IL-2Ra.³⁶⁹ One patient with defective IL-2R β expression also had an immunodeficiency syndrome characterized by autoimmunity,668 somewhat analogous to IL-2RB-deficient mice. Given that mutations in IL-7Ra in humans cause T-B+NK+ SCID,²⁰⁶ mutations in IL-7 might be predicted to cause a similar syndrome. The one major difference might be that IL-7-deficient humans might not be capable of receiving a successful bone marrow transplant if stromal IL-7 is required for the graft. Such patients have not yet been identified. Given the defective NKcell development and CD8+ memory T-cell development in IL-15- and IL-15R α -deficient mice, it is likely that these types of defects would also occur in humans lacking either of these proteins. However, again, such patients have not vet been identified. Although IL-9 transgenic mice develop lymphomas,669 IL-9-deficient mice exhibit defects related to mast cells and mucous production rather than lymphoid defects. Thus, defects related to the IL-9 system seem unlikely as causes of SCID. At present, defective expression of IL-2, IL-2R α , IL-2R β , IL-7R α , γ_c , and JAK3 are the only cytokinerelated mutations that have been found to cause SCID, with TYK2 being implicated in another form of immunodeficiency. More time will be required to determine whether mutations in other cytokines, cytokine receptors, JAKs, or STATs can also cause SCID.

Defects in the Ability to Clear Mycobacterial Infections and Chronic Mucocutaneous Candidiasis

A number of immunodeficiencies have been characterized where affected individuals cannot properly clear mycobacterial infections. These have also turned out to be diseases of defective cytokine signaling. Mutations have been found in the components of either IL-12 itself or in the IFN or IL-12/ IL-23 receptors, with mutations having been found in either the gene encoding the p40 subunit of IL-12 (which as noted previously is also a component of IL-23),⁶⁷⁰ in IL-12R β 1 (a component of both the IL-12 and IL-23 receptors),⁶⁷¹ or in either the IFNGR-1 or IFNGR-2 components of IFN γ receptors.^{672,673} The critical role of IL-12 for Th1 cell–mediated differentiation and production of IFN γ provides the explanation for finding similar clinical syndromes in humans lacking the p40, IL-12R β 1, IFNGR1, or IFNGR-2. Moreover, one patient with a mutation in the STAT1 gene was also identified with a similar clinical syndrome,⁶⁷⁴ indicating that as anticipated, STAT1 is a critical mediator of IFN γ signaling. Interestingly, this patient had a mutation on only one STAT1 allele, but the mutation was a dominant negative mutations that selectively inhibits the formation of STAT1 dimers (hence abrogating IFN γ signaling) but yet had at most only a modest effect on the ability to form ISGF3, hence leaving signaling in response to IFN α/β relatively intact. Chronic mucocutaneous candidiasis can be caused by autosomal dominant IL-17F or autosomal recessive IL-17RA deficiency or by gain-of-function heterozygous STAT1 mutant alleles that impair IL-17 immunity.⁶⁷⁵

Somatic mutations that activate STAT3 occur in benign liver adenomas, suggesting a role for IL-6–STAT3 pathway in human hepatocellular tumorigenesis.⁶⁷⁶

Mutations in the WSX-1/TCCR Type I Receptor

Interestingly, there is a type I cytokine receptor denoted as TCCR or WSX-1 that is related to IL-12 β 2 and its mutations results in defective Th1-related responses and diminished IFN γ production, resulting in susceptible to *Leishmania major* and *Listeria monocytogenes*.^{254,677,678} TCCR/WSX-1 is an essential component of the receptor for IL-27³⁰⁰ and also has been found to be required for resistance to *Trypanosoma cruzi*.^{679,680}

Other Diseases Associated with Cytokine Receptors

A number of other diseases have been reported that related to cytokine receptors. First, mutations in the growth hormone receptor have been found in a form of dwarfism (Laron dwarfism)⁶⁸¹ in which target cells cannot respond to growth hormone. Interestingly, some aspects of STAT5B deficiency are related to this syndrome. Second, a single patient with a form of congenital neutropenia (Kostmann syndrome) has been found to have a mutation in one of his G-CSF receptor alleles.⁶⁸² Third, a kindred of patients with familial erythrocytosis has truncation in the erythropoietin receptor, resulting in hypersensitivity to Epo.⁶⁸³ Fourth, an altered virally encoded form (v-mpl) of the thrombopoietin receptor (c-mpl) was originally identified as the oncogene of the myeloproliferative leukemia virus.⁶⁸⁴ Finally, gainof-function mutations in IL7R⁶⁸⁵ and genomic aberrations of TSLPR (also known as CRLF2)^{686–688} have been found in childhood acute lymphoblastic leukemias, sometimes associated with mutations in JAK2 or JAK1 or TLSPR itself.

Modulation of Cytokines and the Clinic

Certain diseases are associated with increased levels of cytokines or other situations where treatment with an anticytokine receptor antibody is a rationale therapy. One

major example is Castleman disease, which is associated with overproduction of IL-6 by lymph node cells, leading to the successful treatment of this disease with IL-6 receptor blockade.^{257,689} Anti-IL-6R-based therapy also has utility for rheumatoid arthritis and possibly for Crohn disase.^{257,690} Blocking the IL-2 receptor has been used in the treatment of patients with adult T-cell leukemia and other neoplasias, and the use of humanized and conjugated antibodies have produced responses in a number of individuals. Humanized anti-Tac monoclonal antibody, marketed under the name daclizumab, has shown very strong efficacy in the treatment of allograft rejection as well as in T-cell-mediated autoimmune disorders, including multiple sclerosis, uveitis, and tropical spastic paraparesis. Conjugated antibodies to both IL-2R α and IL-2R β are also being tested for use in a variety of malignant disorders, wherein the malignant cells express these proteins. Thus, there is the possibility of therapy, either based on blocking the cytokine or based on eliminating the responding cells.⁶⁹

CONCLUSION

Type I cytokines and IFNs are involved in the regulation of an enormous number of immunologic and nonimmunologic processes. There has been a progressive transition from viewing these as discrete molecules with special actions to sets of molecules that can be grouped according to shared receptor components and common signaling pathways. Signaling is one area where our understanding has greatly expanded; the pathways that are activated are similar for many cytokines, even when the biologic functions they induce are dramatically different. Although some of the differences can be explained by "compartmentalization" according to which cells produce the cytokine and which cells express receptors that allow them to respond to the cytokine, a tremendous amount still needs to be learned about how distinctive signals are triggered as well as more regarding the sets of genes that are induced by each cytokine. These will provide vital information important to the quest to completely understand the mechanisms by which type I cytokines and IFNs can effect their actions. At the same time, the generation of knockout mice for most cytokines and their receptors, as well as many signaling molecules, has provided in vivo clues as to vital functions served by these cytokines. Caution is clearly needed, however, in generalizing from these findings to human biology, given some apparently major differences in roles served, such as the essential role played by IL-7 in both humans and mice for T-cell development, whereas IL-7 is also essential for B-cell development in mice but not in humans. The identification of so many humans disorders associated with cytokines and cytokine receptors has tremendously helped to teach us more about normal human biology as well.

CHAPTER

The Interleukin-1 Family

Charles A. Dinarello • Mihai G. Netea

INTRODUCTION

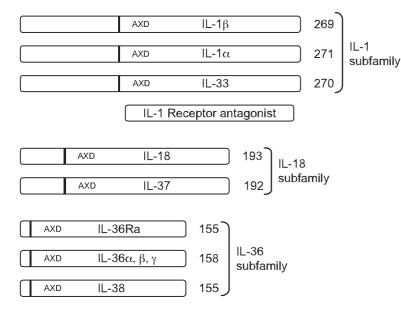

More than any other cytokine family, the interleukin (IL)-1 family of ligands and receptors is primarily associated with acute and chronic inflammation. Also, more than any other cytokine family, the IL-1 family plays a fundamental role in the nonspecific innate response to infection that facilitates specific immunologic responses such as antibodies and cytotoxic T-lymphocytes. This nonspecific response to infection is now termed the "innate immune response." The cytosolic segment of each member of the IL-1 receptor family contains the toll-IL-1-receptor (TIR) domain. This domain is also present in each toll-like receptor (TLR), receptors that respond to microbial products, viruses, and nucleic acids. TIR is the functional domain for both the TLR and IL-1 receptor families, as mutations in this domain result in loss of response to IL-1 and TLR agonists. The biologic properties of both IL-1 family ligands and TLR agonists characteristically are proinflammatory and act as adjuvants for specific immune responses to antigen. Thus, the IL-1 family of ligands and receptors is fundamental to innate immunity. Of the 11 members of the IL-1 family, IL-1 β has emerged as a therapeutic target for an expanding number of systemic and local inflammatory conditions termed "autoinflammatory" diseases. These diseases are distinct from autoimmune diseases and include rare hereditary conditions. But autoinflammatory diseases are also common diseases such as heart failure, gouty arthritis, and type 2 diabetes. For these, neutralization of IL-1ß results in a rapid and sustained reduction in disease severity. Another member of the IL-1 family, IL-1 α , is also a mediator of inflammation but is classified as an "alarmin" because the cytokine is present in most cells and readily released upon cell death. Whereas treatment for autoimmune diseases often includes immunosuppressive drugs, neutralization of IL-1 β or blocking the IL-1 receptor is mostly anti-inflammatory.

With one exception, all members of the IL-1 family are initially translated as precursors lacking a signal peptide for secretion via the Golgi. The precursors are found in the cytosol and exit the cell following death by necrosis, not apoptosis. For example, once released, IL-1 α , IL-33, and IL-36 can be processed extracellularly by neutrophil proteases into active cytokines. Although IL-1 β is primarily processed intracellularly by the cysteine protease caspase-1, the IL-1 β precursor can also be cleaved extracellularly into an active cytokine by similar serine proteases of neutrophils. The one member of the IL-1 family that is readily secreted is the IL-1 receptor antagonist (IL-1Ra). IL-1Ra is translated with a signal peptide (Fig. 26.1), although an intracellular form also exists.¹ IL-1Ra is produced in health and is found circulating in mice and humans where the antagonist serves as a brake on inflammation driven by endogenous IL-1 α or IL-1B. IL-1Ra binds to the IL-1RI and blocks the receptor from binding to either IL-1 α or IL-1 β (see Fig. 26.1C). Mice as well as humans born with a deficiency in functional IL-1Ra exhibit increased systemic and local inflammation; in humans, a deficiency in IL-1Ra is lethal. The IL-36 receptor antagonist (IL-36Ra), another member of the IL-1 family, inhibits the activity of endogenous IL-36 α , β , and γ . Although IL-36Ra is not readily secreted, individuals with a mutation in IL-36Ra develop a severe form of psoriasis. One may conclude that most members of the IL-1 family primarily promote inflammation and enhance specific acquired immune responses. But there are also members that provide a brake on inflammation. The primary characteristics of the each member of the IL-1 family are depicted in Table 26.1.

INTERLEUKIN-1 FAMILY AND INNATE RESPONSES

Independent of the type of organism or its products, the innate response is one of inflammation in which the host musters its defenses to increase the production and infiltration of phagocytic cells to the area of the invading microbe in an attempt limit infection and kill-off the invader. Systemically, the liver increases the synthesis of acute phase proteins, include antiproteases. Even in humans, in most cases this process protects the subject without the use of antibiotics. For example, a break in the skin allows bacteria to gain access to the dermis and subsequent inflammation provides activation of complement, the release of preformed cytokines from keratinocytes, an increase in vascular wall adhesions molecules, and the extravasation of neutrophils. This response has functioned to battle against invaders for millions of years and can be traced back to fruit flies.

The skin, lung, and intestinal tract each provide a first line of defense against microbial invasion and the lining cells, whether keratinocytes of the skin, the alveolar epithelial cells of the pulmonary tree, or the epithelial cells of the entire gastrointestinal tract, each contain preformed IL-1 α , IL-18, and IL-33 as well as the members of the IL-36 subfamily. Because these members of the IL-1 family are each preformed in these cells, their release is a consequence of injury and is immediate. Therefore, they are termed "alarmins" as they alert the host to initiate the response. There are other "alarmins" from the lining cells that participate in defense, for example, defensins, which are directly antimicrobial.

Each of the constitutively present IL-1 family members in lining cells is present as a precursor. In the case of IL-1 α , the precursor is fully active; in the case of the other members, the precursors are weakly active at first but are converted to more active cytokines upon the infiltration of neutrophils and processing by extracellular neutrophil proteases. In the end, the infection is contained, the invading microorganism is eliminated, and skin begins its process of repair.

Following the cloning of the mouse IL-1 receptor,² the cytosolic domain of the IL-1 receptor was found to be homologous to toll of the fruit fly.³ Moreover, at the same time, the TIR domain for IL-1 signaling (Fig. 26.2A) was shown by Heguy to be required for IL-1 signaling.⁴ Toll had been initially studied since its discovery in 1985 because of its central role in establishing dorsal ventral polarity in *Drosophila*. Only since 1996 was toll linked to survival in fruit flies infected with fungi.⁵ However, it had already been reported, back in 1988, that a member of the IL-1/TLR family, human IL-1 β , protected mice from lethal *Pseudomonas* infection.⁶

IL, interleukin.

FIG. 26.1. Organization of the Interleukin (IL)-1 Family into Three Subfamilies. The number of amino acids of the fulllength of each member is shown at the C-terminal end. The consensus sequence (A-X-D) is common to all IL-1 family members and serves to locate the N-terminus nine amino acids forward from this site, as shown by the *dark vertical bar*. The N-terminus results in propieces of various lengths. The IL-1Ra has a bonafide signal peptide and is shown by comparison.

IL-1 receptor family and TLR family signaling; a mutation in the TIR domain severely impairs responses to IL-1 family ligands as well to a large number of microbial products.⁷

The TIR domain binds MyD88 (see Fig. 26.2A and E), itself a TIR domain—containing protein, through TIR/TIR interactions triggering a cascade of kinases that propagate the IL-1 signal and result in transcription of a large number of genes, the majority of which code for other cytokines, chemokines, and a host of inflammatory mediators. Of these is IL-1 and other members of the IL-1 family such as IL-36 and IL-18.

The "innate immune response" regulates to the "acquired immune response." The late Charles Janeway proposed that the innate response assists the host in mounting an acquired immune response. This relationship between a nonspecific cytokine providing help for a specific response to a microbial antigen is simply the adjuvant property of some cytokines. The adjuvant property of some cytokines functions by upregulating lymphocyte growth factors such as IL-2, IL-4, and IL-6, or lymphocyte receptors resulting in expansion of lymphocyte clones, which will either rid the host of the invading microorganism with neutralizing antibodies or in generation of cytotoxic T cells to eliminate viral infections. In 1979, purified human IL-1 β , a nonspecific macrophage product, was shown to augment the T-cell response to specific antigen.8 It was nearly 20 years later that TLR were identified as inducing IL-1 β from monocytes.

ORGANIZATION OF THE INTERLEUKIN-1 FAMILY OF LIGANDS AND THE CONSENSUS SEQUENCE

As depicted in Figure 26.1, the IL-1 family can be divided into subfamilies according to the length of the precursor and the length of the propiece for each precursor. The IL-1 subfamily is comprised of IL-1 α , IL-1 β , and IL-33. This subfamily has the longest proteins with the longest propieces. In the case of IL-1 β , the propiece is cleaved intracellularly by caspase-1 and then the mature cytokine is secreted. In the case of IL-1 α , cleavage appears to be by the membrane protease calpain, but

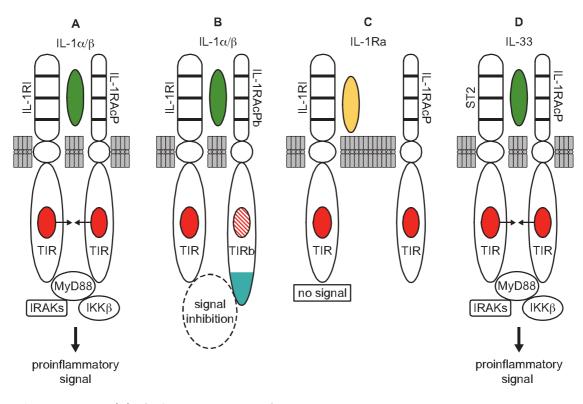

FIG. 26.2. Interleukin (IL)-1 Subfamily. A: IL-1α or IL-1β binds to the IL-1RI and recruits the coreceptor IL-1RAcP. The heterodimeric IL-1 receptor complex results in a close approximation of the toll-IL-1-receptor (TIR) domains on each receptor chain (*arrows*), resulting in the binding of intracellular MyD88 to the complex followed by phosphorylation of MyD88. Subsequent phosphorylations of IRAKs and IKKβ, increased NF-κB, and IL-1R AcP-1 translocation to the nucleus take place followed by expression of proinflammatory genes. B: In the central nervous system, IL-1α or IL-1β bind IL-1RI recruiting IL-1RAcP but can also recruit the coreceptor IL-1RAcPb. IL-1RAcPb contains an altered TIR domain, which results in a reduced signal. C: IL-1Ra binds to IL-1RI. There is no recruitment of the co-receptor IL-1RAcP, no approximation of the TIR domains, and no signal. D: IL-33 binds to its specific receptor, ST2, and recruits the coreceptor IL-1RAcP, the TIR domains approximate, and signal transduction is initiated resulting in the induction of proinflammatory gene profile.

extracellular neutrophil proteases can also cleave the IL-1 α precursor. Extracellular neutrophil proteases account for the cleavage of the propiece of IL-33. The exception in the IL-1 subfamily is IL-1Ra, which contains a signal peptide.

The IL-18 subfamily is comprised of IL-18 and IL-37. By comparison, this subfamily has a smaller propiece. IL-18 requires the cleavage of its propiece by caspase-1 in order to be active. IL-37 is part of the IL-18 subfamily because the cytokine binds to the IL-18R α chain. It is unclear how the propiece of IL-37 is removed. The IL-36 subfamily comprised of IL-36 α , β , and γ , as well as IL-36Ra. In addition, IL-38 likely belongs to this family due to its binding to the IL-36R. The IL-36 subfamily has the shortest propiece.

A consensus sequence in all members of the IL-1 family is A-X-D, where A is an aliphatic amino acid such as isoleucine, methionine, or leucine; X is any amino acid; and D is aspartic acid. The aspartic acid of the consensus sequence is not the aspartic acid of the caspase-1 cleavage recognition site. The A-X-D motif is conserved in the IL-1 family where it plays a role in three-dimensional structure of the active cytokine. The actual N-terminus is often located nine amino acids before the A-X-D site. By eliminating the amino acids before the N-terminus, the first beta-sheet structure common to all members of the IL-1 family can form. For example, with the tenth amino acid before A-X-D consensus site as the N-terminus, the specific activity of the IL-36 subfamily (IL-36 α , IL-36 β , IL-36 γ and the IL-36Ra) is low. However, with the ninth amino acid as the N-terminus, there was a marked increased in the activity.⁹ In the case of IL-1 β , the ninth amino acid before the A-X-D site coincides exactly with the N-terminal alanine generated by the caspase-1 site.

THE INFLUENCE OF INTERLEUKIN-1 FAMILY ON TH17 RESPONSES

The IL-1 family plays a significant role in interferon (IFN) γ production, which is essential for the defense against intracellular pathogens. On the other hand, Th2 cells are characterized by the production of IL-4 and are important in the host defense against parasitic infections. For more than one decade, the dichotomy between Th1 and Th2 has been the focus of studies on differentiation of cluster of differentiation (CD)4+T-lymphocytes. More recently, Th17 helper cells have been described and are characterized by their production of IL-17. IL-17 plays a major role in neutrophil recruitment and host defense against extracellular bacteria and fungi. Th17 cells produce a distinct cytokine profile, namely IL-17A, IL-17F, IL-21, and IL-22. The cytokines produced

by Th17 cells, in addition to activating neutrophils, are also crucial for nonimmune cells, for example, induction of defensins by IL-22 in epithelial cells and keratinocytes, which are part of mucosal and skin defenses. It has become apparent that Th17 responses are associated with chronic inflammation and autoimmune diseases such as multiple sclerosis, type 1 diabetes, Crohn disease, and psoriasis. Furthermore, Th17 responses are fundamental for host defense against many microorganisms, although they also contribute to the inflammation during infection.

Whereas IL-4 and IL-12 were the first cytokines described as influencing Th-cell differentiation, cytokines of the IL-1 family also influence cytokine differentiation. IL-18 was initially described as IFN γ -inducing factor due to its strong stimulatory effect on Th1/IFN γ responses.¹⁰ It is now known that IL-18 is, in fact, a crucial cytokine directing the development of Th1 cells, and one role of IL-12 is the induction of the expression of IL-18 receptors. In contrast, binding of IL-33, another member of the IL-1 family, to its ST2 receptor plays a role in inducing Th2 responses,¹¹ and it thus appeared as if distinct members of the IL-1 family of cytokines directed Th1 versus Th2 differentiation. Considering these effects of IL-18 and IL-33, it came as no surprise that IL-1, the most well-known member of the family, participates in the function of Th cells.

Known for over 30 years that IL-1 enhances T-cell activation and recognition of antigen, one of the early names of IL-1 was lymphocyte activation factor. The specificity of this response was, however, not known. Although initially only IL-23, IL-6, IL-21, and transforming growth factor- β were suggested to play a role in the development of Th17 responses in mice, there is no dearth of data that a more complex picture exists. Thus, IL-1 β , IL-6, and transforming growth factor- β have been reported to induce the development of Th17 cells, whereas IL-23 has been reported to be important for the maintenance of Th17 cells. The combination of IL-23 and IL- 1β induce the development of human Th17 cells expressing IL-17A, IL-17F, IL-22, IL-26, the chemokine CCL20, and transcription factor RORyt.12 Interestingly, these cells also released IFNy, displaying a phenotype common to both Th17 and Th1 cells.¹² The strong capacity of IL-1 to induce Th17 differentiation has been also linked to its well-known capacity to induce the release of prostaglandins, as reviewed in Dinarello.¹³ PGE2 induced by COX-2 is a stimulator of Th17 induction, and inhibitors of cyclooxygenase decrease IL-17 production.¹⁴ On the other hand, engagement of the aryl hydrocarbon receptor, a pathway demonstrated to be crucial for the generation of Th17 cells, has been shown to strongly induce IL-1^β.¹⁵ In addition to inducing IL-17 production from the Th17 subset of lymphocytes, IL-1 β is required for the production of IL-17 by natural killer (NK) T cells¹⁶ and of IL-22 from NK cells.¹⁷

Thus, cytokines of the IL-1 family have an important role in the differentiation of the Th subsets, with IL-1 β strongly inducing Th17 responses, IL-18 being crucial for the generation of Th1 cells, and IL-33 being important in Th2 responses. Interestingly, reciprocal regulation has been demonstrated between the various Th subsets, with cytokines released by Th2 cells inhibiting Th1 responses, whereas IFN γ release from Th1 cells impairing both Th2 and Th17 responses.

INTERLEUKIN-1*α*

From an evolutionary viewpoint, IL-1 α is the oldest member of the IL-1 family and its primary amino acid sequence is closely related to that of the fibroblast growth factor family. Like fibroblast growth factor, IL-1a does not have signal peptide, binds to nuclear deoxyribonucleic acid (DNA), exits the cell upon death, and binds to its receptor as an unprocessed precursor. As shown in Figure 26.2A, IL-1a binds to the IL-1RI and recruits the IL-1R accessory protein (IL-1RIAcP) to form a heterodimeric complex, which signals to induce inflammation. In health, primary cells contain constitutive levels of the IL-1 α precursor but not IL-1 β .¹⁸ The IL-1 α precursor is present in keratinocytes, thymic epithelium, hepatocytes, endothelial cells, the epithelial cells of mucus membranes, including the entire gastrointestinal tract, and fibroblasts, regardless of their location. The propiece of IL- 1α precursor can be cleaved extracellularly by neutrophil proteases, a step that increases its biologic activity. However, IL-1 α can also be active as a membrane-associated cytokine. Most cell lines, including tumor cell lines, contain constitutive levels of IL-1 α .^{19–21} Using an epithelial cell line, what was considered to be intrinsic IFNy activities depended largely on constitutively expressed IL-1a. IFNy activities were inhibited by antibodies to IL-1 α , but not to IL-1 β .²⁰ The concept that IL-1 α acts as an autocrine growth factor assumes that the intracellular IL-1 α precursor regulates normal cellular differentiation, particularly in epithelial and ectodermal cells. In support of the concept, an antisense oligonucleotide to IL-1a reduces senescence in endothelial cells.²² In fibroblasts, the constitutive IL-1 α precursor binds to HAX-1, a nonreceptor substrate for tyrosine kinases in hematopoietic cells. In fibroblasts, the IL-1 α HAX-1 complex translocates to the nucleus.²³ Although the concept is that IL-1 α acts as an autocrine growth factor in fibroblasts or endothelial cells in vitro, the data should be interpreted carefully as mice deficient in IL-1 α show no demonstrable defects in growth and development, including skin, fur, epithelium, and gastrointestinal function.²⁴ However, mice deficient in IL-1a still retain the N-terminal propiece, which functions as nuclear factor.21 In fact, in another study, the N-terminal propiece of IL-1 α was shown to bind HAX-1.²⁵

Is there is a role for intracellular precursor IL-1 α in normal cell function? The IL-1 α precursor is present in cells that also contain large amounts of the intracellular form of the IL-1Ra (icIL-1Ra), as reviewed in Arend.¹ This form of the IL-1Ra also binds to the IL-1 receptor and prevents signal transduction. In fact, icIL-1Ra is thought to compete with the intracellular pool of precursor IL-1 α for nuclear binding sites.

Membrane-Associated Interleukin-1a

Precursor IL-1 α can be found on the surface of several cells, particularly on monocytes and B-lymphocytes, where it is referred to as membrane IL-1 α .²⁶ Membrane IL-1 α is biologically active²⁷; its biologic activities are neutralized by antibodies to IL-1 α but to IL-1 β . Endothelial cells undergoing stress-induced apoptosis release membrane apoptotic bodylike particles containing nuclear fragments and histones as well as full-length IL-1 α precursor and the processed ma-

Processing and Secretion of Interleukin-1 α

Although the IL-1 α precursor is biologically active, the processed form is more active. Furthermore, the binding of IL- 1α to the IL-1RI has been modeled using recombinant IL-1 α with an N-terminus at 113. The processing of the IL-1 α precursor is accomplished by calpain II, a membrane-associated, calcium-dependent cysteine protease.²⁹ In macrophages treated with hydroquinone, calpain II levels fall and are associated with inhibition of IL-1a precursor processing.²⁹ Not surprisingly, calcium influx induced IL-1 α secretion of the processed form.³⁰ The secretion of IL-1 α requires the presence of IL-1 β , as IL-1 β -deficient mice do not secrete IL-1 α .³¹ IL-1 α binding to IL-1 β has been reported in which IL-1 β acts as a chaperone for the secretion mechanism via caspase-1.³¹ In another study, IL-1 β was shown to bind to, and enhance the activity of, high-mobility group protein B1 (HMGB1).³² It is thus possible that both IL-1 α exits the cell bound to IL-1 β and HMGB1.

Biologic Functions of Constitutive Interleukin-1 α : Interleukin-1 α and Sterile Inflammation

Large numbers of reports use bacterial and fungal products to induce cytokines as models of inflammatory disease; however, most inflammatory diseases are sterile. For example, the inflammation associated with atherosclerosis, myocardial infarction, stroke, cancer, and renal and liver failure is sterile. The hypoxic insult that takes place in ischemia results in local necrosis and release of cellular contents, including nucleic acids. Members of the IL-1 family contribute to sterile inflammation, and IL-1 α plays a significant role in this regard. Upon cell death by necrosis, the IL-1 α precursor is released^{33,34} and binds to the IL-1 receptor on nearby tissue macrophages and epithelial cells, triggering a response.35,36 For example, infiltration of neutrophils occurs first and followed by influx of monocytes.³⁵ Extracts of tumor cells induce neutrophilic inflammation, which does not occur in mice deficient in IL-1RI and is prevented by neutralization of IL-1 α , not neutralization of IL-1 β .³⁷ Sterile inflammation is independent on TLR2 and TLR4.³⁷

Thus, IL-1 α , either the unprocessed precursor or the calpain cleavage form, is classified as an "alarmin" because the cytokine is preformed and triggers an inflammatory response rapidly. Endothelial cells subjected to nutritional stress release inflammatory apoptotic bodies, which contain both the precursor and processed forms of IL-1 α .²⁸ Inflammatory apoptotic bodies induce chemokine and neutrophilic infiltration into the peritoneal cavity, both of which are IL-1 α dependent.²⁸ Platelets also contain IL-1 α as well as IL-1 β .³⁸ Platelet-derived IL-1 induces chemokines such as IL-8 from endothelial cells³⁹ and monocyte chemotactic protein (MCP-1) from monocytes.⁴⁰ Platelet-derived IL-1 α is important in brain injury in stroke models⁴¹ and in atherosclerosis.⁴²

Studies in Interleukin-1 α –Deficient Mice

Mice deficient in IL-1 α are born healthy and develop normally. In some models of local inflammatory responses, wild-type and IL-1 α -deficient mice develop fever and acutephase proteins, whereas IL-1B-deficient mice do not.²⁴ In addition, although the inflammation-associated induction of glucocorticoids was suppressed in IL-1 β -deficient mice, this suppression was not observed in IL-1 α -deficient mice. However, expression of IL-1ß messenger ribonucleic acid (mRNA) in the brain decreased 1.5-fold in IL-1 α -deficient mice, whereas expression of IL-1 α mRNA decreased more than 30-fold in IL-1 β -deficient mice. These data suggest that IL-1 β exerts greater control over production of IL-1 α than does IL-1 α over the production of IL-1 β . In caspase-1– deficient mice, IL-1 α production is also reduced,⁴³ further suggesting that production of IL-1 α is under the control of IL-1 β . It is important that caspase-1–deficient mice are also deficient in caspase-11.44

In mice fed a high-fat diet, serum amyloid A protein, a marker of inflammation in atherogenesis, was markedly lower in IL-1 α -deficient mice compared to wild-type or IL-1 β -deficient mice.⁴⁵ IL-1 α -deficient mice had significantly higher levels of non-high-density lipoprotein cholesterol. The beneficial effect of IL-1 α deficiency was due to hematopoietic cells transferred from the bone marrow of IL-1 α -deficient mice, resulting in a reduction in aortic lesion size twice that observed in mice transplanted with IL-1 β -deficient bone marrow cells. Therefore, IL-1 α appears to play a greater role in the pathogenesis of lipid-mediated atherogenesis than IL-1 β , and this may be due to an effect of membrane IL-1 α .

INTERLEUKIN-1β Interleukin-1β: The Master Cytokine in the Interleukin-1 Family

More than any other member of the IL-1 family, IL-1 β has been the focus of most studies. IL-1 β is a highly inflammatory cytokine, particularly in humans, as reviewed in Dinarello.⁴⁶ As shown in Figure 26.2A, IL-1 β and IL-1 α bind to the same IL-1RI and trigger a proinflammatory signal. The interest in IL-1 β is also due, in part, to it being a secreted cytokine from macrophages and to the importance of the macrophage in antigen presentation before the era of dendritic cells. The inactive IL-1 β precursor is converted into an active cytokine by the intracellular cysteine protease caspase-1. In particular, persons with activating mutations in one of the key genes that control the activation of caspase-1 can develop life-threatening systemic inflammation, which is reversed by either blocking the IL-1 receptor or through the use of a neutralizing antibody to IL-1B. Other chronic inflammatory diseases are mediated by IL-1 β , as neutralizing antibodies have been used to treat a broad spectrum of diseases.

The IL-1 β -mediated illnesses fall into the category of "autoinflammatory" diseases, which are to be distinguished from the classic "autoimmune" diseases. Although inflammation is common to both autoinflammatory and autoimmune diseases, in the case of IL-1-mediated disease, there is no evidence for role of adaptive immunity in its induction.

Interleukin-1ß is an Inducible Cytokine

Unlike IL-1 α , the IL-1 β precursor is not present in health. Also unlike IL-1 α , IL-1 β is primarily a product of monocytes, macrophages, and dendritic cells, as well as B-lymphocytes and NK cells. In health, circulating human blood monocytes or bone marrow cells do not constitutively express mRNA for IL-1 β . Endothelial cells, skin keratinocytes, fibroblasts, and epithelial cells contain constitutive IL-1 α and constitutive IL-33 as precursors as well as mRNA, but these cells do not express IL-1 β mRNA even upon stimulation with TLR ligands. Melanoma cells do express IL-1 β as a precursor, and the more aggressive and metastatic the melanoma, the greater the likelihood of active caspase-1 and IL-1β secretion.⁴⁷ In the bone marrow neutrophil precursors, IL-1 β gene expression is inducible but mature neutrophils in the circulation no longer produce IL-1^β. Neutrophil IL-1^β plays a pathologic role in the severe inflammation of mice with a mutant form of the phosphatase SHP1.48 Several malignant tumors do express IL-1 β as part of their neoplastic nature, particularly acute myelogenous leukemia, melanoma, multiple myeloma, and juvenile myelogenous leukemia, each of which exhibit constitutive expression of IL-1^β. Unlike most cytokine promoters, IL-1ß regulatory regions are distributed over several thousand base pairs upstream from the transcriptional start site. In addition to a cAMP response element, there are NF-kB-like and activating protein-1 sites. IL-1ß gene regulation has been reviewed in detail.⁴⁹ Although steady-state mRNA levels for IL-1 β may be present, there is distinct dissociation between transcription and translation of the IL-1 β precursor. Non-TLR ligands such as the complement component C5a, hypoxia, adherence to surfaces, or clotting of blood induce the synthesis of large amounts of IL-1ß mRNA in monocytic cells without significant translation into the IL-1 β protein. In these cells, the IL-1 β mRNA assembles into large polyribosomes, but there is no significant elongation of the peptide.⁵⁰ This failure to complete the translation into IL-1 β protein may be due to the instability element present in the coding region. This instability region is also found in IL-18 and IL-37, and appears to limit the mRNA of these cytokines.⁵¹ However, completion of translation of the mRNA into the respective cytokines can be accomplished by adding low concentrations of TLR ligands or IL-1 itself to the "primed" monocytes.⁵²

Processing and Secretion of Interleukin-1 β via the Caspase-1

Nearly all microbial products induce IL-1 β via TLR activation; in addition, IL-1 (either IL-1 α or IL-1 β) induces itself both in vivo and in monocytes in vitro.⁵³ Other studies supporting this concept of IL-1–induced IL-1 have been reported.^{54–57} Regardless of the stimulus, processing and secretion of IL-1 β requires conversion of procaspase-1 to active caspase-1, although in some studies processing of the IL-1 β precursor is caspase-1 independent.⁵⁸ The activation to active caspase-1 is dependent on a complex of intracelular proteins termed the "inflammasome" by the late Juerg Tschopp.^{59,60} The critical component of the inflammasome is NACHT, LRR, and PYD domains containing protein 3

(NLRP3). NLRP3 is also termed cryopyrin as the gene was initially discovered in patients with "familial cold autoin-flammatory syndrome," a genetic disease characterized by constitutional symptoms, fevers, and elevated acute-phase proteins following exposure to cold.⁶¹

As monocytes exit the bone marrow, they circulate in the bloodstream for approximately 3 days. In the absence of disease, it is likely that these cells do not enter tissues but are destroyed in the spleen or undergo apoptosis. There is no dearth of reports that circulating human blood monocytes release processed IL-1 β upon stimulation starting 4 hours after stimulation with TLR agonists and continue to release the cytokine during the following 20 to 40 hours. Following lipopolysaccharide (LPS), IL-1\(\beta\) mRNA levels rise rapidly within 15 minutes but begin to decline after 4 hours due to the short half-life of their mRNA or the action of micro RNA. In contrast, using IL-1 itself as a stimulant, IL-1 β mRNA levels are sustained for over 24 hours.⁵² Raising intracellular cAMP levels with histamine enhances IL-1-induced IL-1 gene expression and protein synthesis. Monocytes of patients with autoinflammatory diseases such as cryopyrinassociated periodic syndrome (CAPS) and hyper Ig Δ syndrome (HIDS) release IL-1 β even without TLR stimulation during a 24-hour incubation.^{62,63}

When obtained from the venous blood of healthy subjects, human blood monocytes contain active caspase-1. Active caspase-1, as determined by its cleavage into the active dimer, is present even in the absence of stimulation.⁶⁴ Active caspase-1 present in freshly obtained monocytes is nevertheless dependent on the presence of the key components of the inflammasome, namely ASC and NLRP3.⁶⁴ However, during subsequent incubation, extracellular levels of adenosine triphosphate (ATP) increase in the supernatant as IL-1 β also increases and inhibition of ATP by oxidized ATP reduces the secretion of IL-1 β .⁶⁴ The inhibition of IL-1 β secretion by oxidized ATP is consistent with the role of the P2X7 receptor, which binds ATP and opens the potassium channel for release of intracellular potassium. The presence of active caspase-1 in circulating blood monocytes suggests that the rate limiting step in the processing and release of IL-1 β is at the level of gene expression.

However, upon differentiation of the same blood monocytes into macrophages in vitro, TLR-induced IL-1β release requires activation of caspase-1 by exogenous ATP.⁶⁴ The assembly of the inflammasome components with inactive pro-caspase-1 takes place following a fall in intracellular potassium triggered by ATP binding to the P2X7 receptor. ATP activation of the P2X7 receptor opens the potassium channel, and simultaneously, as potassium levels fall, caspase-1 is activated by the inflammasome.65-69 Without exogenous ATP, there is little or no processing of the IL-1 β precursor in differentiated monocyte-derived macrophages. Alveolar macrophages obtained from the lungs of healthy human also do not release IL-1 β with LPS stimulation unless exogenous ATP is added.⁶⁴ In addition to ATP activation of P2X7, activation of IL-1 β processing can also take place with a cathelicidin-derived peptide termed LL37, which is released from neutrophils.69

The cleavage of the IL-1 β precursor by active caspase-1 can take place in the specialized secretory lysosomes or in the cytoplasm. However, more than one pathway seems available for processed IL-1 β to exit the cell. These include by exocytosis of the secretory lysosomes,^{65,66} shedding of plasma membrane microvesicles, and direct release via transporters or multivesicular bodies containing exosomes.⁷⁰ In general, the release of processed IL-1 β takes place before there is significant release of lactate dehydrogenase,⁷¹ although in vitro cell death eventually takes place. Pyroptosis is a caspase-1–dependent form of cell death and is induced by certain bacteria using Ipaf, a member of the Nod-like receptor (NLR) family of intracellular receptors.⁷² An increase in intracellular calcium is also required for the mature IL-1 β to exit the cell and is phospholipase C dependent.⁶⁶

Gain of Function Mutation in Cryopyrin

Diseases associated with single amino acid activating mutations in cryopyrin are termed CAPS. In monocytes from patients with CAPS, activation of caspase-1 occurs without a requirement for a rapid fall in the level of intracellular potassium.⁵⁷ Therefore, mutated cryopyrin allows for the assembly of the complex of interacting proteins in the presence of normal intracellular levels of potassium. Although often studied using LPS-induced synthesis of the IL-1ß precursor,⁷³ it is unlikely that LPS plays a role in autoinflammatory diseases. On the other hand, spontaneous secretion of IL-1 β from monocytes of patients is due to endogenous IL-1 β stimulation. In patients with CAPS, there is a decrease in steady state levels of pro-caspase-1 mRNA with IL-1Ra treatment,⁵⁴ suggesting that IL-1β stimulates its own production and processing. Thus, in any disease process that includes an increase in the steady state levels of procaspase-1 mRNA, components of the inflammasome or the IL-1 β precursor explain the "autoinflammatory" nature of the disease. Type 2 diabetes appears to be an example of an autoinflammatory disease where glucose induces IL-1 β production from the insulin-producing beta cell and IL-1ß induces the beta cell to produce its own IL-1 β .⁷⁴

Polymorphisms in P2X7 and the Activation of the Inflammasome

Patients with classic autoinflammatory diseases such as Familial Mediterranean Fever (FMF) or CAPS have nearly identical clinical parameters, secrete more IL-1 β , and respond dramatically to IL-1 receptor blockade yet have no mutation in NALP3. It is therefore possible that mutations in P2X7 itself or regulation of the other genes controlling potassium channels⁷⁵ may account for dysfunctional secretion of IL-1 β . For example, monocytes from patients with rheumatoid arthritis are more sensitive to release of IL-1 β following ATP activation of the P2X7 receptor compared to monocytes from healthy controls.⁷⁶ However, monocytes from subjects with a P2X7 Glu496Ala loss-offunction polymorphism secrete significantly less IL-1 β .⁷⁷ Monocytes from subjects homozygous for this polymorphism also released significantly less IL-18.⁷⁸ Another P2X7 receptor polymorphism is associated with increased mortality in patients undergoing allogenic stem cell transplantation.⁷⁹ Bacteremia was documented in 68% of patients with this polymorphism compared to 18% in wild-type control patients.⁷⁹

In mice deficient in P2X7 receptors, inflammation, pain, and IL-1 β -mediated IL-6 production are markedly reduced.⁸⁰ In addition to a fall in intracellular potassium, ATP triggers formation of peroxynitrite, which is required for caspase-1 activation because peroxynitrite scavengers prevent IL-1 β secretion.⁸¹ Pannexin-1, a mammalian protein that functions as a hemichannel for the uptake of dyes, is required for caspase-1 processing and release of IL-1 β via the P2X7 receptor.⁸² Pannexin-1 can also function for LPSinduced IL-1 β synthesis in the absence of TLR4.⁸³ P2X7 receptor activity is also regulated by "regeneration and tolerance factor."⁸⁴

Non–Caspase-1 Processing of Interleukin-1^β

Non-caspase-1 mechanisms also exist to generate active forms of IL-1 β . For example, sterile inflammation induces fever, elevated IL-6, and increased production of hepatic acute-phase proteins. These responses are absent in mice deficient in IL-1 β but present in mice deficient in caspase-1.^{85,86} Sterile inflammation is often associated with neutrophilic infiltration and neutrophils produce IL-18. Because neutrophils are short-lived cells dying within hours upon emigration, release of the IL-1 β precursor from intracellular stores is not unexpected. Processing of the IL-1 β precursor extracellularly into an active cytokine has been reported for the common neutrophil protease, proteinase-3.86,87 Proteinase-3 also contributes to the processing of IL-18.88 Other proteases such as elastase, matrix metalloprotease 9, and granzyme A process the IL-1 β precursor extracellularly. In addition, a mast cell chymase generates active IL-1 β .

Mice with a targeted IKK β deletion in myeloid cells are more susceptible to LPS-induced shock than control mice,⁵⁵ and markedly elevated levels of IL-1 β are found in the circulation associated with a prominent neutrophilia.55 The elevated levels of IL-1 β are lethal as blockade with IL-1Ra protects these mice from death. The source of the IL-1 β in these mice is the neutrophil. When incubated with proteinase-3, cleavage of the IL-1 β precursor is observed yielding molecular weights of 25,000 and 15,000 Daltons.⁵⁵ Because the cleavage of the IL-1 β precursor by proteinase-3, elastase, and cathepsin G are within three amino acids of the caspase-1 cleavage site, the products of the non-caspase-1 cleavage are biologically active.^{86,87} Therefore, in inflammatory conditions such as urate crystal arthritis, which is characterized by a prominent neutrophilic infiltration, proteinase-3 cleavage of extracellular IL-1β precursor likely takes place.⁸⁹ Mice deficient in caspase-1 are not protected against urate-induced inflammation. Although IL-1Ra is effective in treating gout, IL-1Ra would be equally effective in any disease with extracellular processing of the precursor.^{90–92} The importance of extracellular processing of the IL-1ß precursor by serine proteases may explain, in part, the anti-inflammatory properties of alpha-1-antitrypsin.⁹³

Reactive Oxygen Species and Interleukin-1 β Processing

Is there a role for reactive oxygen species (ROS) in the activation of the IL-1 β inflammasome? It was reported that uric acid crystals added to human monocytes result in the generation of ROS, which bind to and activate NLRP3 with subsequent secretion of IL-1^β.⁹⁴ However, mice deficient in ROS production exhibit a proinflammatory phenotype.95 Humans with chronic granulomatous disease (CGD) due to mutations in p47-phox cannot generate ROS and are severely affected by inflammatory granuloma. Uric acid crystal activation of primary monocytes from persons with CGD produced fourfold higher levels of IL-1ß compared to monocytes from unaffected persons.⁹⁶ In contrast to previous studies,94 the small molecule ROS inhibitor diphenyleneiodonium, which reduces the production of IL-1 β , does so due to inhibition of IL-1 β gene expression rather than decreased caspase-1 activation.⁹⁶ Another study identified phagocyte oxidase-defective monocytes from CGD patients as a source of elevated IL-1^{β,97} These findings support the concept that ROS likely dampens inflammasome activation and may explain the presence of an inflammatory phenotype characterized by granulomas and inflammatory bowel disease occurring in patients with CGD. In fact, patients with CGD-related inflammatory bowel disease improve upon IL-1 receptor blocking therapy.98

Effects in Mice Deficient in Interleukin-1ß

After 10 years of continuous breeding, mice deficient in IL-1β exhibit no spontaneous disease. However, upon challenge, IL-1 β -deficient mice exhibit specific differences from their wild-type controls. The most dramatic is the response to local inflammation induced by a subcutaneous injection of an irritant. Within the first 24 hours, IL-1 β -deficient mice do not manifest an acute-phase response, do not develop anorexia, have no circulating IL-6, and have no fever.^{85,99} These findings are consistent with those reported in the same model using anti-IL-1R type I antibodies in wild-type mice.85,99 IL-1 β -deficient mice also have reduced inflammation due to zymosan-induced peritonitis.85,100 In contrast, IL-1βdeficient mice have elevated febrile responses to LPS, IL-1β, or IL-1a compared to wild-type mice.¹⁰¹ Nevertheless, IL-1β-deficient mice injected with LPS have little or no expression of leptin mRNA or protein.¹⁰²

Mice deficient in IL-1 β were compared to mice deficient in IL-1 α after exposure to chemical carcinogens.¹⁰³ In IL-1 β -deficient mice, tumors developed slower or did not develop in some mice. A deficiency in IL-1 α , on the other hand, did not impair tumor development compared to wild-type mice injected with the same carcinogen. In IL-1Ra-deficient mice, tumor development was the most rapid. A leukocyte infiltrate was found at the site of carcinogen injection. The neutrophilic infiltrate was almost absent in IL-1 β -deficient mice, whereas in IL-1Ra-deficient mice, a dense neutrophilic infiltrate was observed. In wild-type mice, the leukocytic infiltrate was sparse and the infiltrate that was observed in IL-1 α -deficient mice was similar to that of control mice. These findings may reflect the fact that IL-1 β is secreted into the microenvironment resulting in the emigration of monocytes and neutrophils, whereas IL-1 α remaining cell-associated is less likely to affect the microenvironment.

Interleukin-1 α and Autophagy

Autophagy is an ancient process of recycling cellular components, such as cytosolic organelles and protein aggregates, through degradation mediated by lysosomes. Autophagy is activated in conditions of cell stress, hypoxia, starvation, or growth factor deprivation; it promotes cell survival by generating free metabolites and energy through degradation of the endogenous cellular components.¹⁰⁴ However, in addition to its role in the pathophysiology of cancer, neurodegenerative diseases, or aging, autophagy is also a modulator of inflammation.¹⁰⁵ A role for autophagy in production of proinflammatory cytokines, particularly of IL-1 β , has emerged with deletion of ATG16-L1. For example, macrophages from ATG16L1-deficient mice produce higher levels of IL-1 β and IL-18 after stimulation with TLR4 ligands.¹⁰⁶ The data suggest that higher activation of caspase-1 in the ATG16L1-deficient mice accounts for the higher production level.¹⁰⁶ This observation was related to the specific degradation of the IL-1 β precursor in autophagosomes in mouse macrophages.¹⁰⁷ Additional studies in the ATG16L1deficient mice point toward a regulatory effect of autophagy on caspase-1 activation through modulation of the NLRP3 inflammasome.94,108,109

This role of autophagy in the secretion of IL-1 β was also observed in human primary monocytes, in which specific inhibition of autophagy leads to increased production of IL-1 β .¹¹⁰ However, in the same cells, tumor necrosis factor (TNF) α production was decreased by autophagy inhibition. These data suggest divergent effects of autophagy on the production of these two important proinflammatory cytokines. In mice, the increase in IL-1 β production is ascribed to increased activation of the inflammasome, but in human cells, it is IL-1 β mRNA transcription that is elevated when autophagy was inhibited, whereas no effects were observed on caspase-1 activation.^{106,107,110} Despite these differences between mouse and human cells, the inhibition of autophagy increases the production of IL-1 β but not TNF α .

The modulation of inflammation by autophagy in humans has been studied in Crohn disease. Genome-wide association studies in large cohorts of patients with Crohn disease have revealed that genetic variants in two autophagy genes, ATG16L1 and IRGM, result in increased susceptibility to the disease. A nonsynonymous polymorphism in ATG16L1 on chromosome 2q37.1 and two polymorphisms in IRGM on chromosome 5q33.1 were significantly associated with Crohn disease risk.^{111,112} Another study revealed a significant association of Crohn disease susceptibility with an intronic polymorphism in the autophagy gene ULK1.¹¹³ Moreover, autophagy defects have been reported in individuals bearing nucleotide oligomerization domain (NOD)2 mutations and are consistent with the concept that impaired bacterial clearance and increased bacterial persistence are part of the pathogenesis of Crohn disease.¹¹⁴

The mechanism through which polymorphisms in autophagy genes influence susceptibility to Crohn disease appears to involve IL-1β production. The ATG16L1 300Ala risk allele was associated with elevated production of IL-1 β and IL-6; however, this finding was only observed in cells stimulated with the NOD2 ligand muramyl dipeptide. In contrast, the expected levels of IL-1 β and IL-6 were produced upon stimulation with TLR2 and TLR4 ligands.¹¹⁵ The increased production of IL-1 β was associated with an increase in the steady state levels of IL-1ß mRNA rather than increased activation of the inflammasome.115 Studying the same polymorphism (ATG16L1 Thr300Ala) in human dendritic cells, Cooney et al. reported defective NOD2-induced, but not TLR-induced, autophagy and antigen presentation.¹¹⁶ Furthermore, effects of this polymorphism on antibacterial autophagy in epithelial cells have been observed.¹¹⁷ The specific effect of the ATG16L1 polymorphism on the NOD2 pathway, and not on TLR-induced stimulation, is likely related to the fact NOD2 and ATG16L1 form a protein complex that is essential for NOD2-induced autophagosome formation.¹¹⁸ Because the ATG16L1 Thr300Ala polymorphism affects protein stability,¹¹⁹ defective induction of autophagy and therefore enhanced IL-1ß mRNA transcription upon triggering of NOD2 may be due to the presence of defective complex.

INTERLEUKIN-33 Interleukin-33 as a Member of the Interleukin-1 Subfamily

Formerly termed IL-1F11, IL-33 belongs to the IL-1 subfamily and has been studied for its role in the Th2 paradigm of immune responses. IL-1 β is also linked to the Th2 response. The existence of IL-33 was predicted in 1994 following the discovery of a novel member of the IL-1 receptor family termed ST2.¹²⁰ ST2 is the ligand binding chain for IL-33 (Table 26.2) and is structurally similar to the ligand binding chain of IL-1 α and IL-1 β . In addition, the coreceptor for IL-33 is the IL-1RACP, which is also the coreceptor for IL-1 α and IL-1 β . It was not until 2005 that IL-33 was reported as the ligand for ST2.¹¹ ST2 is regulated by the estrogen inducible transcription factor Fos,¹²⁰ and this property of estrogens may be related to the large number of studies on the effect of estrogens to regulate IL-1 and inflammation.

Similar to most members of the IL-1 receptor family, ST2 is comprised of three extracellular immunoglobulin domains and an intracellular TIR domain. Although the name ST2 is still used, the correct term is the IL-33 receptor α chain (IL-33R α). As shown in Figure 26.2D, the IL-33R α chain similar to the IL-1R1 in that it is the ligand binding chain for IL-33 but requires the IL-1RAcP to signal.^{121,122}

Before the discovery of IL-33, several studies suggested that the putative ligand (IL-33) for the ST2 orphan receptor was playing a role in allergic type diseases. It became clear that activation of ST2 was uniquely driving Th2 responses. Structurally, IL-33 is closer to IL-18 than IL-1 β . Biologically, IL-33 is closest to IL-1 α , as the precursors for IL-1 α and IL-33 are constitutively present in all endothelial cells. As discussed in the following, like IL-1 α , IL-33 functions as a DNA-binding molecule. The dominant property of IL-33 is the induction of IL-4, IL-5, and IL-13, as well as other properties anticipated for a Th2 type cytokine. Diseases thought to be due to increased immunoglobulin production may also be related to IL-33. IL-33 induces the production of IL-6, IL-1 β , and PGE2 from mast cells.

Interleukin-33 and Th2 Responses

The properties of recombinant IL-33 recapitulate much of the existing data that ST2 promotes Th2-type responses. For example, before its discovery, a role for IL-33 in the Th2 response was observed using soluble extracellular forms of ST2.¹¹ However, IL-33 has properties that go beyond its role in the Th2 paradigm because, similar to IL-1 α , IL-1 β and IL-36, IL-33 forms a heterodimeric complex with IL-1RAcP for signal transduction.^{121,122} Although the IL-1RAcP is expressed on most nucleated cells, ST2 is somewhat restricted to low expression on most cells with the notable exception of mast cells.

There are several mechanisms by which IL-33 favors the Th2 response. Similar to IL-1 β , IL-33 induces IL-6, an adjuvant for antibody production. IL-33 induction of IL-6 is prevented by a blocking antibody to IL-1RAcP.¹²² IL-33 initiates signal transduction via activation of NF- κ B, which

TABLE 26.2	nterleukin-1 Receptor Family		
Name	Designation	Ligands	Coreceptor
IL-1RI	IL-1R1	IL-1α, IL-1β, IL-1Ra	IL-1RAcP (IL-1R3)
IL-1RII	IL-1R2	IL-1β, IL-1β precursor	IL-1RAcP (IL-1R3)
IL-1RAcP	IL-1R3	IL-1α, IL-1β, IL-33, IL-36	Not applicable
ST2/IL-33R $lpha$	IL-1 R4	IL-33	IL-1RAcP (IL-1R3)
IL-18Rα	IL-1R5	IL-18, IL-37	IL-18Rβ (IL-1R7)
IL-1Rrp-2	IL-1R6	IL-36α, β, γ	IL-1RAcP (IL-1R3)
IL-18Rβ	IL-1R7	IL-18	Not applicable
TIGIRR-2/IL-1RAPL	IL-1R8	Unknown	Unknown
TIGIRR-1	IL-1R9	Unknown	Unknown
SIGIRR	TIR8	Unknown	Unknown

IL, interleukin; SIGIRR, single immunoglobulin IL-1-related receptor; TIGIRR, three immunoglobulin IL-1-related receptor.

is typical of IL-1 α , IL-1 β and IL-18,¹¹ but other studies have shown that antibody cross-linking of ST2 does not result in activation of NF- κ B but rather activating protein-1. IL-33 treatment also increased serum immunoglobulin A and immunoglobulin E, an expected response for a switch from Th1 to Th2.

Processing of the Interleukin-33 Precursor

Initially, IL-33 was considered closely related to IL-1 β and IL-18 because the IL-33 precursor contains a caspase-1 site, which upon activation would cleave the IL-33 precursor and release the active cytokine,¹¹ similar to that for IL-1 β and IL-18. Indeed, the first recombinant forms of IL-33 were produced with an N-terminus at the caspase-1 site.¹¹ Although recombinant IL-33 was active, the concentrations required for activity were considerably higher than those of other members of the IL-1 family. Indeed, subsequent studies revealed that caspase-1 actually results in loss of IL-33 activity and that the full-length IL-33 precursor binds to ST2 and is active,¹²³ similar to the ability of the IL-1 α precursor to bind to IL-1RI. In addition, it was reported that the caspase-1 cleavage site at 178 is similar to the consensus sequence for caspase-3 and that intracellular IL-33 precursor is a substrate for caspase-3.¹²³

Using immobilized IL-33 precursor, neutrophil proteinase 3 (PR3) was isolated from human urinary proteins.¹²⁴ Neutrophil PR3 is known to process the IL-1 β precursor into an active cytokine.86 PR3 converted human and mouse precursor IL-33 proteins to biologic active forms; however, increasing the incubation time of PR3 abrogated IL-33 activities.¹²⁴ Using the consensus amino acid sequence sites for PR3, six human and mouse recombinant IL-33 proteins were produced and assessed for biologic activities; varying levels of activity were reported.¹²⁴ Another study also demonstrated cleavage of the IL-33 precursor by neutrophil proteases such as PR3, neutrophil elastase, and cathepsin G,¹²⁵ resulting in the generation of IL-33 with different N-termini and varying levels of activity. These studies support the concept that extracellular IL-33 is released as a precursor, is rapidly processed by neutrophil enzymes, and generates active forms with varying levels of activity. The implications for generation of active IL-33 by neutrophil enzymes for Th2 polarization remain unclear. It may be more relevant to study the effect of proteases from eosinophils in the processing of the IL-33 precursor. Nevertheless, the IL-33 precursor binds to ST2 and recruits the accessory chain for signal transduction, but compared to IL-33 generated by neutrophil proteases, the activity of IL-33 precursor is weak.^{124,125}

There was no dearth of studies on ST2 tissue–specific localization, regulation of its expression, effects in transgenic mice overexpressing ST2, as well as deletion, neutralization, and antibody cross-linking of ST2. Elevated levels of the soluble form of ST2 were present in the circulation of patients with a various inflammatory diseases and that exogenous administration of pharmacologic doses of soluble ST2 neutralized endogenous levels of the then putative ligand IL-33 and reduced inflammation.¹²⁶ IL-33 activates Th2 lymphocytes, mast cells, basophils, and eosinophils, as well as NK T cells and blood monocytes. One of the most studied properties of IL-33 is the induction of IL-5 and IL-13 and their respective roles in lung inflammation such as allergic type asthma. For example, instillation of IL-33 into the airways triggers an immediate allergic response in the lung of naïve mice and worsens the response in mice sensitized to antigen peripherally but challenged by exposure of antigen in the lung.¹²⁷

Mice deficient in ST2 do not develop a Th2 response to Schistosoma egg antigen. Indeed, several studies have focused on the role of IL-33 in the pathogenesis of helminth worm infections. The Th2 response by the host contributes to the elimination of these worm infestations, which are worldwide and afflict hundreds of millions. The role of IL-33 in the induction of IL-4, IL-5, and IL-13 is of paramount importance in terms of pulmonary and intestinal complications that reduce lifespan. Using mice deficient in IL-33, a crucial role was demonstrated in mice to rid an infection with Strongyloides venezuelensis.¹²⁸ The infection induces a unique class of cells called natural helper cells or nuocytes, which upon activation by IL-33 produce IL-5 and IL-13, resulting in eosinophilic infiltration into the lungs. In this model, pulmonary inflammation causes damage via eosinophilic infiltration, which is IL-33 and IL-5 dependent.¹²⁸

Mice injected with human IL-33 exhibit impressive pathologic changes in the arterial walls, lungs, and intestinal tissues.¹¹ Of particular relevance to the concept that IL-33 drives a Th2 response, eosinophilic infiltration was a prominent finding in the lung and in allergic rhinitis as well as allergic conjunctivitis.¹²⁹ These initial observations have been confirmed by other reports.¹³⁰ Although the interpretation of in vivo effects following the administration of an exogenous cytokine should be conservative, the findings are clearly consistent with IL-33 being a proinflammatory ligand of the IL-1 receptor family. Even before the ability to test IL-33-mediated activation, others had reported that neutralization of the putative ST2 ligand using soluble ST2 markedly reduced joint inflammation, synovial hyperplasia, and joint erosion when given in the therapeutic phase of collagen-induced arthritis in mice.¹²⁶

Interleukin-33 as an Anti-inflammatory Cytokine

Members of the IL-1 family of ligands bind to their specific cell surface receptors and recruit an accessory chain. The IL-1RIAcP is used by IL-1 α and IL-1 β but also by IL-36 and IL-33. The accessory chain for IL-18 is related to the IL-1RIAcP but is encoded by a distinct gene. We now recognize that other members of the IL-1 receptor family will bind more than one cytokine. The best example is IL-1 α and IL-1 β . Both bind with similar affinities to IL-1RI, but the three-dimensional structure of IL-1 α and IL-1 β are hardy identical.¹³¹ The IL-1 β precursor binds to IL-1RII as well as a processed form with the first 112 amino acids cleaved from the precursor. IL-37 binds to the IL-18 receptor alpha chain,¹³² and both IL-36 and IL-38 bind to the IL-36 receptor.¹³³

IL-33 forms a complex with ST2 IL-1RIAcP but also with single immunoglobulin IL-1–related receptor (SIGIRR).¹³⁴

This complex plays a role in the Th2 response by reducing IL-33 signaling,¹³⁴ and consistent with these observations, Th2 responses are increased in mice deficient in SIGIRR. Furthermore, there is high expression of SIGIRR in Th2 polarized cells and in models of Th2 antigen sensitization; SIGIRR-deficient mice exhibit a greater Th2 response.¹³⁴ The complex with SIGIRR and IL-33 may explain the anti-inflammatory properties of IL-33. ST2 can sequester TLR adaptor molecules such as MyD88 and Mal.¹³⁵

In mice deficient in ST2, there is myocardial hypertrophy, ventricle dilation, and fibrosis upon pressure overload, suggesting that IL-33 plays a protective role in the heart.¹³⁶ Furthermore, elevated levels of the extracellular domain of ST2 predict outcomes in patients with systolic heart failure or following a myocardial infarction.¹³⁶ In a model of cardiomyocyte hypertrophy induced by chronic administration of phenylephrine, administration of recombinant IL-33 inhibited the phosphorylation of IKB and reduced the hypertrophy and fibrosis.¹³⁶ One of the more challenging aspects of the properties of IL-33 to act as a Th2 cytokine is its role as an antagonist in the ApoE-deficient mouse model of atherosclerosis. In this model, arterial wall plaques of mice on a high-fat diet contain IL-33 and ST2. In mice treated with IL-33, the atherosclerotic plaques were markedly reduced.¹³⁷ In mice treated with soluble ST2 to neutralize IL-33, the disease worsened.137

Interleukin-33 as a Transcription Factor

Similar to IL-1 α , there is another side to IL-33. Although IL-33 binds to its specific surface receptor, IL-33 is identical to a nuclear factor dominantly expressed in high endothelial venules.¹³⁸ This nuclear factor is termed NF-HEV. In addition to endothelial cells, constitutive nuclear localization of IL-33 has been reported in several cell types such as type II lung epithelial cells,¹²⁸ epithelial cells,¹³⁹ and pancreatic stellate cells.¹⁴⁰ In fact, IL-33 binding to DNA and acting as a nuclear factor is similar to IL-1 α binding to chromatin and functioning as a nuclear factor.^{21,33,141} A short IL-33 peptide similar to a sequence in Kaposi sarcoma virus binds chromatin.¹⁴² The full-length IL-33 precursor, but not mature IL-33, binds to the N-terminal Rel homology domain of NF-κB p65.¹⁴³ In cells overexpressing the IL-33 precursor, there was a reduction in IL-1 β -induced TNF α .¹⁴³ These data are consistent with other data that IL-33 possesses antiinflammatory properties (see previous discussion) and the mechanism for this property of IL-33 appears to be nuclear sequestration similar to that of IL-1 α .³³

INTERLEUKIN-18 AND INTERLEUKIN-37 SUBFAMILY Interleukin-18

Background

IL-18 was first described in 1989 as "IFN γ -inducing factor" isolated in the serum of mice following an injection of endotoxin. The mice had been pretreated with *Proprionibacterium acnes*, which stimulates the reticuloendothelial system, particularly the Kupffer cells of the liver. Many investigators concluded that the serum factor was IL-12. With molecular cloning of "IFNy-inducing factor" in 1995,144 the name was changed to IL-18. Surprisingly, the new cytokine was related to IL-1 and particularly to IL-1 β . Similar to IL-1 β , IL-18 lacks a signal peptide, is first synthesized as an inactive precursor, and remains as an intracellular cytokine. The tertiary structure of the mature form of IL-18 closely resembles that of IL-1 β ,¹⁴⁴ although the IL-18 precursor is closely related to the IL-37 precursor. Since 1995, many studies have used neutralization of endogenous IL-18 or IL-18-deficient mice to demonstrate the role for this cytokine in promoting inflammation and immune responses.¹⁴⁵ However, the biology of IL-18 is hardly the recapitulation of IL-1 β . There are several unique and specific differences between IL-18 and IL-1 β . For example, in healthy human subjects and also in healthy mice, gene expression for IL-1 β in blood mononuclear cells and hematopoietic cells is absent, and there is no evidence that the IL-1 β precursor is constitutively present in epithelial cells.¹⁴⁶ In contrast, in the same blood cells, large amounts of the IL-18 precursor are present. Peritoneal macrophages and mouse spleen contain the IL-18 precursor in the absence of disease.¹⁴⁶ The IL-18 precursor is also present in keratinocytes and nearly all epithelial cells. In this regard, IL-18 is similar to IL-1 α and IL-33.

Processing of the Interleukin-18 Precursor

The IL-18 precursor has a molecular weight of 24,000 and is processed by caspase 1 cleavage into a mature molecule of 18,000. Compared to wild-type mice, following an injection of endotoxin into caspase-1-deficient mice, circulating IFNy is absent. IL-12-induced IFNy is also absent in caspase-1deficient mice.¹⁴⁷ Importantly, any phenotypic characteristic of capsase-1-deficient mice must be studied as to whether the deficiency is due to reduced IL-1 β or IL-18 activity. For example, the caspase-1-deficient mouse is resistant to colitis,¹⁴⁸ but the IL-1 β -deficient mouse is susceptible in the same disease. Because neutralizing antibodies to IL-18 are protective in the colitis model, caspase-1 deficiency appears to prevent processing of IL-18.148,149 On the other hand, there are examples where caspase-1 processing of IL-18 is not required. For example, Fas ligand stimulation results in release of biologically active IL-18 in caspase-1-deficient murine macrophages.¹⁵⁰ Similar to IL-1ß processing, proteinase-3 appears to activate processing to mature IL-18.⁸⁸

Similar to IL-1 α and IL-33, the IL-18 precursor is constitutively expressed in endothelial cells, keratinocytes, and intestinal epithelial cells throughout the gastrointestinal tract. Macrophages and dendritic cells are the primary sources for the release of active IL-18, whereas the inactive precursor remains in the intracellular compartment of mesenchymal cells. Also, similar to IL-1 α and IL-33, the IL-18 precursor is released from dying cells and processed extracellularly, most likely by neutrophil proteases such as proteinase-3.

The IL-1 family consensus sequence (A-X-D) in IL-18 is I-N-D at amino acid 50, but the N-terminus generated by caspase-1 is 14 amino acids before the consensus sequence rather than 9 amino acids (see Fig. 26.1). Although the IL-18 as well as the IL-1 β precursor can be cleaved extracellularly by proteianse-3, there is an additional enzyme that cleaves the IL-18 precursor into an active cytokine. Merprin β is a member of the merpin family of zinc metalloproteinases, which are expressed on the membrane surface of epithelial cells of the intestine and kidney but also on myeloid cells.^{151,152} Merprin α will cut the IL-1 β precursor into an active cytokine, and inhibitors of merprin α markedly reduce serum levels of IL-1 β in mice subjected to cecal ligation and puncture.¹⁵¹ Merprin β will cleave the IL-18 precursor and generate an active cytokine on cells bearing the IL-18R.¹⁵³ In a model of dextran sulfate sodium (DSS) colitis, serum IL-18 is elevated on days 3 and 5, during which time the mice develop inflammatory colitis. However, in merprin β -deficient mice, there is a statistically significant reduction in serum IL-18.¹⁵³ The role of IL-18 and caspase-1 in DSS colitis is discussed in the following.

Signal Transduction by Interleukin-18

As shown in Figure 26.3A, IL-18 forms a signaling complex by binding to the IL-18 alpha chain (IL-18R α), which is the ligand binding chain for mature IL-18; however, this binding is of low affinity. In cells that express the coreceptor, termed IL-18 receptor beta chain (IL-18R β), a high-affinity complex is formed, which then signals. The complex of IL-18 with the IL-18R α and IL-18R β chains is similar to that formed by other members of the IL-1 family with the coreceptor, the IL-1R accessory chain IL-1RACP. Following the formation of the heterodimer, the TIR domains approximate, and it appears that the cascade of sequential recruitment of MyD88, the four IRAKs, and TRAF-6 followed by the degradation of I κ B and release of NF κ B are nearly identical as that for IL-1.¹⁵⁴ There are differences between IL-1 and IL-18 signaling that remains unexplained. With few exceptions, IL-1 α or IL-1 β are active on cells in the low nanogram/mL range and often in the picogram/mL range. In contrast, IL-18 activation of cells expressing the two IL-18 receptor chains requires 10 to 20 ng/mL and sometimes higher levels.^{155,156}

Although nearly all cells express the IL-1RI, not all cells express IL-1RAcP. Similarly, most cells express the IL-18R α but not all cell express the IL-18R β . IL-18R β is expressed on T cells and dendritic cells but not commonly expressed in mesenchymal cells. The best example is the A549 cell. This cell line, derived from a lung carcinoma epithelial cell, does not express IL-18R β ,¹⁵⁷ and there is no signal unless IL-12 is added to induce IL-18R β ,¹⁰ In the absence of IL-18R β , IL-18 binds to IL-18R α without a proinflammatory signal. In A549 cells transfected with IL-18R β , IL-18 induces IL-8 and a large number of genes. One of these genes is the former IL-2-induced gene termed NK4,¹⁵⁸ now termed IL-32.¹⁵⁷ IL-32 is not a member of the IL-1 family but plays an important role in the regulation of cytokines such as IL-1 β and TNF α .

Interleukin-18 as an Immunoregulatory Cytokine

Together with IL-12, IL-18 participates in the Th1 paradigm. This property of IL-18 is due to its ability to induce IFN γ either with IL-12 or IL-15. Without IL-12 or IL-15, IL-18 does not induce IFN γ . IL-12 or IL-15 increases the IL-18R β , which is essential for IL-18 signal transduction. Without IL-12 or IL-15, IL-18 plays a role in Th2 diseases.¹⁵⁹ The importance of IL-18 as an immunoregulatory cytokine

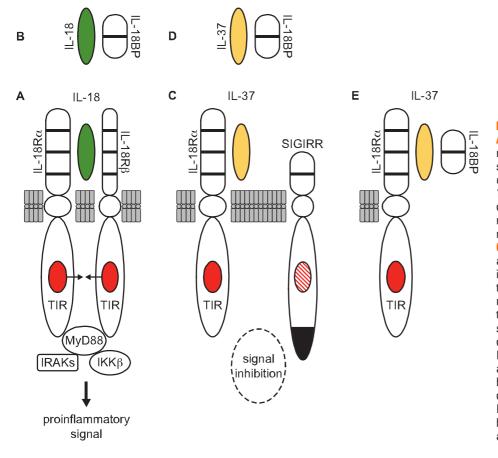

FIG. 26.3. Interleukin (IL)-18 Subfamily. A: IL-18 binds to the IL-18R α chain and recruits the coreceptor IL-18RB. The signaling cascade of the IL-18 receptor complex is nearly the same as that of IL- 1α and IL-1 β , resulting in the expression of proinflammatory genes. B: The natural occurring IL-18BP binds IL-18, thus neutralizing the activity of the cytokine. C: IL-37 also binds to the IL-18R α but with an affinity lower than that of IL-18 binding to the same receptor. Furthermore, the binding of IL-37 to IL-18R α does not recruit the coreceptor IL-18R β and therefore there is no proinflammatory signal. The anti-inflammatory properties of IL-37 require single immunoglobulin IL-1-related receptor, which may act as a "decoy" for MyD88. D: IL-18BP also binds to IL-37, thus preventing binding of IL-37 to the IL-18Ra. E: IL-37 binds to IL-18BP forming a complex, which then binds to the IL-18R α , enhancing the anti-inflammatory property of IL-18BP.

is derived from its prominent biologic property of inducing IFNy from NK cells. Macrophage-colony stimulating factor induces human blood monocytes to develop into a subset of macrophages; these cells express a membrane-bound form of IL-18.160 Membrane IL-18 is expressed in 30% to 40% of macrophage-colony stimulating factor-primed macrophages. In contrast, monocytes, dendritic cells, and monocytes differentiated into M1 macrophages did not express membrane IL-18. Although the expression of membrane IL-18 is caspase-1 dependent,¹⁶⁰ LPS treatment was necessary for the release of membrane IL-18.160 A major immunoregulating role for IL-18 is on the NK cell. Upon shedding of membrane IL-18 into a soluble form, NK cells expressed CCR7 and produced high levels of IFNy. As expected, IFNy production was prevented by neutralization of IL-18. This mechanism may account for the role of IL-18 as major IFNYinducing factor from NK cells and the role of NK cells in the pathogenesis of autoimmune diseases.

The induction of IFNγ by IL-18 has been studied with coinducer IL-12. For example, mice injected with the combination of IL-18 plus IL-12 develop high levels of IFNγ and die with hypoglycemia, intestinal inflammation, and inanition.¹⁶¹ In leptin-deficient mice, IL-18 plus IL-12 induce acute pancreatitis.¹⁶² Several human autoimmune diseases are associated with elevated production of IFNγ and IL-18. Diseases such as systemic lupus erythematosus, rheumatoid arthritis, type 1 diabetes, Crohn disease, psoriasis, and graft-versus-host disease are thought to be mediated, in part, by IL-18.

Proinflammatory Properties of Interleukin-18

IL-18 exhibits characteristics of other proinflammatory cytokines, such as increases in cell adhesion molecules, nitric oxide synthesis, and chemokine production. Blocking IL-18 activity reduces metastasis in a mouse model of melanoma; this is due to a reduction in IL-18-induced expression of vascular call adhesion molecule-1.163 A unique property of IL-18 is the induction of Fas ligand (FasL), which may account for the hepatic damage that takes place in macrophage activation syndrome.^{150,164} The induction of fever, a well-studied property of IL-1 α and IL-1 β as well as TNF α and IL-6, is not a property of IL-18. Injection of IL-18 into mice, rabbits, or humans does not produce fever.^{165,166} Unlike IL-1 and TNFα, IL-18 does not induce cyclooxygenase-2 and hence there is no production of prostaglandin E2.156,167 IL-18 has been administered to humans for the treatment of cancer in order to increase the activity and expansion of cytotoxic T cells. Not unexpectedly and similar to several cytokines, the therapeutic focus on IL-18 has shifted from its use as an immune stimulant to inhibition of its activity.145,168

Because IL-18 can increase IFN γ production, blocking IL-18 activity in autoimmune diseases is an attractive therapeutic target as anti–IL-12/23 reduces the severity of Crohn disease as well as psoriasis. As discussed subsequently, there appears to be a role for blocking IL-18 in Crohn disease. However, there are several activities of IL-18 that are independent of IFN γ . For example, IL-18 inhibits proteoglycan synthesis in chondrocytes,¹⁶⁹ and proteoglycan synthesis is essential for maintaining healthy cartilage. IL-18 also increases vascular call adhesion molecule-1 expression in

endothelial cells independently of IFNγ. Vascular call adhesion molecule-1 plays a major role in multiple sclerosis, other autoimmune diseases, as well as in the metastatic process.¹⁷⁰

Role of Interleukin-18 in Models of Inflammatory Bowel Disease

Inflammatory bowel disease such as Crohn disease is a complex autoimmune disease. Treatment is initially based on immunosuppressive drugs. Not surprisingly, anticytokines such as neutralizing monoclonal antibodies to $TNF\alpha^{171}$ or to IL-12/23 provide effective treatment for many patients.^{172,173} The reduction of IFN γ in Crohn disease is linked to the clinical response to these agents.¹⁷³ IL-18 is found in affected intestinal lesions from patients with Crohn disease as a mature protein, but the IL-18 precursor form is present in uninvolved intestinal tissues.¹⁷⁴ This observation was confirmed in a similar assessment of mucosal biopsies from patients with Crohn disease.¹⁷⁵ Antisense RNA to IL-18 decreased IFN γ production in lamina propria mononuclear cells.¹⁷⁵

A commonly used mouse model for colitis is DSS, which is added to the drinking water and which damages the intestinal wall. Thus in DSS-induced colitis, the epithelial barrier defenses against luminal bacterial products are breeched. In this model, reducing IL-18 with a neutralizing antibody is protective and linked to a reduction in IFNy.149 Blocking IL-18 with the IL-18 binding protein (IL-18BP) also reduces colitis induced by antigen sensitization.¹⁷⁶ Because generation of active IL-18 requires caspase-1, studies have also been performed in mice deficient in caspase-1 and subjected to DSS colitis. Nevertheless, despite many studies, the role of caspase-1 in DSS colitis remains unclear. The first study showed that mice deficient in caspase-1 were protected.^{148,177} In addition, treatment of mice with a specific caspase-1 inhibitor was also effective in protecting against the colitis.¹⁷⁸⁻¹⁸⁰ In both studies, the effect of caspase-1 deficiency was linked to reduced IL-18 activity, whereas reducing IL-1 activity with the IL-1Ra was ineffective.¹⁴⁸ In support of the role of IL-18 in DSS colitis, inhibition of endogenous merprin β to reduce the generation of active IL-18 was protective in DSS colitis.¹⁵³

However, a conundrum has developed whether caspase-1 deficiency is protective or detrimental in DSS colitis. DSS colitis is not the optimal model for Crohn disease, as the model is one of rapid loss of the protective barrier of the intestinal epithelium exposing the lamina propria mononuclear cells to a large amount and variety of bacterial products. Using the same DSS model, mice deficient in the adapter protein inflammasome component ASC experienced increased disease, morbidity, and precancerous lesions compared to wild-type mice exposed to DSS.¹⁸¹ Similarly, mice deficient in caspase-1 died rapidly from DSS compared to wild-type mice,¹⁸² whereas mice deficient in caspase-12, in which caspase-1 is enhanced, were protected.¹⁸² Administration of exogenous IL-18 restored mucosal healing in caspase-1-deficient mice.¹⁸² Also, mice deficient in NLRP3 were more susceptible to either DSS or 2,4,6-trinitrobenzene sulfonic acid (TNBS)-induced colitis and exhibited decreased IL-1ß as well as decreased beta-defensins.¹⁸³ Macrophages from NLRP3-deficient mice failed to respond to muramyl dipeptide.¹⁸³ Mice deficient in NLRP6 are also more vulnerable to DSS,^{37,184} and the susceptibility appears to be due to lack of sufficient IL-18.

How to reconcile these data in mouse models of colitis was addressed by Siegmund¹⁸⁵? It is likely that IL-18 being constitutive in the intestinal epithelium has a protective role in that the cytokine contributes to maintaining the intestinal barrier. With loss of the barrier, the microbial products stimulate macrophages in the lamina propria and caspase-1–dependent processing of IL-18 results in inflammation. In this model, inhibition of IL-18 production in caspase-1–deficient mice or treatment of wild-type mice with anti–IL-18 antibodies or caspase-1 inhibitors is protective. Worsening of disease in mice deficient in caspase-1 or NLRP3 or NLRP6 may lower the levels of active endogenous IL-18 needed to protect the epithelial barrier. Similarly, active endogenous IL-1 β may be needed to protect to maintain the epithelial barrier by inducing growth factors.

Although it remains unclear why caspase-1 deficiency worsens DSS colitis, in humans with Crohn disease, natalizumab, the antibody that blocks the very late antigen-4, is highly effective in treating the disease. Very late antigen-4 is the α 4 subunit of the β -1 integrin. Anti–very late antigen-4 binds to the surface of macrophages and other myeloid cells, and prevents the binding of these cells to the very late antigen-4 receptor on endothelial cells known as vascular cell adhesion molecule-1. Thus, the antibody disables the function of vascular cell adhesion molecule-1 and prevents the passage of macrophages and other myeloid cells into tissues such as the intestine in Crohn disease and the brain in multiple sclerosis. Because IL-18 induces vascular cell adhesion molecule-1, blocking IL-18 would also reduce the passage of cells through the endothelium into to intestine.

Interleukin-18, Hyperphagia, and the Metabolic Syndrome

Whereas there is no constitutive gene expression for IL-1 β in freshly obtained human peripheral blood mononuclear cells (PBMC), the same cells express constitutive mRNA for IL-18.146 In western blot analysis from the same cells, the IL-18 precursor was present but not the IL-1β precursor. Similar observations were also made in mice.146 These findings suggest that IL-18 may act as regulator of homeostasis. Starting at age 16 weeks of age, IL-18-deficient mice start to overeat, become obese, and exhibit lipid abnormalities; there is increased atherosclerosis, insulin resistance, and diabetes mellitus reminiscent of the metabolic syndrome.¹⁸⁶ IL-18R α -deficient mice also develop a similar phenotype. The higher body weight is attributed to enhanced food intake, in which the IL-18-deficient mice begin to diverge from wild-type animals at a relatively early age, and to reach values 30% to 40% higher than that of wild-type mice. Others have observed similar findings.¹⁸⁷ A striking finding was an increase of more than 100% in the percent of adipose tissue in the IL-18-deficient animals that was accompanied by fat deposition in the arterial walls. The insulin resistance in these mice is corrected by exogenous recombinant IL-18. Mice deficient in IL-18 respond normally to a challenge with exogenous leptin, suggesting that expression of the leptin receptor is unaffected. The unexpected and unique mechanism is responsible for the higher food intake in the IL-18-deficient animals appears to be due to a central nervous system loss of appetite control. IL-18-deficient mice eat throughout the day, whereas wild-type mice eat once, nocturnally.

Interleukin-18 as a Protected Cytokine

As stated previously, mice deficient in caspase-1 experience increased disease severity when subjected to DSS colitis and that administration of exogenous IL-18 restored mucosal healing in these mice.¹⁸² In addition, mice deficient in NLRP3 were more susceptible to DSS colitis, which is thought to be due to decreased IL-18.¹⁸³ Mice deficient in NLRP6 are also more vulnerable to DSS,^{37,184} and the susceptibility appears to be due to lack of sufficient IL-18. Thus, there are a growing number of studies that support a protective role for IL-18. The fact that mice deficient in IL-18 develop a metabolic syndrome-like phenotype is consistent with a role for IL-18 in homeostasis. A study in age-related macular degeneration is also consistent with a protective role for IL-18. In that study, drusen, which is mixture of complement-derived and apolipoproteins and lipids, was shown to activate NLRP3 and induce the production of mature IL-1ß and IL-18.¹⁸⁸ In a mouse model of "wet" age-related macular degeneration, the disease was worse in mice deficient in NLRP3 but not in IL-1RI–deficient mice.¹⁸⁸ Therefore, IL-18 rather than IL-1 α or IL-1 β were protective; upon administration of IL-IL-18, the disease severity improved. Taken together, there is a case for IL-18 being a protective rather than inflammatory cytokine.

Interleukin-18 Binding Protein

The discovery of the IL-18BP took place during the search for the soluble receptors for IL-18.¹⁸⁹ IL-18BP is a constitutively secreted protein with an exceptionally high affinity for IL-18 (400 pM) (see Fig. 26.3B). Present in the serum of healthy humans at a 20-fold molar excess compared to IL-18,¹⁹⁰ IL-18BP may contribute to a default mechanism by which a Th1 response to foreign organisms is blunted in order to reduce triggering an autoimmune responses to a routine infection. Although IL-18BP is readily secreted, it falls into the functional category of being a shed soluble receptor. As shown in Figure 26.3B, IL-18BP contains only one immunoglobulin G domain, whereas the type II IL-1 receptor contains three domains. In this regard, the single immunoglobulin G domain of IL-18BP is similar to SIGIRR, which also has a single immunoglobulin G domain and also functions as a decoy receptor. The salient property of IL-18BP in immune responses is in downregulating Th1 responses by binding to IL-18 and thus reducing the induction of IFNY.159 Because IL-18 also affects Th2 responses, IL-18BP also has properties controlling a Th2 cytokine response.¹⁵⁹ IL-18BP has a classic signal peptide and therefore is readily secreted. Serum levels in healthy subjects are in the range of 2,000 to 3,000 pg/mL compared to the levels of IL-18 in the same sera of 80 to 120 pg/mL/mL. Moreover, IL-18BP binds IL-18 with an affinity of 3 to 5 nM,¹⁸⁹ an affinity significantly higher than that of IL-18R α . Because a single IL-18BP molecule binds a single IL-18 molecule, one can calculate bound versus free IL-18 in a mixture of both molecules.¹⁹⁰

If one examines immunologically mediated diseases where IFNy plays a pathologic role such as Wegener granulomatosis and systemic lupus erythematosus, one must consider the level of free IL-18 compared to IL-18 bound to IL-18BP. In fact, in these diseases both IL-18BP and IL-18 are high,^{191,192} but the level of IL-18BP is not sufficiently high enough to neutralize IL-18 and therefore, the level of free IL-18 is higher than in healthy subjects. In macrophage activation syndrome where IFN γ plays a pathologic role, both IL-18BP and IL-18 are also high but the clinical and hematologic abnormalities correlate with elevated free IL-18.¹⁶⁴

A unique property of IL-18BP is that the molecule also binds IL-37¹⁹³ and in doing so, enhances the ability of IL-18BP to inhibit the induction of IFNy by IL-18. IL-37 binds to the IL-18R α with a very low affinity but in mice expressing human IL-37, a profound anti-inflammatory effect is observed,¹⁹⁴ particularly of LPS-induced cytokines and dendritic cell maturation.¹⁹⁴ Human IL-37-expressing mice are also resistant to colitis.¹⁹⁵ Thus, the anti-inflammatory property of IL-37 can be affected by the concentration of IL-18BP. As the concentration of IL-18BP increases and binds IL-37, there is the possibility that IL-37 becomes less available as an anti-inflammatory cytokine. Indeed, this has been observed in mice injected with IL-18BP. At low dosing of IL-18BP, there is reduced inflammation in a model of rheumatoid arthritis but as the doing of IL-18BP increases, the anti-inflammatory properties of IL-18BP are lost.¹⁹⁶

IL-18BP is highly regulated at the level of gene expression and unexpectedly, IFN γ increases gene expression and synthesis of IL-18BP.^{197,198} Therefore, IFN γ driving an increase in the natural and potent inhibitor of IL-18 falls into the category of a negative feedback loop. The concept is supported by clinical data showing that patients being treated with IFN α for hepatitis have elevated levels of IL-18BP.^{199,200} IL-27, like IFN γ , functions as both a pro- as well as an anti-inflammatory cytokine and both may accomplish their roles as anti-inflammatory cytokines at the level of increased production of IL-18BP. In the skin, IL-27 also acts through a negative feedback loop for inflammation. IL-27 is acting, as is IFN γ , by induction of IL-18BP gene expression and synthesis.²⁰¹

Viral Interleukin-18 Binding Protein

Natural neutralization of human IL-18 by IL-18BP takes place during a common viral infection. In *Molluscum contagiosum* infection, characterized by raised but bland eruptions, there are large numbers of viral particles in the epithelial cells of the skin, but histologically there are few inflammatory or immunologically active cells in or near the lesions. Clearly, the virus fails to elicit an inflammatory or immunologic response. Amino acid similarity exists between human IL-18BP and a gene found in various members of the poxviruses; the greatest degree of homology is found to be expressed by *Molluscum contagiosum* gene.²⁰² The ability of viral IL-18BP to reduce the activity of mammalian IL-18 likely explains the lack of inflammatory and immune cells in the infected tissues and provides further evidence for the natural ability of IL-18BP to interfere with IL-18 activity.

Interleukin-37

IL-37 was formerly termed IL-1F7. IL-37 lacks a signal peptide and has a caspase-1 site, but the secretion of IL-37 has not been documented with any certainty. It is likely, however, that similar to IL-1 α and IL-33, with loss of membrane integrity upon cell death, the IL-37 precursor exits from the cell. The recombinant form of the IL-37 precursor suppresses LPS-induced IL-1 β , IL-6, and TNF α . However, this is observed primarily in macrophages that have been differentiated into the M1 phenotype by 5 days in the presence of granulocyte macrophage-colony stimulating factor. There are two consensus sequences (A-X-D) in N-terminal domain of IL-37: IHD and LED. A recombinant form of IL-37 with an N-terminus nine amino acids from the IHD site is active in suppressing LPS-induced TNF α and IL-6. Whether this short form of recombinant IL-37 exists in nature is unclear.

Interleukin-37 Reduces Interleukin-1β and Lipopolysaccharide-Induced Inflammation in Vivo

A mouse homologue for human IL-37 has not been identified. Therefore, to define the in vivo functional role of IL-37, a strain of transgenic mice was generated.¹⁹⁴ The full-length IL-37 complementary DNA was inserted into a vector using the standard cytomegalovirus (CMV) promoter for constitutive expression of the transgene in all cells. Both heterozygous and homozygous IL-37 transgenic mice (IL-37 tg) mice breed normally and exhibit no obvious phenotype. Despite the presence of the CMV promoter, the IL-37 transcript is not constitutively expressed in the tissues of the IL-37 transgenic mice. The failure to express IL-37 is likely due to a functional instability sequence found in IL-37, which limits the half-life of IL-37 mRNA.⁵¹ Nevertheless, upon stimulation with LPS or IL-1 β , levels of IL-37 increase after 4 to 24 hours. Once the transcript is present, the IL-37 precursor can be found in peripheral blood cells taken from the transgenic mice.203

IL-37 transgenic mice are protected against LPS challenge compared to similarly challenged wild-type mice. IL-37 transgenic mice exhibit significantly less hypothermia, acidosis, hyperkalemia, hepatitis, and dehydration.¹⁹⁴ In addition, circulating cytokines are significantly reduced as well as cytokines induced in whole blood cultures and in lung and spleen cell homogenates. In addition to LPS-induced cytokines, whole blood cultures from IL-37 transgenic mice produce significantly less IL-6 and TNF α when stimulated by IL-1 β or the combination of IL-12 plus IL-18. The antiinflammatory activity of IL-37 was not limited to a reduction of the cytokines and chemokines of innate immunity. Dendritic cells isolated from the spleen of IL-37 transgenic mice upon LPS stimulation revealed a marked reduction (75% and 89%) in expression of CD86 and MHC II, respectively.¹⁹⁴ The total numbers of dendritic cells, macrophages, NK cells, and CD4+ T cells were similar in all strains and experimental conditions.

A Role for Interleukin-37 During Experimental Colitis

IL-37 transgenic mice have been subjected to DSS-induced colitis. Despite the presence of a CMV promoter to drive expression of IL-37, mRNA transcripts were not present in colons in the resting state.¹⁹⁵ Expression was observed only upon disruption of the epithelial barrier, with a six- to sevenfold increase on days 3 and 5 after continuous exposure to DSS. During the development of colitis, clinical disease

scores were reduced by 50% and histologic indices of colitis were one-third less in IL-37 transgenic mice compared with wild-type counterparts. Reduced inflammation was associated with decreased leukocyte recruitment into the colonic lamina propria. In addition, release of IL-1 β and TNF α from ex vivo colonic explant tissue was decreased 5- and 13-fold, respectively, compared with wild-type mice, whereas IL-10 was increased 6-fold. However, IL-10 was not required for the anti-inflammatory effects of IL-37 because IL-10 receptor antibody blockade did not reverse IL-37–mediated protection. Mechanistically, IL-37 originating from hematopoietic cells was sufficient to exert anti-inflammatory effects because wild-type mice reconstituted with bone marrow from IL-37 transgenic mice were protected from colitis.

A Nuclear Role for Interleukin-37

In stable transfectants of human IL-37 in RAW macrophages stimulated with LPS, levels of TNF α , IL-1 α , IL-6, as well as the chemokine MIP-2 were substantially reduced (72% to 98%) compared with LPS-stimulated cells transfected with the empty plasmid.²⁰⁴ Similar to IL-1 α and IL-33, IL-37 translocates to the nucleus following stimulation.²⁰⁴ In mouse RAW macrophages stably expressing IL-37, the mature carboxyl-terminal was detected in the nucleus. Furthermore, a specific caspase-1 inhibitor markedly reduced nuclear entry of IL-37.²⁰⁴ The data demonstrate that IL-37 translocates to the nucleus after caspase-1 processing and may act as a transcriptional modulator reducing the production of LPS-stimulated proinflammatory cytokines, consistent with IL-37 being an anti-inflammatory member of the IL-1 family.

IL-37 was identified in a proteomics-based search for proteins that interacted with Smad3.²⁰⁵ To test for a functional interaction of Smad3 with IL-37, IL-37 was transfected into A549 cells. IL-37 colocalized with phospho-Smad3 and was found in perinuclear and cytosolic regions, and a IL-37-Smad3 complex was observed.¹⁹⁴ A specific inhibitor of Smad3 reversed the inhibition of IL-6 and IL-1 β expression in RAW cells stably transfected with IL-37. In stable human macrophage lines expressing IL-37, depletion of Smad3 by lentiviral introduction of short hairpin RNA that inhibits Smad3 expression prevented the ability of IL-37 to reduce IL-1 β - or LPS-induced production of IL-8, IL-6, and TNF. These in vitro findings were confirmed in vivo. IL-37 transgenic mice were pretreated intranasally with a Smad3 specific small interfering RNA and then challenged with intranasal LPS. The reduction of lung cytokines in IL-37 transgenic mice was reversed in transgenic mice with a lung knockdown of Smad3.194

Role of Interleukin-18R for Interleukin-37

From the first reports on IL-37, it was observed that the recombinant forms bound to the IL-18R α .^{132,206} This is shown in Figure 26.3C and E. The binding of IL-37 to IL-18R α has also been observed in cells from IL-37 transgenic mice using immunofluoresence, immunoprecipitation, and fluorescence resonance energy transfer analysis.²⁰⁷ IL-37 specifically binds to the third domain of the IL-18R α .¹⁹³ Despite these studies showing binding of IL-37 to the IL-18R α chain, IL-37 does not act as a classical receptor antagonist for IL-18 in that the ability of recombinant IL-18 to induce IFN γ is not inhibited by high concentrations of IL-37. However, in the presence of low concentrations of IL-18BP, recombinant IL-37 modestly reduces IL-18-induced IFNy.¹⁹³ The concept that IL-37 binds to the IL-18Rα and reduces cytokine production is supported, in part, with the finding embryonic fibroblasts from mice deficient in IL-18Ra produce 10-fold more IL-6 in response to IL1 β than do wild-type embryonic fibroblasts.²⁰⁸ In addition, silencing of IL-18Ra in primary human blood monocytes results in a fourfold increase in the secretion of LPS-induced IL-1β, IL-6, IFNy, and CD40 ligand.²⁰⁸ Thus, the seemingly paradoxical hyperresponsive state in cells deficient in IL-18Ra supports the concept that IL-18R α participates in both pro- and anti-inflammatory responses and that the endogenous ligand IL-37 engages the IL-18R α to deliver an inhibitory signal.

Role of Single Immunoglobulin Interleukin-1–Related Receptor in the Anti-inflammatory Property of Interleukin-37

The mechanism by which an IL-1 β or an LPS signal is suppressed by IL-37 requires an understanding of SIGIRR (Fig. 26.4G). The IL-1RAcP serves as the coreceptor for IL-1 α , IL-1 β , IL-36 α , IL-36 β , IL-36 γ , and IL-33, each a proinflammatory cytokine. However, in the IL-1 family of receptors, three coreceptors contain unusually long intracellular domains. These are SIGIRR (Fig. 26.4G), a variant of the IL-1RAcP termed IL-1RAcPb (Fig. 26.4F) and receptors termed "three immunoglobulin IL-1-related receptors" (TIGIRRs). As shown in Figure 26.4H, there are two TIGIRRs: TIGIRR-1 and TIGIRR-2. IL-1RacPb is expressed only in the brain, and TIGIRR has limited expression. However, SIGIRR is expressed in most cells. The TIR domain of the three coreceptors is also different from that of other members of the IL-1 coreceptor family in that the TIR domain contains an amino acid sequence different from that of wild-type TIR.²⁰⁹ As shown in Figure 26.2B, IL-1RAcPb forms the expected complex with IL-1 and IL-1R1 but does not recruit MyD88 or phosphorylate IRAK4.²⁰⁹ Therefore, most IL-1 signaling is arrested. But as some genes are increased in response to the formation of the IL-1RI/IL-1RAcPb complex, partial IL-1 signaling must take place. Nevertheless, IL-1RAcPb functions as an inhibitory receptor chain but only in the brain. Mice deficient in IL-1RAcPb exhibit a normal inflammatory response in the periphery but greater neurodegeneration in the brain. As such, IL-1RAcPb could play a role in chronic inflammatory responses in the brain by "buffering" IL-1mediated neurodegeneration.

Like IL-1RAcPb, SIGIRR contains the same amino acids differences in its TIR domain, termed TIRb. Compared to wild-type TIR, TIRb likely has reduced binding of MyD88.²⁰⁹ In addition to an altered TIR domain, SIGIRR has a carboxyl extension of 140 amino acids. Carboxyl extensions are also present in IL-1RAcPb as well as the two TIGIRRs. TIGIRR-2, which is associated with an X-linked cognitive deficiency, is apparently independent of IL-1 function. Little is known whether these C-terminal segments contribute to the inhibitory properties of these receptors. Nevertheless,

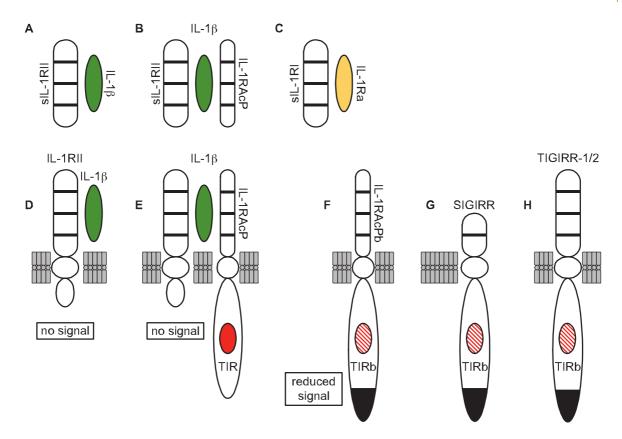

FIG. 26.4. Anti-Inflammatory Receptors of the Interleukin (IL)-1 Receptor Family. A: Soluble (extracellular) IL-1RII (sIL-1RII) binds and neutralizes either the precursor or mature form of IL-1 β . B: A complex of IL-1 β , sIL-1RII, and sIL-1RACP neutralizes IL-1 β activity. C: Soluble (extracellular) IL-1RI (sIL-1RI) binds IL-1Ra and prevents IL-1Ra from its function as a receptor antagonist. Similarly, IL-1 α can bind to the sIL-1RI (not shown). D: IL-1RII expressed on the membrane binds mature IL-1 β acting as a decoy receptor, preventing IL-1 β from binding to its signaling receptor. E: A complex of membrane IL-1RII, IL-1 β , and membrane IL-1RACP also prevents IL-1 β from signaling. F: The IL-1RACP is expressed in brain tissue (see Fig. 26.2B). G: Single immunoglobulin IL-1–related receptor is expressed in myeloid cells and epithelial cells and function in damped inflammation due to the TIRb domain. H: Three immunoglobulin IL-1–related receptor is also an anti-inflammatory member of the IL-1 due to the toll-IL-1-receptor b domain.

it seems likely that the alternative sequence in the TIRb domain of SIGIRR may act as a partial decoy for MyD88. MyD88 is phosphorylated upon TLR4 as well as IL-1 β and IL-18 signaling, and results in downstream phosphorylation of IRAK-4. In cells expressing SIGIRR and activated by IL-37 binding to the IL-18R α , the signal from either IL-1 or LPS initiates phosphorylation of MyD88. However, the decoy effect by the mutated TIRb of SIGIRR reduces the degree of phosphorylation of MyD88 and thus the phosphorylation of IRAK-4. The reduction, however, is partial. Indeed, the suppression by IL-37 added to blood macrophages is in the range of 20% to 50% and unlike the total loss of activation by a deficiency in MyD88.

Upon binding to the IL-18R α , the IL-37 precursor may activate SIGIRR and provide a negative signal (see Fig. 26.3C). An inhibitory signal from IL-37 is enhanced by a low concentration of IL-18BP.¹⁹³ As shown in Figure 26.3D, IL-18BP binds IL-37¹⁹³ and likely presents the complex of the cytokine with the binding protein to the IL-18R α (see Fig. 26.3E). Because A549 cells express SIGIRR, it is likely that the inhibitory signal from IL-37 activates SIGIRR or alternatively IL-37 recruits SIGIRR as the accessory chain. The inhibitory signal of SIGIRR is established in several mouse models of inflammation in which SIGIRR-deficient mice exhibit more inflammation compared to wild-type control mice.²¹⁰ In differentiated human blood M1 macrophages, recombinant IL-37 suppresses LPS-induced TNFa and IL-6 production 50% to 70%. A source of IL-18BP in this culture may be fetal calf serum. During the differentiation of macrophages into the M1 subset by granulocyte macrophage-colony stimulating factor, it is possible that SIGIRR expression increases whereas the level of IL-18R β decreases (see Fig. 26.3A). In the absence of IL-18R β , a proinflammatory complex is not formed with IL-18R α and thus IL-37 binding to IL-18R α may recruit or activate SIGIRR. Thus, expression of SIGIRR and the absence of IL-18R β would best explain the inhibitory properties of recombinant IL-37 reducing the response to LPS induction of IL-6 and TNF α .

INTERLEUKIN-36 SUBFAMILY

The IL-1 family members IL-1F5, IL-1F6, IL-1F8, and IL-1F9 are now termed IL-36Ra, IL-36 α , IL-36 β , and IL-36 γ , respectively.²¹¹ As shown in Figure 26.5A, each member of the IL-36

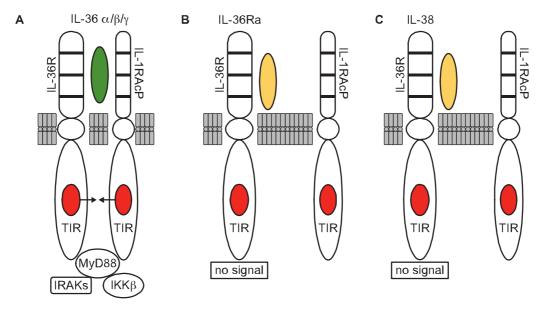

FIG. 26.5. Interleukin (IL)-36 Subfamily. A: IL-36 α , IL-36 β , or IL-36 γ bind to the IL-36R and recruit the coreceptor IL-1RAcP. The heterodimeric IL-36 receptor complex results in a close approximation of the toll-IL-1-receptor (TIR) domains on each receptor chain (*arrows*), resulting in the binding of intracellular MyD88 to the complex with phosphorylation of MyD88. Subsequent phosphorylations of IRAKs and IKK β , increased NF- κ B, and activating protein-1 translocation to the nucleus take place, followed by expression of proinflammatory genes. B: IL-36Ra binds to IL-36R. There is no recruitment of the coreceptor IL-1RAcP, no approximation of the TIR domains, and no signal. C: IL-38 binds to IL-36R but there is no signal and acts similar to IL-36Ra.

subfamily binds to the IL-1Rpr2, now termed IL-36R.²¹² Because IL-38 also binds to the IL-36R (Fig. 26.5C),¹³³ IL-38 is included in the IL-36R subfamily. The IL-36 subfamily is closely related to the IL-1 subfamily because, similar to the IL-1 α and IL-1 β and IL-33, the IL-36R forms a signaling complex with the IL-1RAcP (Fig. 26.5A).^{122,212} Thus of the 11 members of the entire IL-1 family, 6 members use IL-1RAcP as the coreceptor for signal transduction.

Interleukin-36

The IL-36R is the ligand binding chain and therefore is comparable to the ligand binding IL-1R1 and the IL-18R α . However, two members of the IL-36 subfamily bind to the IL-36R but do not signal, the IL-36 receptor antagonist (IL-36Ra) and IL-38 (see Fig. 26.5B and C). As such, these function as receptor antagonists.^{9,133} An unusual property of IL-38 is that low concentrations (1 to 10 ng/mL) are able to reduce the activity of endogenous IL-36,¹³³ whereas in the case of IL-1Ra, higher concentrations are required to prevent the activating of endogenous IL-1 α or IL-1 β .

None of the members of the IL-36 subfamily have a signal peptide, indicating the generation of the N-terminus and secretion via the Golgi. In addition, each member of the IL-36 subfamily has an unusually short propiece compared to those of the IL-1 α , IL-1 β and IL-33 (see Fig. 26.1). Like IL-1 β and IL-18, there is no true caspase-1 cleavage site for generation of an N-terminus in the IL-36 subfamily. It remains unknown which specific proteases generate the various N-termini of the IL-36 subfamily; nevertheless, each member has a unique N-terminus with a different levels of biologic activity.⁹ What determines the N-terminus with optimal biologic activity in the IL-36 subfamily? Each member of the IL-36 subfamily contains the IL-1 family consensus sequence of A-X-D. The aspartic acid is not the recognition amino acid for caspase-1 or caspase-3, but rather participates in the stabilization of the first beta sheet of the three-dimensional structure that characterizes the entire IL-1 family.

The "A" of the consensus sequence is for any aliphatic amino acid, for example, leucine or isoleucine. Nine amino acids before the "A" of the consensus sequence is the N-terminal site, which results in the cytokine with the greatest activity.⁹ For example, the biologic activity of IL-36 γ increases by a factor of 1,000 when the N-terminus is at the site nine amino acids before the consensus sequence and in the case of the IL-36 β , there is a 10,000-fold increase.9 The nine amino acid forward site from the consensus sequence is not only the N-terminus for the agonist members of the IL-36 family but also the IL-36 receptor antagonist (IL-36Ra),9 which increases from a low level of blocking of IL-36 family ligands to a high degree of blockade. It is unclear what specific protease cleaves at this site as the amino acid is different for each member of the IL-36 subfamily. Moreover, the site for the N-terminus of the IL-36Ra (valine) is but one amino acid from the N-terminal precursor methionine and yet IL-36Ra with an N-terminus at the valine site is 10,000-fold more potent that the IL-36 precursor. It is also an unusual situation that proteases that usually are inflammatory in processing members of the IL-1 family in that case of IL-36Ra generate an anti-inflammatory molecule.

Interleukin-36 α , β , and γ , Proinflammatory Members of the Interleukin-36 Subfamily

IL-36 α was highly expressed in the murine model of glomerulonephritis²¹³ where the cytokine was localized to the kidney epithelium and also in CD3 T cells surrounding the tubules. IL-36 α is also found in the kidneys of the MRL/ lupus, nephritic syndrome, and streptozotocin-induced diabetic models.²¹³ IL-36y increases IL-8, CXCL3, and the Th17 chemokine CCL20 in human lung fibroblasts,²¹⁴ and thus may account for acute neutrophilic lung inflammation. In addition to CD4+ T cells, human articular chondrocytes and synovial fibroblasts express the IL-36R.²¹⁵ In chondrocytes, there is also constitutive gene expression of IL-36 β . Following stimulation with IL-1 β or TNF α , levels of the IL-36 β precursor rise intracellularly but the cytokine is not secreted. Although IL-36 β levels were detected in the joint fluids of patients with rheumatoid arthritis as well as in serum samples, there was no correlation with disease severity.²¹⁵ It is likely that IL-36 ligands are functional only when released from dying cells and can be processed extracellularly by enzymes present in inflammatory conditions such as the joints of patients with rheumatoid arthritis. It unclear to what extent IL-36 β plays a role in joint disease, although constitutive expression in primary chondrocytes may indicate a role for the cytokine in osteoarthritis.²¹⁵

High levels of this cytokine are found in mouse embryonic tissues rich in epithelial cells.²¹⁶ In humans, IL-36 α is observed in keratinocytes, not fibroblasts, and is thought to contribute to the inflammation of psoriasis. Upon forming the heterodimer with IL-36R and IL-1RAcP, IL- 36α activates NF- κ B similar to that of IL-1 β .²¹² In addition to NF- κ B activation, IL-36 α also activates MAPK, JNK, and ERK1/2.²¹² In the mouse, bone marrow-derived dendritic cells and CD4+ T cells express IL-36 receptors in health. In a comparison with IL-1 as a stimulant, the three IL-36 ligands are more active in inducing IL-1β, IL-6, IL-12, TNFα, and IL-23.²¹⁷ In addition, IL-36 ligands induced the production of IFNy, IL-4, and IL-17 from CD4+ T cells. Not unexpectedly, cytokines induced by IL-36 lands were prevented by 100- to 1,000-fold excess IL-36Ra.²¹⁷

Interleukin-36 in Psoriasis

Several studies implicate IL-36 ligands in the pathogenesis of psoriasis.^{218–220} IL-36 γ is highly expressed in keratinocytes from healthy human skin and increases upon stimulation with TLR polyI:C.²²¹ Furthermore, polyI:C induced caspase-3, which resulted in cell death and the release of IL-36 γ . Unexpectedly, stimulation of IL-36 γ gene expression was dependent on caspase-1.²²¹ The caspase-1 dependency may be due to IL-18 as this cytokine is constitutively present in keratinocytes as is IL-1 α . With the release of IL-36 γ falls into the category of being an alarmin in the skin, particularly due to infection.²²¹ There is also a role for IL-36 in the production of IL-17: studies suggest that each of the IL-36 ligands is expressed in the skin and dependent on IL-22.²²² Furthermore, the expression of IL-36 ligands in the psoriatic skin correlated with IL-17.²²² Similar to other models in the IL-1 family, auto- and coinduction accounts for a role in a pathologic process.

Overexpression of IL-36 in mice results in inflammatory skin lesions that resemble psoriasis in humans, as reviewed in Towne and Sims.²²³ Likewise, mice deficient in endogenous IL-36Ra results in a severe lesion similar to that of humans with pustular psoriasis. The role of IL-36 in pustular psoriasis may include IL-1 α , as humans with pustular psoriasis responds to an antibody that neutralizes IL-1 α . Both IL-36 and IL-1 α are found in the keratinocytes in healthy skin.

A Role for Interleukin-36R in Metabolic Regulation

Obesity is characterized by chronic low-grade inflammation originating from expanding adipose tissue. Human adipogenic tissue levels of IL-36 α is primarily present in adipose tissue resident macrophages and induced by inflammation; however, IL-36 β is absent.²²⁴ IL-36 α , but not IL-36 β , reduces adipocyte differentiation, as shown by a significant decrease in PPAR γ gene expression. Both IL-36 α and IL-36 β induce inflammatory gene expression in mature adipocytes.²²⁴ Therefore, IL-36 α and IL-36 β are present in adipose tissue and are involved in the regulation of adipose tissue gene expression. Importantly, IL-36 α inhibits PPAR γ expression, which may lead to reduced adipocyte differentiation suggesting metabolic effects of this cytokine.

Although IL-36Ra is known to occupy the IL-36R and act as a receptor antagonist, earlier studies revealed that IL-36Ra inhibited the induction of IL-1 β by LPS. The role of IL-36Ra was also examined in the brain. IL-36Ra injected into the rat brain induced IL-4 and also in glial cells in vitro.²²⁵ Moreover, the reduction in LPS-induced IL-1 β was not observed in cells deficient in IL-4 and also not observed in cell deficient in SIGIRR.²²⁵ However, these unique properties of IL-36Ra were not observed in peripheral monocytes or dendritic cells but only in the brain.

Role of Interleukin-36 in Human Disease

The importance of any cytokine in human biology can be found in mutations that result in a profound clinical picture. In the case IL-1, a mutation in the naturally IL-1Ra (see Fig. 26.5B) results in severe systemic inflammation with erosive bone lesions, sterile meningitis, and death; the syndrome is called deficiency of IL-1Ra.^{226,227} In case of the IL-36 family, persons with a mutation in the naturally occurring IL-36Ra suffer with a severe form of pustular psoriasis.^{228,229} These human studies are consistent with the data from transgenic mice overexpressing IL-36 α in the skin and with the ability of IL-36Ra to suppress the severity of the inflammation.²¹⁸ In mice overexpressing IL-36a in the skin, crossing the mice to generate a strain of mice heterozygous for natural IL-36Ra knockout results in worsening of the skin lesions.²¹⁸

Interleukin-38

IL-38 is the name for the IL-1 family member 10. During the nomenclature revision of the IL-1 family in 2010,²¹¹ the term IL-38 was assigned to IL-1F10 without any known biologic function. Since then, IL-38 has been shown to bind to the IL-36 receptor (formerly IL-1Rrp2) (see Fig. 26.5C).¹³³ In order to find the receptor for IL-38, each member of the IL-1 receptor family was immobilized and recombinant IL-38 precursor containing 152 amino acids was added and binding assessed using an antibody to the ligand. IL-38 bound only to the IL-36 receptor, as did IL-36Ra.¹³³ To assess the biologic function of IL-38, heat-killed *Candida albicans* was used to stimulate memory T-lymphocyte cytokine production in freshly obtained human peripheral blood mononuclear cells from healthy subjects. The addition of recombinant IL-38 inhibited the production of T-cell cy-

tokines IL-22 and IL-17. The dose-response suppression of IL-38 as well as that of IL-36Ra of *Candida*-induced IL-22 and IL-17 was not that of the classic IL-1 receptor antagonist, because low concentrations were optimal for inhibiting IL-22 production.¹³³ These data provide evidence that IL-38 binds to the IL-36R, as does IL-36Ra, and that IL-38 and IL-36Ra have similar biologic effects on immune cells by engaging the IL-36 receptor.

CONCLUSION

In conclusion, IL-1 family of cytokines is one of the most important families of proinflammatory mediators, that have profound local and systemic effects. The importance of these molecules has been demonstrated in homeostasis, as well as in autoinflammatory diseases, and treatment strategies based on modulation of IL-1 cytokines have begun to be employed successfully. Furthermore, important and novel biologic roles are currently being described for the members of IL-1 family of cytokines, and it is to be expected that this will represent one of the most dynamic areas of research in immunology in the coming years.

CHAPTER

Tumor Necrosis Factor—Related Cytokines in Immunity

Carl F. Ware

INTRODUCTION

Lymphocytes are highly mobile, transiting the vascular and lymphatic circulatory systems with limited stopovers in organized lymphoid tissues (lymph nodes, spleen, and Peyer's patches) in which they commune to initiate immune responses. Cytokines, both secreted and membrane-anchored proteins, serve as the communication media of the immune system. Cytokines in the tumor necrosis factor (TNF) superfamily (TNFSF) help orchestrate the development, homeostasis, and effector actions of cells in the immune system. The diversification of the TNFSF is evidenced by its roles in regulating cells of neuronal, skeletal, and ectodermal origin. This chapter's focus is on members in the TNFSF that are primarily involved in regulating immunity.

The ligands belonging to the TNFSF initiate intercellular communication by binding specific receptors on the surface of the receiving cell. The TNF-related ligands are membrane-bound and require cell-cell contact to initiate signaling, although some ligands may be secreted in soluble form influencing cellular responses at locations distant from the source of production. The TNF receptors (TNFRs) form a corresponding superfamily of cognate membrane proteins that initiate intracellular signaling pathways that influence cellular growth, differentiation, and survival. Each ligandreceptor pair forms a "system" with over 40 distinct ligandreceptor systems. Many of the ligands and receptors engage more than one cognate, thereby forming "circuits" of signaling systems, which often function together as coordinated or integrated networks with other cytokines to regulate a specific cellular process. The signals delivered to the cytosol activate transcription factors such as NF-kB and AP1, which in turn initiate the expression of hundreds of genes that alter cellular differentiation. Additionally, some TNFRs activate cell death pathways, both apoptotic and necrotic, terminating cellular life. Genetic mutations have revealed the importance of individual TNFSF members in human immune responses and development. Moreover, the beneficial effect of TNF antagonists in patients with certain autoimmune diseases brings the need to understand the complexities of the TNFSF into sharp focus.

The nomenclature of the TNFSF is a bit of a morass for students new to the field, although introduction of a numerical system standardizing gene names (www.genenames. org/) helps in accessing genomic databases. However, the use of more common, often colorful, acronyms continues. The name, rank, and genomic identification of each ligand (Table 27.1) and receptor (Table 27.2) is tabulated along with additional pertinent information for human and mouse genes.

TUMOR NECROSIS FACTOR LIGAND FAMILY

The TNF-related cytokines are type II transmembrane proteins (intracellular N-terminus) with a short cytoplasmic tail (15 to 25 residues in length) and a larger extracellular region (~150 amino acids) containing the signature TNF homology domain where the receptor binding sites are located (Fig. 27.1). The TNF homology domain assembles into trimers, the functional unit of the ligand. Atomic analysis of several members of the family¹⁻⁵ revealed the ligands have a highly conserved tertiary structure folding into a β sheet sandwich, yet amino acid sequence conservation is limited to < 35% among the family members. The conserved residues defining this superfamily are primarily located within the internal β strands that form the molecular scaffold, which promote assembly into trimers. The residues in the loops between the external β -strands are variable and in specific loops make contact with the receptor. Although most of the TNF ligands self-assemble into homotrimers, heterotrimers can also form between LTα and LTβ⁶ and APRIL and BAFF.⁷ The stoichiometry of the LT heterotrimer is 1:2 (LT $\alpha\beta$ 2), which imparts its distinct receptor specificity from the $LT\alpha$ homotrimer. Interestingly, complement component C1q and several related proteins are structurally related to the TNF family, containing a TNF homology domain, a rather surprising finding given the apparent functional divergence between the complement and TNF systems.⁸ Alternate splicing can also generate distinct ligands, such as the splice form joining TWEAK and APRIL (TWE-PRIL),9 the alternate ligands for ectodysplasin receptor,¹⁰ and a cytosolic form of LIGHT.11

The genetic organization of TNF ligands is highly conserved and typically encoded in three or four exons, with the fourth exon encoding most of the extracellular TNF homology domain. The genes encoding TNF, $LT\beta$, and LT α reside adjacent to each other in a compact loci in the class III region of the major histocompatibility complex (MHC) (in humans at chromosome 6p21) sandwiched between the antigenic-peptide presenting MHC proteins encoded by MHC class I and II genes.^{6,12} Three other genetic clusters of TNF-related cytokines are found within the corresponding MHC paralogous regions, located on chromosomes 1, 9, and 19. These genetic clusters share a remarkably conserved gene structure and transcriptional orientation, and a similar function linked to regulating cellular immune responses.¹¹ The evolutionary pressures retaining this genetic configuration of the MHC in general is encompassed in the paralogy theory of genome

evolution.¹³ Conservation of gene structure of the TNF ligands outside these MHC paralogs is limited. An evolutionarily conserved pathway in *Drosophila melanogaster*, Eiger-Wengen system, is structurally and functionally related to the TNFSF-related signaling pathway, although this system is predominantly expressed in the nervous system in invertebrates.¹⁴⁻¹⁶

TUMOR NECROSIS FACTOR RECEPTOR FAMILY

Members of the TNF receptor superfamily (TNFRSF) include proteins of vertebrate and viral origin. Most of the signaling receptors in the TNFRSF are type I transmembrane glycoproteins (N-terminus exterior to the cell). However, several TNFRSF members lack a membraneanchor domain, are proteolytically cleaved from the surface, or are anchored via glycolipid linkage (eg, TNF-related apoptosis inducing ligand [TRAIL]R3). These soluble receptors, termed "decoy receptors," retain their ligand-binding properties and compete with cellular receptors for the specific ligands, thus earning the title of decoy. The structural motifs in the cytoplasmic domains further categorize the TNFR into two groups based on their signaling properties: those contain a death domain (DD) and others that engage TNFR-associated factors (TRAFs).

The cysteine-rich domain (CRD) in the extracellular, ligand-binding region defines membership in the TNFRSF (see Fig. 27.1). Each CRD typically contains six cysteine residues forming three disulfide bonds. The CRD is pseudorepeated in different members ranging from one to six. Based upon the crystal structures solved for several TNFRSF members, the CRD confers an elongated shape and sidedness to the ectodomain.^{17,18} The crystal structure of the complex between TNFR1 and one of its ligands, the LT α homotrimer, revealed FIG. 27.1. Structure of Tumor Necrosis Factor (TNF) and **TNF Receptors (TNFRs).** Top: TNF. The β -sandwich of the TNF monomer (1A8M.pdf) (shown as a ribbon diagram) contains two stacked β -pleated sheets each formed by five antiparallel β strands (wide ribbons given letter designations, A-G) that fold into a Greek key or "jelly-roll" topology.²¹⁹ The inner β -sheet (strands A, A', H, C, and F) is involved in contacts between adjacent subunits, which promotes assembly into a trimer. The trimer is formed such that one edge of each subunit is packed against the inner sheet of its neighbor. The outer β sheet (strands B, B', D, E, and G) is surface exposed. The trimeric structure is characteristic of all TNF-related ligands. The type II configuration of TNF (N-terminus inside the cell) anchors TNF to the membrane. The TNF trimer is ~60 Å in height with a relatively flat base residing close to the membrane, resembling a bell-shape (shown as surface representation with different shades of gray used for each subunit of the trimer). The surface exposed loops between A-A' and D-E strands are involved in receptor binding. TNF is cleaved by TNF α -converting enzyme (TACE), a member of the ADAM family of metalloproteinases (ADAM17) involved in processing of many cell surface proteins. TACE is a type 1 transmembrane protein that cleaves TNF between residues Val77 and Ala76, when all three sites in the trimer are cleaved TNF is released from the membrane. Bottom: TNFR and ligand complex. The ectodomain of TNFR1 forms an elongated molecule with CRD1 proximal to the N-terminus (ribbon diagram). The face of TNFR1 on the left engages $LT\alpha$. In the ligand-receptor complex, the elongated receptor (dark) lies along the cleft formed between adjacent subunits. Shown (space-filling) is a single TNFR1 in complex with two subunits of $LT\alpha$ (*lighter shades*); the receptor N-terminus points upward, closest to the base of the ligand (transorientation). In the exploded view, TNFR1 is removed from in front of the ligand revealing the contact residues in the ligand, which are primarily located in the D–E and the A-A" β -strands (dark shade). TNFR1 is rotated 180 degrees, exposing the contact residues in the receptor (light shade). Structures from 1TRN.pdf¹⁷ as visualized with MacPyMOL (www.pymol.org).

that residues in CRD2 and 3 of TNFR1 contact the ligand. Variation in binding interactions has been identified; for example, the receptors for BAFF have one functional CRD.^{2,19}

RECEPTOR-LIGAND COMPLEX

The binding specificity of the various members of the TNF ligand and receptor superfamilies show monotypic interaction, yet several members interact with multiple partners²⁰ (Figs. 27.2 and 27.3). The binding interactions between TNFrelated ligands and TNFR are typically high affinity, with equilibrium binding constants measured in the high pM to low nM range. The membrane position of the ligands further enhances the binding interaction with their receptors. In the membrane anchored position, the ligands and receptors must be in trans to form a complex. In the LT α -TNFR1 complex, the surface loops between A-A" and D-E β strands contain many of the amino acid residues that make contact

with the receptor, with the receptor binding site formed as a composite of adjoining subunits in the trimeric ligand¹⁷ (see Fig. 27.1).

The trimeric architecture of the TNF ligands, containing three equivalent receptor-binding sites, provides the basis for initiating signaling through aggregation or clustering of receptors. This concept is supported by the finding that receptor-specific bivalent antibodies can act as agonists mimicking the signaling activity of the natural ligand.²¹ Indeed, antibodies or peptide mimetic to TNFR can function as antagonists, blocking the ability of the natural ligand to bind the receptor while simultaneously activating the receptor as an agonist.²² Some ligands such as FasL, TRAIL, and BAFF form higher ordered oligomers of the basic trimer. These higher ordered oligomers promote supraaggregation of receptors, enhancing or sustaining signaling pathways in the receptor-bearing cell.^{23,24} Overexpression of TNFR in cells can also lead to ligand-independent signaling, a

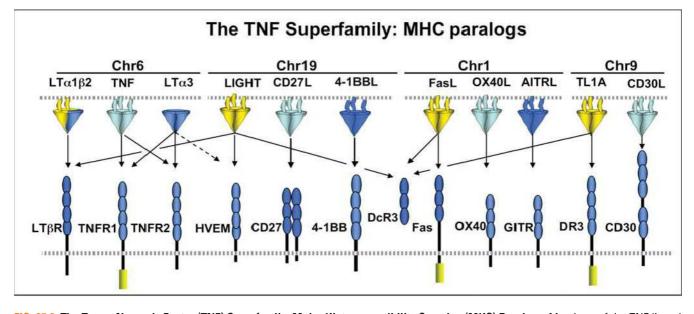

FIG. 27.2. The Tumor Necrosis Factor (TNF) Superfamily–Major Histocompatibility Complex (MHC) Paralogs. Members of the TNF ligand superfamily (*above*) and their corresponding receptors (*below*) are identified by connecting *arrows*. The ligands are grouped according to their chromosomal locations in the MHC paralogous regions. The number of cysteine-rich domains are depicted for each TNF receptor, and TNF receptors containing a death domain are identified by cylinder in the cytoplasmic tail. (Modified from Ware³³⁶).

feature bestowed in part by the propensity of the cytosolic tails to self-associate.²⁵ In the physiologic setting, the expression level and compartmentalization of these receptors are tightly controlled. A subregion in the first CRD of TNFR1 known as the preligand assembly domain may restrict the orientation of the unligated receptor to prevent spontaneous activation.²⁶ It is not known if this mechanism applies to all TNFRSF. Interestingly, some patients with periodic fever syndrome have mutant TNFR1 that form abnormal disulfide-linked oligomers that are retained intracellullarly and provoke misfolded protein response.²⁷

Alternate Ligands

There is significant divergence in the ligands and the mechanisms of ligand binding by the TNFR family. A major branch point is exemplified by the ligands for p75 neurotrophin receptor (nerve growth factor and the other neurotrophins), which are structurally unrelated to TNF ligand family. Molecular contacts between NGF and p75NTR occur through two spatially separated binding regions located at the first and second CRD and the junction between the CRD3 and CRD4.28 The p75NTR functions in complex with two other proteins, Nogo66 and LINGO, to engage myelin-associated inhibitory factors. Taj/TROY can supplant p75NTR in this complex.²⁹ Like p75 NTR, DR6, ILGF1R, and TROY/Taj do not bind any of the known TNF ligands but do engage other ligands. The pathways activated by p75NTR and TROY/Taj systems show both positive and inhibitory regulation of axonal regeneration.^{29,30}

The herpesvirus entry mediator (HVEM; TNFRSF14) provides an example of a TNFR system that binds alternate ligands. Although HVEM engages two TNF-related ligands,

LIGHT and LT α , it also engages two members of immunoglobulin (Ig) superfamily, B- and T-lymphocyte attenuator (BTLA)³¹ and cluster of differentiation (CD)160.³² BTLA binding to HVEM occurs in CRD1, on the opposite face of where LIGHT/LT α bind in CRD2 and 3. The BTLA binding site in CRD1 of HVEM is a region also targeted by herpesviruses.^{33–35} Recent evidence indicates the neurotrophin and chondrocyte growth factor–like protein progranulin interacts with TNFR1 and TNFR2 and competes with TNF for binding.³⁶

An insulin growth factor–like protein was recently identified as a ligand for a TNFR-like type 1 transmembrane protein (insulin growth factor–like R, formerly TMEM149).³⁷ Insulin growth factor–like R has conserved positioning of cysteines delineating a CRD1, but atypical CRD2/3. Insulin growth factor–like messenger ribonucleic acid (mRNA) is expressed in psoriatic skin lesions and the receptor is detected in T cells suggesting a possible role in skin inflammation.

Death receptor-6 (DR6) engages the growth factor–like domain in β -amyloid precursor protein^{38,39} and thus may function as a negative regulator more like p75 neurotrophin receptor.⁴⁰ Emerging evidence suggests DR6 has a role in neuroimmune function. In a mouse experimental autoimmune encephalomyelitis (EAE) model, DR6-deficiency was shown to protect against central nervous system demyelination and leukocyte infiltration, but also enhanced overall CD4+ T-cell proliferation and T_H2 differentiation, underscoring a role for DR6 in mediating T_H1-specific immune responses in EAE progression.⁴¹ Taj/TROY and RELT also do not bind any of the known TNFSF ligands; however, recent evidence indicates that Taj/TROY functions more like p75NTR, capable of binding myelin inhibitory factors.^{29,30} A role for Taj/ TROY and RELT in immune function is presently unclear.

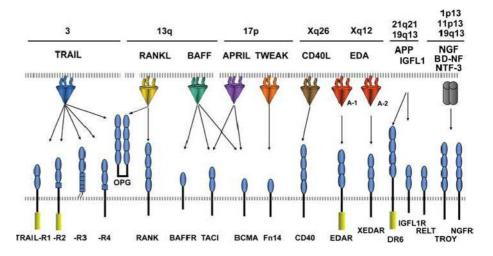

FIG. 27.3. The Tumor Necrosis Factor (TNF) Superfamily—Part 2. Members of the TNF ligand superfamily (*above*) and their corresponding receptors (*below*) are identified by connecting *arrows*. The ligands are grouped according to their chromosomal locations. The number of cysteine-rich domains are depicted for each TNF receptor, and TNF receptors containing a death domain are identified by cylinder in the cytoplasmic tail. (Modified from Ware³³⁶).

The engagement of ligands distinct from TNFSF members implicates a higher level of integration with other signaling pathways.

Viral Orthologs

TNFR-like proteins are found in the genomes of several viral pathogens representing captured cellular genes that have evolved as part of that pathogen's immune evasion strategy (Table 27.3). Poxviruses were the first pathogens identified harboring a version of a cellular TNFR.⁴³ Poxvirus TNFR displays significant sequence homology to TNFR2 and binds TNF and LTα. The rabbit poxvirus protein T2 is secreted by virally infected cells and contributes to the virulence of infection.^{44,45} Smallpox virus, the former scourge of mankind, also harbored viral versions of TNFR2.⁴⁶

SIGNALING PATHWAYS AND CELLULAR RESPONSES

Regulation

The cellular response activated by a TNF-related cytokine depends on several factors including the temporal patterns of expression of the ligands and receptors on the interacting cells, and the cellular context (the state of differentiation of the responding cell). Regulation is achieved at the level of transcriptional and translational controls, and by modulating the availability of the ligand or receptors (Fig. 27.4). For some ligands, transcriptional activation is a critical feature controlling the duration of mRNA expression. Some ligands exhibit inducible, transient expression of mRNA following signals from antigen receptors or innate receptor recognition systems. The half-life of mRNA

TABLE 27.3 Viral Orthologs and Modulators of the Tumor Necrosis Factor Superfamily					
Virus	Name/ORF	Ortholog ^a	Mechanism		
Poxvirus					
Myxoma	T2	Soluble TNFR2	TNF and LT $lpha$ decoy		
Variola	crm B (G2R)	Soluble TNFR2	TNF and LT $lpha$ decoy		
Cowpox	vCD30	Soluble CD30	CD30 ligand inhibitor		
Herpesvirus					
HSV1&2	Glycoprotein D	BTLA	Entry; HVEM blockade		
HCMV	UL144	HVEM	BTLA activation		
EBV	LMP1	CD40 intracellular	TRAF activation		
γHV	vFLIP	FLIP	Caspase 8 blockade		
Adenovirus	E3-10.4, 14.5, 6.7	?	Fas and TRAILR downmodulation		
Retrovirus					
EIAV	Envelope gp90	?	HVEM entry factor		
FIV	Envelope gp95	?	Ox40 entry factor		
ASLV	Envelope gp85	?	TRAILR entry factor		
Rabies virus	Envelope RVG	?	NTRp75 entry factor		

ASLV, avian sarcosis and leukosis virus; BTLA, B- and T-lymphocyte attenuator; CD, cluster of differentiation; EBV, Epstein-Barr virus; HCMV, human cytomegalovirus; HSV, herpes simplex virus; γHV, equine gamma herpesvirus; ElAV, equine infectious anemia virus; FIV, feline immunodeficiency virus; TNFR, tumor necrosis factor receptor; TRAF, TNFR-associated factor; TRAIL, TMF-related apoptosis inducing ligand; ?, no homology recognized.

*Relationship determined by sequence or structural homology to the indicated TNF superfamily member.

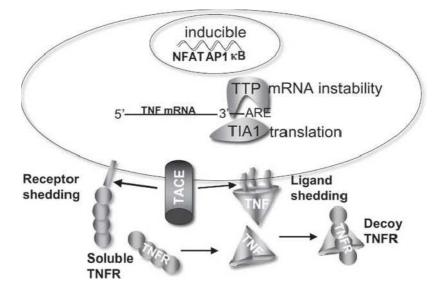

FIG. 27.4. Regulation of Tumor Necrosis Factor (TNF) Bioavailability. The expression of TNF is regulated at the transcriptional and translational levels, and bioavailability by altering its physical location and cellular receptors. TNF transcription is regulated by the action of multiple transcription factors including nuclear factors of activated T cells (NFAT), activated protein-1 (AP1), and NF-KB. NFAT is a predominant acting transcription factor regulating TNF transcription in T- and B-lymphocytes, and NF-kB and AP1 are important in myeloid lineage cells following activation via innate pattern recognition receptors, such as the toll-like receptors. TNF messenger ribonucleic acid (mRNA) stability is controlled by an adenylate-uridylate-rich element (ARE) in the 3' untranslated region present in many transiently expressed inflammatory genes.³³⁷ Stability of TNF mRNA is decreased by the action of tristetraprolin, and T-cell intracellular antigen silences translation of TNF mRNA through the ARE.338 TACE proteolytically controls TNF at the membrane, generating the soluble form of TNF. TACE also cleaves TNFR1 and 2,339 downregulating cell surface receptors and releasing soluble receptors that retain TNF binding activity. Soluble TNFR can stabilize the TNF trimer at sub saturating concentrations, and at higher, saturating concentrations act as decoys competing for TNF binding to cellular receptors.³⁴⁰

for TNF is short, controlled by an adenylate-uridylate-rich element in the 3' untranslated region.⁴⁷ Deletion of the adenylate-uridylate-rich element in TNF mRNA in mice leads to a profound inflammatory disease.^{47,48} TNF mRNA is inducible in macrophages by multiple pathways, particularly innate activation pathways such as toll-like receptor signaling, whereas other ligands like 41BBL and OX40L are constitutively expressed in differentiated antigen-presenting dendritic cells (DCs). T- and B-lymphocytes require activation prior to expression of TNF. In these cells, signals via the antigen receptor utilizing nuclear factor of activated T cells (NFAT) transcription factors are needed for the induction of TNF transcription. The inducible or constitutive patterns of expression are also observed with some receptors as well.

Posttranslational regulation of signaling is achieved by proteolytic cleavage of the ligand or receptor from the cell's surface, which places the protein into the soluble phase, where its half-life may be dramatically shortened. TNF and Fas ligand, for example, are shed from the surface by membrane proteases. ADAM17 (also known as TNF α -converting enzyme [TACE]), the enzyme that processes TNF into a soluble form, is involved in cleaving multiple cell surface proteins including transforming growth factor α , L-selectin, and TNFR1 and 2. Production of soluble TNFR1 and 2 may be important in regulating TNF bioavailability (see Fig. 27.4).

Most of the TNF-related ligands are expressed by DCs, activated lymphocytes, and myeloid cells, particularly macrophages, but can also be produced by nonlymphoid cells. TNF is an example of a ligand expressed by many cell types depending on the stimulus. Expression of TNFR is widespread. TNFR1 is expressed on most cells, while TNFR2 is limited to cells of hematopoietic origin and is expressed following activation of B or T cells. Macrophages are a primary source of TNF in response to toll-like receptor signaling, and T cells produce TNF when activated by antigenic stimuli. Fibroblasts also produce TNF in response to virus infection, and nonlymphoid tumor cells may ectopically express TNF. FasL is another example of a ligand with a varied cellular expression pattern. FasL is expressed by effector T cells and natural killer (NK) cells as a component of their cell lytic activity, yet FasL mRNA is also detected in reproductive organs and epithelium of the eye, which may use this TNFSF member to kill organ infiltrating inflammatory cells as a mechanism to dampen inflammation.

Signal Transduction Pathways

TNF receptors initiate signaling pathways that alter gene expression patterns, changing the differentiation status of a cell, as well as apoptotic pathways that terminate cellular life. The propagation of signals from receptor to enzymatically active proteins is mediated by two distinct types of signaling motifs in the cytosolic domain of the TNFR: DDs and TRAF-binding motifs. TNFR that contain a DD include Fas, TNFR1, DR3, and TRAILR1 and 2. Other TNFRs have TRAF recruitment motifs. Three basic schemes are used by TNF receptors to connect to enzymatically-driven signaling pathways (Fig. 27.5A). Adaptor molecules are required to establish the signaling connections between the receptor and signaling enzymes. The DD connects TNFR to cytosolic proteins containing a Death Effector Domain (DED), which in turn link to caspases (cysteine based, aspartic acid specific proteinases). Alternately, the TRAF proteins connect to the cytosolic domain of the TNFR, altering ubiquitin-dependent pathways that regulate key serine kinases that activate NFkB and AP1 transcription factors. The third scheme involves an indirect link between the death domain and TRAFs via the adaptor TNFR-associated death domain (TRADD).

The apoptotic and NF- κ B pathways activated by the TNFR family help regulate cellular homeostasis by controlling cell death and survival. In the immune system, apoptosis is essential for homeostasis and for eliminating antigen-bearing cells from the host. Many TNFR can induce activation of survival or death pathways depending in part on the differentiated state of that cell. In all nucleated cells, apoptosis is the default pathway; that is to say, all of the constituents of the pathway are expressed and ready to be activated (Fig. 27.6), whereas cellular survival requires transcriptional control of genes that encode regulatory proteins that suppress the progression of the apoptotic pathway.

Apoptosis

Ligation of TNFR promotes assemble of the death-inducing signaling complex (DISC) that promotes dimerization of procaspase 8 forming an active enzyme complex.⁴⁹ Activated caspase 8 acts directly to cleave procaspase 3 and 7, which are known as the executioner caspases as they directly cleave critical cellular substrates leading to apoptotic death. Caspase 8 also cleaves BID, a crucial connector to the mitochondria-associated death mechanism, which greatly amplifies the apoptotic process.⁵⁰ A cell must be capable of actively transcribing and translating genes to resist apoptosis signaling. A variety of genes can inhibit apoptosis and cell death pathways. For example, the cellular inhibitor of apoptosis (XIAP) is a direct caspase inhibitor that is regulated at the level of gene expression by transcription factor NF- κ B. Another regulator, FLIP (FLICE inhibitory protein), is also an NF-KB-regulated gene that contains a DED and a pseudocaspase domain that attenuates the apoptotic pathway by blocking conversion of procaspase 8 to the active form.⁵¹ Many viral pathogens parasitize the transcriptional capabilities of the cell and prevent the cell from making new survival proteins, allowing apoptosis to proceed. As expected,

viruses have evolved many different strategies to alter proapoptotic pathways (eg, viral orthologs of XIAP and FLIP prevent premature death of the cell) (see Fig. 27.6).

Cell Survival Signaling

Activation of transcription factors by TNFR utilizes the TRAF adaptors. There are seven members of the TRAF family (given numerical designations) that play key roles in regulating TNFR signaling and activation of host defenses. Each TRAF appears to play different roles in modulating signaling. Each TRAF protein contains a TRAF homology domain that binds TNFR and a RING and/or zinc finger domain characteristic of E3 ubiquitin ligases.^{52–54} Ubiquitination plays an essential role in regulating signal transduction by TNFR^{55,56} and in the pathogen recognition receptors as part of innate host defenses.⁵⁷

Clustering of the TNFR promotes the recruitment of TRAFs into a complex with the receptor through two different mechanisms. TRAF2, 3, and 5 bind directly to the receptor's cytosolic domain recognizing a consensus PXQS/T motif,⁵⁸ whereas TNFR1 uses TRADD to couple to TRAF2. TRAF3 and TRAF6 are preassociated with different proteins, including protein kinases involved in multiple signaling pathways including the pathogen recognition and interferon (IFN) pathways.^{53,59} TRAF adaptors link TNFR directly to protein kinase cascades, which in turn lead to activation of transcription factors including NF-κB and AP1.

The NF-KB family of transcription factors control expression of genes critical for cell survival, inflammatory, and immune responses. In mammalian cells, the NF-KB family consists of five members: RelA, RelB, c-Rel, p50/NFKB B1, and p52/NFkB B2 (proteolytic processing of p105 and p100 yields the active forms p50 and p52, respectively).^{60,61} Activation of NF-KB releases inhibitors that restrict nuclear translocation.62 Homo- and heterodimers of NF-KB family members are held inactive in the cytosol by inhibitors of κB (I κB), such as I $\kappa B\alpha$, that mask nuclear localization motifs on the NF- κ B dimers. A complex consisting of the kinase catalytic subunits IKK α and IKK β and the regulatory/scaffold subunit IKKy form the IKK complex that mediates phosphorylation and ubiquitination of IKB, leading to its degradation and release of the active transcription factor. IKB is the common target of a variety of signals that control the activation of the RelA NF-κB transcription factor, which in turn regulates expression of many proinflammatory genes within a signal responsive cell.⁶³

A distinct pathway regulates the activation of RelB NF- κ B through the NF- κ B-inducing kinase (NIK) and IKK α kinases. In unstimulated cells, NIK levels are maintained at vanishing low levels by ubiquitination and proteosome degradation through an E3 ligase complex comprised of TRAF3, TRAF2, and CIAP1/2.⁵² Receptor ligation releases the active form of NIK by competitively displacing TRAF3, preventing further ubiquitination and allowing NIK to accumulate.⁶⁴ NIK phosphorylates IKK α , which induces the proteosome dependent processing of p100 to p52, degrading the inhibitory domain of p100 and allowing the RelB/p52 complex to activate gene transcription.

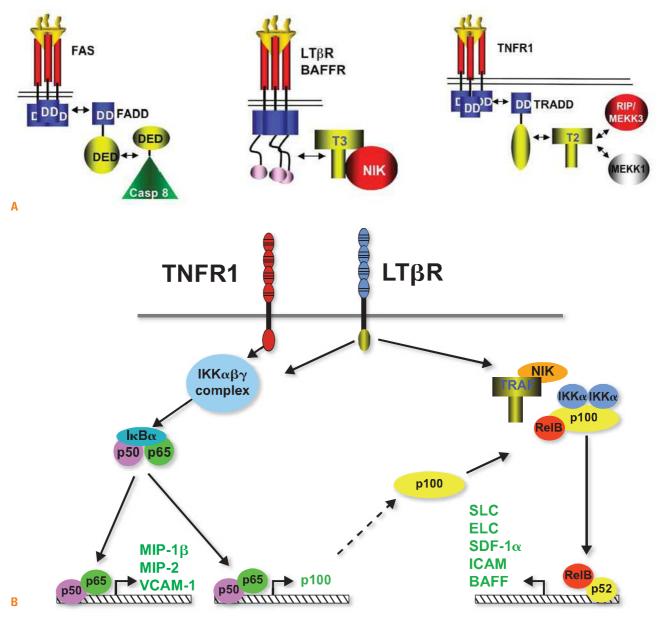

FIG. 27.5. Signaling Pathways and NF-κB. A: Adaptors link tumor necrosis factor receptors (TNFRs) to proteinases and kinases (upper panel). Three basic schemes link activated TNFRs to signaling pathways: the death inducing signaling complex formed with Fas is initiated by ligand clustering of Fas, promoting death domain (DD) interactions, which recruits Fas-associated death domain (FADD) (heterotypic interaction). The death effector domain of FADD links to the death effector domain of procaspase 8. The proximity of multiple procaspase 8 domains forms an active enzyme that can process other caspase 8 molecules. By contrast, TNFRs bind TNFassociated factor (TRAF) adaptors via short peptide motifs that release TRAF from associated kinases, such as NF-KB-inducing kinase (NIK). The third scheme is a combination of DD and TRAF recruitment. TNFR1 uses the DD protein TRADD to recruit RIP and TRAF2, promoting the activation of NF-kB. There are currently seven TRAF members with distinct interaction patterns with the TNFR family. TRAF proteins may function as regulators of key kinases. TRAF2, 3, and 6 function as modulators of several different kinases involved in toll-like receptor signaling, induction of type 1 interferon responses, and signaling by some TNFR family members. TRAF proteins contain an N-terminal RING finger motif, a coiled coil domain (isoleucine zipper), and the receptor association domain (TRAF) domain. The TRAF are trimers formed through their TRAF and coiled domains. The TRAF domain can bind to several different TNFR through a relatively short proline-anchored sequence that is responsible for binding directly to the mushroom head of various TRAF molecules.³⁴¹ The zinc RING of TRAF6 functions together with Ubc13 and Uev1A as ubiquitin E3 ligase targeting proteins for proteosome degradation. TRAF2, 3 and cIAP form the ubiquitin E3 ligase that targets NIK. Modified with permission from Ware CF. Tumor necrosis factors. In: Bertino JR, ed. Encyclopedia of Cancer. San Diego, CA: Academic Press, Inc.: 2002;475–489. B: NF-κB activation. TNFR1 and LTβR induce distinct forms of the NF-KB family of transcription factors. TNFR1 signaling is a potent activator of ReIA/p50 but does not activate the RelB pathway, whereas lymphotoxin β R can activate both. The RelA and RelB forms of the κ B family control transcription of distinct sets of genes; however, the two pathways are interrelated through the control of p100 expression by the RelA/p50 complex. Modified from Dejardin et al.66

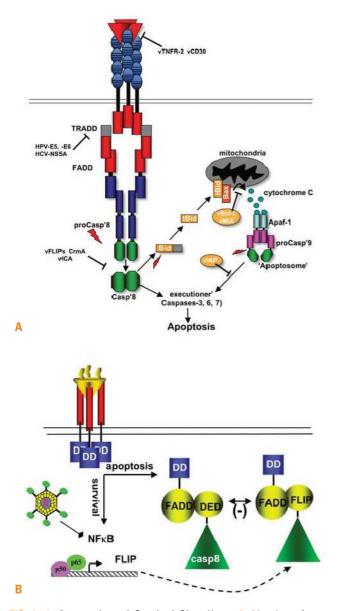

FIG. 27.6. Apoptosis and Survival Signaling. A: Ligation of tumor necrosis factor (TNF) receptor 1, Fas, or TNF-related apoptosis inducing ligand 1 and 2 activates apoptosis pathways. The nascent death-inducing signaling complex can directly cleave the executioner caspases 3, 6, and 7. Caspase 8 also cleaves BID to tBID, activating the mitochondrial regulated apoptotic pathway, dramatically accelerating cellular death. A number of viral proteins interfere with apoptosis induced through TNF pathway including human papilloma virus, hepatitis C virus, herpesvirus vFLIP, and virus orthologs of BCL2 and vMIA act on the mitochrondria. Adapted with permission.¹¹¹ B: The components of the apoptotic pathway are preformed in the cytosol enabling the cell to respond rapidly to death signaling. In contrast, the key regulators of the apoptotic pathway, including Bcl2 and inhibitor of apoptosis, require new gene expression controlled by NF- κ B. An important NF- κ B-induced gene is cellular FLIP, which contains a pseudocaspase domain. The cFLIP protein interferes with caspase 8 activation, blocking the prodeath pathway. If the cell is transcriptionally inactive or unable to activate NF- κ B, which often occurs in a pathogen-infected cell, then the proapoptotic pathway dominates the signals emanating from the TNF receptor 1 signaling complex leading to apoptosis and curtailing parasitism of the cell.

As examples, TNFR1 and LTBR activate separate yet related pathways that lead to distinct forms of NF-KB, the RelA/p50, and RelB/p52 complexes.⁶⁵ Each form of NF-κB activates a large number of genes with distinct roles in physiology (see Fig. 27.5B). TNFR1 signaling rapidly mobilizes (within minutes) the RelA/p50 complex, which controls expression of many proinflammatory and survival genes. By contrast, the processing of p100 and accumulation of nuclear RelB/p52 takes several hours after the initial stimulus. RelB-dependent genes are often involved in lymphoid tissue organogenesis and homeostasis. NIK is also required for NF-KB RelB and RelA activation by CD27, CD40, and BAFF-R, but not by TNFRI, which is restricted to activating RelA/p50 complex.^{66,67} Components of the NF-κB pathway, including TRAF3, cIAP, NIK, and A20, are frequently mutated in cancer, leading to constitutive expression of survival factors such as the BCL2 family.⁶⁸

THE IMMEDIATE LYMPHOTOXIN AND TUMOR NECROSIS FACTOR FAMILY

TNF (formerly TNF α or TNFSF2) and lymphotoxin (LT) α (formerly TNF β or TNFSF1) were originally pursued and characterized as inducers of tumor cell death, holding promise as antitumor therapeutics. However, the potent inflammatory action of TNF, particularly in the cardiovasculature, was quickly realized by the response of cancer patients injected with recombinant protein. We now recognize that TNF and LT α are two components of an interconnected network of "signaling circuits" that include LT-B, LIGHT (TNFSF14), and their specific receptors and regulatory proteins (Fig. 27.7). Each individual pathway has unique and cooperative signaling activities with other members of this immediate family. The immunologic processes controlled by this cytokine network are extensive, ranging from the development and homeostasis of lymphoid organs to the mobilization of innate defense systems to cosignaling activity promoting adaptive immune responses.^{69–71}

TNF, LT α , LT β , and LIGHT define the immediate group of TNF-related ligands that bind four cognate cell surface receptors with distinct but shared specificities. TNF and LT α both bind two distinct receptors, TNFR1 (p55-60, *TNFR1A*) and TNFR2 (p75-80, *TNFR1B*). The heteromeric LT $\alpha\beta2$ complex binds the LT β R, which also binds LIGHT (TNFSF14). LIGHT also engages the HVEM (TNFRSF14), which acts as a ligand for BTLA and CD160,³¹ an Ig superfamily member. Two distinct human herpesviruses, herpes simplex virus and cytomegalovirus, target the HVEM-BTLA pathway using different mechanisms^{35,72} (see Fig. 27.7).

TNF mediates a diverse range of cellular and physiologic responses linked to acute and chronic inflammatory processes. The diversity of responses is due in part to the broad expression of TNFR1 and the release of TNF as a soluble mediator where it can act in a systemic fashion. TNF production is triggered by many of the innate recognition systems, such as the toll-like receptors and by T and B cells. In chronic inflammation, TNF production can lead to tissue damage and organ failure. Genes expressed in response to TNF signaling

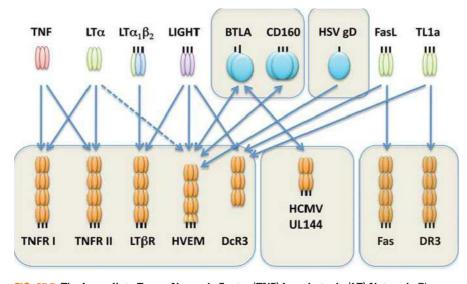

FIG. 27.7. The Immediate Tumor Necrosis Factor (TNF) Lymphotoxin (LT) Network. The cartoon depicts the signaling network formed between TNF, $LT\alpha$, $LT\beta$, and LIGHT, and their receptors. Each *arrow* indicates a ligand-receptor interaction. The network is defined by the extensive cross-utilization of ligand and receptors. Herpesvirus entry mediator (HVEM) forms a switch between positive cosignaling through LIGHT-HVEM interaction and inhibitory signaling through B- and T-lymphocyte attenuator (BTLA). LIGHT bound to HVEM activates TNF receptor–associated factor–dependent activation of NF- κ B, whereas HVEM-BTLA acts through an immunoreceptor tyrosine-based inhibitory motif of BTLA to recruit the phosphatase SHP2, attenuating kinases activated by T-cell receptor signaling. The herpes simplex viron envelope protein gD attaches to HVEM acting as an entry step for infection. UL144 gene of human cytomegalovirus binds BTLA, but not LIGHT, selectively mimicking the inhibitory pathway of HVEM-BTLA. Fas Ligand and TL1A are included in this network through their interaction with decoy receptor-3.

coordinate the physiologic responses during inflammation (Table 27.4). The responses will reflect the characteristic of the inflamed organ, the local or systemic source of TNF, and the duration of TNF signaling. Acute inflammatory responses involve rapid changes in hemodynamics (plasma leakage and edema) and leukocyte adherence, extravasation, and organ infiltration induced by TNF. TNF production during chronic inflammation may contribute to systemic metabolic derangements and wasting (cachexia) or loss of organ structure and function (bone erosion in joints of patients with rheumatoid arthritis [RA]). In some models, TNF can promote an inflammatory environment that promotes tumor formation.^{73–75}

Elucidation of the functions associated with this TNF/LT signaling network has been aided by studies with genetically modified mice engineered with null or transgene expression of the cytokine or receptor (Table 27.5). Deficiency in TNF or TNFR1, but not TNFR2, have similar phenotypes with alterations in host defense to intracellular bacterial pathogens, like *Listeria monocytogenes* and *Mycobacterium tuberculosis*, but surprisingly modest susceptibility to some viral pathogens. These results demonstrated a role for TNF in acute-phase response of the host defense system. In contrast, LT α -deficient mice showed a failure in formation of peripheral lymphoid organs, a phenotype not observed in mice deficient in either TNFR or TNF, which implicated the LT $\alpha\beta$ complex signaling through the LT β R as a key developmental pathway for lymphoid organogenesis.

$\label{eq:lambda} \begin{array}{l} \text{Lymphotoxin} \alpha\beta\text{-Lymphotoxin}\beta\text{R} \text{, A Mammalian Organ} \\ \text{Development Pathway} \end{array}$

Gene-deficient mice sharing a common phenotype of no lymph nodes revealed the framework of a signaling pathway involved in mammalian organ development. LT α -, LT β -, or LT β R-deficient mice fail to develop secondary lymphoid tissues.^{76,77} Several other knockout mice, including the transcriptional regulators Ikaros, ID2, and ROR γ t, also lack lymph nodes,^{78–82} as do mice deficient in components of the NF- κ B

activation pathway, including TRAF6, NIK, IKKα, and Rel B, and their gene targets. Target genes including CXCR5, the receptor for CXCL13, show defective lymphoid organ structure, as do CCR7-/-mice (receptor for CCL19/CCL21). The developmental program of secondary lymphoid organ formation initiates at 9 days post coitus progressing in organized fashion from dorsal to lateral movement, with intestinal Peyer's patches forming during the first postnatal week.83 The defect is irreversible in that transferring $LT\alpha\beta$ -sufficient bone marrow into an adult LT-mutant mouse failed to induce lymph node formation. Accumulating studies indicate that the formation of lymphoid organs involves two distinct cell types, an embryonic LTBR-expressing mesenchymal stromal cell that responds to $LT\alpha\beta$ expressed in a cell of hematopoietically derived lineage, termed the lymphoid tissue inducer cell. The lymphoid tissue inducer cell develops separately from lymphocytes and myeloid cells in a pathway dependent on ID2 and RORyt and different cytokines including interleukin (IL)7, RANK ligand (TRANCE, TNFSF11), and TNF. These cytokines induce surface $LT\alpha\beta$ in lymphoid tissue inducer cells that differentially engenders formation of lymph nodes and Peyer's patches.⁸⁴ Cells of the lymphoid tissue inducer lineage are maintained in the adult tissues at low levels (0.5%), presumably aiding in the homeostasis of lymphoid organs.^{85,86}

The microarchitecture of the white pulp in the spleen⁸⁷ is disrupted in LT- and TNF-deficient mice.⁸⁸ Multiple abnormal features of the architecture are observed in LT- and TNF-deficient mice, including missing macrophages in the marginal sinus and the loss of positional segregation of T and B cells into discrete zones. The segregation of T and B cells into discrete compartments depends on expression of the tissue organizing chemokines CCL19 and CCL21, which attract T cells, and CXCL13, which attracts B cells. CCL19

and CCL21 act through the chemokine receptor CCR7 expressed on T cells, and CXCL13 binds CXCR5 on B cells to promote localization in the follicles. An LT-chemokine circuit is formed by migration of B cells to $LT\beta R$ + stromal cells expressing CXCL13, which in turn induces expression of LT $\alpha\beta$ on B cells.^{89–91} Circulating B cells lack surface LT $\alpha\beta$, but expression is regained upon reentry into the CXCL13 rich microenvironment.⁹¹ The formation of the splenic microarchitecture depends on B-cell expression of $LT\alpha\beta$, which induces differentiation of specialized stromal cells (eg, secretion CCL20 and CXCL13 chemokines) in the spleen during postnatal maturation. Remodeling of the microarchitecture of the secondary lymphoid organs occurs during immune responses, which requires both TNF and LT pathways signaling on fibroblastic reticular cells.92 A viral pathogen, cytomegalovirus, can induce specific changes in the splenic microenvironment through modulation of CCL21 expression.⁹³

The LT β R and TNFR pathways facilitate lymphocyte entry into lymphoid tissues in part by modulating expression of adhesion molecules, such as peripheral node and mucosal addressins on high endothelial venules.⁹⁴ LTβR signaling is necessary to maintain networks of follicular DCs involved in capturing antigen and immune complexes that aid in activating B cells. These cellular interactions are further enhanced by $LT\beta R$ signals that provide growth signals for some conventional myeloid DC (CD8- subsets) within the lymphoid organ, whereas TNF plays a role in differentiation of DC progenitors in bone marrow.95

T and B cells can communicate with stromal and myeloid cells via the LT $\alpha\beta$ -LT β R pathway and thus modify their immediate microenvironment during the course of an immune response. Nonlymphoid tissues suffering from chronic inflammation associated with autoimmune disease, graft

rejection, or microbial infection often contain organized accumulations of lymphocytes reminiscent of secondary lymphoid organs, called tertiary lymphoid organs. Activated T and B cells provide the source of $LT\alpha\beta$ that helps drive the process of forming these structures, but as antigen is cleared, immune responsiveness subsides and these structures resolve. A gradation of features may be found in the tertiary lymphoid organs including presence of DCs, expression of chemokines, high endothelial venules, segregated regions of T and B cells, and germinal centers, but these structures typically lack the permanence of a lymph node. TNF also contributes to formation of granuloma that assists in walling off bacteria.⁹⁶ Thus, the $LT\alpha\beta$ and TNF pathways operative in embryonic life also play critical roles in the adult in the formation of tertiary lymphoid structures.

Influence of the Lymphotoxin $\alpha\beta$ Pathway on Lymphocyte Development

Mounting evidence indicates the $LT\alpha\beta$ -LT β R pathway contributes to the ontogeny of unconventional T cells, including $\gamma\delta$ T cells and invariant NK T cells, whereas conventional T cell subsets are normal in mice deficient in the TNF and LTBR pathways. The LTBR pathway seems to operate at distinct levels during thymic development.97 Double positive thymocytes regulate the differentiation of early thymocyte progenitors and $\gamma\delta$ T cells via the LT β R pathway,⁹⁸ yet the LTβR is not expressed in thymocytes, suggesting an indirect mechanism. In this regard, $LT\beta R$ signaling is required for the proper formation and function of the thymic stroma, which influences T-cell development.99 The thymic medulla appears to control the export of invariant NK T cells from the thymus.^{100,101} In addition, LTβR signaling in thymic stroma affects central tolerance to peripherally restricted antigens, which may be either dependent or independent upon the autoimmune regulator Aire.¹⁰² Thymic differentiation depends on the LTBR pathway to mediate the cellular communication between lymphoid and stromal compartments.

Autoimmunity

Dysregulated expression of several members of the TNFSF leads to autoimmune-like diseases in humans and animal models. For example, enforced expression of TNF or LIGHT, which overrides the normal transient expression, causes severe autoimmune and inflammatory processes in mice.^{103–105} LT α or LT $\alpha\beta$ transgenic expression in the pancreas leads to insulitis and formation of tertiary lymphoid structures.¹⁰⁶ These types of results have implicated members of the TNF superfamily as immune regulators and support the notion that LT $\alpha\beta$ and LIGHT pathways contribute to inflammation and tissue destructive processes.

Infectious Diseases

TNF is a major inflammatory cytokine required for the acutephase response to bacterial infection. For instance, lipopolysaccharide in gram-negative bacteria is a potent inducer of TNF secretion through the TLR4 innate recognition system. In mice, lipopolysaccharide induces a shock syndrome that is rapidly lethal owing to profound changes in blood circulation. However, mice survive lipopolysaccharide in the genetic absence of TNFR1 or if treated with an TNF-neutralizing antibody, indicating that host-derived TNF mediates pathogenesis.^{107–109} On the other hand, TNFR1 is essential for resistance to infection with a live organism, such as *Listeria monocytogenes*, through multiple processes including enhancement of phagocytosis and bacteriocidal destruction by macrophages. By contrast, T-cell immunity is not overtly impaired in TNFR1–/– mice. Humans treated with TNF inhibitors show some increase in susceptibility to selective pathogens, particularly *Mycobacterium tuberculosis*, reinforcing the role of TNF as a critical host defense system.¹¹⁰

In contrast, LT-deficient mice showed significant variability in susceptibility to individual pathogens (Table 27.6). Increased susceptibility resulted from either developmentally controlled aspects of lymphoid organ structure (eg, lymphocytic choriomeningitis virus, *Leishmania*) or a requirement for LT $\alpha\beta$ -LT β R pathway as an effector system in innate and adaptive immune systems (eg, murine cytomegalovirus). Viewed from an evolutionary perspective, this variation in the requirement for LT signaling may reflect specific contributions from the pathogen used to evade the broader TNF- and LT-dependent pathways.^{35,111}

TUMOR NECROSIS FACTOR SUPERFAMILY AND T-CELL COSIGNALING

Antigen recognition together with cooperating signaling "cosignaling" systems determine the quality of the adaptive immune responses. Lymphocyte responses to antigen are dynamic processes that start with the activation of naïve cells and transition through effector and memory phases. Cosignaling systems assist these phases by promoting more efficient engagement of antigen-binding TCR molecules to enhance initial cell activation and cell division (clonal expansion), augment cell survival (clonal contraction or memory cell differentiation), or induce effector functions such as cytokine secretion or killer function. Negative signals (inhibitory cosignaling) may also be delivered to T cells depending upon the particular system, which may prevent initial cellular activation or eliminate excess activated cells to dampen inflammation. Cosignaling can be quantitative, modifying thresholds of common signaling intermediates, or qualitative, involving signals distinct from other cosignaling systems or the TCR. Cosignaling receptors and ligands can be up- or downregulated at the transcriptional and protein levels depending on the stage of the T-cell response and the inflammatory milieu. In the absence of cosignaling, T cells may become unresponsive (anergic) or die.

The TNFRSR is one of two major families of cosignaling regulators that modulate T cells. The other cosignaling systems belong to the Ig superfamily, such as CD28,¹¹² cytotoxic T-lymphocyte (CTL)A-4,¹¹³ ICOS,¹¹⁴ PD1,¹¹⁵ and BTLA.^{116,117} TNFRSF members involved in T-cell cosignaling include OX40, 41BB, DR3, CD27, CD30, and HVEM,^{118–122} whereas CD40 and BAFFR are more involved in cosignaling in B lymphocytes.^{123,124} However, considerable crossover of activities in both lymphocyte populations can be demonstrated. Death

TABLE 27.6 Lympho	toxins in Host Defer	nse: Mouse Models		
Pathogen ^a	Mouse Model ^b	Susceptibility	Mechanism	Reference
Herpesvirus				
MHV68	LTα-/-	Minimal	nd	349

receptors such as Fas and TNFR1 are thought to be involved in clonal contraction through apoptosis of activated effector cells, although TNF via TNFR2 also shows costimulatory action in naïve T cells. In tissue culture models, several of the TNF-related signaling pathways show costimulatory activities for T cells, which probably reflects the common induction of NF- κ B–dependent survival genes, a common trait of TNFRSF members. However, analyses of physiologic models using genetically deficient mice reveal distinct roles for these molecules in the life cycle of T cells. Cosignaling systems are emerging as important targets to enhance immune responses to tumors or attenuate autoimmune diseases.^{114,125–129}

Expression and Function of Tumor Necrosis Factor Receptor Superfamily Cosignaling Molecules During Primary T-Cell Responses

The TNFRs encoded on Chr 1p36 share a common function as cosignaling systems for T cells.^{120,122} This region (human 1p36.33-1p36.21; syntenic with mouse 4E2-D3) contains the genes encoding GITR, OX40, HVEM, DR3, 41BB, CD30, and TNFR2, and is paralogous to the region on Chr 12p13 where genes for TNFR1, LT β R, and CD27 reside. The TNF-related ligands for these receptors are linked in the MHC paralogs on Chr 1, 6, 9, and 19, reflecting a common functional link as costimulatory molecules modulating T-cell differentiation (see Fig. 27.2).

Expression of TNFRSF members by T cells follows several distinct patterns during T-cell activation: expression on naïve T cells in peripheral lymphoid tissues (eg, CD27 and HVEM) that are upregulated or downregulated, respectively, following activation. OX40, 4-1BB, TNFR2, and CD30 are only expressed by T cells after initial activation¹²⁰; TNFR2 is rapidly downmodulated following cleavage by TACE-generating soluble receptors that modulate TNF availability. The differing time course of expression of these molecules determines the phase of when they act in T-cell differentiation.

Experimental activation of TNFRSF members can be achieved with agonist monoclonal antibodies. Antibodies specific to OX40, 4-1BB, CD30, or CD27 all augment T-cell clonal expansion and TCR-induced cytokine expression in tissue culture and mouse models. For example, CD27, which is expressed at very early stages of T-cell activation, mediates initial cytokine production, cell division, and/or survival,^{130,131} whereas OX40 and 4-1BB, which are expressed after cellular activation, promote T-cell survival and proliferation during the later stages of the primary response.^{132–134} CD30-CD30L interactions promote primary CD8+ T-cell expansion and with OX40 act to promote CD4+ T-cell memory,^{135,136} suggesting functional parallels with other TNFRSF molecules. Cowpox virus encodes a specific CD30 mimic to block the action of CD30L as part of its immune evasion strategy (see Table 27.6).

Death receptor-3 (DR3) engages TL1A, promoting IFN γ expression by proinflammatory TH1 cells in mouse¹³⁷ and humans,¹³⁸ especially in intestinal tissues.¹³⁹ Polymorphisms in TL1A are associated with inflammatory bowel disease.^{140,141} The LIGHT-HVEM-LT β R pathway is also associated with T-cell inflammatory processes in mucosal tissues.^{104,142} Similar cosignaling activities are reported for GITR,¹⁴³ with the potential of these systems to affect different subsets of T cells, such as GITR expression on T-regulatory subsets. The role of TNFRSF in regulating different T-cell subsets is an active area of research.

HVEM appears to play a role as an inhibitor of naïve T-cell activation through engagement of the Ig superfamily members BTLA and CD160.^{144,145} In this situation, HVEM acts as a ligand for BTLA, which limits signaling by antigen receptor-associated tyrosine kinases through a phosphatase recruitment domain (immunoreceptor tyrosine-based inhibitory motif) in its cytosolic tail.^{146,147} Naïve T cells coexpress HVEM and BTLA, forming an intrinsic complex that limits HVEM activation by its ligands expressed in the surrounding microenvironment. The BTLA binding site on HVEM is distinct from the position occupied by LIGHT, yet membrane LIGHT can disrupt the HVEM-BTLA complex, suggesting that HVEM acts as a regulatory switch between inhibitory and stimulatory cosignaling. Interestingly, like LIGHT, BTLA and CD160 can activate HVEM in trans, promoting cell survival gene expression in cells expressing HVEM.¹⁴⁸ This pathway appears particularly effective in controlling CD4 T-cell activation,144,149 but it is also important in regulating differentiating memory CD8 T cells.¹⁵⁰

T-Cell Memory

Cosignaling through several TNFRSF members promotes the differentiation of memory T cells. Mice deficient in OX40-OX40L, CD27-CD70, CD30-CD30L, or HVEM pathways all display defective memory responses to antigen.^{131,135,151-154} The OX40 system is illustrative of the costimulatory signals provided to T cells by these TNFR. Pharmacologic stimulation of OX40 with an agonist antibody or ligand during a primary antigen-specific response in mice enhances the generation of memory CD4 T cells.¹⁵⁵ The enhanced response of T cells includes increased accumulation of antigen-specific effector T cells producing effector cytokines such as IFNy at the site of inflammation.¹⁵⁶ Moreover, blockade of OX40-OX40L interactions during recall responses with monoclonal antibody specific to Ox40L ameliorates inflammation in models of collagen-induced arthritis157 and experimental allergic lung inflammation.¹⁵⁸ In OX40-deficient mice, CD8 T cells expand normally, but their accumulation and survival at later times in the primary response was significantly impaired. T cells from OX40-deficient mice also failed to fully differentiate as measured by loss of expression of effector cell surface markers and decreases in synthesis of cytokines and cytotoxic activity. By contrast, the formation of extrafollicular plasma cells, germinal centers, and antibody responses was independent of OX40. OX40 signaling induces transcription of survival genes such as BCL2 and survivin in T cells, which may serve as the key targets that allow memory cell differentiation.^{159,160}

The discovery that HVEM can elicit inhibitory signaling in T cells through engagement with the Ig family member BTLA highlights the possibility that, in certain situations, TNFRSF molecules can counter regulate the stimulatory actions during T-cell responses. Indeed, 4-1BB-deficient CD4+ T cells in some models are hyperresponsive,¹⁶¹ and stimulation of 4-1BB can suppress immune responses in several models of autoimmune disease.^{162–165} Although activation of 4-1BB enhances the expansion of human antiviral memory CD8+ T cells in vitro,¹⁶⁶ several studies demonstrate that the absence of 41BB in mice leads to enhanced T-cell responses,161,167 reminiscent of the phenotype associated with HVEM-deficient mice.^{168,169} Moreover, CD30 signals can, in some circumstances, suppress cytotoxic T-lymphocyte activity.¹⁷⁰ The expression of TNFRSF molecules such as GITR or OX40 on T-regulatory cells suggests that costimulatory pathways may enhance the suppressive function of these cells during immune responses.

Mouse models of autoimmune diseases such as EAE and diabetes uncover critical roles for OX40-Ox40L.^{171,172} Blockade of the CD27-CD70 pathway also ameliorates EAE through the suppression of TNF induction, but not T-cell priming.¹⁷³ Furthermore, blockade of OX40, 4-1BB, CD27, or CD30 costimulation can all reduce transplant rejection and/or graft-versus-host disease.^{174–177}

Stimulation of these pathways may also be applicable for the treatment of diseases such as cancer and infectious diseases where antigen-specific T-cell responses are ineffective. Stimulation of OX40, 4-1BB, CD30, and CD27 with agonist antibodies augments T-cell-mediated killing of a variety of tumors. The critical roles of the cosignaling TNF-TNFRSF members are discerned in immune responses to infectious pathogens. Similar to the immediate TNF family, the role of a specific cosignaling pathway in mediating protective T-cell responses during infection depends on the pathogen (Table 27.7).

CD40L AND BAFF SYSTEMS

The CD40 and BAFF systems play a major role in coordinating a range of costimulatory signals important to B-cell function, such as affinity maturation, isotype switching, Ig production, and clonal expansion.^{123,178-181} In common with other TNFSF members, the CD40 system (see Fig. 27.3) is a key communication mechanism in host defense, autoimmunity, and cancer. Often, these pathogenic processes are centered on the function of B cells. CD40 ligand maps to the X chromosome and is regulated at the transcriptional level by NFAT, resulting in inducible CD40 ligand expression by T helper cells that promotes humoral immunity. CD40 ligand is also expressed in a variety of other cells including activated B cells, endothelial cells, basophils, mast cells, and platelets. CD40 is expressed on many cells, prominently on B cells, and utilizes both TRAF3 and 6 to activate NF-KB and AP1 transcription factors, among other signaling pathways.^{182,183} Epstein-Barr virus, a B-cell-transforming herpesvirus, mimics the CD40 pathway though its LMP1 protein, driving naïve B cells into a memory state.¹⁸⁴⁻¹⁸⁶

Adapted from Croft.¹²⁰

CD40 signaling is necessary for induction of activationinduced cytidine deaminase, a key enzyme in class switching and somatic mutation of Ig genes. This process occurs in B cells in contact with T helper cells, which express CD40 ligand. The importance of CD40 system in the activity of B cells was revealed in patients with hyper-IgM syndrome. Several mutated genes underlie this syndrome including CD40 ligand and CD40,^{187,188} the RelA NF-κB activating kinase subunit, IKKy (NEMO), and activation-induced cytidine deaminase, among others.¹⁸⁹ Patients with hyper-IgM syndrome with mutated CD40L have elevated levels of IgM, often with no serum IgG, IgE, or IgA, and display increased susceptibility to bacterial and opportunistic infections. Treatment of these patients with passive transfer of human immune IgG corrects infection by bacteria, but not opportunistic pathogens, such as Pneumocystis *carinii*. This latter result reflects the importance of CD40 system in T-cell-mediated macrophage activation, which controls these opportunistic pathogens. In some patients with hyper-IgM syndrome, significant amounts of IgA and IgE are present in serum, even in the complete absence of CD40L, a result indicating that another mechanism(s) can induce Ig class switching. Evidence has emerged that the BAFF/APRIL system can induce Ig class switch independent of CD40 system.¹⁹⁰

Since the discovery of B-cell-activating factor of the TNFSF (BAFF, TNFSF13B; BLyS) and a proliferation-inducing ligand (APRIL, TNFSF13), much has been elucidated with regard to CD40L-independent isotype switching and B-cell development and survival in the periphery, as well as the implications of BAFF-APRIL dysregulation in autoimmune disease and lymphomas.^{124,191} Although human BAFF maps to Chr 13q34 and APRIL to 17p13.1, the proteins are strikingly more conserved (~50% homology) than other TNF ligands. TWEAK (TNF-related ligand with weak apoptosis activity) maps adjacent to APRIL, part of a clade of genetically similar members that also includes ectodermal dysplasin (EDA1/EDA2). BAFF and APRIL form homo- and heterotrimers that interact with multiple receptors to form a complex signaling circuit (see Fig. 27.3). Membrane BAFF is shed via a furin protease at the cell surface, while APRIL is

processed in the Golgi and secreted only in soluble form,¹⁹² although the receptor binding domain of APRIL can be membrane-anchored via an unusual splice variant with the TWEAK cytosolic and transmembrane domain (TWE-PRIL).¹⁹³ The significance of membrane-restricted local BAFF expression to systemic availability of soluble BAFF and APRIL remains to be established, although BAFF-APRIL heterotrimers are detected in serum from patients with systemic rheumatic diseases.⁷ BAFF and APRIL are inducibly expressed in monocytes, macrophages, DCs, and T cells in the spleen and lymph nodes in response to certain cytokines in different cell types, such as type I and II IFN, IL-10, and other TNF family members like CD40 and LTBR signaling. BAFF can be expressed in some B-cell-derived chronic lymphocytic leukemia cells, and some epithelial-derived cancer cell lines and primary tumor tissues express APRIL. Stromal cell expression of BAFF maintains the major mature B-cell pool, whereas inducible BAFF expression in myeloid cells aids in local B-cell survival at sites of inflammation.

Three cognate receptors mediate the biological actions of BAFF. BAFFR (TNFRSF13C), transmembrane activator and calcium signal modulating cyclophilin ligand interactor (TACI; TNFRSF13B), and B-cell maturation antigen (BCMA; TNFRSF17) are expressed on B cells and on other cell types. APRIL also engages matrix proteoglycans with weak binding, which may serve to enhance access to TACI and BCMA or function as a distinct receptor-ligand interaction.¹⁹⁴ Signaling through BAFFR and BCMA are required for B-cell survival and differentiation at different stages of B-cell–mediated humoral response. BAFFR–/– mice display an almost complete loss of mature and marginal zone B cells beginning from the late transitional phase of B-cell maturation, whereas BCMA deficiency impairs the survival of long-lived bone marrow plasma cells.^{195,196}

By contrast, APRIL–/– mice develop normally but have altered class switching to IgA.^{197,198} TACI signaling may antagonize BAFFR and BCMA, as TACI–/– mice have elevated numbers of mature B cells.¹⁹⁹ Both classical and alternative NF- κ B pathways have been implicated BAFFR and BCMA survival signals, with BCL2 expression rescuing the B-cell defect in BAFFR–/– mice. BAFFR and TACI engagement has also been shown to provide the necessary signals for CD40L-independent class switch recombination, to IgG and IgE for BAFFR, and IgG, IgE, and IgA for TACI, though IgA production seems specifically dependent upon APRIL-TACI interaction.²⁰⁰ BAFFR is also connected to promoting the B-cell coreceptor complex CD19/CD21/CD81, which binds to C3b-opsonized antigens to enhance rapid T-independent antibody responses. Overall impairment of T-independent antibody responses appears to be greatest in TACI-/- mice, and is dependent upon APRIL-TACI interactions in B1 B cells. BAFFR, and not TACI, has also been proven to be important in T cell costimulation in in vitro and in vivo mouse models of allograft rejection response, where BAFFR-/and BAFF-/-, but not TACI-/- nor BCMA-/-, mouse recipients prolong graft survival due to weakened alloproliferative response.²⁰¹

Elevated levels of BAFF and APRIL have been detected in the serum, and especially the synovial fluid, of patients suffering from inflammatory autoimmune disorders such as systemic lupus erythematosus, RA, Sjörgen syndrome, and multiple sclerosis.²⁰² These levels tend to correlate with increasing amounts of autoreactive antibodies in serum, and in mouse models of lupus and collagen-induced arthritis, soluble TACI-Ig treatment can lessen the severity of disease symptoms and progression.²⁰³ It is hypothesized that these excess quantities of BAFF and APRIL may contribute to the formation of autoreactive B-lymphocytes and loss of tolerance during development and perpetuating their survival as plasmablasts. Emerging evidence connects the BAFF and APRIL system to the pathology of B-cell-derived cancers like B-cell chronic lymphocytic leukemia, non-Hodgkin lymphoma, and multiple myeloma. Malignant myeloma cells express high levels of BAFF and APRIL and receive ligand-induced survival signals, with upregulation of antiapoptotic Bcl-2 and Mcl-1 molecules.204 Therefore, BAFF and APRIL may bolster tumor survival via autocrine and paracrine signaling mechanisms.

TWEAK-FN14 SYSTEM

The TWEAK-Fn14 system is emerging as an important signaling system between the immune system and epithelial and stromal tissues.²⁰⁵ TWEAK is limited to a monogamous interaction with Fn14, its cognate receptor, which is a fibroblast growth factor-2-inducible gene (see Fig. 27.3). Fn14 has one CRD and binds TWEAK homotrimers in a manner similar to BAFF, APRIL, and their receptors.^{206,207} TWEAK, like BAFF and APRIL, is cleaved by furin protease to produce an active soluble form.²⁰⁶ Human and mouse TWEAK share \geq 90% sequence identity in the receptor binding domain and manifest high affinity cross-species interaction to respective Fn14 homologues.¹⁹² The biologic functions of TWEAK-Fn14 system are broad and perhaps paradoxical, promoting both cell survival and death. TWEAK/Fn14 signaling induces apoptosis in some cancer lines (HT29, HSC3) and primary neurons.²⁰⁸⁻²¹⁰ TWEAK is produced primarily by leukocytes, whereas Fn14 expression is induced during inflammatory and tissue destructive processes. TWEAK-Fn14 system may provide important homeostatic functions to promote regenerative processes that conclude inflammatory responses. These homeostasis-promoting functions include induction of survival and growth in endothelial cells, migration and wound closure in endothelial cells, and angiogenesis.^{206,207} Fn14 contributes to the activation of progenitor cell types including liver, skeletal muscle, and mesenchymal lineage progenitors such as osteoblast, chondrocyte and adipocyte, and neuronal progenitors.

TWEAK regulates the shift from innate to adaptive immune responsiveness by repressing innate inflammatory cytokines (IL-12, IFNy) important in promoting TH1 immunity-a potential counterbalance to the proinflammatory actions of TNF.²⁰⁸ TWEAK may also have a potentiating influence in chronic tissue inflammation when dysregulated, such as its role in excessive demyelination and ultimate progression to excessive autoimmune encephalomyelitis.²¹¹ In a mouse collagen-induced arthritis model, elevated levels of TWEAK in serum correspond to severe disease progression and enhanced arthritogenic mediator molecules.²¹² In obese patients with type 2 diabetes, TWEAK-Fn14 signaling augments proinflammatory cytokine release by adipocytes.²¹³ In rats, TWEAK may prevent excessive luteinization after gonadotrophin-induced ovulation by controlling progesterone production.²¹⁴ The seemingly contradictory functions of TWEAK/Fn14 are less puzzling when TWEAK/Fn14 is viewed as an important signaling system that aids in achieving homeostasis following inflammation, as cell death and survival are essential for homeostasis.

DEATH RECEPTORS AND LIGANDS Fas Ligand and Fas System

The Fas (CD95, TNFRSF6)-Fas ligand (TNFSF6) system is an example of a direct signaling pathway to apoptotic cell death. The importance of the Fas-FasL system in immune regulation was revealed by the recognition that mice with the autoimmune-like disorders, lymphoproliferative (lpr) and generalized lymphproliferative disorder (gld) harbored mutations in Fas and Fas ligand and humans with the autoimmune lymphoproliferative syndrome have mutations in Fas.^{215–217} Mice with *lpr* or *gld* mutations display autoimmune phenotypes with high accumulation of activated T cells in the periphery and CD4-CD8- T cells in the lymph nodes (lymphoadenopathy) and autoantibody production. The Fas-FasL system is involved in proinflammatory responses, tumor survival, and nonimmune tissue homeostasis in osteoclastogenesis and angiogenesis.²¹⁸ Activated lymphocytes are particularly sensitive to Fas-induced apoptosis, suggesting a role for Fas in the clonal contraction phase of the immune response. The epithelial cells in the eye express FasL, which may limit inflammation in organs sensitive to immune damage. FasL is thought to be one of several proapoptotic systems used as a killing mechanism by cytotoxic T cells and NK cells. In primates, Fas ligand binds Fas and decoy receptor-3, which also binds LIGHT and TL1A.²¹⁹

FasL can undergo cleavage by matrix metalloproteases to produce soluble FasL, which may induce markedly different events when it engages Fas compared to the membrane-bound form, such as loss in cytotoxicity.²²⁰ Other findings suggest that soluble FasL may counteract the proinflammatory properties of membrane-associated FasL as an immunosuppressive, particularly in the eye and tumor environments.^{221,222} Conversely, Fas has also been linked to lymphoproliferation and lymphocyte activation via NF-κB–signaling pathways.

Essential biologic roles FasL-Fas include regulating lymphocyte homeostasis (via contraction of clonally expanded effector T and NK cells), directing CTL-mediated apoptosis and lysis (immune surveillance), and establishing immune privileged organs and sites. Fas is expressed in a wide variety of tissues such as the thymus, spleen, heart, and liver, whereas FasL can be found on activated T cells, NK cells, tumor cells, immune privileged sites, lung, and other tissues.^{218,223,224} In mature activated T and NK cells, Fas-FasL signaling plays a critical role in inducing apoptosis during the latter stages of inflammation, or activation-induced cell death, and shifts lymphocyte population numbers back to baseline.²²⁵ In certain organs like the liver, lung, and small intestine, FasL on stromal cells can be upregulated to control the overabundance of activated T cells after an inflammatory response and ultimately reduce tissue damage. Alternately, dysregulation during hepatitis C infections can lead to death of hepatocytes and acute liver damage.²²⁶ The Fas system has also been implicated in curtailing autoantibody production by damping T cell helper-induced B-cell activation and direct elimination of activated B cells, where CD40 stimulation also upregulates Fas expression.²¹⁸

The Fas-FasL system, together with perforin and granzymes, is a mechanism vital to CTL-mediated destruction and clearance of tumor and virally infected cells. Viruses have evolved multiple mechanisms of suppressing Fas signaling,¹¹¹ including downmodulation of Fas²²⁷ or blockade of caspase 8 activation.²²⁸ Tumor genome instability may lead to mutations that aid in escaping or resisting death pathways, conducive to developing the metastatic phenotype.²²⁹ Uterine and breast cancer patients may have elevated levels of soluble FasL and Fas, which may aid in neutralizing CTLand NK cell-induced lysis or even killing Fas-expressing effector cells. Herpes simplex virus-1 infection in vitro of human neonatal neutrophils upregulates Fas and FasL surface expression, leading to apoptosis, exemplifying a theme of pathogenic modulation of apoptotic signaling events to evade or attenuate immune response.²³⁰ FasL is constitutively expressed in the eye, central nervous system, testis, fetal trophoblast, and placenta, where any lymphocyte infiltration could lead to unrestricted, irreversible bystander damage to these tissues.²³¹ The implications of immune privilege have been applied to tissue transplantation rejection therapies; however, conflicting results as to whether FasL expression reduces likelihood of allograft rejection^{232,233} or potentates effector responses^{234,235} emphasize that induction of immune privilege by the Fas L system is complex. Fas-FasL interactions are at the core of graft-versus-host disease, where contaminating donor effector T cells in an allograft expand to damage the recipient's tissues. In a mouse model for acute graft-versus-host disease, p53-dependent upregulation of Fas on host stem cells leads to subsequent bone marrow depletion through FasL-mediated apoptosis.²³⁶ With regard

to tissue homeostasis, FasL has been reported to enhance RANKL-mediated osteoclastogenesis and differentiation in mouse bone marrow–derived macrophages.²³⁷ Fas is also implicated in pulmonary inflammatory diseases resulting in fibrosis after acute lung injury.²²³

TRAIL RECEPTOR SYSTEM

TRAIL (TNFSF10) is closely related to FasL and TNF based on sequence homology. Interest in TRAIL was spurred by its ability to selectively induce apoptosis in tumor cells.²³⁸ TRAIL binds five different receptors: TRAILR1 (DR4, TNFRSF10A), TRAILR2 (DR5, TNFRSF10B), TRAILR3 (DcR1, TNFRSF10C), TRAILR4 (DcR2, TNFRSF10D), and osteoprotegerin (OPG, OCIF, TNFRSF11B) (see Fig. 27.3). TRAILR1, 2, and 4 are type I transmembrane proteins and are membrane associated, whereas the more distantly related OPG is a dimeric, soluble decoy receptor. TRAILR3 is a type III transmembrane protein.239 TRAILR1 and 2 contain highly homologous DD in their cytoplasmic tails that form the death-inducing signaling complex^{240,241} responsible for apoptosis. TRAILR3 is anchored to the membrane via a glycophosphatidyl inositol tail, whereas TRAILR4 has a truncated, nonfunctional DD.^{219,242,243} The lack of a functional DD indicates TRAILR3 and 4 antagonize TRAIL-induced apoptosis. Alternative splicing is a common feature amongst TRAIL and its receptors, and is believed to regulate programmed cell death.²⁴⁴⁻²⁴⁶ The genetic organization of the TRAIL receptor loci in the mouse differs from that of the human. The mouse genome has TRAILR2, 3, and 4 homologues, but the TRAILR4 homologue does not bind TRAIL.

TRAIL-TRAILR signaling system induces apoptosis and to a lesser degree NF- κ B activation. For example, the apoptotic function of TRAIL system is necessary for regulating the response of memory CD8+ T cells to rechallenge with antigen. In the absence of CD4 T-cell help, CD8 T cells undergo apoptosis mediated by TRAIL.^{247,248} In much the same way as Fas, TRAILR death domains are thought to recruit FADD and initiator caspases 8 and/or 10 into the DISC to activate downstream effector caspases in apoptosis. Caspase 8 contribution to this process is well defined, but caspase 10 involvement was less so until recent studies in patients with autoimmune lymphoproliferative syndrome II and some carcinoma cell lines found that mutant caspase 10 ablates TRAIL-induced apoptosis.²⁴² In some cell types, the extrinsic mitochondrial pathway is important in amplifying DISC signals in TRAIL-induced apoptosis, which is analogous to mechanisms for Fas-FasL signaling.²⁴⁹ TRAIL is being intensely pursued as an anticancer therapeutic and has proved particularly potent in combination with chemotherapy, because TRAILR2 expression can be increased in response to deoxyribonucleic acid damage.250

TRAIL seems most involved in regulating immune homeostasis and immune surveillance, or clearing virally infected and cancerous cells. IFN γ treatment of tumor cells increases sensitization to TRAIL-induced death. This has been observed in melanoma and ovarian carcinoma cells,²⁴² and is analogous to Fas-FasL apoptotic signaling in the human colorectal carcinoma line, HT-29. IFN α possesses powerful antiviral and antitumor properties as well, and have been shown to upregulate TRAIL via JAK-STAT pathways in stimulated human multiple myeloma in vitro. TRAIL is also upregulated on NK cells in response to IFN_γ, enhancing antitumor effector function.²⁵¹

TL1A-DR3 SYSTEM

The TL1A-DR3 system provides essential signals that promote the expansion of effector T cells at the sites of inflammation.¹³⁹ However, the broad tissue expression profile of DR3 indicates its involvement is a range of cellular responses beyond T cells. TL1A (TNFSF15) is a paralog of FasL, LIGHT, and LT β , and its receptor, DR3, is a homolog of TNFR1. TL1A also binds decoy receptor-3, potentially limiting any TL1A signaling mediated by DR3. Gene deletion experiments of TL1A or DR3 in mice revealed poor T-cell responses, but no overt developmental abnormalities.^{137,252–254} Specific mutations in the ligand-binding domain of DR3 are linked to RA and interestingly appear to parallel other TNFRSF members and associated autoimmune pathologies.²⁵⁵

RANK LIGAND, RANK, AND OSTEOPROTEGERIN SYSTEM

OPG (TNFRSF11B) was initially identified as key mechanism regulating bone density²⁵⁶ (see Fig. 27.3). As a soluble receptor, OPG is a regulator of the RANK (receptor activator of NF-κB, TNFRSF11A) and RANK ligand (also known as TRANCE) signaling pathway involved in the differentiation of bone-resorptive osteoclasts from hematopoietic progenitors (osteoclastogenesis).²⁵⁷⁻²⁵⁹ However, this system is also crucial for development of mammary glands,²⁶⁰ lymph nodes, and DC-T-cell interactions.^{261,262} Bone remodeling needed to sustain skeletal integrity and calcium homeostasis is regulated by a dynamic equilibrium between osteoblasts (bone forming) and osteoclasts (bone resorbing), which is regulated by RANKL-RANK-OPG system. Dysregulation of the RANKL-RANK-OPG system has consequences in inflammatory, osteologic, and cancer pathophysiology, such as bone loss in inflammatory autoimmune diseases, preferential breast and prostate tumor metastasis to the bone, and gender bias in osteoporosis.

OPG functions as a decoy receptor that binds RANKL with high affinity, and also binds TRAIL, albeit at low affinity in comparison to RANKL.^{263,264} Despite such a weak binding, in vitro studies show that OPG can block TRAIL-mediated apoptosis, which suggests the OPG-TRAIL system contributes to osteoclastogenesis. RANK interacts with TRAF2, 5, and 6. The membrane-proximal TRAF site is highly specific for TRAF6, and several studies have shown TRAF6 to be essential in RANKL-RANK signaling in osteoclastogenesis and lymph node genesis.^{265,266} Several "osteotropic" factors have been reported to regulate RANKL and OPG expression in osteoblast and osteoclast lineages, such as transforming growth factor β , IL-1, TNF, estrogen, prostaglandin E2, glucocorticoids, and vitamin D3.^{265,267} In a few cases, OPG and RANKL are differentially modulated by the same factor;

for example, parathyroid-related protein increases RANKL while decreasing OPG mRNA expression in osteoclast-like odontoclasts.²⁶⁸ The components in the RANK signaling triad are widely expressed. RANK is upregulated on CD40L-stimulated maturing DCs, while RANKL is upregulated during T-cell activation and is constitutively expressed in some tumors and mammary gland epithelial cells.

RANK-/- and TRAF6-/- mice lack NF-κB activation in osteoclasts and exhibit abnormally high bone density (osteopetrosis).^{269,270} Osteoblasts and stromal cells stimulate differentiation via direct cell contact with osteoclast precursors. Macrophage colony stimulating factor cooperates with RANKL-expressing osteoblasts to transmit positive signals through c-Fms and RANK expressed on precursors promoting their differentiation,²⁵⁹ whereas OPG negatively regulates by competitively binding RANKL, thus ablating all signals through RANK. RANK-/- and RANKL-/- mice phenocopy each other, displaying severe osteopetrosis due to the lack of osteoclasts.²⁷¹ Complementing the observations in RANKL and RANK deficiencies, OPG blocks osteoclast differentiation in a dose-dependent manner. OPG overexpression in transgenic mice causes acute osteopetrosis, while OPG-deficient mice suffer from osteoporosis due to excessive osteoclastogenesis. In humans, OPG and RANK mutations are linked to juvenile Paget disease, familial expansile osteolysis, and other osteolytic disorders.^{258,265}

The RANKL-RANK system is proving to be an important enhancer of cell-mediated immune responses by promoting DC survival and naïve T-cell proliferation. RANKL stimulates DCs to produce proinflammatory cytokines like IL-12.^{272,273} The RANK pathway may serve to bolster CD40-CD40L interaction between DC and T cells after T-cell receptor stimulation, or prolong survival of activated DCs to ensure the establishment of T-cell memory. For instance, in CD40L–/– mice, RANKL-RANK costimulation is protective against *Leishmania* infection by inducing IL-12 secretion and consequent T_H1 immune response.²⁷⁴

Bone loss in autoimmune and infectious models of inflammatory disease is mediated through slightly different mechanisms. In recent studies, activated, CD4+RANKL+ T cells have been shown to support osteoclastogenesis and mediate bone loss in humanized mouse models of *Actinobacillus*-specific periodontal disease, suggesting a role for T_H1 immunity in inflammatory bone destruction.^{275,276} In patients with human immunodeficiency virus, the viron envelop gp120 induces disease-related osteoporosis via induction of RANKL on CD4+ T cells and augmentation of osteoclastogenesis.²⁷⁷

In mouse models of tumor metastasis, high OPG and RANK levels are risk factors for metastasis to the bone and subsequent osteolysis, especially in breast tumors.²⁷⁸ OPG from human bone marrow stroma can protect prostate tumors from TRAIL-mediated apoptosis,²⁷⁹ and treatment with anti-TRAIL neutralizing antibodies reduces osteoclastogenesis in mixed lymphocyte-bone marrow cultures from patients with multiple myeloma, presumably by interfering with OPG-TRAIL complexes formed by activated T cells expressing TRAIL, OPG, and RANKL.²⁸⁰ The

TABLE		tic Diseases Associated or Necrosis Factor	
System	Disease	Mutation	
TNFR1	Familial periodic fever	Mutation in first cysteine-rich domain	
CD40 Ligand	Hyper-IgM syndrome	Multiple mutations affect- ing receptor binding and processing	
EDA	X-linked hypohidrotic ectodermal dysplasia	Multiple mutations affecting receptor binding, trimerization, and secretion	
RANK	Familial expansile osteolysis	Mutation in the signal peptide	
Fas	Autoimmune lymphoproliferative syndrome	Multiple mutations/ deletion in Fas	

CD, cluster of differentiation; EDA, ectodermal dysplasin A; Ig, immunoglobulin; TNFR, tumor necrosis factor receptor.

RANKL-RANK-OPG system has also been implicated in diabetes-associated osteopenia, as serum levels of OPG are higher in patients with type I and II diabetes.²⁸¹ Interestingly, these patients are at greater risk for developing atherosclerotic plaques, which is perhaps reflected in the phenotype of OPG-deficient mice. These mice suffer from arterial calcification,²⁸² presumably from unrestricted bone resorption and calcium release. Although elevated endogenous OPG levels are considered a risk factor in certain disease manifestations, the complexity of the cytokine networks that regulate RANKL-RANK-OPG interactions and vice versa render the clinical data difficult to interpret.

TUMOR NECROSIS FACTOR SUPERFAMILY IN THE THERAPY OF HUMAN DISEASE Tumor Necrosis Factor Inhibitors

The TNFSF is associated with a wide range of human diseases, evidenced by genetic deficiencies or mutations in individual components of the TNFSF and in the therapeutic efficacy of TNF inhibitors in autoimmune diseases (Table 27.8). Although cancer therapy was the original motivation in developing TNF, the success of TNF inhibitors in limiting symptoms in several autoimmune diseases provides significant motivation to explore therapeutics targeting other members of the TNFSF, currently an active area of research. Research into the function of TNFSF in human diseases is providing strong rationale for testing both inhibitors and agonists of these cytokines (Table 27.9).

TNF inhibitors are specific antibodies or soluble receptors and are classified as biologics (protein-based drugs). These biologic-based drugs provide specificity and desirable pharmacodynamic properties (Fig. 27.8). Both antibody- and receptor-based drugs function as competitive antagonists, sterically hindering the binding of ligand to receptor. The approved antibody-based drugs include a partially humanized mouse monoclonal antibody to human TNF (infliximab), two fully human antibodies (adalimumab and golimumab), and a monovalent Fab fragment of a TNF antibody (certolizumab pegol). Certolizumab is derivatized with polyethylene glycol to enhance half-life. To create a soluble "decoy" receptor, the extracellular domain of TNFR-2 was genetically linked to the Fc region of human IgG1, forming a bivalent molecule (etanercept) that has higher avidity for TNF than naturally occurring soluble receptors. Etanercept binds both TNF and LTa, whereas anti-TNF antibodies are specific for TNF and do not cross-react with $LT\alpha$.

Fab-PEG, fragment of antibody polyethyleneglycoylated; IBD, inflammatory bowel diseases; LT, lymphotoxin; Ps, psoriasis; RA, rheumatoid arthritis; TNF, tumor necrosis factor; TNFR, tumor necrosis factor receptor superfamily.

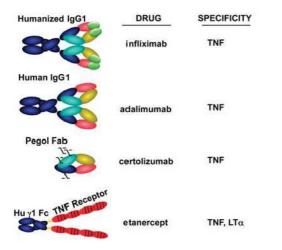

FIG. 27.8. Tumor Necrosis Factor (TNF) Inhibitors. The diagram depicts the structural features of the antibody- and receptor-based drugs targeted at TNF that are approved for use in patients with autoimmune diseases. Monoclonal antibody specific for human TNF derived from mice and partially humanized (infliximab), a fully human antibody (adalimumab) containing both heavy and light immunoglobulin chains, and an antibody-binding fragment (Fab) of a human anti-TNF antibody (certolizumab). Certolizumab is monovalent and derivatized with polyethyleneglycol to extend half-life in vivo. TNF decoy receptor (etanercept) created as a genetic fusion protein of the ectodomain of TNF receptor 2 with the Fc region of human immunoglobulin G1 forms a disulfide-linked dimer. Both immunoglobulin and receptor-based inhibitors are approved for use in treating autoimmune diseases: rheumatoid arthritis, psoriasis, and inflammatory bowel diseases.

Bivalent antibodies directed to TNFRs can function as agonists, mimicking the ligand but specific for a single receptor, a feature that may distinguish an antibody from ligand such as TRAIL, which has multiple receptors. Moreover, antibodies are inherently more stable than the native ligand, providing better pharmacodynamics (serum half-life and bioavailability). Agonist receptor antibodies (eg, anti-TRAILR, anti-Ox40) are in preclinical studies and clinical trials.

Impact of Tumor Necrosis Factor Blockade in Inflammatory Diseases

TNF inhibitors are approved for use in the treatment of RA, psoriatic arthritis, ankylosing spondylitis, juvenile rheumatoid arthritis, Crohn disease, and ulcerative colitis. RA is a chronic autoimmune joint disease that occurs in genetically predisposed individuals. Treatment of RA is usually initiated with disease-modifying antirheumatic drugs such as methotrexate or corticosteroids to improve symptoms and reduce joint damage. The American College of Rheumatology uses clinical and laboratory measures to assess improvement in response to therapy in RA. A patient with a 70% or greater improvement according to these parameters is designated as having an ACR-70 response. TNF inhibitors in combination with methotrexate (the most widely used disease-modifying antirheumatic drugs) produce ACR-70 responses in 33% to 40% of patients with early RA and in 10% to 27% in established RA. In comparison to patients receiving methotrexate alone, the ACR-70 responses occurred in 19% to 21% of early RA patients and fewer than 5% of patients with established disease.²⁸³ In RA, joint damage begins early in the disease course as articular erosions when visualized by radiographic techniques in 40% of patients in the first year of disease and 90% by the second year.²⁸⁴ TNF inhibitors slow radiographic progression in RA.²⁸⁵ Interestingly, in a randomized controlled trial of 428 patients with active RA, the combination of infliximab and methotrexate reduced the radiographic progression.²⁸⁶

The inflammatory bowel diseases, ulcerative colitis (limited to colon and bowel), and Crohn disease (entire intestine) are chronic inflammatory conditions where TNF is disproportionately expressed when the disease is active. Monocytes from patients with inflammatory bowel disease produce significantly higher levels of TNF after stimulation by lipopolysaccharide.²⁸⁷ The formation of fistulating inflammatory granulomas is a pathologic feature of Crohn disease. Clinical trials demonstrated an initial response in 59% to 69% of patients, and a dose-dependent clinical remission that ranged between 28% to 38% in nonfistulating Crohn disease and 64% to 97% of patients with complete fistula disease, when categorized by location.^{288,289} In ulcerative colitis, controlled trials (800 patients with active ulcerative colitis) showed an initial response in 8 weeks with 65% response in patients treated with anti-TNF (infliximab) versus 35% in the placebo group, with remission achieved in 35% and 15% in patients treated with infliximab and placebo, respectively.290 Anti-TNF (adalimumab) was efficacious in controlled trials in patients with moderate to severe Crohn disease.²⁸⁸ By contrast, soluble TNFR2-Fc (etanercept) at doses known to be effective in RA failed to produce benefit in a controlled trial for Crohn disease.²⁹¹

Erythrosquamous lesions containing infiltrating leukocytes and epidermal hypertrophy characterize psoriasis, a chronic inflammatory skin disease. Skin lesions of psoriatic patients contain elevated levels of TNF, and following treatment with TNF inhibitors, serum and skin levels of TNF decrease with remarkable clinical response.^{292,293} A significant subset of patients with psoriasis develops inflammatory, erosive arthritis.²⁹⁴ In clinical trials, both etanercept and infliximab significantly inhibited disease activity and improved the quality of life in patients with psoriatic arthritis.^{295–299}

Serious Adverse Effects

TNF inhibitors are inherently safe because of their specificity. However, side effects occur with the use of TNF inhibitors and include lupus-like syndrome, aplastic anemia, hepatotoxicity, interstitial lung disease, optic neuritis, and exacerbations of quiescent multiple sclerosis. TNF inhibition is associated with diminished host defense, perhaps expected based on the role of TNF in innate and adaptive immune responses. The rate of serious skin and soft-tissue infections is higher in treated patients, and there is an increase risk of intracellular bacterial infections, primary tuberculosis and reactivation of latent Mycobacterium tuberculosis among patients treated with TNF inhibitors.^{300,301} Risk due to infection can be minimized and controlled (eg, a tuberculosis skin test prior to treatment in patients that have not been previously vaccinated for *Mycobacterium*). The contribution of anti-TNF therapy to the increase the risk of cancer is still unclear. A systematic review of randomized clinical trials using infliximab and adalimumab found a dose-related increase of malignancies in patients with RA patients.³⁰² Some of the increase risk of malignancy (ie, lymphoma) is difficult to dissect due to the increased association of lymphoma with RA.³⁰¹ TNF has been implicated in the pathogenesis of cardiac dysfunction, in part due to the negative ionotropic activities in vitro and in vivo; however, TNF blockade significantly increased the incidence of cardiac death. This observation led to the recommendation that TNF inhibitors be discontinued in patients with cardiac dysfunction.³⁰³⁻³⁰⁵ Limiting adverse effects have been observed with biologics targeting other TNFSF members. Although interference with CD40L ameliorated autoimmune disease and allograft rejection in animal models,³⁰⁶⁻³¹⁰ anti-CD40L had an unacceptable impact on platelet function in transplantation and autoimmune diseases. The use of monovalent Fab of anti-CD40L may avoid these problems.^{311–313} Another TNFRSF member, OPG, was dropped out of clinical investigation because the recombinant protein induced antibody responses that limited its therapeutic effects. Thus, dose- or mechanism-limiting toxicities can impact physiology in unanticipated ways, limiting successful clinical outcomes.

Anti-RANK Ligand

The central function of RANK-RANKL system in osteoclastogenesis has led to the development of anti-RANKL antibodies to treat bone-resorbing conditions. Human anti-RANKL monoclonal antibody (denosumab) to disrupt RANKL-RANK signaling has been approved for the treatment of osteoporosis in postmenopausal women and for treatment of skeletal changes from metastasis of solid tumors. Anti-RANKL therapy reduces osteoclastic bone resorption, thereby increasing bone mineral density at both the lumbar spine and the hip. Treatment with anti-RANKL for 36 months decreased the risk of vertebral, nonvertebral, and hip fractures.³¹⁴ There is no apparent increased risk of cancer or serious infection associated with anti-RANKL therapy in subjects with osteoporosis, although longer study periods are needed.

Treatment of patients with prostate cancer with androgen deprivation therapy and patients with breast cancer with aromatase inhibitors leads to increased bone loss and increased risk of fracture. Anti-RANKL is prescribed to increase bone mass both of these patient populations.^{315,316} In a double-blind phase III clinical trial, women with nonmetastatic breast cancer who received anti-RANKL therapy had an increased lumbar spine bone mineral density of 7.6% after 24 months of treatment compared to placebo.³¹⁶ Similarly, patients with prostate cancer on androgen deprivation therapy that were treated with anti-RANKL in a phase III clinical trial had increased bone mineral density at all measured sites (hip, femoral neck, radius, and whole body) compared to placebo.³¹⁵ Anti-RANKL reduced the overall risk of bone fracture in the prostate cancer trial, while the phase III trial of patients with breast cancer treated with aromatase inhibitors was not designed to evaluate risk of fracture.^{315,316}

In addition to patients with prostate and patients with breast cancer undergoing hormone deprivation therapy, anti-RANKL aids in prevention of skeletal-related events in patients with bone metastasis from solid tumors.^{317–319} Three independent phase III clinical trials compared anti-RANKL with zoledronic acid, a drug prescribed to alleviate bone pain and reduce fracture risk in cancer patients with bone metastasis.^{317–319} Anti-RANKL therapy delayed the time to the first skeletal changes in patients with metastatic breast cancer and metastatic, castration-resistant prostate cancer.^{317,319} In a third phase III trial of patients with solid tumors (excluding breast and prostate) or multiple myeloma, anti-RANKL was equivalent to zoledronic acid in reducing fracture risk.³¹⁸

Anti-BAFF

Systemic lupus erythematous is characterized by hyperreactive B cells, production of antideoxyribonucleic acid antibodies, and overproduction of BAFF.^{320,321} The anti-BAFF antibody (belimumab) was approved in 2011 for the treatment of systemic lupus erythematosus, becoming the first new drug to gain approval for the condition in 56 years. In a phase III clinical trial, anti-BAFF decreased the rate of disease flares and increased the time between disease flares compared with placebo.³²² Anti-BAFF treatment increased systemic lupus erythematosus responder index (a reduction of SELENA-SLEDAI score of four or more points) compared to placebo.³²²

Tumor Necrosis Factor Superfamily in Cancer Therapy

Tumor angiogenesis, the formation of vessels to support cancer growth, is a process essential for tumor growth. The ability of TNF to induce apoptosis of tumor-associated endothelial cells can result in the impairment of the tumor vasculature leading to necrosis of the tumor. This mechanism involves perturbation of cell-cell adhesive junctions and inhibition of $\alpha v\beta 3$ -integrin signaling in tumorassociated vessels.323 However, clinical phase I and II studies in cancer patients receiving recombinant TNF reported "septic shock-like syndrome," a dose-limiting toxicity in quantities 10 times lower than the calculated antitumor dose extrapolated from animal studies.^{324,325} Animal studies also revealed the strong hemodynamic effects of TNF in the mediation of septic shock.³²⁶ Although there are anecdotic reports of tumor regression following TNF administration,³²⁷ due to the induction of vasoplegia, TNF use as an antitumor agent has been limited to treatment of locally advanced tumors by isolated limb perfusion, which limits systemic toxicity of TNF.328

A number of studies are in progress to determine whether TRAIL and its death receptors can be used in treatment of cancer.³²⁹ In phase 1/2 studies, TRAIL and agonist mAb to TRAILR1 or R2 showed no dose-limiting toxicities.^{330–333}

Early clinical trials are in progress for other members of the TNFSF. For example, antibodies to LT α and LT β R-Fc decoy are in clinical trials for suppressing inflammation in autoimmune diseases. Agonist antibodies to OX40 appear promising for induction of tumor immunity.³³⁴ Redirecting T cells using a retroviral-based vector incorporating 41BB can eliminate leukemic cells.³³⁵ It is not surprising that several other TNFSF systems are being targeted to modify inflammatory, infectious, and malignant diseases.
