Preface to Handbook of Child Psychology, *Sixth Edition*

WILLIAM DAMON

Scholarly handbooks play several key roles in their disciplines. First and foremost, they reflect recent changes in the field as well as classic works that have survived those changes. In this sense, all handbooks present their editors' and authors' best judgments about what is most important to know in the field at the time of publication. But many handbooks also influence the fields that they report on. Scholars—especially younger ones—look to them for sources of information and inspiration to guide their own work. While taking stock of the shape of its field, a handbook also shapes the stock of ideas that will define the field's future. It serves both as an indicator and as a generator, a pool of received knowledge and a pool for spawning new insight.

THE *HANDBOOK*'S LIVING TRADITION

Within the field of human development, the *Handbook of Child Psychology* has served these key roles to a degree that has been exceptional even among the impressive panoply of the world's many distinguished scholarly handbooks. The *Handbook of Child Psychology* has had a widely heralded tradition as a beacon, organizer, and encyclopedia of developmental study for almost 75 years—a period that covers the vast majority of scientific work in this field.

It is impossible to imagine what the field would look like if it had not occurred to Carl Murchison in 1931 to assemble an eclectic assortment of contributions into the first *Handbook of Child Psychology.* Whether or not Murchison realized this potential (an interesting speculation in itself, given his visionary and ambitious nature), he gave birth to a seminal publishing project that not only has endured over time but has evolved into a thriving tradition across a number of related academic disciplines.

All through its history, the *Handbook* has drawn on, and played a formative role in, the worldwide study of human development. What does the *Handbook*'s history tell us about where we, as developmentalists, have been, what we have learned, and where we are going? What does it tell us about what has changed and what has remained the same in the questions that we ask, in the methods that we use, and in the theoretical ideas that we draw on in our quest to understand human development? By asking these questions, we follow the spirit of the science itself, for developmental questions may be asked about any endeavor, including the enterprise of studying human development. To best understand what this field has to tell us about human development, we must ask how the field itself has developed. In a field that examines continuities and changes, we must ask, for the field itself, what are the continuities and what are the changes?

The history of the *Handbook* is by no means the whole story of why the field is where it is today, but it is a fundamental part of the story. It has defined the choices that have determined the field's direction and has influenced the making of those choices. In this regard, the *Handbook*'s history reveals much about the judgments and other human factors that shape a science.

THE CAST OF CHARACTERS

Carl Murchison was a scholar/impresario who edited *The Psychological Register;* founded and edited key psychological journals; wrote books on social psychology,

politics, and the criminal mind; and compiled an assortment of handbooks, psychology texts, autobiographies of renowned psychologists, and even a book on psychic beliefs (Sir Arthur Conan Doyle and Harry Houdini were among the contributors). Murchison's initial *Handbook of Child Psychology* was published by a small university press (Clark University) in 1931, when the field itself was still in its infancy. Murchison wrote:

> Experimental psychology has had a much older scientific and academic status [than child psychology], but at the present time it is probable that much less money is being spent for pure research in the field of experimental psychology than is being spent in the field of child psychology. In spite of this obvious fact, many experimental psychologists continue to look upon the field of child psychology as a proper field of research for women and for men whose experimental masculinity is not of the maximum. This attitude of patronage is based almost entirely upon a blissful ignorance of what is going on in the tremendously virile field of child behavior. (Murchison, 1931, p. ix)

Murchison's masculine allusion, of course, is from another era; it could furnish some good material for a social history of gender stereotyping. That aside, Murchison was prescient in the task that he undertook and the way that he went about it. At the time Murchison wrote the preface to his *Handbook,* developmental psychology was known only in Europe and in a few forward-looking American labs and universities. Nevertheless, Murchison predicted the field's impending ascent: "The time is not far distant, if it is not already here, when nearly all competent psychologists will recognize that one-half of the whole field of psychology is involved in the problem of how the infant becomes an adult psychologically" (Murchison, 1931, p. x).

For his original 1931 *Handbook,* Murchison looked to Europe and to a handful of American centers (or "field stations") for child research (Iowa, Minnesota, the University of California at Berkeley, Columbia, Stanford, Yale, Clark). Murchison's Europeans included a young "genetic epistemologist" named Jean Piaget, who, in an essay on "Children's Philosophies," quoted extensively from interviews with 60 Genevan children between the ages of 4 and 12 years. Piaget's chapter would provide American readers with an introduction to his seminal research program on children's conceptions of the world. Another European, Charlotte Bühler, wrote a chapter on children's social behavior. In this chapter, which still is fresh today, Bühler described intricate play and communication patterns among toddlers, patterns that developmental psychology would not rediscover until the late 1970s. Bühler also anticipated the critiques of Piaget that would appear during the sociolinguistics heyday of the 1970s:

> Piaget, in his studies on children's talk and reasoning, emphasizes that their talk is much more egocentric than social . . . that children from 3 to 7 years accompany all their manipulations with talk which actually is not so much intercourse as monologue . . . [but] the special relationship of the child to each of the different members of the household is distinctly reflected in the respective conversations. (Buhler, 1931, p. 138)

Other Europeans included Anna Freud, who wrote on "The Psychoanalysis of the Child," and Kurt Lewin, who wrote on "Environmental Forces in Child Behavior and Development."

The Americans whom Murchison chose were equally notable. Arnold Gesell wrote a nativistic account of his twin studies, an enterprise that remains familiar to us today, and Stanford's Louis Terman wrote a comprehensive account of everything known about the "gifted child." Harold Jones described the developmental effects of birth order, Mary Cover Jones wrote about children's emotions, Florence Goodenough wrote about children's drawings, and Dorothea McCarthy wrote about language development. Vernon Jones's chapter on "children's morals" focused on the growth of *character,* a notion that was to become lost to the field during the cognitive-developmental revolution, but that reemerged in the 1990s as the primary concern in the study of moral development.

Murchison's vision of child psychology included an examination of cultural differences as well. His *Handbook* presented to the scholarly world a young anthropologist named Margaret Mead, just back from her tours of Samoa and New Guinea. In this early essay, Mead wrote that her motivation in traveling to the South Seas was to discredit the views that Piaget, Levy-Bruhl, and other nascent "structuralists" had put forth concerning "animism" in young children's thinking. (Interestingly, about a third of Piaget's chapter in the same volume was dedicated to showing how Genevan children took years to outgrow animism.) Mead reported some data that she called "amazing": "In not one of the 32,000 drawings (by young 'primitive' children) was there a single case of personalization of animals, material phenomena, or

inanimate objects" (Mead, 1931, p. 400). Mead parlayed these data into a tough-minded critique of Western psychology's ethnocentrism, making the point that animism and other beliefs are more likely to be culturally induced than intrinsic to early cognitive development. This is hardly an unfamiliar theme in contemporary psychology. Mead also offered a research guide for developmental fieldworkers in strange cultures, complete with methodological and practical advice, such as the following: Translate questions into native linguistic categories; don't do controlled experiments; don't do studies that require knowing ages of subjects, which are usually unknowable; and live next door to the children whom you are studying.

Despite the imposing roster of authors that Murchison assembled for the 1931 *Handbook of Child Psychology,* his achievement did not satisfy him for long. Barely 2 years later, Murchison put out a second edition, of which he wrote: "Within a period of slightly more than 2 years, this first revision bears scarcely any resemblance to the original *Handbook of Child Psychology.* This is due chiefly to the great expansion in the field during the past 3 years and partly to the improved insight of the editor" (Murchison, 1933, p. vii). The tradition that Murchison had brought to life was already evolving.

Murchison saw fit to provide the following warning in his second edition: "There has been no attempt to simplify, condense, or to appeal to the immature mind. This volume is prepared specifically for the scholar, and its form is for his maximum convenience" (Murchison, 1933, p. vii). It is likely that sales of Murchison's first volume did not approach textbook levels; perhaps he received negative comments regarding its accessibility.

Murchison exaggerated when he wrote that his second edition bore little resemblance to the first. Almost half of the chapters were virtually the same, with minor additions and updating. (For the record, though, despite Murchison's continued use of masculine phraseology, 10 of the 24 authors in the second edition were women.) Some of the authors whose original chapters were dropped were asked to write about new topics. So, for example, Goodenough wrote about mental testing rather than about children's drawings, and Gesell wrote a general statement of his maturational theory that went well beyond the twin studies.

But Murchison also made some abrupt changes. He dropped Anna Freud entirely, auguring the marginalization of psychoanalysis within academic psychology. Leonard Carmichael, who was later to play a pivotal role in the *Handbook* tradition, made an appearance as author of a major chapter (by far the longest in the book) on prenatal and perinatal growth. Three other physiologically oriented chapters were added as well: one on neonatal motor behavior, one on visual-manual functions during the first 2 years of life, and one on physiological "appetites" such as hunger, rest, and sex. Combined with the Goodenough and Gesell shifts in focus, these additions gave the 1933 *Handbook* more of a biological thrust, in keeping with Murchison's longstanding desire to display the hard science backbone of the emerging field.

Leonard Carmichael was president of Tufts University when he organized Wiley's first edition of the *Handbook.* The switch from a university press to the long-established commercial firm of John Wiley & Sons was commensurate with Carmichael's well-known ambition; indeed, Carmichael's effort was to become influential beyond anything that Murchison might have anticipated. The book (one volume at that time) was called the *Manual of Child Psychology,* in keeping with Carmichael's intention of producing an "advanced scientific manual to bridge the gap between the excellent and varied elementary textbooks in this field and the scientific periodical literature" (Carmichael, 1946, p. viii).

The publication date was 1946, and Carmichael complained that "this book has been a difficult and expensive one to produce, especially under wartime conditions" (Carmichael, 1946, p. viii). Nevertheless, the project was worth the effort. The *Manual* quickly became the bible of graduate training and scholarly work in the field, available virtually everywhere that human development was studied. Eight years later, now head of the Smithsonian Institution, Carmichael wrote, in the preface to the 1954 second edition, "The favorable reception that the first edition received not only in America but all over the world is indicative of the growing importance of the study of the phenomena of the growth and development of the child" (Carmichael, 1954, p. vii).

Carmichael's second edition had a long life: Not until 1970 did Wiley bring out a third edition. Carmichael was retired by then, but he still had a keen interest in the book. At his insistence, his own name became part of the title of the third edition; it was called, improbably, *Carmichael's Manual of Child Psychology,* even though it had a new editor and an entirely different cast of authors and advisors. Paul Mussen took over as the editor, and once again the project flourished. Now a two-volume set,

the third edition swept across the social sciences, generating widespread interest in developmental psychology and its related disciplines. Rarely had a scholarly compendium become both so dominant in its own field and so familiar in related disciplines. The set became an essential source for graduate students and advanced scholars alike. Publishers referred to *Carmichael's Manual* as the standard against which other scientific handbooks were compared.

The fourth edition, published in 1983, was now redesignated by John Wiley & Sons to become once again the *Handbook of Child Psychology.* By then, Carmichael had passed away. The set of books, now expanded to four volumes, became widely referred to in the field as "the Mussen handbook."

WHAT CARMICHAEL CHOSE FOR THE NOW EMERGENT FIELD

Leonard Carmichael, who became Wiley's editor for the project in its now commercially funded and expanded versions (the 1946 and 1954 *Manuals*), made the following comments about where he looked for his all-important choices of content:

> Both as editor of the *Manual* and as the author of a special chapter, the writer is indebted . . . [for] extensive excerpts and the use of other materials previously published in the *Handbook of Child Psychology, Revised Edition.* (1946, p. viii)

> Both the *Handbook of Child Psychology* and the *Handbook of Child Psychology, Revised Edition,* were edited by Dr. Carl Murchison. I wish to express here my profound appreciation for the pioneer work done by Dr. Murchison in producing these handbooks and other advanced books in psychology. The *Manual* owes much in spirit and content to the foresight and editorial skill of Dr. Murchison. (1954, p. viii)

The first quote comes from Carmichael's preface to the 1946 edition, the second from his preface to the 1954 edition. We shall never know why Carmichael waited until the 1954 edition to add the personal tribute to Carl Murchison. Perhaps a careless typist dropped the laudatory passage from a handwritten version of the 1946 preface and its omission escaped Carmichael's notice. Or perhaps 8 years of further adult development increased Carmichael's generosity of spirit. (It also may be possible that Murchison or his family complained.) In any case, Carmichael acknowledged the roots of his *Manuals,* if not always their original editor. His choice to start with those roots is a revealing part of the *Handbook*'s history, and it established a strong intellectual legacy for our present-day descendants of the early pioneers who wrote for the Murchison and Carmichael editions.

Although Leonard Carmichael took the 1946 *Manual* in much the same direction established by Murchison back in 1931 and 1933, he did bring it several steps further in that direction, added a few twists of his own, and dropped a couple of Murchison's bolder selections. Carmichael first appropriated five Murchison chapters on biological or experimental topics, such as physiological growth, scientific methods, and mental testing. He added three new biologically oriented chapters on animal infancy, physical growth, and motor and behavioral maturation (a tour de force by Myrtal McGraw that instantly made Gesell's chapter in the same volume obsolete). Then he commissioned Wayne Dennis to write an adolescence chapter that focused exclusively on physiological changes associated with puberty.

On the subject of social and cultural influences in development, Carmichael retained five of the Murchison chapters: two chapters on environmental forces on the child by Kurt Lewin and by Harold Jones, Dorothea McCarthy's chapter on children's language, Vernon Jones's chapter on children's morality (now entitled "Character Development—An Objective Approach"), and Margaret Mead's chapter on "primitive" children (now enhanced by several spectacular photos of mothers and children from exotic cultures around the world). Carmichael also stayed with three other Murchison topics (emotional development, gifted children, and sex differences), but he selected new authors to cover them. But Carmichael dropped Piaget and Bühler.

Carmichael's 1954 revision, his second and final edition, was very close in structure and content to the 1946 *Manual.* Carmichael again retained the heart of Murchison's original vision, many of Murchison's original authors and chapter topics, and some of the same material that dated all the way back to the 1931 *Handbook.* Not surprisingly, the chapters that were closest to Carmichael's own interests got the most significant updating. Carmichael leaned toward the biological and physiological whenever possible. He clearly favored experimental treatments of psychological processes. Yet he still kept the social, cultural, and psychological analyses by Lewin, Mead, McCarthy, Terman, Harold Jones, and

Vernon Jones, and he even went so far as to add one new chapter on social development by Harold and Gladys Anderson and one new chapter on emotional development by Arthur Jersild.

The Murchison and Carmichael volumes make for fascinating reading, even today. The perennial themes of the field were there from the start: the nature-nurture debate; the generalizations of universalists opposed by the particularizations of contextualists; the alternating emphases on continuities and discontinuities during ontogenesis; and the standard categories of maturation, learning, locomotor activity, perception, cognition, language, emotion, conduct, morality, and culture—all separated for the sake of analysis, yet, as authors throughout each of the volumes acknowledged, all somehow inextricably joined in the dynamic mix of human development.

These things have not changed. Yet, much in the early editions is now irrevocably dated. Long lists of children's dietary preferences, sleeping patterns, elimination habits, toys, and somatic types look quaint and pointless through today's lenses. The chapters on children's thought and language were written prior to the great contemporary breakthroughs in neurology and brain/behavior research, and they show it. The chapters on social and emotional development were ignorant of the processes of social influence and self-regulation that soon would be revealed through attribution research and other studies in social psychology. Terms such as *cognitive neuroscience, neuronal networks, behavior genetics, social cognition, dynamic systems,* and *positive youth development* were of course unknown. Even Mead's rendition of the "primitive child" stands as a weak straw in comparison to the wealth of cross-cultural knowledge available in today's *cultural psychology.*

Most telling, the assortments of odd facts and normative trends were tied together by very little theory throughout the Carmichael chapters. It was as if, in the exhilaration of discovery at the frontiers of a new field, all the facts looked interesting in and of themselves. That, of course, is what makes so much of the material seem odd and arbitrary. It is hard to know what to make of the lists of facts, where to place them, which ones were worth keeping track of and which ones are expendable. Not surprisingly, the bulk of the data presented in the Carmichael manuals seems not only outdated by today's standards but, worse, irrelevant.

By 1970, the importance of theory for understanding human development had become apparent. Looking back on Carmichael's last *Manual,* Paul Mussen wrote, "The 1954 edition of this *Manual* had only one theoretical chapter, and that was concerned with Lewinian theory which, so far as we can see, has not had a significant lasting impact on developmental psychology" (Mussen, 1970, p. x). The intervening years had seen a turning away from the norm of psychological research once fondly referred to as "dust-bowl empiricism."

The Mussen 1970 edition—or *Carmichael's Manual,* as it was still called—had a new look and an almost entirely new set of contents. The two-volume edition carried only one chapter from the earlier books, Carmichael's updated version of his own long chapter on the "Onset and Early Development of Behavior," which had made its appearance under a different title in Murchison's 1933 edition. Otherwise, as Mussen wrote in his preface, "It should be clear from the outset . . . that the present volumes are not, in any sense, a *revision* of the earlier editions; this is a completely new *Manual*" (Mussen, 1970, p. x).

And it was. In comparison to Carmichael's last edition 16 years earlier, the scope, variety, and theoretical depth of the Mussen volumes were astonishing. The field had blossomed, and the new *Manual* showcased many of the new bouquets that were being produced. The biological perspective was still strong, grounded by chapters on physical growth (by J. M. Tanner) and physiological development (by Dorothy Eichorn) and by Carmichael's revised chapter (now made more elegant by some excerpts from Greek philosophy and modern poetry). But two other cousins of biology also were represented, in an ethological chapter by Eckhard Hess and a behavior genetics chapter by Gerald McClearn. These chapters were to define the major directions of biological research in the field for at least the next 3 decades.

As for theory, Mussen's *Handbook* was thoroughly permeated with it. Much of the theorizing was organized around the approaches that, in 1970, were known as the "three grand systems": (1) Piaget's cognitive-developmentalism, (2) psychoanalysis, and (3) learning theory. Piaget was given the most extensive treatment. He reappeared in the *Manual,* this time authoring a comprehensive (and, some say, definitive) statement of his entire theory, which now bore little resemblance to his 1931/1933 sortings of children's intriguing verbal expressions. In addition, chapters by John Flavell, by David Berlyne, by Martin Hoffman, and by William Kessen, Marshall Haith, and Philip Salapatek all gave major treatments to one or another aspect of Piaget's

body of work. Other approaches were represented as well. Herbert and Ann Pick explicated Gibsonian theory in a chapter on sensation and perception, Jonas Langer wrote a chapter on Werner's organismic theory, David McNeill wrote a Chomskian account of language development, and Robert LeVine wrote an early version of what was soon to become "culture theory."

With its increased emphasis on theory, the 1970 *Manual* explored in depth a matter that had been all but neglected in the book's previous versions: the mechanisms of change that could account for, to use Murchison's old phrase, "the problem of how the infant becomes an adult psychologically." In the process, old questions such as the relative importance of nature versus nurture were revisited, but with far more sophisticated conceptual and methodological tools.

Beyond theory building, the 1970 *Manual* addressed an array of new topics and featured new contributors: peer interaction (Willard Hartup), attachment (Eleanor Maccoby and John Masters), aggression (Seymour Feshback), individual differences (Jerome Kagan and Nathan Kogan), and creativity (Michael Wallach). All of these areas of interest are still very much with us in the new millenium.

If the 1970 *Manual* reflected a blossoming of the field's plantings, the 1983 *Handbook* reflected a field whose ground cover had spread beyond any boundaries that could have been previously anticipated. New growth had sprouted in literally dozens of separate locations. A French garden, with its overarching designs and tidy compartments, had turned into an English garden, a bit unruly but glorious in its profusion. Mussen's two-volume *Carmichael's Manual* had now become the four-volume Mussen *Handbook,* with a page-count increase that came close to tripling the 1970 edition.

The grand old theories were breaking down. Piaget was still represented by his 1970 piece, but his influence was on the wane throughout the other chapters. Learning theory and psychoanalysis were scarcely mentioned. Yet the early theorizing had left its mark, in vestiges that were apparent in new approaches, and in the evident conceptual sophistication with which authors treated their material. No return to dust bowl empiricism could be found anywhere in the set. Instead, a variety of classical and innovative ideas were coexisting: Ethology, neurobiology, information processing, attribution theory, cultural approaches, communications theory, behavioral genetics, sensory-perception models, psycholinguistics, sociolinguistics, discontinuous stage theories, and continuous memory theories all took their places, with none quite on center stage. Research topics now ranged from children's play to brain lateralization, from children's family life to the influences of school, day care, and disadvantageous risk factors. There also was coverage of the burgeoning attempts to use developmental theory as a basis for clinical and educational interventions. The interventions usually were described at the end of chapters that had discussed the research relevant to the particular intervention efforts, rather than in whole chapters dedicated specifically to issues of practice.

This brings us to the efforts under the present editorial team: the *Handbook*'s fifth and sixth editions (but really the seventh and eighth editions, if the germinal two pre-Wiley Murchison editions are counted). I must leave it to future commentators to provide a critical summation of what we have done. The volume editors have offered introductory and/or concluding renditions of their own volumes. I will add to their efforts here only by stating the overall intent of our design and by commenting on some directions that our field has taken in the years from 1931 to 2006.

We approached our editions with the same purpose that Murchison, Carmichael, and Mussen before us had shared: "to provide," as Mussen wrote, "a comprehensive and accurate picture of the current state of knowledge—the major systematic thinking and research—in the most important research areas of the psychology of human development" (Mussen, 1983, p. vii). We assumed that the *Handbook* should be aimed "specifically for the scholar," as Murchison declared, and that it should have the character of an "advanced text," as Carmichael defined it. We expected, though, that our audiences may be more interdisciplinary than the readerships of previous editions, given the greater tendency of today's scholars to cross back and forth among fields such as psychology, cognitive science, neurobiology, history, linguistics, sociology, anthropology, education, and psychiatry. We also believed that research-oriented practitioners should be included under the rubric of the "scholars" for whom this *Handbook* was intended. To that end, for the first time in 1998 and again in the present edition, we devoted an entire volume to child psychology in practice.

Beyond these very general intentions, we have let chapters in the *Handbook*'s fifth and sixth editions take their own shape. We solicited the chapters from authors who were widely acknowledged to be among the leading experts in their areas of the field, although we know that, given an entirely open-ended selection process and

no limits of budget, we would have invited a large number of other leading researchers whom we did not have the space—and thus the privilege—to include. With very few exceptions, every author whom we invited agreed to accept the challenge. Our only real, and great, sadness was to hear of the passing of several authors from the 1998 edition prior to our assembly of the present edition. Where possible, we arranged to have their collaborators revise and update their chapters.

Our directive to authors was simple: Convey your area of the field as you see it. From then on, the authors took center stage—with, of course, much constructive feedback from reviewers and volume editors. No one tried to impose a perspective, a preferred method of inquiry, or domain boundaries on any of the chapters. The authors expressed their views on what researchers in their areas attempt to accomplish, why they do so, how they go about it, what intellectual sources they draw on, what progress they have made, and what conclusions they have reached.

The result, in my opinion, is still more glorious profusion of the English garden genre, but perhaps contained a bit by some broad patterns that have emerged over the past decade. Powerful theoretical models and approaches—not quite unified theories, such as the three grand systems—have begun once again to organize much of the field's research and practice. There is great variety in these models and approaches, and each is drawing together significant clusters of work. Some have been only recently formulated, and some are combinations or modifications of classic theories that still have staying power.

Among the formidable models and approaches that the reader will find in this *Handbook* are the dynamic system theories, the life span and life course approaches, cognitive science and neuronal models, the behavior genetics approach, person-context interaction theories, action theories, cultural psychology, and a wide assortment of neo-Piagetian and neo-Vygotskian models. Although some of these models and approaches have been in the making for some time, they have now come into their own. Researchers are drawing on them directly, taking their implied assumptions and hypotheses seriously, using them with specificity and control, and exploiting their implications for practice.

Another pattern that emerges is a rediscovery and exploration of core processes in human development that had been underexamined by the generation of researchers just prior to the present one. Scientific interest has a way of moving in alternating cycles (or spirals, for those who wish to capture the progressive nature of scientific development). In our time, developmental study has cycled away from classic topics such as motivation and learning—not in the sense that they were entirely forgotten, or that good work ceased to be done in such areas, but in the sense that they no longer were the most prominent subjects of theoretical reflection and debate. Some of the relative neglect was intentional, as scholars got caught up in controversies about whether psychological motivation was a "real" phenomenon worthy of study or whether learning could or should be distinguished from development in the first place. All this has changed. As the contents of our current edition attest, developmental science always returns, sooner or later, to concepts that are necessary for explaining the heart of its concerns, progressive change in individuals and social groups over time, and concepts such as learning and motivation are indispensable for this task. Among the exciting features of this *Handbook* edition are the advances it presents in theoretical and empirical work on these classic concepts.

The other concept that has met some resistance in recent years is the notion of development itself. For some social critics, the idea of progress, implicit in the notion of development, has seemed out of step with principles such as equality and cultural diversity. Some genuine benefits have accrued from that critique; for example, the field has worked to better appreciate diverse developmental pathways. But, like many critique positions, it led to excesses. For some, it became questionable to explore issues that lie at the heart of human development. Growth, advancement, positive change, achievement, and standards for improved performance and conduct, all were questioned as legitimate subjects of investigation.

Just as in the cases of learning and motivation, no doubt it was inevitable that the field's center of gravity sooner or later would return to broad concerns of development. The story of growth from infancy to adulthood is a developmental story of multifaceted learning, acquisitions of skills and knowledge, waxing powers of attention and memory, growing neuronal and other biological capacities, formations and transformations of character and personality, increases and reorganizations in the understanding of self and others, advances in emotional and behavioral regulation, progress in communicating and collaborating with others, and a host of other achievements documented in this edition. Parents, teachers, and

other adults in all parts of the world recognize and value such developmental achievements in children, although they do not always know how to understand them, let alone how to foster them.

The sorts of scientific findings that the *Handbook*'s authors explicate in their chapters are needed to provide such understanding. The importance of sound scientific understanding has become especially clear in recent years, when news media broadcast story after story based on simplistic and biased popular speculations about the causes of human development. The careful and responsible discourse found in these chapters contrasts sharply with the typical news story about the role of parents, genes, or schools in children's growth and behavior. There is not much contest as to which source the public looks to for its information and stimulation. But the good news is that scientific truth usually works its way into the public mind over the long run. The way this works would make a good subject for developmental study some day, especially if such a study could find a way to speed up the process. In the meantime, readers of this edition of the *Handbook of Child Psychology* will find the most solid, insightful and current set of scientific theories and findings available in the field today.

Acknowledgments

A work as significant as the *Handbook of Child Psychology* is always produced by the contributions of numerous people, individuals whose names do not necessarily appear on the covers or spines of the volumes. Most important, we are grateful to the more than 150 colleagues whose scholarship gave life to the Sixth Edition. Their enormous knowledge, expertise, and hard work make this edition of the *Handbook* the most important reference work in developmental science.

In addition to the authors of the chapters of the four volumes of this edition, we were fortunate to have been able to work with two incredibly skilled and dedicated editors within the Institute for Applied Research in Youth Development at Tufts University, Jennifer Davison and Katherine Connery. Their "can-do" spirit and their impressive ability to attend to every detail of every volume were invaluable resources enabling this project to be completed in a timely and high quality manner.

It may be obvious, but we want to stress also that without the talent, commitment to quality, and professionalism of our editors at John Wiley & Sons, this edition of the *Handbook* would not be a reality and would not be the cutting-edge work we believe it to be. The breadth of the contributions of the Wiley staff to the *Handbook* is truly enormous. Although we thank all these colleagues for their wonderful contributions, we wish to make special note of four people in particular: Patricia Rossi, Senior Editor, Psychology, Linda Witzling, Senior Production Editor, Isabel Pratt, Associate Editor, and Peggy Alexander, Vice President and Publisher. Their creativity, professionalism, sense of balance and perspective, and unflagging commitment to the tradition of quality of the *Handbook* were vital ingredients for any success we may have with this edition. We are also deeply grateful to Pam Blackmon and her colleagues at Publications Development Company for undertaking the enormous task of copy editing and producing the thousands of pages of the Sixth Edition. Their professionalism and commitment to excellence were invaluable resources and provided a foundation upon which the editors' work was able to move forward productively.

Child development typically happens in families. So too, the work of editors on the *Handbook* moved along productively because of the support and forbearance of spouses, partners, and children. We thank all of our loved ones for being there for us throughout the several years on which we have worked on the Sixth Edition.

Numerous colleagues critiqued the chapters in manuscript form and provided valuable insights and suggestions that enhanced the quality of the final products. We thank all of these scholars for their enormous contributions.

William Damon and Richard M. Lerner thank the John Templeton Foundation for its support of their respective scholarly endeavors. In addition, Richard M. Lerner thanks the National 4-H Council for its support of his work. Nancy Eisenberg thanks the National Institute of Mental Health, the Fetzer Institute, and The Institute for Research on Unlimited Love—Altruism, Compassion, Service (located at the School of Medicine, Case Western Reserve University) for their support. K. Ann Renninger and Irving E. Sigel thank Vanessa Ann Gorman for her editorial support for Volume 4. Support from the Swarthmore College Provost's Office to K. Ann Renninger for editorial assistance on this project is also gratefully acknowledged.

Finally, in an earlier form, with Barbara Rogoff's encouragement, sections of the preface were published in *Human Development* (April 1997). We thank Barbara for her editorial help in arranging this publication.

CHAPTER 1

Developmental Science, Developmental Systems, and Contemporary Theories of Human Development

RICHARD M. LERNER

Much like the universities within which they are typically formulated, theoretical innovations in human development usually move at glacial speed. As described by Cairns and Cairns (Chapter 3, this *Handbook,* this volume), decades may elapse between the formulation of a new approach to human development and its ascendancy and proliferation in variations of the initial model as it is used in research and organized into a network, or "family" (Reese & Overton, 1970) of related theories. Finally, it passes from the scene, losing its role as an active or influential frame for research and application. This diminution of influence can occur for many reasons.

There may be the identification of (a) fundamental conceptual flaws, including empirically counterfactual assertions (e.g., see Overton, Chapter 2, this *Handbook,* this volume, for examples of theories that split nature-variables from nurture-variables in attempting to account for human development, and also Lerner, 2004a, 2004b, for a discussion of these problems in behavior genetic and sociobiological instances of such split conceptions); (b) irreparable problems with the methods associated with the empirical tests of ideas derived from the theory (e.g., see Gottlieb, Walhsten, & Lickliter, Chapter 5, this *Handbook,* this volume, Garcia Coll, Bearer, & Lerner, 2004, and Lerner, 2002, for discussions of such problems in behavior genetics and sociobiology); or (c) substantive "overreaching," that is, attempting to account for phenomena beyond the scope of the model (e.g., see Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Horowitz, 2000; Shweder et al., Chapter 13, this *Handbook,* this volume; Suomi, 2004a, 2004b, for discussions of this problem in genetic reductionist accounts, as occur in behavior genetics and sociobiology, of social behavior or of the social and cultural institutions of society; see Fischer & Bidell, Chapter 7, this *Handbook,* this volume, and Thelen & Smith, Chapter 6, this *Handbook,* this volume, for discussions of this problem in neonativist accounts of cognitive development; and see Bloom, 1998, for a discussion of this problem in behaviorist accounts of language development).

The preparation of this chapter was supported in part by grants from the National 4-H Council and from the John Templeton Foundation.

Cairns and Cairns (Chapter 3, this *Handbook,* this volume) note as well that a theoretical innovation in one period may actually constitute a return to ideas from an earlier era. When theoretical ideas are initially introduced, they may not become popular or even accepted for several reasons. There may be a lack of conceptual preparedness for the ideas or vocabulary used in a theory (e.g., see Flavell, 1963, for a discussion of why Piaget's early formulations, e.g., in 1923, were not embraced in the United States for almost 40 years). In addition, the ideas in a theory may not be able to be tested optimally because of methodological limitations (e.g., the absence of statistical procedures for modeling multilevel, hierarchically embedded, and reciprocal relations across time; e.g., see Nesselroade & Ram, 2004). Moreover, the "spirit of the times," the *zeitgeist* (Boring, 1950), may preclude acceptance of ideas that would require realigning the sociology of the science. Cairns and Cairns (Chapter 3, this *Handbook,* this volume) recount the challenges of instituting a truly multidisciplinary field of child development given the more than 50-year predominance of psychologists and of psychogenic (and reductionist) theories in that field.

Nevertheless, such conceptual, methodological, and sociological constraints on the acceptance of a theoretical orientation may be overcome (e.g., through the sort of evidentiary process involved in the paradigmatic revolutions discussed by Kuhn, 1962). As such, a theory introduced in one historical period may be rediscovered or a newer instantiation of it may be generated, albeit being "old wine in a new bottle."

The focus within the contemporary study of human development on concepts and models associated with developmental systems theories (Cairns & Cairns, Chapter 3, this *Handbook,* this volume; Gottlieb et al., Chapter 5, this *Handbook,* this volume; Lerner, 2002; Overton, Chapter 2, this *Handbook,* this volume) is a case in point, especially given that the roots of these models may be linked to ideas in developmental science that were presented at least as early as the 1930s and 1940s (e.g., Maier & Schneirla, 1935; Novikoff, 1945a, 1945b; von Bertalanffy, 1933), if not even significantly earlier. Table 1.1 presents the defining features of developmental systems theories and, as Cairns and Cairns (Chapter 3, this *Handbook,* this volume) illustrate, there are parallels between the ideas presented in this table and the interests of and concepts used by late nineteenth-century and early twentieth-century founders of the study of child development.

Among the interrelated, and in fact "fused" (Tobach & Greenberg, 1984), defining features of contemporary developmental systems theories of human development are (a) relationism, the integration of levels of organization; (b) historical embeddedness and temporality; (c) relative plasticity; and (d) diversity (Damon & Lerner, 1998; Lerner, 2004a, 2004b). As discussed in the Cairns and Cairns chapter, these four components of developmental systems theories of human development have a long and rich tradition in the history of the field (Cairns & Cairns, Chapter 3, this *Handbook,* this volume). For example, Cairns and Cairns describe James Mark Baldwin's (1897/1906) interest in the study of development-in-context, and thus in integrated, multilevel, and hence interdisciplinary scholarship. These interests were shared as well by Lightner Witmer, the founder in 1896 of the first psychological clinic in the United States (Cairns & Cairns, Chapter 3, this *Handbook,* this volume; Lerner, 1977).

Cairns and Cairns also describe the conception of developmental processes within developmental systems theories—involving reciprocal interaction, bidirectionality, plasticity, and biobehavioral organization (all modern emphases)—as integral in the thinking of the founders of the field of human development. Wilhelm Stern (1914) stressed the holism that is associated with a developmental systems perspective about these developmental processes. Other contributors to the foundations and early progress ofthe field of human development (e.g., John Dewey, 1916; Kurt Lewin, 1935, 1954; and John B. Watson, 1928) stressed the importance of linking child development research with application and child advocacy (Bronfenbrenner, 1974; Zigler, 1998). This orientation toward the application of developmental science is a contemporary view as well, derived from the stress on plasticity and temporal embeddedness within developmental systems theories.

FROM DEVELOPMENTAL PSYCHOLOGY TO DEVELOPMENTAL SCIENCE

In the almost decade that has passed between placing the fifth edition of the *Handbook of Child Psychology* into production and the appearance of the sixth edition, there has been a remarkably rapid change in the predominant theoretical foci used to study human development. Nevertheless, it is possible to interpret the contemporary

TABLE 1.1 Defining Features of Developmental Systems Theories

A Relational Metatheory
Predicated on a postmodern philosophical perspective that transcends Cartesian dualism, developmental systems theories are framed by a relational metatheory for human development. There is, then, a rejection of all splits between components of the ecology of human development (e.g., between nature- and nurture-based variables), and between continuity and discontinuity and between stability and instability. Systemic syntheses or integrations replace dichotomizations or other reductionist partitions of the developmental system.

The Integration of Levels of Organization
Relational thinking and the rejection of Cartesian splits is associated with the idea that all levels of organization within the ecology of human development are integrated, or fused. These levels range from the biological and physiological through the cultural and historical.

Developmental Regulation across Ontogeny Involves Mutually Influential Individual ← → Context Relations
As a consequence of the integration of levels, the regulation of development occurs through mutually influential connections among all levels of the developmental system, ranging from genes and cell physiology through individual mental and behavioral functioning to society, culture, the designed and natural ecology and, ultimately, history. These mutually influential relations may be represented generically as Level 1 ← →, Level 2 (e.g., Family ← → Community), and in the case of ontogeny may be represented as individual ← → context.

Integrated Actions, Individual ← → Context Relations, Are the Basic Unit of Analysis within Human Development
The character of developmental regulation means that the integration of actions—of the individual on the context and of the multiple levels of the context on the individual (individual ← → context)—constitute the fundamental unit of analysis in the study of the basic process of human development.

Temporality and Plasticity in Human Development
As a consequence of the fusion of the historical level of analysis—and therefore temporality—in the levels of organization comprising the ecology of human development, the developmental system is characterized by the potential for systematic change, by plasticity. Observed trajectories of intraindividual change may vary across time and place as a consequence of such plasticity.

Relative Plasticity
Developmental regulation may both facilitate and constrain opportunities for change. Thus, change in individual ← → context relations is not limitless, and the magnitude of plasticity (the probability of change in a developmental trajectory occurring in relation to variation in contextual conditions) may vary across the life span and history. Nevertheless, the potential for plasticity at both individual and contextual levels constitutes a fundamental strength of all human development.

Intraindividual Change, Interindividual Differences in Intraindividual Change, and the Fundamental Substantive Significance of Diversity
The combinations of variables across the integrated levels of organization within the developmental system that provide the basis of the developmental process will vary at least in part across individuals and groups. This diversity is systematic and lawfully produced by idiographic, group differential, and generic (nomothetic) phenomena. The range of interindividual differences in intraindividual change observed at any point in time is evidence of the plasticity of the developmental system, and makes the study of diversity of fundamental substantive significance for the description, explanation, and optimization of human development.

Optimism, the Application of Developmental Science, and the Promotion of Positive Human Development
The potential for and instantiations of plasticity legitimate an optimistic and proactive search for characteristics of individuals and of their ecologies that, together, can be arrayed to promote positive human development across life. Through the application of developmental science in planned attempts (interventions) to enhance (e.g., through social policies or community-based programs) the character of humans' developmental trajectories, the promotion of positive human development may be achieved by aligning the strengths (operationized as the potentials for positive change) of individuals and contexts.

Multidisciplinarity and the Need for Change-Sensitive Methodologies
The integrated levels of organization comprising the developmental system require collaborative analyses by scholars from multiple disciplines. Multidisciplinary knowledge and, ideally, interdisciplinary knowledge is sought. The temporal embeddedness and resulting plasticity of the developmental system requires that research designs, methods of observation and measurement, and procedures for data analysis be change-sensitive and able to integrate trajectories of change at multiple levels of analysis.

emphases on developmental systems theories, not as a new lens for the study of human development, but as a return to the historical roots of the field (e.g., in taking an integrative approach to nature and nurture, in stressing multidisciplinarity, in considering the role of spirituality as a vital dimension of human life, and in applying developmental science). What Cairns (1998) and I (Lerner, 1998) observed in our respective chapters in the fifth edition of the handbook as theoretical trends or cutting-edge interests in developmental science have become, at this writing, clear indicators of the mainstream and distinctive features of the field. Indeed, the

centrality of systemic and multidisciplinary thinking, spanning and integrating basic and applied scholarship, has been associated with a change in the very label of the field during this time period.

A decade ago, most scholars studying human development labeled the field either as *developmental psychology* or, if they were not themselves psychologists (e.g., Elder, 1998), as a field wherein psychological science was the predominant lens through which to study the span of human life. Today, however, the field has become much more deeply and broadly multidisciplinary (and, in some subareas, actually interdisciplinary or, in other words, disciplinarily integrative, e.g., see Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Gottlieb et al., Chapter 5, this *Handbook,* this volume; Shweder et al., Chapter 13, this *Handbook,* this volume). As a consequence, more and more scholars of human development refer to their field as developmental science (e.g., see Cairns & Cairns, Chapter 3, this *Handbook,* this volume; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume), and at least one leading graduate textbook in the field has changed its title from *Developmental Psychology* (Bornstein & Lamb, 1999) to *Developmental Science* (Bornstein & Lamb, 2005).

The change of name for the field studying the human life span reflects in large part key intellectual changes across the past decade: (a) the certain demise of split conceptions of the nature-nurture issue, and of reductionistic approaches to either nature formulations (sociobiology or behavior genetics) or to nurture formulations (e.g., S-R [stimulus-response] models or functional analysis approaches) (Overton, Chapter 2, this *Handbook,* this volume; Valsiner, Chapter 4, this *Handbook,* this volume); (b) the ascendancy of focus on developmental systems models, conceptions that seek to fuse systemically the levels of organization involved in the ecology of human development (from biology and physiology through culture and history; e.g., see Baltes, Lindenberger, & Staudinger, Chapter 11, this *Handbook,* this volume; Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Gottlieb et al., Chapter 5, this *Handbook,* this volume; Thelen & Smith, Chapter 6, this *Handbook,* this volume); and (c) the emphasis on relations among levels and not on the main effects of any level itself, as constituting the fundamental units of analysis of developmental analysis (e.g., see Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Brandtstädter, Chapter 10, this *Handbook,* this volume; Fischer & Bidell, Chapter 7, this *Handbook,* this volume; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume; Rathunde & Csikszentmihalyi, Chapter 9, this *Handbook,* this volume).

The range of chapters in this edition of the *Handbook* illustrates the diverse theoretical family of models that are instances of or, at the least, are framed by developmental systems ideas about the relational processes linking the multiple, integrated levels of organization within the ecology of human development. These models conceptualize both traditional areas of interest within the study of human development, such as biological development (Gottlieb et al., Chapter 5, this *Handbook,* this volume); perceptual and motor development (Thelen & Smith, Chapter 6, this *Handbook,* this volume); personality, affective, and social development (Brandtstädter, Chapter 10, this *Handbook,* this volume; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume; Rathunde & Csikszentmihalyi, Chapter 9, this *Handbook,* this volume); culture and development (Shweder et al., Chapter 13, this *Handbook,* this volume); and cognitive development (Baltes et al., Chapter 11, this *Handbook,* this volume; Fischer & Bidell, Chapter 7, this *Handbook,* this volume), and emergent areas of intellectual interest such as spiritual and religious development (Oser, Scarlett, & Bucher, Chapter 17, this *Handbook,* this volume); the development of diverse children (Spencer, Chapter 15, this *Handbook,* this volume); and positive human development (Benson, Scales, Hamilton, & Sesma, Chapter 16, this *Handbook,* this volume).

Indeed, the potential plasticity of human development that is a defining feature of ontogenetic change within the dynamic, developmental system (Baltes et al., Chapter 11, this *Handbook,* this volume; Gottlieb et al., Chapter 5, this *Handbook,* this volume; Thelen & Smith, Chapter 6, this *Handbook,* this volume) provides a rationale for both the application of developmental science (Cairns & Cairns, Chapter 3, this *Handbook,* this volume) and for the possibility that positive development may be promoted across the life course of humans through the identification and alignment of resources in individuals and their contexts that foster health and positive growth (Benson et al., Chapter 16, this *Handbook,* this volume). Moreover, the emphasis on how the individual acts on the context to

contribute to the plastic relations with the context that regulate adaptive development (Brandtstädter, Chapter 10, this *Handbook,* this volume) fosters an interest in person-centered (compared with variable-centered) approaches to the study of human development (Magnusson & Stattin, Chapter 8, this *Handbook,* this volume; Overton, Chapter 2, this *Handbook,* this volume; Rathunde & Csikszentmihalyi, Chapter 9, this *Handbook,* this volume). Furthermore, given that the array of individual and contextual variables involved in these relations constitute a virtually open set (e.g., there are over 70 trillion potential human genotypes and each of them may be coupled across life with an even larger number of life course trajectories of social experiences; Hirsch, 2004), the diversity of development becomes a prime, substantive focus for developmental science (Lerner, 2004a; Spencer, Chapter 15, this *Handbook,* this volume). The diverse person, conceptualized from a strength-based perspective (in that the potential plasticity of ontogenetic change constitutes a fundamental strength of all humans; Spencer, Chapter 15, this *Handbook,* this volume), and approached with the expectation that positive changes can be promoted across all instances of this diversity as a consequence of health-supportive alignments between people and setting (Benson et al., Chapter 16, this *Handbook,* this volume), becomes the necessary subject of developmental science inquiry.

These theoretical emphases in developmental science have been coupled with enormous advances in quantitative statistical approaches, arguably especially in the longitudinal methods required to appraise the changing relations in the developmental system between the individual and the context (e.g., see Duncan, Magnuson, & Ludwig, 2004; Laub & Sampson, 2004; McArdle & Nesselroade, 2003; Molenaar, 2004; Nesselroade & Ram, 2004; Phelps, Furstenberg, & Colby, 2002; Singer & Willett, 2003; Skrondal & Rabe-Hesketh, 2004; von Eye, 1990; von Eye & Bergman, 2003; von Eye & Gutiérrez Peña, 2004; Willett, 2004; Young, Savola, & Phelps, 1991). Moreover, there has been an increased appreciation of the importance of qualitative methods, both as valuable tools for the analysis of the life course and as a means to triangulating quantitative appraisals of human development. As such, there has been a growth in the use of traditional qualitative methods, along with the invention of new qualitative techniques (e.g., Mishler, 2004).

Finally, this exciting and innovative period in developmental theory and methodology has been framed by a renewed appreciation of the philosophical grounding of developmental science in postmodern ideas. The philosophical ideas that have had the most attraction to developmental scientists are relational conceptions that transcend fruitless debates (e.g., regarding maturation versus early experience as the basis for learning, or neonativist versus empiricist bases of early cognitive development; e.g., see Spelke & Newport, 1998) predicated on false dichotomies that split apart the fused developmental system (e.g., see Overton, 1998, 2003, Chapter 2, this *Handbook,* this volume; Valsiner, 1998, Chapter 4, this *Handbook,* this volume).

IMPLICATIONS OF RELATIONAL METATHEORIES FOR DEVELOPMENTAL SCIENCE

The ascendancy of a developmental systems frame for the conduct of developmental science has been a product and a producer of a shift in the paradigm, or philosophy of science, framing discourse within the field (Overton, 1998, 2003, Chapter 2, this *Handbook,* this volume). As noted, the field has changed from being predicated on a positivist and reductionist metatheory, wherein a key assumption was that the universe was uniform and that it was permanent. It has shifted to a postmodernist conception that transcends Cartesian splits between the real and the epiphenomenal (e.g., as instantiated within past eras as nature versus nurture, maturation versus learning, continuity versus discontinuity, stability versus instability, or simply constancy versus change; Brim & Kagan, 1980; Lerner, 2002; Overton, Chapter 2, this *Handbook,* this volume). The integrative, relational metatheory that has emerged by avoiding all splits (Overton, 1998, Chapter 2, this *Handbook,* this volume) focuses instead on the construction of relations across the range of levels of organization constituting the ecology of human development (e.g., Baltes, 1997; Baltes et al., Chapter 11, this *Handbook,* this volume; Bronfenbrenner, 2005; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Thelen & Smith, Chapter 6, this *Handbook,* this volume).

Moreover, within the context of the relational metatheory that has served as a product and a producer of developmental systems thinking (Lerner, 2002), there has been a rejection of an idea that is derived from the positivist and reductionist notion that the universe is uniform and permanent—that the study of human behavior should be aimed at identifying nomothetic laws that pertain to the generic human being. This idea was replaced by a stress on the individual, on the importance of attempting to identify both differential and potentially idiographic laws as involved in the course of human life (e.g., Block, 1971; Magnusson, 1999a, 1999b), and on regarding the individual as an active producer of his or her own development (Brandtstädter, 1998, 1999, Chapter 10, this *Handbook,* this volume; Lerner, 1982; Lerner & Busch-Rossnagel, 1981; Lerner, Theokas, & Jelicic, 2005; Rathunde & Csikszentmihalyi, Chapter 9, this *Handbook,* this volume). Similarly, the changed philosophical grounding of the field has altered developmental science from a field that enacted research as if time and place were irrelevant to the existence and operation of laws of behavioral development to a field that has sought to identify the role of contextual embeddedness and temporality in shaping the developmental trajectories of diverse individuals and groups (e.g., see Baltes et al., Chapter 11, this *Handbook,* this volume; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Elder, Modell, & Parke, 1993; Elder & Shanahan, Chapter 12, this *Handbook,* this volume).

Arguably, the most profound impact of the relational metatheory on the practice of developmental science has occurred in the conceptualization of diversity, of interindividual differences, in developmental trajectories (Lerner, 2004a, 2004b; Spencer, Chapter 15, this *Handbook,* this volume). From the perspective of the uniformity and permanence assumptions, individual differences—diversity—were seen, at best, through a lens of error variance, as prima facie proof of a lack of experimental control or of inadequate measurement. At worst, diversity across time or place, or in the individual differences among people, was regarded as an indication that a deficit was present. Either the person doing the research was remiss for using a research design or measurement model that was replete with error (with a lack of experimental control sufficient to eliminate interindividual differences), *or* the people who varied from the norms associated with the generic human being—the relations among variables that were generalizable across time and place—were in some way deficient (cf. Gould, 1981, 1996). They were, to at least some observers, less than normatively human.

FROM DEFICIT TO DIVERSITY IN DEVELOPMENTAL SCIENCE

For colleagues trained in developmental science within the past decade, the prior philosophical grounding and associated philosophical assumptions about science may seem either unbelievably naive or simply quaint vestiges from an unenlightened past. In what, for the history of science, is a very short period (Cairns & Cairns, Chapter 3, this *Handbook,* this volume), participants in the field of human development have seen a sea change that perhaps qualifies as a true paradigm shift in what is thought of as the nature of human nature and in the appreciation of time, place, and individual diversity for understanding the laws of human behavior and development (Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Overton, Chapter 2, this *Handbook,* this volume; Shweder et al., Chapter 13, this *Handbook,* this volume; Valsiner, Chapter 4, this *Handbook,* this volume).

The publication in 1998 of the fifth edition of the *Handbook of Child Psychology,* edited by William Damon, heralded that the field of human development rejected the hegemony of positivism and reductionism. As evidenced by the chapters in all four volumes of the Damon (1998) *Handbook,* and arguably especially in the volume of that edition that corresponds to the present one, *Theoretical Models of Human Development* (Damon & Lerner, 1998), the majority of the scholarship then defining the cutting edge of the field of human development was associated with the sorts of developmental systems models of human development that fill the pages of the present edition of this volume of the *Handbook* and that, as projected by Cairns and Cairns in 1998, were at the threshold of their time of ascendancy within developmental science.

The view of the world that emerged from the chapters in the fifth edition of Volume 1 of the *Handbook* (Damon & Lerner, 1998) and that is confirmed across the chapters of the present volume (including those chapters represented in both editions and those chapters new to this edition) is that the universe is dynamic and variegated. Time and place therefore are matters of substance, not

error; and to understand human development, one must appreciate how variables associated with person, place, and time coalesce to shape the structure and function of behavior and its systematic and successive change (Baltes et al., Chapter 11, this *Handbook,* this volume; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Benson et al., Chapter 16, this *Handbook,* this volume; Elder, 1998; Elder, Modell, & Parke, 1993; Magnusson, 1999a, 1999b; Magnusson & Stattin, 1998, Chapter 8, this *Handbook,* this volume; Shweder et al., Chapter 13, this *Handbook,* this volume; Spencer, Chapter 15, this *Handbook,* this volume; Valsiner, Chapter 4, this *Handbook,* this volume).

Accordingly, diversity of person and context has moved into the foreground of the analysis of human development (Lerner, 1991, 1998, 2002, 2004a, 2004b). The dynamic, developmental systems perspective framing the contemporary study of human development does not reject the idea that there may be general laws of human development. Instead, there is an insistence on the presence of individual laws as well and a conviction that any generalizations about groups or humanity as a whole require empirical verification, not preempirical stipulation (Lerner, 2002; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume; Overton, Chapter 2, this *Handbook,* this volume).

To paraphrase the insight of Kluckhohn and Murray (1948), made more than a half century ago, all people are like all other people, all people are like some other people, and each person is like no other person. Today, then, the science of human development recognizes that there are idiographic, differential, and nomothetic laws of human behavior and development (e.g., see Emmerich, 1968; Lerner, 2002). Each person and each group possesses unique and shared characteristics that need to be the core targets of developmental analysis.

Differences, then, among people or groups are not necessarily indicators of deficits in one and strengths in the other (Spencer, Chapter 15, this *Handbook,* this volume). Certainly, it is not useful to frame the study of human development through a model that a priori sets one group as the standard for positive or normative development and where another group, when different from this normative one, is therefore defined as being in deficit. If there is any remaining place in developmental science for a deficit model of humans, it is useful only for understanding the thinking of those individuals who continue to treat diversity as either by definition indicative of error variance or as necessarily reflective of a deficiency of human development.

VESTIGES OF REDUCTIONIST MODELS

Despite the contemporary emphasis on a relational metatheory and on developmental systems theories, the remnants of reductionism and deficit thinking still remain at the periphery of developmental science. These instances of genetic reductionism exist in behavior genetics (e.g., Rowe, 1994; Plomin, 2000), in sociobiology (e.g., Rushton, 1999, 2000), and in at least some forms of evolutionary psychology (e.g., Buss, 2003). These approaches constitute today's version of the biologizing errors of the past, such as eugenics and racial hygiene (Proctor, 1988).

As explained by Collins et al. (2000), these ideas are no longer seen as part of the forefront of scientific theory. Nevertheless, their influence on scientific and public policy persists. Renowned geneticists, such as Bearer (2004), Edelman (1987, 1988), Feldman (e.g., Feldman & Laland, 1996), Ho (1984), Lewontin (2000), Müller-Hill (1988), and Venter (e.g., Venter et al., 2001); and eminent colleagues in comparative and biological psychology, such as Greenberg (e.g., Greenberg & Haraway, 2002; Greenberg & Tobach, 1984), Gottlieb (1997, 2004), Hirsch (1997, 2004), Michel (e.g., Michel & Moore, 1995), and Tobach (1981, 1994; Tobach, Gianutsos, Topoff, & Gross, 1974), alert us to the need for continued intellectual and social vigilance, lest such flawed ideas about genes and human development become the foci of public policies or social programs.

Such applications of counterfactual ideas remain real possibilities, and in some cases unfortunate realities, due at least in part to what Horowitz (2000) described as the affinity of the "Person in the Street" to simplistic models of genetic effects on behavior. These simple and, I must emphasize, erroneous models are used by the Person in the Street to form opinions or to make decisions about human differences and potentials.

Genetic reductionism can, and has, led to views of diversity as a matter of the "haves" and the "have nots" (e.g., Herrnstein & Murray, 1994; Rushton, 1999, 2000). There are, in this view, those people who manifest the normative characteristics of human behavior and development. Given the diversity-insensitive assumptions and research that characterized much of the

history of scholarship in human development even into the 1990s, these normative features of human development were associated with middle-class, European American samples (Graham, 1992; McLoyd, 1998; Shweder et al., Chapter 13, this *Handbook,* this volume; Spencer, 1990, Chapter 15, this *Handbook,* this volume). In turn, there are those people who manifest other characteristics, and these individuals were generally non-European American and non-middle-class. However, if the former group is regarded as normative, then the characteristics of the latter groups are regarded as nonnormative (Gould, 1996). When such an interpretation is forwarded, entry has thus been made down the slippery slope of moving from a description of between-group differences to an attribution of deficits in the latter groups (Lerner, 2002, 2004a, 2004b).

Such an attribution is buttressed when seen through the lens of genetic reductionism because in this conception, it must be genes that provide the final, material, and efficient cause of the characteristics of the latter groups (e.g., see Rowe, 1994; Rushton, 2000). These non-European American or non-middle-class groups are, in the fully tautological reasoning associated with genetic reductionism, behaviorally deficient because of the genes they possess, *and* because of the genes they possess, they have behavioral deficits (e.g., see Rushton, 2000). Simply, the genes that place one in a racial group are the genes that provide either deficits or assets in behavior, and one racial group possesses the genes that are assets and the other group possesses the genes that are deficits.

As shown in Table 1.2, these genetic reductionist ideas may have profound and dire effects on public policies and social programs (Lerner, 2004a, 2004b). The table presents "A" beliefs about whether genetic reductionist ideas are believed to be either (1) true or (2) false. The table presents also "B" public policy and social program implications that would be associated with genetic reductionism were it in fact (1) true or (2) false under either of the two belief conditions involved in "A." Moreover, the "A.2.B.2." quadrant of the table not only presents the policy and program implications of believing that the genetic reductionist conception is believed to be false when it is in fact false. In addition, this quadrant illustrates the policy and program implications of believing developmental systems theory to be true when it is in fact the case. Table 1.2 demonstrates that if genetic reductionism is believed to be true, then irrespective of whether it is in fact true (and, it must be emphasized that it is incontrovertibly *not* true), a range of actions may be promoted that constrain people's freedom of association, reproductive rights, and even survival.

In contrast, Table 1.3 presents the different implications for policies and programs of strict environmental (radical contextual) reductionist theories. As emphasized by Overton (1998, 2003, Chapter 2, this *Handbook,* this volume), split and reductionist conceptions are equally philosophically problematic and empirically flawed. Both of these split conceptions thus can be expected to result in problems for the conduct of science and for the application of science to policies and programs. This comparability of problems between genetic

TABLE 1.2 Policy and Program Implications That Arise If the Hereditarian (Genetic Reductionist) "Split" Conception of Genes (A) Were Believed to Be True or False; and (B) Were in Fact True or False

A. Hereditarian "split" conception is believed to be:			
1. True		2. False	
B. Public policy and social program implications if hereditarian "split" position were in fact:			
1. True	2. False	1. True	2. False
Repair inferior genotypes, making them equal to superior genotypes	Same as A.1, B.1	Wasteful and futile humanitarian policies	Equity, social justice, equal opportunity, affirmative action
Miscegenation laws		Wasteful and futile programs of equal opportunity, affirmative action, equity, and social justice	Celebration of diversity
Restrictions of personal liberties of carriers of inferior genotypes (separation, discrimination, distinct social tracts)		Policies and programs to quell social unrest because of unrequited aspirations of genetically constrained people	Universal participation in civic life
Sterilization		Deterioration of culture and destruction of civil society	Democracy
Elimination of inferior genotypes from genetic pool			Systems assessment and engagement
			Civil society

TABLE 1.3 Policy and Program Implications That Arise If the Strict Environmentalist (Radical Contextual) "Split" Conception of Context (A) Were Believed to Be True or False; and (B) Were in Fact True or False

A. Strict environmental "split" conception is believed to be:			
1. True		2. False	
B. Public policy and social program implications if environmentalist "split" position were in fact:			
1. True	2. False	1. True	2. False
Provide all children with same educational or experiential regimen to maximize their common potential/aptitude Eliminate all individualized educational or training programs Standardized assessments for all children Penalties for parents, schools, and communities when children manifest individual differences in achievement Educate all parents, caregivers, and teachers to act in a standard way in the treatment of all children	Same as A.1, B.1	Wasteful and counterproductive diversity-sensitive policies Wasteful and counterproductive programs based on individual differences Policies and programs to quell social unrest because of unrequited aspirations of people promised that the individualized program they received would make them equal to all other people Deterioration of culture and destruction of civil society	Programs that are sensitive to individual differences and that seek to promote a goodness of fit between individually different people and contexts Affirmative actions to correct ontogenetic or historical inequities in person-context fit Celebration of diversity Universal participation in civic life Democracy Systems assessment and engagement Social justice Civil society

and environmental reductionist approach can be seen in the A.2.B.1. quadrant of Table 1.3. In turn, and as was also the case for the A.2.B.2 quadrant in Table 1.2, this quadrant of Table 1.3 presents the policy and program implications of believing that the split, environmentalist conception is (correctly) believed to be false and is in fact false. As in Table 1.2, then, this quadrant illustrates the policy and program implications of believing developmental systems theory to be true when, in fact, it is true.

Both tables demonstrate that if the split, reductionist conceptions of human development are believed to be true, then irrespective of whether they are in fact true (and they incontrovertibly are *not* true; e.g., see Gottlieb, 1997; Hirsch, 1997; Horowitz, 2000; Lerner, 2002; Venter et al., 2001), a range of actions constraining the freedom of association, reproductive rights, and even survival of people would be promoted. Thus, as shown in Table 1.2, if the hereditarian conception were correctly regarded as false (and conversely the developmental systems conception were correctly seen as true), then policies and programs aimed at social justice and civil society for the diverse families and children of the United States would be promoted. Similarly, Table 1.3 shows that if the developmental systems perspective is correctly seen as true and if the strict environmentalist conception is correctly regarded as false, corresponding results for social justice and civil society are promoted. This result obtains although the strict environmentalist perspective is associated with a set of problematic policy and program implications that differ from those problems linked to the hereditarian perspective.

Despite the theory and research that lends support to a dynamic conception of gene ↔ experience coaction, some proponents of genetic reductionism maintain that concepts and methods regarding genes as separable from context are valid and overwhelmingly, or irrefutably, evident. The media continue to tell this story and, perhaps more often than not, the Person in the Street is persuaded by it.

The challenge that such language use and public discourse represents is not merely one of meeting our scientific responsibility to amend incorrect dissemination of research evidence. Horowitz (2000) reminds us that an additional, and ethical, responsibility is to support social justice. She emphasizes that such action is critical in the face of the simplistically seductive ideas of genetic reductionism, especially when coupled with the deficit model. She explains:

> If we accept as a challenge the need to act with social responsibility then we must make sure that we do not use single-variable words like genes or the notion of innate in such a determinative manner as to give the impression that they constitute the simple answers to the simple questions asked by the Person in the Street lest we contribute to belief systems that will inform social policies that seek to limit

> experience and opportunity and, ultimately, development, especially when compounded by racism and poorly advantaged circumstances. Or, as Elman and Bates and their colleagues said in the concluding section of their book *Rethinking Innateness* (Elman et al., 1998), "If our careless, under-specified choice of words inadvertently does damage to future generations of children, we cannot turn with innocent outrage to the judge and say 'But your Honor, I didn't realize the word was loaded.' " (Horowitz, 2000, p. 8)

Overton (Chapter 2, this *Handbook,* this volume) points also to the need to appreciate the subtlety of language to avoid loading our scientific language with phrases that, on a manifest level, may seem to reject the split thinking of genetic reductionism but, on a deeper, structural level, employ terms that legitimate the language of such thinking remaining part of scientific discourse. He notes:

> In its current split form no one actually asserts that matter, body, brain, genes or society, culture, and environment provide *the* cause of behavior or development: The background idea of one or the other being the privileged determinant remains the silent subtext that continues to shape discussions. The most frequently voiced claim is that behavior and development are the products of the *interactions* of nature and nurture. But interaction itself is generally conceptualized as two split-off pure entities that function *independently* in cooperative and/or competitive ways (e.g., Collins et al., 2000). As a consequence, the debate simply becomes displaced to another level of discourse. At this new level, the contestants agree that behavior and development are determined by *both* nature *and* nurture, but they remain embattled over the relative merits of each entity's essential contribution. (Overton, Chapter 2, this *Handbook,* this volume, p. 33)

Similarly, he explains:

> Moving beyond behavior genetics to the broader issue of biology and culture, conclusions such as "contemporary evidence confirms that the expression of heritable traits depends, often strongly, on experience" (Collins et al., 2000, p. 228) are brought into question for the same reason. Within a relational metatheory, such conclusions fail because they begin from the premise that there are pure forms of genetic inheritance termed "heritable traits" and within relational metatheory such a premise is unacceptable. (Overton, Chapter 2, this *Handbook,* this volume, p. 36)

Whereas contemporary development science rejects the philosophical, theoretical, and (in large part) methodological features of the split thinking associated with genetic reductionist approaches to human development, found in both behavior genetics and sociobiology, subtle and nuanced problems of language continue to suggest that these split approaches to human development remain legitimate. I have noted the potentially enormous negative consequences of such problematic language in our scientific discourse—especially if the Person in the Street believes that employing such terms means that the genetic reductionist ideas about social policy should be countenanced. As a consequence, we must be assiduous and exact in the terms we use to explain why split conceptions in general, and genetic reductionist ones in particular, fail as useful frames for scientific discourse about human development. Indeed, as Lewontin (1981, p. 245) has cautioned, "The price of metaphor is eternal vigilance."

USING THE DEVELOPMENTAL SYSTEMS PERSPECTIVE FOR THEORY, RESEARCH, AND APPLICATION

Developmental systems theories offer another vision of and vocabulary for the role of genes and, more generally, of biology in human development. As illustrated in Tables 1.2 and 1.3, these theories of human development provide a different view of the role of genes in behavior and development and offer a different, if admittedly more complex, story to the Person in the Street (Lerner, 2004a, 2004b). It is predicated on a relational metatheory (Overton, Chapter 2, this *Handbook,* this volume) and thus eschews splits between nature and nurture, organism and environment, or any of the other Cartesian dualities that have been part of the discourse in past historical eras of developmental science (see Cairns & Cairns, Chapter 3, this *Handbook,* this volume; Overton, Chapter 2, this *Handbook,* this volume; Valsiner, Chapter 4, this *Handbook,* this volume). Developmental systems theories stress that genes, cells, tissues, organs, whole organisms, and all other, extraorganism levels of organization composing the ecology of human development are fused in a fully coacting, mutually influential, and therefore dynamic system (Bronfenbrenner, 2005; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Gottlieb et al., Chapter 5, this *Handbook,* this volume; Thelen & Smith, Chapter 6, this *Handbook,* this volume; Tobach, 1981).

This bidirectional relation between the individual and the complex ecology of human development may be

represented as the individual ↔ context. Because the broadest level of the context is history, temporality is always a part of the fused systems of individual ↔ context relations. Thus the potential for systematic change (plasticity) exists across the life span (Baltes et al., 1998, Chapter 11, this *Handbook,* this volume; Elder, & Shanahan, Chapter 12, this *Handbook,* this volume). Of course, the system that promotes change through the coaction of multiple levels of organization can also act to constrain it. Therefore, this fusion of the potential for both constancy and change makes plasticity relative and not absolute (Lerner, 1984, 2002).

Nevertheless, the temporality of human development and the presence of at least relative plasticity indicate that one may be optimistic that means may be found, at one or more levels of the ecology of human development, to apply developmental science in ways that promote positive development across the life span (Bronfenbrenner, 2005; Ford & Lerner, 1992; Lerner, 2002, 2004c; Magnusson & Stattin, 1998). Moreover, because no two people, even monozygotic (MZ) twins, will have the same history of individual ↔ context relations across the life span, the individuality of each person is lawfully assured (Hirsch, 1970, 1997, 2004). As noted, the presence of over 70 trillion potential human genotypes means that the probability of two genetically identical children arising from any set of parents is quite small—about one in 6.27 billion—and that the probability of two genetically identical but non-MZ children arising from one specific couple is slightly less than one in 160,000 (Hirsch, 2004); thus, there is an obviously low probability that any two people, with the exceptions of MZs, will have an identical biological genotype (to use a redundancy).

However, the probability that two people, including MZs, will have an identical history of events, experiences, and social relationships, that is, a social genotype (to use an oxymoron), is so dismally small as to be equivalent to what most of us would regard as impossible. The integration of biology and context across time means that each person has a developmental trajectory (a dynamically changing phenotype) that is, at least in part, individually distinct.

DIVERSITY—A FUNDAMENTAL ASSET OF HUMAN DEVELOPMENT

Diversity is a distinctive and, in fact, a defining feature of the human life course (Spencer, Chapter 15, this *Handbook,* this volume). Within an individual over time, diversity—seen as the potential for systematic intraindividual change, represents a potential for life-span change. Therefore, diversity, characterized as intraindividual plasticity, is a key asset or developmental strength that may be capitalized on to promote a person's positive, healthy developmental change. Across people, diversity, characterized as interindividual differences, represents a sample of the range of variation that defines the potential material basis for optimizing the course of human life. *Any* individual *may* have a diverse range of potential developmental trajectories and, as well, *all* groups—because of the necessarily diverse developmental paths of the people within them—*will* have a diverse range of developmental trajectories. Diversity, seen as both intraindividual change and as interindividual differences in intraindividual change, is both a strength of individuals and an asset for planning and promoting means to improve the human condition (Benson et al., Chapter 16, this *Handbook,* this volume; Lerner, 2004c; Spencer, Chapter 15, this *Handbook,* this volume).

The diversity of individual ↔ context relations that comprises change within the dynamic developmental system, along with the optimism about improving human life that derives from the relative plasticity of humans, means that it is possible to apply developmental science to promote positive development across the life span (Benson et al., Chapter 16, this *Handbook,* this volume; Damon, 1997, 2004; Lerner, 2002, 2004a, 2004b, 2004c). As such, it is useful to describe the features and implications for science and application of the positive human development perspective derived from developmental systems theories.

FEATURES AND IMPLICATIONS OF A POSITIVE HUMAN DEVELOPMENT PERSPECTIVE

The fused system of individual ↔ context relations that provides the potential for relative plasticity across the life span constitutes a fundamental strength of each person. This strength is present to differing extents in all infants, children, adolescents, adults, and aged individuals. Relative plasticity diminishes across the life span but, as the research of Baltes, in the Berlin Study of Aging (e.g., Baltes et al., 1998, Chapter 11, this *Handbook,* this volume; Baltes & Smith, 2003; Smith et al., 2002), elegantly demonstrates, there is evidence for the presence of plasticity into the 10th and 11th decades of life.

The fused developmental system provides a potential for change not just in people but also in the contexts in which individuals develop. This latter potential means that families, neighborhoods, and cultures are also relatively plastic and that the level of resources—or developmental assets—that they possess at any point in time may also be altered across history. Contextual strengths and assets in support of positive development may be envisioned within the terms suggested by Benson et al. (Chapter 16, this *Handbook,* this volume), as the community nutrients for healthy and positive development. These assets can be grown, aligned, and realigned to improve the circumstances of human development.

At any given place or point in time, both individuals and levels of the context within this plastic developmental system may manifest problems or may be deficient in some aspect of individual, family, or community life that is needed for improved functioning. The presence of plasticity does not mean that people are not poor or that they do not lack social nutrients that would enhance their development. What relative plasticity across the developmental system does mean, however, is that all people have strengths that, when integrated with the developmental assets of communities, may be capitalized on to promote positive change. As such, problems or deficits constitute only a portion of a potentially much larger array of outcomes of individual ↔ context relations. Problems are not inevitable, and they are certainly not fixed in a person's genes.

The role of developmental science is to identify those relations between individual strengths and contextual assets in families, communities, cultures, and the natural environment, and to integrate strengths and assets to promote positive human development (Lerner, 2004a, 2004b). A system that is open for change for the better is also open for change for the worse. The research and applications of developmental scientists should be aimed at increasing the probability of actualization of the healthy and positive portions of the distribution of potential outcomes of individual ↔ context relations.

The scientific agenda of the developmental scientist is more than just to describe and to explain human development. It is also to work to optimize it (Baltes, 1968, 1987, 1997; Baltes et al., Chapter 11, this *Handbook,* this volume). Efforts to enhance human development in its actual ecology are a way to test theoretical ideas about how systemic relations coalesce to shape the course of life. These efforts stand as well as ethical responsibilities of human development scholars, in their roles both as researchers involved with human lives and as citizens of a civil society (Fisher, 1993, 1994, 2003; Fisher, Hoagwood, & Jenson, 1996; Fisher & Tryon, 1990).

Moreover, without a scientific agenda that integrates description, explanation, and optimization, human development science is, at best, an incomplete scholarly endeavor. A developmental science that is devoid of knowledge of the individual and group ranges among diverse groups, and that is devoid of knowledge of the range of assets in diverse contexts, is an incomplete developmental science. It is also inadequate, when seen from the perspective of the need for evidence-based policy and program applications.

FRAMING THE RESEARCH AGENDA OF HUMAN DEVELOPMENT

What becomes, then, the key empirical question for developmental scientists interested in describing, explaining, and promoting positive human development? The key question is actually five (5) interrelated "what" questions:

1. What attributes (?) of
2. What individuals (?) in relation to
3. What contextual/ecological conditions (?) at
4. What points in ontogenetic, family or generational, and cohort or historical, time (?) may be integrated to promote
5. What instances of positive human development?

Answering these questions requires a nonreductionist approach to methodology. Neither biogenic, nor psychogenic or sociogenic approaches are adequate. Developmental science needs integrative and relational models, measures, and designs (Lerner, Dowling, & Chaudhuri, 2005). Examples of such methodology in developmental systems-oriented research are the scholarship of Eccles and her colleagues on stage ↔ environment fit (e.g., Eccles, Wigfield, & Byrnes, 2003); of Damon and his colleagues on the community-based youth charter (Damon, 1997, 2004; Damon & Gregory, 2003); of Benson and his colleagues at Search Institute on the role of developmental assets in positive youth development (e.g., Benson et al., Chapter 16, this *Handbook,* this volume; Leffert et al., 1998; Scales, Benson, Leffert, & Blyth, 2000); of Theokas (2005; Theokas & Lerner, 2005; see too Lerner

et al., 2005) on the role of actual developmental assets associated with families, schools, and neighborhoods on positive youth development; and of Leventhal and Brooks-Gunn (2004), and of Sampson, Raudenbush, and Earls (1997) on the role of neighborhood characteristics on adolescent development.

The methodology employed in individual ↔ context integrative research must also include a triangulation among multiple and, ideally, both qualitative and quantitative approaches to understanding and synthesizing variables from the levels of organization within the developmental system. Such triangulation may usefully involve the classic approach offered by Campbell and Fiske (1959) regarding convergent and discriminant validation through multitrait-multimethod matrix methodology. Diversity-sensitive measures are needed within such approaches, and they must be used within the context of change-sensitive—and hence longitudinal—designs (Cairns & Cairns, Chapter 3, this *Handbook,* this volume; Lerner et al., 2005; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume). Trait measures developed with the goal of excluding variance associated with time and context are not optimal choices in such research. To reflect the richness and strengths of our diverse humanity, our repertoire of measures must be sensitive to the diversity of person variables, such as race, ethnicity, religion, sexual preferences, physical ability status, and developmental status, *and* to the diversity of contextual variables such as family type, neighborhood, community, culture, physical ecology, and historical moment.

It is particularly important that our designs and our measures be sensitive to the different meanings of time. Insightful formulations about the meanings of time in the dynamic developmental system have been provided by Elder (1998; Elder & Shanahan, Chapter 6, this *Handbook,* this volume), Baltes (Baltes et al., Chapter 11, this *Handbook,* this volume), and Bronfenbrenner (2005; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume). Our methods must appraise, then, age, family, and historical time and must be sensitive to the role of both normative and nonnormative historical events in influencing developmental trajectories.

Finally, our designs should be informed not just by colleagues from the multiple disciplines with expertise in the scholarly study of human development. Our methods should be informed as well by the people and communities we study (Lerner, 2002, 2004a, 2004b, 2004c; Villarruel, Perkins, Borden, & Keith, 2003). They, too, are experts about development—a point our colleagues in cultural anthropology, sociology, and community youth development research and practice have been making for several years. Most certainly, participants in our community-based research and applications are experts in the character of development in their families and neighborhoods. Accordingly, research that fails to capitalize on the wisdom of its participants runs the real danger of lacking authenticity and of erecting unnecessary obstacles to the translation of the scholarship of knowledge generation into the scholarship of knowledge application (Jensen, Hoagwood, & Trickett, 1999).

CONCLUSIONS

Contemporary developmental science—predicated on a relational metatheory and focused on the use of developmental systems theories to frame research on dynamic relations between diverse individuals and contexts—constitutes a complex and exciting approach to understanding and promoting positive human development. It offers a means to do good science, informed by philosophically, conceptually, and methodologically useful information from the multiple disciples with knowledge bases pertinent to the integrated, individual ↔ context relations that compose human development. Such science is also more difficult to enact than the ill-framed and methodologically flawed research that followed split and reductionist paths during the prior historical era (Cairns & Cairns, Chapter 3, this *Handbook,* this volume; Overton, Chapter 2, this *Handbook,* this volume; Valsiner, Chapter 4, this *Handbook,* this volume). Such science is also more difficult to explain to the Person in the Street.

As illustrated eloquently by the work discussed in this volume, the richness of the science and the applications that derive from developmental systems perspectives, as well as the internal and ecological validity of this work, are reasons for the continuing and arguably still growing attractiveness of this approach. Moreover, this approach underscores the diverse ways in which humans, in dynamic exchanges with their natural and designed ecologies, can create for themselves and others opportunities for health and positive development. As Bronfenbrenner (2005) eloquently puts it, it is these relations that make human beings human.

Accordingly, the relational, dynamic, and diversity-sensitive scholarship that now defines excellence in developmental science may both document and extend the power inherent in each person to be an active agent in

his or her own successful and positive development (Brandtstädter, Chapter 10, this *Handbook,* this volume; Lerner, 1982; Lerner & Busch-Rossnagel, 1981; Lerner, Theokas, et al., 2005; Magnusson & Stattin, 1998, Chapter 8, this *Handbook,* this volume; Rathunde & Csikszentmihalyi, Chapter 9, this *Handbook,* this volume). A developmental systems perspective leads us to recognize that, if we are to have an adequate and sufficient science of human development, we must integratively study individual and contextual levels of organization in a relational and temporal manner (Bronfenbrenner, 1974; Zigler, 1998). Anything less will not constitute adequate science. And if we are to serve the United States' and the world's individuals, families, and communities through our science, if we are to help develop successful policies and programs through our scholarly efforts, then we must accept nothing less than the integrative temporal and relational model of diverse and active individuals embodied in the developmental systems perspective.

Through such research, developmental science has an opportunity to combine the assets of our scholarly and research traditions with the strengths of our people. We can improve on the often-cited idea of Kurt Lewin (1943), that there is nothing as practical as a good theory. We can, through the application of our science to serve our world's citizens, actualize the idea that nothing is of greater value to society than a science that devotes its scholarship to improving the life chances of all people. By understanding and celebrating the strengths of all individuals, and the assets that exist in their families, communities, and cultures to promote these strengths, we can have a developmental science that may, in these challenging times, help us, as a scientific body *and* as citizens of democratic nations, to finally ensure that there is truly liberty and justice for all.

CHAPTER 2

Developmental Psychology: Philosophy, Concepts, Methodology

WILLIS F. OVERTON

Throughout its history, psychology and its sub disciplines, including developmental psychology, have been captives of numerous fundamental contradictory positions. These basic dichotomies, called *antinomies,* include subject-object, mind-body, nature-nurture, biology-culture, intrapsychic-interpersonal, structure-function, stability-change, continuity-discontinuity, observation-reason, universal-particular, ideas-matter, unity-diversity, and individual-society. While often explicitly denying the relevance of philosophy to its operations, psychology has implicitly used the philosophical assumptions of a seventeenth-century ontological dualism, a nineteenth-century epistemological empiricism, and an early twentieth-century neopositivism, to build a standard orthodox approach to the resolution of the antinomies. This approach elevates one concept of the pair to a privileged position, builds a research program on this concept, and then strives to demonstrate observationally that the nonprivileged concept can be denied or marginalized. This standard approach to the antinomies has never been successful because it ultimately represents merely an attempt to suppress one concept, and one research program's suppressed concept becomes another program's privileged base. In the nature-nurture battles, for example, while virtually all combatants these days acknowledge some type of interaction, it is a rare program that promotes nature and nurture as co-equal reciprocally determined complementary processes (Overton, 2004a).

This chapter explores how basic conceptual assumptions have historically shaped, and how they continue to shape, proposed solutions to empirical problems including, very fundamentally, the antinomy problem. The focus

of the chapter is on development. We look at the impact various conceptual models have on our very understanding of the concept of development and, as a consequence, on the theories and methods designed to empirically explore development across several series, including *phylogenesis* (development of the species—evolution), *embryogenesis* (development of the embryo), *ontogenesis* (development of the individual across the life span), *microgenesis* (development across short time spans), *orthogenesis* (normal development), and *pathogenesis* (development of pathology, here psychopathology). My thesis is that historically two broad abstract metatheories, often termed *worldviews,* have constituted the basic conceptual contexts within which alternative ideas about the nature and operations of empirical science, psychology, and especially developmental psychology, have emerged and grown. *Split metatheory,* based on a view of the world as decomposable into a foundation of fixed pure forms, has yielded the antinomies, and associated concepts such as foundationalism, elementarism, atomism, reductionism. *Relational metatheory,* emerging from a view of the world as a series of active, ever-changing forms replaces the antinomies with a fluid dynamic holism and associated concepts such as *self-organization, system,* and *the synthesis of wholes.*

Because the focus of the chapter is a conceptual analysis of development—its concepts, theories, and metatheories—a discussion of the place of concepts in any empirical science, along with a discussion of the nature and functioning of those fundamental conceptual systems called *metatheories,* represent a necessary preamble. Wittgenstein (1958) once remarked that "in psychology there are empirical methods and conceptual confusions" (p. xiv). To avoid validating such a pessimistic judgment, it is essential that psychology, or any empirical science, focus some significant portion of its energy on the clarification of concepts that are central to its theories and methods. Conceptual clarification and the exploration of conceptual foundations have traditionally been the principle provinces of philosophy, and therein lies the rub. Within the psychological community, philosophical thought—and, as a consequence, any focus on conceptual clarification—has tended to be assigned the role of the anti-science. As Robert Hogan (2001) commented, "Our training and core practices concern research methods; the discipline is . . . deeply skeptical of philosophy. We emphasize methods for the verification of hypotheses and minimize the analysis of the concepts entailed by the hypotheses" (p. 27). However, Hogan also raises a warning flag as he goes on to note that "all the empiricism in the world can't salvage a bad idea" (p. 27). Broadly, the marginalization of all things philosophical, and, hence, the marginalization of any extended examination of conceptual foundations, has rested on a forced dichotomy, which locates philosophy in a space of reason and reflection split off from observation and experimentation, and psychology in a space of observation and experimentation split off from reason and reflection.

This marginalization of conceptual foundations in contemporary psychology is ironically itself the product of the acceptance of some basic ontological and epistemological—hence philosophical—assumptions. These assumptions begin with the idea of splitting reason from observation, and follow with the epistemological notion that knowledge and, indeed, reason itself originates in observation and only observation. These assumptions then lead to a particular definition of scientific method as entailing observation, causation, and induction-deduction, and only observation, causation, and induction-deduction. Morris R. Cohen (1931), a philosopher, captured the spirit of this conceptual splitting long ago when he criticized its "anti-rationalism . . . bent on minimizing the role of reason in science" and pointed out that the motto of this approach is the split "Don't think [reason]; find out [observe]" (p. 76).

Over the past 50 or so years, many powerful arguments have been mounted against this split between reason and observation and the subsequent denial of reflection. Some of these arguments are discussed later in this chapter. Indeed, enough arguments have emerged that the attitude itself has often been declared dead, as in the claim that the methodology called *neopositivism* is dead. Yet, like the mythical Hydra, new forms of this split continue to appear and exert a contextual shaping effect. The split is often found in the disparagement of reason itself, as in some contemporary versions of so-called postmodern thought. Sometimes, the split is found in explicit and implicit attacks on theory, as in a particular rhetoric that states that all theories must be induced directly from observations (i.e., must be "data based" or "data driven"). It is also found in a dogmatic retort given to any reflective critique—"that's just philosophy." Often, it is found in the celebration of the analytic over the synthetic, as when analytic methods of observation are presented as the only acceptable tools for expanding our knowledge domain, with the consequence that theory is often reduced to method, as when flow charts illustrating possible relations among empirical variables are offered as

guiding theories. Frequently, it is found in the valuing of the instrumental over the expressive, as when behavior is understood *only* in the context of the success or failure of adjustment to some external criteria and *never* as an index or expression of an embodied self-organizing system that constitutes the psychological subject.

In whatever of these or other multiple forms it appears, the significant point is that the split between reason and observation, along with the subsequent marginalization of reason and reflection, is itself the direct consequence of a conceptual position favoring a particular approach to knowledge building. This conceptual position operates as a foundation for building other concepts, theories, and methods. The position is not in itself a given in any self-evident or directly observational fashion, but simply a specific claim, and, as with any claim or argument, reasons must be presented to support the value of the claim. These reasons and the claim itself require reflection and clarification before they can be rationally accepted as valid or rejected as invalid. It is just possible that the split between reason and observations is part of a very bad foundation for our discipline, but this cannot be decided without further exploring conceptual issues. To paraphrase Hogan, all the observation in the world can't salvage conceptual confusions.

METATHEORY

In scientific discussions, the basic concepts to be explored in this chapter are often termed *metatheoretical.* Metatheories transcend (i.e., "meta") theories in the sense that they define the context in which theoretical concepts are constructed, just as a foundation defines the context in which a house can be constructed. Further, metatheory functions not only to ground, constrain, and sustain theoretical concepts but also functions to do the same thing with observational methods of investigation. When specifically discussing background ideas that ground methods, these are here termed *metamethods. Methodology* would also be an appropriate term here if this were understood in its broad sense as a set of principles that guide empirical inquiry (Asendorpf & Valsiner, 1992) and not as particular methods themselves.

The primary function of metatheory—including metamethod—is to provide a rich source of concepts out of which theories and methods grow. Metatheory also provides guidelines that help to avoid conceptual confusions and what may ultimately be unproductive ideas and methods.

Any discussion of metatheory requires a constant reminder of the importance of maintaining distinctions between various levels of analysis or discourse (Figure 2.1). Theories and methods refer directly to the empirical world, while metatheories and metamethods refer to the theories and methods themselves. The most concrete and circumscribed level of analysis or discourse is the *observational level.* This is one's current commonsense level of conceptualizing—not pristine, interpretation free "seeing"—the nature of objects and events in the world. For example, one might describe the developmental changes in some domain as smooth and continuous, abrupt and discontinuous, or some combination of both. Regardless of which characterization is chosen, or whether this characterization is treated as a narrow observation or a broad inductive inference, the assertion functions at the observational level of dealing with the world.

Although the observational, commonsense, or folk level of analysis has a sense of immediacy and concreteness, we can and do focus our attention on this common-

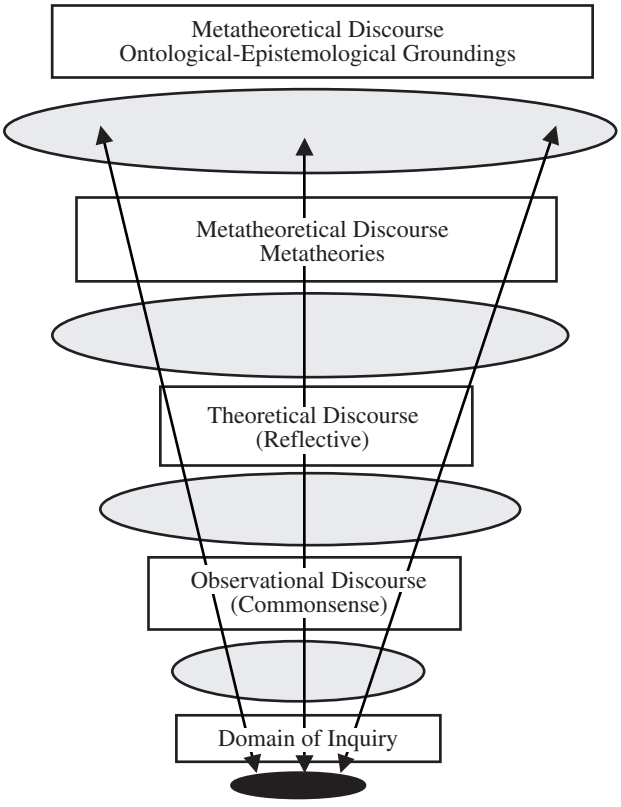

Figure 2.1 Levels of discourse in understanding a domain of inquiry.

sense understanding and we do think about it. In so doing, we have moved to a *reflective level* of analysis, and here the first critical differentiation is the *theoretical level* of discourse. Here, thought is about organizing and reformulating observational understandings in a broader and more abstract field. At the theoretical level, concepts are *about* the observational level and these range from informal hunches to highly refined theories about the nature of things, including human behavior and change. Classical developmental theories such as Piaget's, Vygotsky's, and Werner's, for example, contain theoretical principles (e.g., stages) that hypothesize that ultimately a combination of continuous and discontinuous changes will best define human development. Skinnerian and social learning theories alternatively have hypothesized that all change is best represented as strictly continuous.

Beyond the theoretical level, the next level of reflective thought is the *metatheoretical level* of analysis. Here, thought is about basic concepts that impact on both the theoretical and observational level. A *metatheory* itself is a set of rules, principles, or a story (narrative), that both describes and prescribes what is acceptable and unacceptable as theory—the means of conceptual exploration of any scientific domain. For example, in the metatheory termed "atomism" only continuous change is possible and thus only theories committed to strict continuity are formulated. A *metamethod* is also a set of rules, principles, or a story, but this story describes and prescribes the nature of acceptable methods—the means of observational exploration—in a scientific discipline. When metatheoretical ideas—including metamethod—are tightly interrelated and form a coherent set of concepts, the set is often termed a *model* or *paradigm.* These coherent sets can themselves form a hierarchy in terms of increasing generality of application. Thus, a model that contains the basic concepts from which a theory of memory will be constructed is a relatively low level model because it applies only to memory. Models such as "developmental systems" (e.g., Lerner, 2002) or "equilibrium models" (see Valsiner 1998a) apply to a number of domains including social, cognitive, and emotional domains and function at a higher level in the hierarchy. The hierarchical dimension of any given set of metatheoretical ideas also forms a coherently interrelated system of ideas, and the model operating at the pinnacle of this hierarchy is termed a *worldview* (Overton, 1984). Worldviews are composed of coherent sets of *epistemological* (i.e., issues of knowing) and *ontological* (i.e., issues of reality) principles. In this chapter, much of the discussion concerns ideas that have a very high range of application.

Metatheories and metamethods are closely interrelated and intertwined. For example, when considering the very nature of development, a prevailing metatheory may claim that change of form (transformational change) is a legitimate and important part of the understanding of developmental change. If a prevailing metatheory asserts the legitimacy of transformational change, then theories of development will include some type of "stage," "phase," or "level" because these are theoretical concepts used to designate transformational change: If transformational change and stage, phase, or level are part of one's metatheory, then the related metamethod will prescribe the significance of methods, which assess patterns and sequence of patterns appropriate for empirically examining these concepts in any given specific domain. If a metatheory prescribes that transformational change is unimportant to our understanding of development, then any theoretical concepts of stage, phase, or level, will be viewed negatively, and methods of pattern and sequential assessment will be understood to be of marginal interest.

Broadly, a metatheory presents a vision of the nature of the world and the objects of that world (e.g., a metatheory might present a picture of the child as an "active agent" who "constructs" his or her known world, but another metatheory might picture the child as a "recording device" that "processes" information). A metamethod presents a vision of the tools that will be most adequate to explore the world described by the metatheory.

Any rich understanding of the impact of the metatheoretical requires an historical appreciation of the emergence of specific alternative metatheoretical approaches to knowledge. Developmental psychology was born and spent its early years in a curious metatheoretical world. This world, which began in the seventeenth century, has been called the modern world or "modernity." In the past century, the modern world has undergone major crises and these have formed the context for alternative contemporary metatheories. Before discussing specific metatheories and their historical origins, an examination of the broad ways that metatheory impacts how we understand the very nature of development requires attention. This discussion establishes a developmental framework serving as a general context for the remainder of the chapter.

THE CONCEPT OF DEVELOPMENT

When exploring nature of development the one feature that virtually all agree on is that above all else development is about *change*. It is common to speak of the development of various art forms, societies, different economic systems, religion, philosophy, science, and so on, and in each case changes that the area goes through are the focus of attention. In developmental psychology, the situation is the same. As a branch of psychology, developmental psychology considers changes in behavior and the processes implied by the behavior such as intending, thinking, perceiving, and feeling. As a developmental psychology, the focus is upon these changes as they occur across the entire life span from conception to death, or within certain periods, such as infancy, childhood, adolescence, adulthood, and the late mature years.

Although the focus on change is straightforward and noncontroversial, major problems arise when considering whether every type of change should be accepted as developmental and, if not, what is the peculiar nature of the change we call developmental. Perhaps, general agreement would occur that the types of behavioral changes that occur when we become fatigued or tired would not be termed developmental change. But what about other changes that are transitory or easily reversed? For example, if someone is struck on the head they may change from a conscious to a nonconscious state; is this development change? Or, a pigeon can be trained to peck at a button when a light comes on, and then trained to not peck at the button when the light comes on; is this development change? The answer to these and other questions about the nature of development change depend to a significant degree on the metatheory that is employed to ground a definition of development.

One of the most popular characterizations of developmental change, at least among developmental psychologists, has been some variant of the idea that development is defined as "changes in observed behavior across age." This understanding is certainly a quick and ready pragmatic definition suitable to act as an operational guide to a series of empirical investigations. However, if this understanding were used to broadly give meaning to the domain of inquiry called developmental psychology, some very significant problems would emerge.

The first problem involves linking developmental change to age. On any close examination, it becomes clear that although age may operate fairly well at an observational level of discourse, at a reflective level it fails to make any meaningful distinctions. Age has no unique qualities that differentiate it from time; age is simply one index of time. Most important, there is nothing unique or novel about units of age-time, such as years, months, weeks, minutes, and so on. Should we then say that development is about changes that occur in time as some have (e.g., Elman, 2003), or that time is a "theoretical primitive?" Time can hardly be a theoretical anything, as time, in and of itself, does nothing. As Wohlwill (1973) once pointed out, time cannot be an independent variable, it is merely a dimension along which processes operate. All change—even if entirely transitory—occurs "in" time, so we come back to simply saying that development is about change. The implication here is that to arrive at meaningful distinctions that can direct a broad area of scientific inquiry we must explore further the nature of change itself. Before doing this, however, we shall consider a second problematic outcome of defining development as something like "changes in observed behavior across age." This is the problematic meaning of "change of observed behavior."

What Changes in Development: Expressive-Constitutive and Instrumental-Communicative Functions of Behavior

Behavior is clearly the observational focus of our empirical investigations—the dependent variable of our research efforts. The problem is whether "change in observed behavior" introduces the reflective distinction needed to articulate a broad inquiry. Observed behavior, or action more generally—at any level from the neuronal to the molar—can reflect both expressive-constitutive and instrumental-communicative functions. *Expressive* action expresses or reflects some fundamental organization or system. For example, in human ontogenesis behavior is often understood to be diagnostic of some cognitive, affective, or motivational system (see the systems described in the cubes on the left of Figure 2.2). These systems have characteristic forms of activity that are expressed as actions and patterns of action in the world (center horizontal lines of Figure 2.2). A verbalization may reflect the nature of the child's system of thought. A cry, in a particular context, may reflect the status of the child's attachment system. A series of behaviors may reflect the child's intentional system. This expressive function is *constitutive* in the sense that it en-

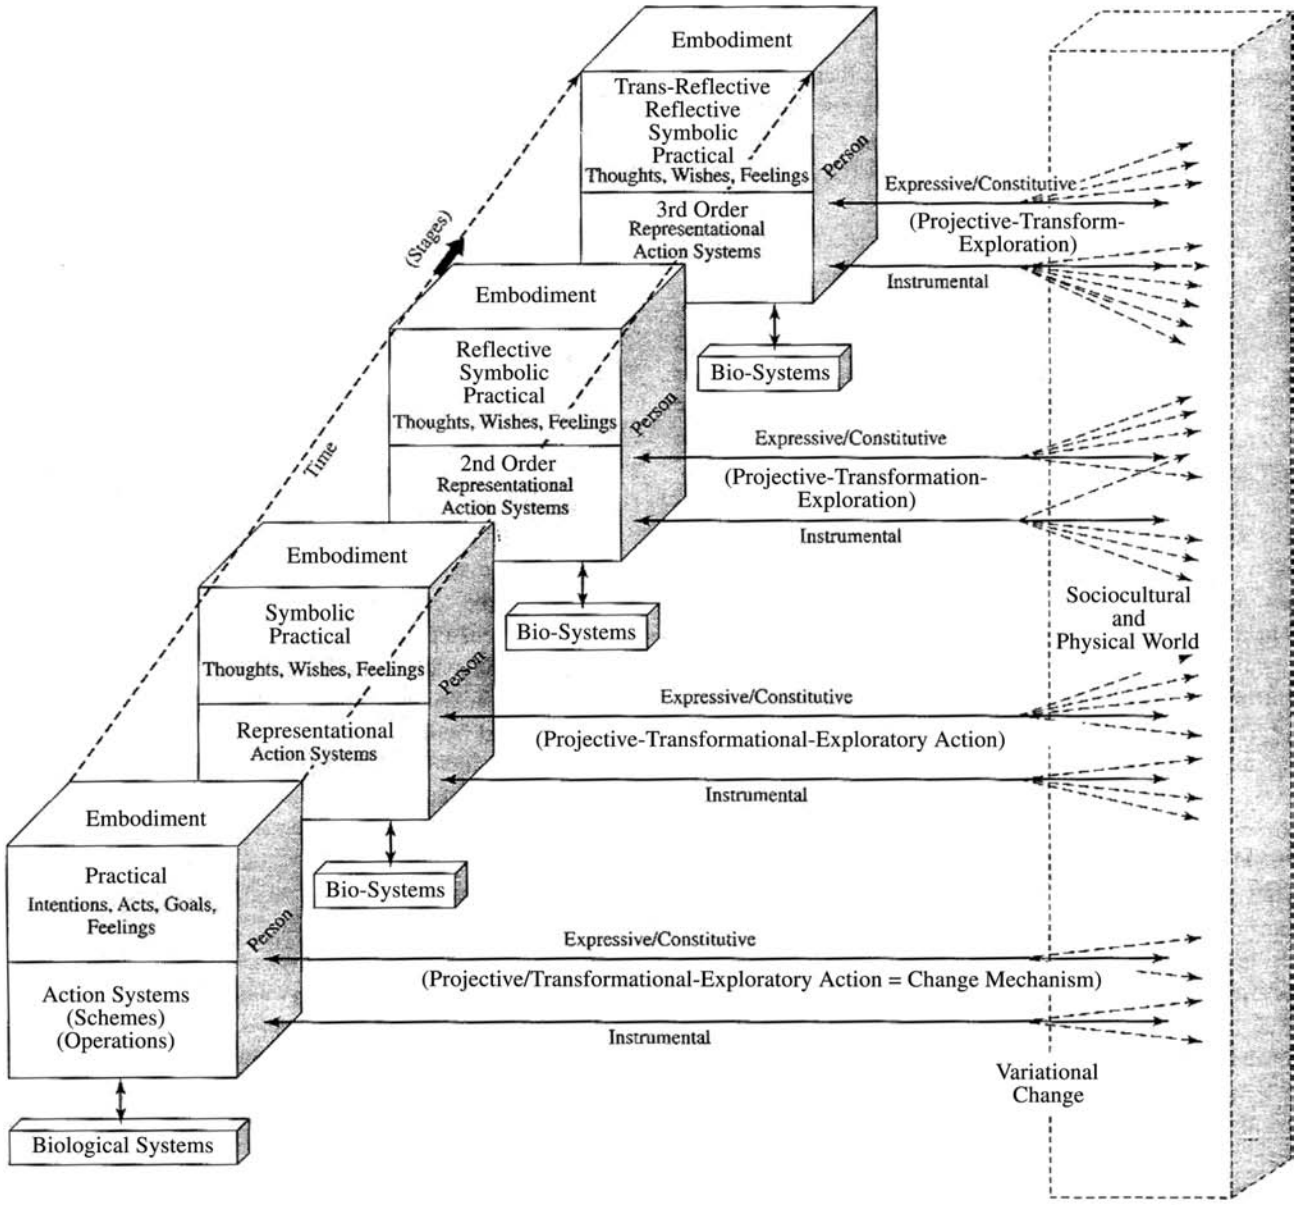

Figure 2.2 The development of the psychological subject: Levels of transformational and variational change emerging through embodied action in a sociocultural and physical world.

tails the creative function of human action (Taylor, 1995). It reflects the base from which new behaviors, intentions, and meanings are constituted. When inquiry is directed toward the assessment or diagnosis of the nature, status, or change of the underlying psychological or biological system, the expressive function is central to inquiry. When exploring the expressive function of an action, the dynamic system that is reflected in the action expression is the *what* that changes in development. Dynamic systems become transformed (left cubes of Figure 2.2) through their action (center horizontal lines of Figure 2.2). We see in the next section that dynamic systems (as a "what" of developmental change) and transformation (as a "type" of developmental change) are closely related.

Instrumental action is behavior that serves as a means to attaining some outcome; it is the pragmatic dimension of action (see center horizontal lines of Figure 2.2). For example, in human ontogenesis an expressive cognitive act or thought may also be the means to solve a problem.

An emotional act of crying may, while being expressive from one perspective, also instrumentally lead to acquiring a caregiver, and walking, which may be expressive when considered as reflecting a broad dynamic system of locomotion, may also be instrumental in acquiring nourishment. *Communicative* action extends action into the domain of the intersubjective (relation of the person cubes at the left and social world at the right of Figure 2.2). Broadly, the expressive-constitutive is the process whereby we come "to have the world we have," and the instrumental-communicative is the process whereby "we order the things in that world" (Taylor, 1995, p. ix). Expressive-constitutive and instrumental-communicative functions of action have each been the focus of developmental investigations. However, conceptual confusions arise and impact on empirical inquiry, if it is left unclear whether the focus of a specific investigation is on the expressive-constitutive or the instrumental-communicative dimension of behavior.

Consider some examples from human ontogenesis that make either expressive-constitutive functions or instrumental-communicative functions the focus of inquiry. Investigations of the infant-caregiver attachment relationship measure the proximity seeking action of the child to the caregiver. When considered as proximity seeking, the action has an instrumental character to it. However, Bowlby and his colleagues have been primarily interested in this action as an expression of an underlying attachment organization; hence, their focus is on the expressive. Bowlby and colleagues use proximity seeking as diagnostic of an underlying attachment system. Piagetian tasks such as the object permanence task, or the conservation task, when examined from an instrumental perspective, constitute successful or unsuccessful problem-solving activities. However, Piaget and his colleagues constructed and used these tasks expressively to diagnosis specific forms of cognitive organization (e.g., schemes, operations). Alternatively, while students' grade point averages may be understood as reflecting, in part, some intellectual organization, the focus of a number of social-cognitive investigations have been on the instrumental quality of this action as an adaptation or adjustment to the social-cultural context. In fact, many investigations that take a sociocultural point of view (see Pinquart and Silbereisen, 2004) limit their developmental interests to instrumental "child outcomes," "coping behaviors," and the other behaviors considered as adaptations to the cultural context. As another example, walking can be examined as an expression of a system of locomotion, but investigations may also focus on walking as instrumental to attaining a goal. Similarly, emotions may be explored as expressions of affective organization (e.g., Boesch 1984; Sroufe, 1979) or as instrumental in attaining a particular outcome (e.g., Saarni, Mumme, & Campos, 1998). Finally, although language development may be, and often has been investigated as a means of communicative functioning, it also has been alternatively examined as an expression of affective-cognitive organization (e.g., Bloom, 1998; Bloom & Tinker, 2001).

From these and other examples it becomes clear that any given action can be understood from the perspective of either its expressive-constitutive or its instrumental-communicative features. Neither the expressive-constitutive nor the instrumental-communicative are given to direct observation, both are reflective characterizations drawn and refined from commonsense understandings, and each may be a legitimate focus of inquiry. When, however, the distinction between expressive-constitutive and instrumental-communicative is not made explicit, "observed behavior" becomes ambiguous. This ambiguity fosters confusion about the specific aim of inquiry and how it contributes to our general understanding of development. Further, this ambiguity allows implicit values to seep in, eventually splitting and contextualizing the field under the influence of hidden metatheoretical assumptions. For example, consider what occurs when "observed behavior" is implicitly framed by historical behavioristic and neopositivistic values. Because early behaviorism and neopositivism excluded the idea that "organization" or "system" could be a fundamental object of inquiry (i.e., excluded the possibility that any person-centered mental systems could be included as legitimate explanations of human behavior), "observed behavior" became implicitly identified with the instrumental-communicative and *only* the instrumental-communicative.

Splitting into a dichotomy and privileging one concept over another in this example leads directly to the theory and methods wars over which concept constitutes the "legitimate" or "significant" or "meaningful" approach to empirical inquiry. For example, the classical battles between the Piagetians, Wernerians, Eriksonians on the expressive-constitutive side, and the Skinnerians, the Spence-Hull learning theorists, and social learning theorists of the Dollard and Miller school on the instrumental-communicative side represented ex-

actly this split. Each side, if not the principal figures themselves, classically assumed that its part constituted the whole. With respect to methods, the effects are more subtle or at least less explored. For example, an examination of issues of validity and reliability illustrates that validity is central to expressive interests and reliability is central to instrumental interests. The often repeated Research Methods 101 lesson, which privileges reliability with the claim that reliability concerns must be the start of measurement, is a story told by classical instrumentalists.

This example of the impact of metatheoretical assumptions represents one of three potential solutions to the relation of the expressive and the instrumental. This "nothing-but" solution takes the instrumental-communicative as privileged and marginalizes the expressive. As another example, this is the solution of any perspective that advocates an exclusively "functional" approach to a topic of inquiry (e.g., see the work on the functional theory of emotions, Saarni et al., 1998); any theory that advocates an exclusively "adaptationist" view of a domain of interest; any theory that explicitly denies or marginalizes the status of mental structures, mental organization, or biological systems as legitimate, if partial, explanations of behavior.

The second potential metatheoretical solution reverses the privileged—marginalization process. This "nothing-but" solution offers the expressive as privileged and the instrumental as the marginal. Approaches offering biological and/or mental systems as both necessary and sufficient for the explanation of behavior would be examples of this solution.

The third metatheoretical solution presents the expressive and the instrumental as co-equal complementary process that function within a relational matrix. In this third approach, expressive and the instrumental are accepted, not as dichotomous competing alternatives, but as different perspectives on the same whole (this solution is illustrated in Figure 2.2). Like the famous ambiguous figure that appears to be a vase from one line of sight and the faces of two people from another line of sight, the expressive and instrumental represent two lines of sight, not independent processes. System and adaptation, like structure and function, are separable only as analytic points of view. Focusing inquiry on the diagnosis of underlying dynamic biological and psychological systems in no way denies that behaviors have an adaptive value; focusing on adaptive value in no way denies that the behaviors originate from some dynamic system (see Overton and Ennis, in press). An interesting example of an approach that begins to promote this kind of integration is found in the in the work of Dodge and colleagues on the development of aggressive behavior. Information processing generally, and Dodge's (1986) social information processing theory specifically, are fundamentally concerned with the instrumental deployment of behaviors during real-time social and physical interactions in the world. However, Dodge and Rabiner (2004) make a very strong, explicit, and clear case for the expressive significance of "latent mental structures" in the developmental process as these impact on how the child "encodes, interprets, and responds in a variety of social situations" (p. 1005; see also Arsenio & Lemerise, 2004; Crick & Dodge, 1994).

To acknowledge both the distinction between expressive-constitutive and instrumental-communicative functions of action, and to acknowledge that they constitute two legitimate parts of a single whole, is to make an assertion of inclusivity. This acknowledgment recognizes that each function assumes a legitimate role in a unified whole of developmental inquiry and that the nature of any specific inquiry is always relative to the goals of that inquiry. From this relational perspective, issues associated with ambiguities arising from contextualizing development as "changes in observed behavior" are reduced significantly by insisting on the substitution of the phrase "changes in expressive-constitutive and instrumental-communicative features of observed behavior." This substitution does not, however, resolve the problem of exactly what kinds of change should be called developmental. For this problem, further reflection is needed on change itself.

The Nature of Developmental Change: Transformational and Variational

If developmental inquiry is to be an inclusive discipline, the issue of "developmental change" needs to be approached from as broad a perspective as possible. Perhaps, the broadest conceptualization of developmental entails the recognition and incorporation of two fundamental types of change; transformational and variational (see Figure 2.2). *Transformational change* is change in the form, organization, or structure of any system. The caterpillar transforms into the butterfly, the tadpole to the frog, water transforms into ice and gas, the seed transforms into the plant, and cells transform into the organism. All nonlinear dynamic systems, including the human psyche, undergo transformational

change. Transformational change results in the *emergence of novelty.* As forms change, they become increasingly complex. This increased complexity is a complexity of pattern rather than a linear additive complexity of elements. As a consequence, new patterns exhibit novel characteristics that cannot be reduced to (i.e., completely explained by), or predicted from, earlier components (indicated by the four system cubes on the left side of Figure 2.2). This emergence of novelty is commonly referred to as *qualitative* change in the sense that it is change that cannot be represented as purely additive. Similarly, reference to "*discontinuity*" in development is simply the recognition of emergent novelty and qualitative change (Overton & Reese, 1981). Concepts of stages, phases, or levels of development are theoretical concepts, which reference transformational change with the associated emergent novelty, qualitative change, and discontinuity. Each of the grand developmental figures of the twentieth century—Piaget, Vygotsky, Werner—acknowledged the centrality of these features of transformational development; Piaget and Werner via their ideas of development proceeding through phases of differentiation and reintegration; Vygotsky (1978) in his argument that development is not "the gradual accumulation of separate changes . . . [but] a complex dialectical process characterized by . . . qualitative transformations of one form into another [with an] intertwining of external and internal factors" (p. 73). (See also Schneirla, 1957.)

The philosopher E. Nagel (1957) articulated the broad dimensions of transformational change when he described development as entailing two fundamental features: (1) "the notion of a system, possessing a definite structure [i.e., organization] . . ." and (2) "the notion of a set of sequential changes in the system yielding relatively permanent but novel increments not only in its structures [i.e., organization] but in its modes of operation [i.e., functions] as well" (p. 17).

It is important to emphasize that transformational change references relatively enduring and irreversible changes in dynamic systems (e.g., the biological system; the psychological subject or person as a system; the cognitive, affective, and motivational systems) and changes that are sequential in nature. The enduring and irreversible characteristic of transformational change eliminates relatively transient or easily reversible changes as developmental change, while the sequential character establishes its *teleological* (goal oriented) nature. Sequence implies an order and any order is necessarily directional in character. A transformational change is one that necessarily implies a direction toward some end state or goal. Here, it is critical to recognize the metatheoretical distinction between subjective and objective teleology. Subjective teleology involves *subjectively held* "purposes," "aims," or "goals" (e.g., "I intend to become a better person") and is irrelevant to the definition of transformational developmental change. Objective teleology involves the construction of principles or rules designed to explain phenomena under investigation (e.g., "the development of x moves from lack of differentiation to more equilibrated levels of differentiation and hierarchic integration"). The rule so constructed conceptually finds, discovers, or identifies the sequential order and the end state. Any theory consists of explanations of some topic or domain and a developmental transformational theory must articulate what is developing.

It is a conceptual confusion to argue that adequate descriptions are more important than the positing of endpoints (e.g., Sugarman, 1987), or similarly to suggest a movement away from endpoints and toward "a more neutral, person-time-and-situation-geared conception of development," (Demetriou & Raftopoulos, 2004, p. 91). There is no neutral standpoint, and no description could occur without a positing of endpoints. The question is what one would possibly describe if one did not understand development as tending toward some specified end? If one wishes to describe/explain the course of acquiring language, then adult language is, of necessity, the endpoint. No description of the language of the child would be possible without this ideal endpoint. In a similar fashion, if one wishes to describe/explain the transformational development of reasoning, thought, problem solving, personality, or anything, a conceptual endpoint must serve as the ideal ultimate model.

A portion of this confusion over the positing of developmental endpoint arises from the mistaken notion that positing an ideal necessarily leads to an "adultomorphic perspective [that] forces one to view earlier behaviors and functions as immature versions of adult functions" (Marcovitch & Lewkowicz, 2004, p. 113). Central to this argument is its failure to recognize that nonlinearity (discontinuity) is characteristic of transformational developmental change. For example, Piaget's interest in examining the development of reasoning process led him to take deductive propositional reasoning as the endpoint of inquiry. However, Piaget described several quite different forms of reasoning (e.g., preoperational and

concrete operational) that function as discontinuous precursors to this adult form. It also needs to be noted that endpoints can be posited with respect to content (e.g., the adult memory model, the adult reasoning model), with respect to structure (e.g., Werner's, 1957, orthogenetic principle "development . . . proceeds from an initial state of relative globality and lack of differentiation to a state of increasing differentiation, articulation, and hierarchic integration," p. 126), and with respect to function (e.g., see Valsiner, 1998a discussion of equilibrium models; Piaget's discussions of levels of adaptation). One cannot condemn the positing of endpoints and then make claims that distal evolutionary (i.e., adaptational) determinants play a role in development (Marcovitch & Lewkowicz, 2004). Distal adaptations are endpoints.

A related conceptual confusion occurs when the concept of "maturation" is introduced into the definition of development as in "development refers to the maturation of various systems." The problems here are twofold. First, if maturation is simply understood according to its traditional dictionary meanings (i.e., "the emergence of personal and behavioral characteristics through growth processes," Merriam-Webster's Online Dictionary, Tenth Edition; "the process of becoming completely developed mentally or emotionally," Cambridge International Dictionary of English, online edition), then it is tautological with and adds nothing to the already discussed definition of transformational features of development. Second, if maturation is taken to suggest the action of biological systems, then the concept of, and potential mechanisms of development have become conflated, and this represents a serious conceptual confusion.

Embryological changes constitute some of the clearest and most concrete examples of transformational or morphological change (Edelman, 1992; Gottlieb, 1992). Through processes of differentiation and reintegration, movement occurs from the single celled zygote to the highly organized functioning systems of the 9-month fetus. Some cognitive and social-emotional phenomena of human ontogenesis have also been conceptualized as reflecting transformational change. For example, overt action may undergo a sequence of transformations to become symbolic thought, and further transformations lead to a reflective symbolic thought exhibiting novel logical characteristics (see boxes on left side of Figure 2.2). Memory may reflect transformational changes moving from recognition memory to recall memory. The sense of self and identity (Chandler, Lalonde, Sokol, & Hallett 2003; Damon & Hart, 1988; Nucci, 1996) have been portrayed by some as moving through a sequence of transformations. Emotions have been understood as differentiations from an initial relatively global affective matrix (Lewis, 1993; Sroufe, 1979). Physical changes, such as changes in locomotion, have also been conceptualized as transformational changes (Thelen & Ulrich, 1991).

Variational change refers to the degree or extent that a change varies from a standard, norm, or average (see the arrows on the right side of Figure 2.2). Take the pecking of the pigeon; changes in where, when, and how rapidly pecking occurs are variational changes. The reaching behavior of the infant, the toddler's improvements in walking precision, the growth of vocabulary, and receiving better or worse grades are all examples of variational change. From an adaptive (instrumental) point of view, developmental variational change is about a skill or ability becoming more precise and more accurate. This type of change can be represented as linear; as completely additive in nature. As a consequence, this change is understood as *quantitative* and *continuous.*

At any given level of form (i.e., any level of a dynamic system), there are quantitative and qualitative variants that constitute variational change. If thinking is understood as undergoing transformational change, then at any given transformational level, variational changes are found in variants of thought (e.g., analytic styles and synthetic styles). If emotions are presented as undergoing transformational change, then at any transformational level, variational change is reflected in differences in the degree of emotionality (more or less anxious, empathic, altruistic, and so on). If identity is thought of as undergoing transformational change, then at any transformational level, there is variational change in the type of identity assumed (i.e., individualistic or communal). If memory undergoes transformational change, there is variational change in differences in memory capacity, memory style, and memory content.

Transformational change has been identified with normative issues such as changes that are typical of phyla, species, and individuals. In ontogenesis, for example, normative changes in cognitive, affective, and motivational systems have been the central issue of concern. The focus here is sequences of universal forms whose movement defines a path or trajectory. As suggested earlier, when tracing developmental trajectories, concepts of irreversibility, discontinuity (nonadditivity,

nonlinearity), sequence, and directionality are associated with transformational change. Variational change has been identified with differential issues across and within individuals and groups. Interest has focused on local individual and group differences that suggest a particularity, and a to-and-fro movement of change. Concepts of reversibility, continuity, and cyclicity are associated with variational change. When change is considered both in terms of life forms and physical systems, transformational change is identified with what has been called the "arrow of time," and variational change is identified with the notion of the "cycles of time" (Overton, 1994a, 1994c; Valsiner, 1994).

Incorporating transformational and variational change into a broad understanding of development raises the issue of how these two forms are to be related. The same three metatheoretical solutions that have historically appeared with respect to the concept of the expressive-instrumental appear again for the transformational-variational. The first solution splits the pair, thus forming a dichotomy, and treats the instrumental as privileged bedrock. This solution marginalizes transformational change by claiming that it is mere description, which itself requires explanation. Essentially, this claim is the promise that all apparent transformational change will ultimately be explained—perhaps as our empirical knowledge increases—as the product of variation and only variation. An important consequence of this solution is that the associated metamethod will prescribe methods that can assess linear additive processes, but will marginalize methods that assess nonlinear processes. A classic example of this general solution was the Skinnerian demonstration that given only variations in pecking and reinforcement, it was possible to train pigeons to hit Ping-Pong balls back and forth over a net. Thus, it was claimed that the apparent developmental novelty of playing Ping-Pong was in reality "nothing-but" the continuous additive modifications in variation. This solution is also adopted by those who portray cognitive development as either a simple increase in representational content (see Scholnick & Cookson, 1994) or as an increase in the efficiency with which this content is processed (Siegler, 1996; Sternberg, 1984).

The second metatheoretical solution treats transformational change as the bedrock reality and marginalizes the significance of variation. Variation is seen as rather irrelevant noise in a transformational system. While this solution is seldom explicitly articulated, some stage theories such as Erik Erikson's (1968) theory of psychosocial development have elevated transformational change to a point that the importance of the variational seems to disappear below the horizon.

As described earlier, the third metatheoretical approach does not split transformation and variation into competing alternatives, but rather it understands the transformational-variational as a fundamentally necessary and real whole containing co-equal complementary processes. This solution asserts a reality in which the processes assume differentiated functional roles, but each process in itself explains and is explained by the other. Transformational systems produce variation and variation transforms the system (this solution is illustrated in Figure 2.2). This relational metatheoretical stance is described in detail later as a "take on reality" that, as suggested earlier, resolves many of developmental inquiry's most controversial problems, and opens new paths of investigation.

A Unified Concept of Development

When transformational-variational change and changes in expressive constitutive instrumental communicative action are cast into a relational matrix, they reflect complementary images of the totality of developmental change. The *expressive-constitutive* and *instrumental-communicative dimension* articulates *what* it is that changes during development. In the domain of developmental psychology, it is the *psychological subject* (or dynamic systems that explain the functioning of the subject) and the *subject's action* that become foreground. Piaget and Skinner, for example, each construct a radically different vision of the nature of the changing subject, but both focus on the subject. Piaget considers both the expressive and instrumental to each be essential features of what changes. "Schemes" and "operations" are identified as the source of the subject's expressive-constitutive action, while "procedures" are conceived as instrumental strategies designed to succeed in the actual world. For Skinner, the expressive is denied or marginalized, and "operants" represent the subject's instrumental adjustments to a changing environment.

The *transformational-variational dimension* articulates the *nature of the change* taking place. It is the *action* rather than the function of the action that becomes the foreground. Here, actions that are expressive-

instrumental in function, vary and transform. Later in the chapter, for example, the neo-Darwinian theory of evolutionary change is discussed, as is developmental systems theory. In these cases, the primary focus is on variational and transformational change of action, while the expressive-instrumental functions of the action fade to background.

Casting the dimensions of what changes, and the nature of change, as complementary lines of sight reveals that the dimensional features can be recombined depending on the goal of inquiry. For example, it is possible to form a transformational-expressive dimension. This focus explores the sequence of system changes—whether affective, emotional, physical, or cognitive system—which become reflected in sequential changes in the cognitive-affective meanings that the psychological subject projects onto her world. Similarly, the variational-instrumental dimension can be thought of as focusing inquiry on variational changes in action that result in procedures or strategies—again whether affective, emotional, physical, cognitive, and so on—which the subject employs in adjustment and adaptation.

These reflections on changes in expressive-instrumental action and transformational-variational change provide a base from which it is possible to suggest a relatively inclusive definition of development that moves beyond the ambiguities of "change in observed behavior across age" and more reasonably begins to carry the load of all of developmental inquiry. Development within this context is understood to refer to *formal (transformational) and functional (variational) changes in the expressive-constitutive and instrumental-communicative features of behavior.* Behavior is understood broadly in this definition, thus not limiting developmental inquiry to a specific field of investigation. Disciplines as diverse as history, anthropology, philosophy, sociology, evolutionary biology, neurobiology, and psychology, as well as natural science investigations of system changes all become potential forms of developmental inquiry. Developmental change within this inclusive definition includes at least—as suggested earlier—phylogenesis (i.e., the development of phyla, or evolutionary change), ontogenesis (i.e., the development of the individual), embryogenesis (i.e., the development of the embryo), microgenesis (i.e., development across short time scales, such as the development of an individual percept or individual memory), pathogenesis (i.e., the development of pathology), and orthogenesis (i.e., normal development). From this perspective, developmental inquiry necessarily becomes interdisciplinary and comparative in nature.

This inclusive relational definition of development is a starting point for further excursions both backward, into the nature and history of the metatheoretical concepts that frame the definition (and other basic features) of developmental inquiry, and forward to conceptual, theoretical, and methodological consequences of understanding development in this fashion. In gazing forward to consequences of this understanding, light is cast on a significant but often obscured conceptual feature of some of the classical developmental controversies. Consider these often debated questions: Is development universal (typical of most people, despite specific biological circumstances, culture, or social background) or particular (typical of only some people)? Is development necessarily directional or contingently directional? Is development irreversible or reversible? Is development continuous (linear; i.e., capable of being represented additively) or discontinuous (nonlinear, i.e., emergent novel forms or stages appear)? Is development fundamentally about biology or culture? Each of these questions becomes a debate only when the conceptual pair is cast as an antinomy. From an inclusive relational metatheoretical position, all such debates necessarily evaporate, as the conceptual pairs become co-equal, indissociable complementarities. Thus, for example, from the relational perpective it is possible to assert with some confidence, on both rational and empirical grounds, that while the content of memory or memory strategies, as well as the content of thinking or thinking styles, is particular (variable change), recall memory and symbolic thought are typical acquisitions of all human ontogenesis (transformational change). Similarly, there would appear to be little doubt that a raised grade point average can be reversed (variable change), but this in no way denies that the movement from babbling to language may be more profitably understood as sequential and directional and irreversible (transformational change). Reflection, as well as commonsense observation, suggests that there is some coherence to behavior and that this coherence becomes expressed (expressive) in action; yet, there is also little to deny that this activity functions in the context of a world that imposes demands on it (variable, instrumental). Reflection on several scientific disciplines, as well as commonsense observation, also suggests that in some arenas novelty emerges (transformational), while

in others arenas changes are more reasonably represented as additive (variational). And hundreds of years of failed attempts to successfully sort behavior into discrete nature piles and nurture piles should suggest that perhaps a relational approach that eliminates all "*which one* and all *how much*" questions might offer a more productive conceptual foundation for investigations into the operation of biology and culture processes in development.

Along with casting light on conceptual debates that have long framed developmental inquiry, an inclusive understanding of development has ripple effects that move out to implications for empirical methods. The most general implication is that empirical inquiry in this context abandons the aim of broad-based debunking found historically in instrumentalist approaches to science (see the later discussion of methodology). Within a relational metamethod, questions of whether stages exist (transformational change, discontinuity, sequence) or are absent (variational change, continuity) disappear. In place of these questions, inquiry that takes the transformational pole of change as its object directs itself to empirically examine the plausibility of various alternative models of stage, phase, or level change (nonlinear change). Inquiry taking variational change as its object would be explicitly recognized as irrelevant to stage issues as such, and relevant to issues such as the stability of individual differences across age, time, or stages. Such change-specific inquiry opens the door to a greater recognition of the importance of change-specific techniques of measurement. For example, investigations with the central aim of examining transformational (nonlinear) and expressive acts often call for the application of contemporary order-scaling techniques and correlational techniques to assess changes in transformational patterns, and latent traits (see, the later discussion of methodology; e.g., Bond & Fox, 2001; Fischer & Dawson, 2002; Sijtsma & Molenaar, 2002). Studies of variational change (stability, continuity), those tracing the trajectory of variational change (i.e., the developmental function), and those exploring instrumental acts typically call for traditional correlational procedures and traditional experimental procedures (see the later discussion of methodology, and, e.g., Appelbaum & McCall, 1983).

The following sections describe and examine in detail the nature of split and relational metatheories, along with an important metatheory nested within the relational. These sections also describe the impact of these metatheories on various concepts and issues in the field of developmental psychology. Following the extended discussion of split and relational metatheories, there is a section devoted to epistemological-ontological issues. There, a history of the philosophical traditions that establish the conceptual frameworks for split and relational approaches will be described along with further implications for concepts and theories of development drawn from these traditions. Finally, these traditions will serve as background for a section exploring split and relational approaches to the metamethods and methods of developmental psychology.

SPLIT AND RELATIONAL METATHEORIES

Earlier it was mentioned that the most general and abstract metatheories have traditionally been called "worldviews." In developmental psychology, the most widely discussed worldviews have been those described by Steven Pepper (1942) as the mechanistic, the contextualist, and the organismic (Ford & Lerner, 1992; Overton, 1984; Overton & Reese, 1973; Reese & Overton, 1970). The worldviews discussed here are closely related to Pepper's categorization. *Split metatheory* entails all of the basic categories described by Pepper as mechanistic, including a commitment to viewing the ultimate nature of the universe, and hence the nature of the psychological subject, as reactive, uniform, and fixed. *Relational metatheory* alternatively embraces most of the basic categories described by Pepper as contextualistic and organismic, including a commitment to understanding the ultimate nature of both universe and persons as active, organized, and changing. Relational metatheory however, departs from Pepper's skepticism about the possibility of uniting contextualism and organism, and offers what it considers to be a productive rapprochement (Overton & Ennis, in press).

Split Metatheory

Split metatheory entails several basic defining principles, including "splitting," "foundationalism," and "atomism." *Splitting*—a concept that emerged from the thinking of Rene Descartes—is the separation of components of a whole into mutually exclusive pure forms or elements. In splitting, these ostensibly pure forms are cast into an exclusive "either/or" framework that forces them to be understood as contradictions in the sense that one category *absolutely* excludes the other (i.e., follows the logical law of contradiction that it is never the case

that A = not A). But, in order to split, one must accept the twin principles of *foundationalism* and *atomism.* These are the metatheoretical axioms that there is ultimately a rock bottom unchanging nature to reality (the foundation of foundationalism), and that this rock bottom is composed of elements—pure forms—(the atoms of atomism) that preserve their identity regardless of context. A corollary principle here is the assumption that all complexity is *simple complexity* in the sense that any whole is taken to be a purely additive combination of its elements.

Splitting, foundationalism, and atomism are all principles of decomposition; breaking the aggregate down to its smallest pieces, to its bedrock (Overton, 2002). This process also goes by other names including *reductionism* and *the analytic attitude* (Overton, 2002). Split metatheory requires another principle to reassemble or recompose the whole. This is the principle of *unidirectional and linear (additive) associative or causal sequences.* The elements must be related either according to their contiguous co-occurrence in space and time, or according to simple efficient cause-effect sequences that proceed in a single direction (Bunge, 1962; Overton & Reese, 1973). Split metatheory admits no determination other than individual efficient causes or these individual causes operating in a conjunctive (i.e., additive) plurality: No truly reciprocal causality is admitted (Bunge, 1962; Overton & Reese, 1973).

All antinomies emerge from a split metatheoretical context. The individual-social or individual-collective or person-social antinomy, for example, represents all behavior and action as the additive product of elementary bedrock pure forms identified as person and sociocultural. Arising from this splitting, behavior is understood as an aggregate composed of these two pure forms, and the question becomes one of the primacy or privileged quality of one or the other. Nativism-empiricism or nature-nurture is a closely related antinomy in which the pure forms consist of, on the one hand, some basic biological form or element (e.g., DNA, genes, neurons) and, on the other hand, some basic environmental element (e.g., parents, society, culture). These examples are explored in this and following sections.

Recently, the pursuit of the person-sociocultural antinomy has been a defining characteristic of contemporary sociocultural (e.g., Cole & Wertsch, 1996; Wertsch, 1991) and social constructivist approaches (e.g., Gergen, 1994). These follow the work of Marx who pursued the broader ideas-matter antinomy, and claimed a bedrock foundational primacy for material sociocultural objects; hence, his presentation of dialectical *materialism.* Wertsch acknowledges Marx's contribution and frames his own work within the person-social antinomy by endorsing both a split interpretation of Vygotsky (i.e., "In pursuing a line of reasoning that reflected their concern with Marxist claims about the *primacy of social forces* Vygotsky and his colleagues . . . contended that many of the design features of mediational means *originated in social life,*" 1991, p. 33, emphasis added) and a split interpretation of Luria:

> As stated by Luria (1981, p. 25), "in order to explain the highly complex forms of human consciousness one must go beyond the human organism. One must seek the origins of conscious activity and 'categorical' behavior *not in* the recesses of the human brain or in the depths of the spirit, *but in* the external conditions of life. Above all, this means that one must *seek these origins in the external processes of social life,* [emphasis added] in the social and historical forms of human existence." (Wertsch, 1991, p. 34)

At times, social constructivist and sociocultural splitting becomes more subtle. Cole and Wertsch (1996) begin one article by acknowledging, on the basis of several direct Piagetian quotes, that Piaget—a traditional villain of both socioculturalist and social constructivists, who is often inaccurately accused of privileging the person—"did not deny the co-equal role of the social world in the construction of knowledge" (p. 251). However, these authors then switch the ground of the issue from the social world specifically to culture mediation entailed by the social world and argue, both in heading ("The Primacy of Cultural Mediation," p. 251) and in text, that culture is to be privileged:

> Social origins take on a special importance in Vygotsky's theories that is less symmetrical than Piaget's notion of social equilibration. . . . For Vygotsky and cultural-historical theorists more generally, the *social world does have primacy over the individual* in a very special sense. Society is the bearer of the cultural heritage. . . . (p. 353, emphasis added)

The field of behavior genetics provides a second example of an approach to inquiry that is grounded and defined within a split metatheory. The broad goal of behavior genetics, using the methods of family, twin, and adoption studies, is to partition (split) the variation in any behavioral score (e.g., a measure of personality, psychopathology, intelligence, language, cognition) into the proportion of the variation caused by foundational

genes (pure form) and the proportion caused by the foundational environment (pure form; Plomin, 1986, 1994). "Behavior genetic models use quantitative genetic theory and quasi-experimental methods to decompose phenotypic (measured) variance into genetic and environmental components of variance" (McGuire, Manke, Saudino, Reiss, Hetherington, & Plomin, 1999, p. 1285). The primary tool employed to effect this splitting is the quantitative formula, called the "heritability index" or "heritability coefficient." This index itself entails a commitment to the additive components-of-variance statistical model (including analysis of variance and all correlation based statistics), which has a basic assumption that each score is a linear function of independent elements (i.e., the score is the sum of component effects, Winer, 1962, p. 151; also see Overton & Reese, 1973). Further, it is generally assumed that the correlational patterns produced through the application of this formula are reflections of an underlying causal reality in which genes and environment primarily contribute additively to the behavior under investigation (Vreeke, 2000). Within the behavior genetic frame, the ultimate goal is to discover the specific genetic causal pathways. The idea here is to unravel and parse conjunctive pluralities of efficient causes believed—within the context of a split metatheory—to explain any behavior, and thereby arrive at an ultimate genetic bedrock of explanation. As Plomin and Rutter (1998) say with respect to the anticipated discovery of genes associated with specific behaviors:

> The finding of genes will provide the opportunity to unravel the complicated causal processes. . . . No longer will we have to focus on how much variation in the general population is genetically influenced; instead we can make the crucial transition from "black box" inferences regarding genetic influences to the observation of specific genes. (p. 1238)

Relational Metatheory

In an analysis of the historical failures of split metatheory, as well as the emptiness of its seeming rival—postmodern thought—Bruno Latour (1993) has proposed a move away from the extremes of Cartesian splits to a center or "middle kingdom" position where entities and ideas are represented not as pure forms, but as forms that flow across fuzzy boundaries. This is a movement toward what Latour terms "relationism" a metatheoretical space where foundations are groundings, not bedrocks of certainty, and analysis is about creating categories, not about cutting nature at its joints. Relational metatheory builds on Latour's proposal. It begins by clearing splitting from the field of play and in so doing it moves toward transforming antinomies into co-equal, indissociable complementarities. As splitting and foundationalism go hand in hand, removing the one also eliminates the other. Splitting involves the conceptual assumption of pure forms, but this assumption itself springs from the acceptance of the atomistic assumption that there is a fixed unchanging bedrock bottom to reality composed of elements that preserve their identity regardless of context. Thus, acceptance of atomism leads directly to the belief that the mental (ideas, mind) and the physical (matter, body) are two absolutely different natural kinds of things. And if nature were composed of such natural kinds, then it would seem reasonable to believe in the possibility of cutting nature at its joints. A relational metatheory rejects atomism and replaces it with holism as a fundamental guiding principle. Within this conceptual frame, fixed elements are replaced by contextually defined parts with the result that—as the philosopher John Searle (1992) has suggested—"the fact that a feature is mental does not imply that it is not physical; the fact that a feature is physical does not imply that it is not mental" (p. 15). Similarly, the fact that a feature is biological does not suggest that it is not cultural; the fact that a feature is cultural does not suggest that it is not biological. Building from this base of holism, relational metatheory moves to specific principles that define the relations among parts and the relations of parts to wholes. In other words relational metatheory articulates principles of analysis and synthesis necessary for any scientific inquiry, which include (a) the identity of opposites, (b) the opposites of identity, and (c) the synthesis of wholes.

Holism

Holism is the conceptual principle that the identities of objects and events derive from the relational context in which they are embedded. The whole is not an aggregate of discrete elements, but an organized and self-organizing system of parts, each part being defined by its relations to other parts and to the whole. Complexity in this context is *organized complexity* (Luhmann, 1995; von Bertalanffy, 1968a, 1968b), in that the whole or dynamic system is not decomposable into elements arranged in additive linear sequences of cause-effect relations (Overton & Reese, 1973). Nonlinear dynamics

are a defining characteristic of this type of complexity. In the context of holism, principles of splitting, foundationalism, and atomism are rejected as meaningless approaches to analysis, and fundamental antinomies are similarly rejected as false dichotomies.

The rejection of pure forms or essences found in holism has broad implications for developmental psychology. For example, as suggested in the last section, the nature-nurture debate is framed by the agenda of splitting and foundationalism. In its current split form, no one actually asserts that matter, body, brain, and genes or society, culture, and environment provide *the* cause of behavior or development: The background idea of one or the other being the privileged determinant remains the silent subtext that continues to shape discussions. The most frequently voiced claim is that behavior and development are the products of the *interactions* of nature and nurture. But interaction itself is generally conceptualized as two split-off pure entities that function *independently* in cooperative and/or competitive ways (e.g., Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000). As a consequence, the debate simply becomes displaced to another level of discourse. At this new level, the contestants agree that behavior and development are determined by *both* nature *and* nurture, but they remain embattled over the relative merits of each entity's essential contribution. Population behavior genetics continues its focus on the classical question of *how much* each form contributes to a particular behavior. Other split approaches continue the battle over *which* of the two pure forms determines the origin and function of a specific behavior. Thus, despite overt conciliatory declarations to the contrary, the classical *which one* and *how much* questions (see Anastasi, 1958; Schneirla, 1956), continue as potent divisive frames of inquiry. However, it would be impossible to cast questions of development as issues of "nativism" and "empiricism" (Spelke & Newport, 1998) were it not for the assumption of pure forms. Rejecting atomism and embracing holism on the other hand eliminates the idea of pure forms and consequently makes any notion of natural foundational splits untenable. This destroys the scientific legitimacy of *which one* and *how much* questions in any arena of inquiry.

But the acceptance of holism does not, in itself, offer a detailed program for resolving the many fundamental antinomies that have framed developmental psychology and other fields of scientific inquiry. Such a program requires principles according to which the individual identity of each concept of a formerly dichotomous pair is maintained, while simultaneously affirming that each concept constitutes, and is constituted by, the other. For example, both nature and nurture maintain their individual identity, while it is simultaneously understood that the fact that a behavior is a product of biology does not imply that it is not equally a product of culture; conversely, the fact that a behavior is a product of culture does not imply that is not equally a product of biology. This is accomplished by considering the identity and differences as two *moments of analysis.* The first moment being based on the principle of the identity of opposites; the second being based on the principle of the opposites of identity.

The Identity of Opposites

The principle of the *identity of opposites* establishes the identity among fundamental parts of a whole by casting them not as exclusive contradictions, as in the split methodology, but as differentiated polarities (i.e., coequals) of a unified (i.e., indissociable) inclusive matrix, as a relation. As differentiations, each pole is defined recursively; each pole defines and is defined by its opposite. In this identity moment of analysis, the law of contradiction is suspended and each category contains and, in fact, *is* its opposite. Further—and centrally—as a differentiation this moment pertains to character, origin, and outcomes. The character of any contemporary behavior, for example, is 100% nature because it is 100% nurture. There is no origin to this behavior that was some other percentage—whether we climb back into the womb, back into the cell, back into the genome, or back into the DNA—nor can there be a later behavior that will be a different percentage. Similarly, any action is both expressive and instrumental, and any developmental change is both transformational and variational.

There are a number of ways of articulating this principle, but perhaps the clearest articulation is found in considering the famous ink sketch by M. C. Escher titled *Drawing Hands.* As shown in Figure 2.3, here a left and a right hand assume a relational posture according to which each is simultaneously drawing and being drawn by the other. In this relational matrix, each hand is *identical*—thus co-equal and indissociable—with the other in the sense of each drawing and each being drawn. This is a moment of analysis in which the law of contradiction (i.e., Not the case that A = not A) is relaxed and identity (i.e., A = not A) reigns. In this *identity moment of analysis,* pure forms collapse and categories flow into each

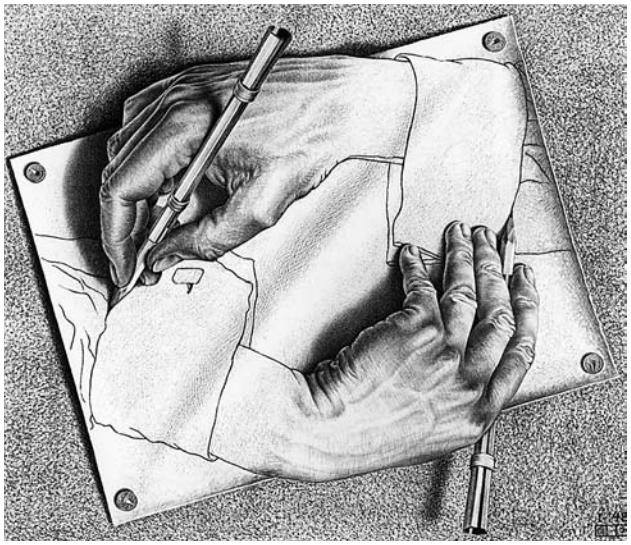

Figure 2.3 *Drawing Hands* by M. C. Escher. ©2006 The M. C. Escher Company–Holland. All rights reserved. www.mcescher.com. Used by permission.

other. Each category contains and *is* its opposite. As a consequence, there is a broad inclusivity established among categories. If we think of inclusion and exclusion as different moments that occur when we observe a reversible figure (e.g., a necker cube or the vase-women illusion), then in this identity moment we observe only inclusion. In the next (opposite) moment of analysis the figures reverse, and there we will again see exclusivity as the hands appear as opposites and complementarities.

Within this identity moment of analysis, it is a useful exercise to write on each hand one of the bipolar terms of a traditionally split antinomies (e.g., person and culture) and to explore the resulting effect. This exercise is more than merely an illustration of a familiar bi-directionality of effects suggested by many scientific investigators. The exercise makes tangible the central feature of the relational metatheory; seemingly dichotomous ideas that are often been thought of as competing alternatives can enter into inquiry as co-equal and indissociable. It also concretizes the meaning of any truly nonadditive reciprocal determination (Overton & Reese, 1973).

If inquiry concerning, for example, person, culture, and behavior is undertaken according to the principle of the identity of opposites various constraints are imposed, as with any metatheory. An important example of such a constraint is that behavior, traits, styles, and so on cannot be thought of as being decomposable into the independent and additive pure forms of person and culture. Thus, from the perspective of relational metatheory, the goals of sociocultural or social constructivist approaches in attempting to elevate society and culture to a privileged primary position is simply a conceptual confusion.

If the principle of the identity of opposites introduces constraints, it also opens possibilities. One of these is the recognition that, to paraphrase Searle (1992), the fact that a behavior is biologically or person determined does not imply that it is not socially or culturally determined, and, the fact that it is socially or culturally determined does not imply that it is not biologically or person determined. The identity of opposites establishes the metatheoretical position that genes and culture, like culture and person, and brain and person, and so on, operate in a truly *interpenetrating* manner.

Because the idea and implications of suspending the law of contradiction in some contexts and applying it in others is not a familiar one, some clarifying comments are needed. Relational metatheory, owes much to the notion of the *dialectic* as this was articulated by the nineteenth-century philosopher G. W. F. Hegel (1770–1831). For Hegel, historical—and by extension developmental—change is a dynamic expressive-transformational process of growth, represented and defined by the dialectic. Central to Hegel's dialectic is the idea of a process through which concepts or fundamental features of a dynamic system *differentiate* and move toward *integration.* Any initial concept or any basic feature of a dynamic system—called a "thesis" or an "affirmation"—contains implicit within itself an inherent *contradiction* that, through action of the system in the world, becomes differentiated into a second concept or feature—the "antithesis" or "negation" of the thesis. As a consequence, even in the single unity of thesis there is the implicit contradictory relation of thesis-antithesis, just as in the unity of the single organic cell there is the implicit differentiation into the unity of multiple cells. This points to the fundamental relational character of the dialectic.

As thesis leads to antithesis—producing the differentiation of a relational polarity of opposites—a potential space between them is generated, and this becomes the ground for the *coordination* of the two. The coordination that emerges—again through the mechanism of action of the system—constitutes a new unity or integration—called the "synthesis." The coordinating synthesis is itself a system that exhibits novel systemic properties while subsuming the original systems. Thus, a new relational dynamic matrix composed of three realms—thesis-antithesis-synthesis—is formed. The integration

that emerges from the differentiation, like all integrations, is incomplete. The synthesis represents a new dynamic action system—a new thesis. Thus, begins a new growth cycle of differentiation and integration.

In this relational scheme, the polarity of opposites (i.e., thesis and antithesis) that emerges from the initial relatively undifferentiated matrix (i.e., thesis) does not constitute cut-off (split) contradictory categories that absolutely exclude each other. Having grown from the same soil as it were, the two, while standing in a contradictory relation of opposites, also share an identity. Hegel referred to this relation as the "identity of opposites" (Stace, 1924) and illustrated it in his famous example of the master and slave. In this example, Hegel demonstrated that it is impossible to define or understand the freedom of the master without reference to the constraints of slavery; and consequently impossible to define the constraints of slavery without the reference to the freedom of the master. Freedom thus contains the idea of constraint as constraint contains the idea of freedom, and in this we see the identity of the opposites freedom and constraint.

The justification for the claim that a law of logic—for example, the law of contradiction—can reasonably both be applied and relaxed depending on the context of inquiry requires a recognition that the laws of logic themselves are not immutable and not immune to background ideas. In some metatheoretical background traditions, the laws of logic are understood as immutable realities given either by a world cut off from the human mind or by a prewired mind cut off from the world. However, in the background tradition currently under discussion the traditional laws of logic are themselves ideas that have been constructed through the reciprocal action of human minds and world. The laws of logic are simply pictures that have been drawn or stories that have been told. They may be good pictures or good stories in the sense of bringing a certain quality of order into our lives, but they are still pictures or stories, and it is possible that other pictures will serve us even better. Wittgenstein (1953/1958), whose later works focused on the importance of background or what we are calling metatheoretical ideas, made this point quite clearly when he discussed another law of logic—the law of the excluded middle—as being one possible picture of the world among many possible pictures:

> The law of the excluded middle says here: It must either look like this, or like that. So it really . . . says nothing at all, but gives us a picture. . . . . And this picture *seems* to determine what we have to do and how—but it does not do so. . . . Here saying "There is no third possibility" . . . expresses our inability to turn our eyes away from this picture: a picture which looks as if it must already contain both the problem and its solution, while all the time we *feel* that it is not so. (para. 352)

The transformation of competing alternatives into co-equal, indissociable partners is illustrated in a recent exchange of comments concerning research on the topic that social psychology refers to as the "fundamental attribution error." In this exchange, one group (Gilovich & Eibach, 2001) proceeded from a split position and noted that "human behavior is not easily parsed into situational and dispositional causes" (p. 23); they further claimed that it is difficult to establish "a precise accounting of how much a given action stems from the impinging stimulus rather than from the faculty or disposition with which it makes contact" (p. 24). The reply to this comment, from a group committed to an identity of opposites (Sabini, Siepmann, & Stein, 2001), asserts that they reject such a position because it reflects confusion between competing and complementary accounts. They argue that the problem with the question:

> How much John's going out with Sue stems from her beauty rather than from his love of beautiful women . . . is not that it is difficult to answer; it is that it is conceptually incoherent. It is incoherent because it construes two classes of accounts that are in fact complementary as if they were competing. The heart of our argument is that one must take this point seriously: All behavior is jointly a product of environmental stimuli and dispositions. (p. 43)

A similar, but somewhat more subtle, example is found in a recent dialogue on spatial development. Uttal (2000) began this dialogue with the *seemingly* complementary view that his claims about spatial development "are based on the assumption that the relation between maps and the development of spatial cognition is reciprocal in nature" (p. 247). However, in an analysis of Uttal's position, Liben (1999) raises the question of whether Utall is operating within the context of an identity of opposites, which she proposes as her own approach:

> As I read his thesis, Uttal seems to be suggesting an *independent* contribution of maps, positing that exposure to maps can play a *causal* role in leading children to develop basic spatial concepts. My own preference is to propose a

> more radically *interdependent* [emphasis added] role of organismic and environmental factors. (p. 272)

A third, more general, illustration of the power of the principle of the identity of opposites to transform competing alternatives into co-equal, indissociable partners is found in returning to the nature-nurture debate. As already suggested, within relational metatheory behavior, traits, and styles cannot be thought of being decomposable into independent and additive pure forms of genes and environment. From this perspective, the goals of behavior genetics simply represent conceptual confusion. The percentages derived from the application of heritability indices, whatever their value, can never be taken as a reflection of the separate contributions of genes and environment to individual differences because the relation of genes and environment (a left and a right Escherian hand) is not independent and additive. Moving beyond behavior genetics to the broader issue of biology and culture, conclusions such as "contemporary evidence confirms that the expression of heritable traits depends, often strongly, on experience" (Collins et al., 2000, p. 228) are brought into question for the same reason. Within a relational metatheory, such conclusions fail because they begin from the premise that there are pure forms of genetic inheritance termed "heritable traits" and within relational metatheory such a premise is unacceptable.

Within the nature-nurture debate, and in other areas, the identity of opposites also calls for a reinterpretation of the very notion of interaction. In split metatheory, "interaction" has been defined as two independent pure forms—biological and cultural—that join to produce an event. This has been called "conventional interactionism" (Oyama, 1989; see also, Lerner, 1978; Overton, 1973). In this metatheoretical context, it is possible for interaction to be understood as the cooperation or competition among elements (e.g., Collins et al., 2000) or as a quantitative situation in which one or the other element contributes more or less to a behavior (e.g., Scarr, 1992). But consider again Escher's drawings. Do the two hands contribute to the drawing and in some sense interact? They do interact, but not in an additive fashion such that contributions to drawing and being drawn could be parceled out and ascribed to one or the other hand. In the relational approach, any concept of *interaction* (e.g., interaction, co-action, transaction) must be taken to entail interpenetration; interdefinition; fusion (Tobach & Greenberg, 1984); and, most broadly, *relations.* Here independent items represent an abstraction that may prove useful for certain analytic purposes, but such abstractions in no way deny the underlying identity of opposites. The analytic and the synthetic are, themselves, two poles of a relational matrix, as are the notions of abstract and concrete (e.g., Lerner, 1978; Overton, 1973; see also Magnusson & Stattin, 1998, for an extended discussion of alternative forms of interaction).

The Opposites of Identity

While the identity of opposites sets constraints and opens possibilities, it does not in itself set a positive agenda for empirical inquiry. The limitation of the identity moment of analysis is that, in establishing a flow of categories of one into the other, a stable base for inquiry that was provided by bedrock elements of the split metatheory is eliminated. Re-establishing a stable base within relational metatheory requires moving to a second moment of analysis. This is the oppositional moment, where the figure reverses and the moment becomes dominated by exclusivity. In this opposite moment of analysis, it becomes clear that despite the earlier identity, Escher's sketch shows a *right* hand and a *left* hand. In this moment, the law of contradiction (i.e., Not the case that A = not A) is reasserted and categories again exclude each other. As a consequence of this exclusion, parts exhibit *unique* identities that differentiate each from the other. These unique differential qualities are stable within any general dynamic system and may form relatively stable platforms for empirical inquiry. The platforms created according to the principle of the opposites of identity become *standpoints, points of view, or lines of sight,* in recognition that they do not reflect absolute foundations (Harding, 1986). They may also be considered under the common rubric *levels of analysis,* when these are not understood as bedrock foundations. Again, considering Escher's sketch, when left as left and right as right are the focus of attention, it then becomes quite clear that—were they large enough—one could stand on either hand and examine the structures and functions of that hand. Returning to the nature-nurture example, while explicitly recognizing that any behavior is 100% biology and 100% culture, alternative points of view permit the scientist to analyze the behavior from a *biological* or a *cultural standpoint.* Biology and culture no longer constitute competing alternative explanations; rather, they are two points of view on an object of inquiry that has been both created by, and will only be fully understood through multiple viewpoints.

To state this more generally, the unity that constitutes human identity and human development becomes discovered only in the diversity of multiple interrelated lines of sight.

The Synthesis of Wholes

Engaging fundamental bipolar concepts as relatively stable standpoints opens the way, and takes an important first step, toward establishing a broad stable base for empirical inquiry within a relational metatheory. However, this solution is incomplete as it omits a key relational component, the relation of parts to the whole. The oppositional quality of the bipolar pairs reminds us that their contradictory nature still remains, and still requires a resolution. Further, the resolution of this tension cannot be found in the split approach of reduction to a bedrock reality. Rather, the relational approach to a resolution is to move away from the extremes to the center and above the conflict, and to here discover a novel system that will coordinate the two conflicting systems. This is the principle of the synthesis of wholes, and this synthesis itself will constitute another standpoint.

At this point, the Escher sketch fails as a graphic representation. While *Drawing Hands* illustrates the identities and the opposites, and while it shows a middle space between the two, it does not describe a coordination. The synthesis for this sketch is an unseen hand that has drawn the drawing hands and is being drawn by these hands. The synthesis of interest for the general metatheory would be a system that is a coordination of the most universal bipolarity imaginable. Undoubtedly, there are several candidates for this level of generality, but the polarity between *matter or nature,* on the one hand, and *society,* on the other, seems sufficient for present purposes (Latour, 1993). Matter and society represent systems that stand in an identity of opposites. To say that an object is a social object in no way denies that it is matter; to say that an object is matter in no way denies that it is social. The object can be analyzed from either a social or a physical standpoint, and the question for synthesis becomes the question of what system will coordinate these two systems. Arguably, the answer is that it is *life* or living systems that coordinate matter and society. Because our specific focus of inquiry is the psychological, we can reframe this matter-society polarity back into our nature-nurture polarity of *biology* and *culture.* In the context of psychology then, as an illustration, write "biology" on one and "culture" on the other Escher hand, and what system coordinates these systems?—the human organism, the *person* (see Figure 2.4a). Persons—as integrated self-organizing dynamic system of cognitive, emotional, and motivational processes and the actions this system expresses—represent a novel level or stage of structure and functioning that emerges from, and constitutes a coordination of, biology and culture (see Magnusson & Stattin, 1998, for an analysis of a methodological focus on the person).

At the synthesis then, there is a standpoint that coordinates and resolves the tension between the other two members of the relation. This provides a particularly broad and stable base for launching empirical inquiry. A *person standpoint* opens the way for the empirical investigation of universal dimensions of psychological structure-function relations (e.g., processes of perception, thought, emotions, values), their individual differences, and their development across the life span. Because universal and particular are themselves relational concepts, no question can arise here about whether the focus on universal processes excludes the particular, it clearly doesn't as we already know from the earlier discussion of polarities. A process viewed from a universal standpoint in no way suggests that it is not contextualized. The general theories of Jean Piaget (1952), Heinz Werner (1940/1957), James Mark Baldwin (1895), William Stern (1938), and Erik Erikson (1968); the attachment theory and object relations theories of John Bowlby (1958); Harry Stack Sullivan (1953); and Donald Winnicott (1965, 1971) all are examples of developmentally oriented relational person standpoints.

It is important to recognize that one standpoint of synthesis is relative to other synthesis standpoints. Life and society are coordinated by matter, and thus, within psychological inquiry, *biology* represents a *standpoint* as the synthesis of *person and culture* (Figure 2.4b). The implication of this is that a relational biological approach to psychological processes investigates the biological conditions and settings of psychological

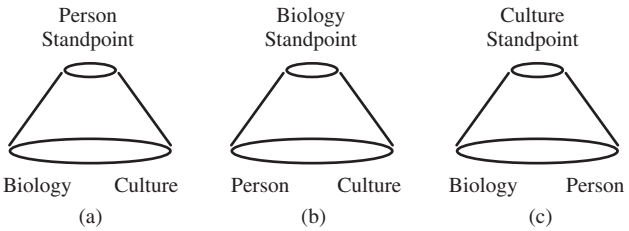

Figure 2.4 Relational standpoints in psychological inquiry: (a) person, (b) biology, and (c) culture.

structure-function relations and the behaviors they express. This exploration is quite different from split—foundationalist approaches to biological inquiry that assume an atomistic and reductionistic stance toward the object of study. The neurobiologist Antonio Damasio's (1994, 1999) work on the brain-body basis of a psychological self and emotions is an excellent illustration of this biological relational standpoint. And in the context of his biological investigations Damasio (1994) points out:

> A task that faces neuroscientists today is to consider the neurobiology supporting adaptive supraregulations [e.g., the psychological subjective experience of self]. . . . I am not attempting to reduce social phenomena to biological phenomena, but rather to discuss the powerful connection between them (p. 124). . . . Realizing that there are biological mechanisms behind the most sublime human behavior does not imply a simplistic reduction to the nuts and bolts of neurobiology. (p. 125)

A similar illustration comes from the Nobel laureate neurobiologist Gerald Edelman's (1992; Edelman & Tononi, 2000) work on the brain-body base of consciousness:

> I hope to show that the kind of reductionism that doomed the thinkers of the Enlightenment is confuted by evidence that has emerged both from modern neuroscience and from modern physics. . . . To reduce a theory of an individual's behavior to a theory of molecular interactions is simply silly, a point made clear when one considers how many different levels of physical, biological, and social interactions must be put into place before higher order consciousness emerges. (Edelman, 1992, p. 166)

A third synthesis standpoint recognizes that life and matter are coordinated by society, and again granting that the psychological inquiry is about psychological processes, *culture* represents a standpoint as the synthesis of *person* and *biology* (Figure 2.4c). Thus, a relational cultural approach to psychological processes explores the cultural conditions and settings of psychological structure-function relations. From this *cultural standpoint* the focus is upon cultural differences in the context of psychological functions as complementary to the person standpoint's focus on psychological functions in the context of cultural differences.

This standpoint is illustrated by "cultural psychology," or "developmentally oriented cultural psychology." However, not all cultural psychologies emerge from relational metatheory: For example, when a cultural psychology makes the social constructivist assertion that social discourse is "prior to and constitutive of the world" (Miller, 1996, p. 99), it becomes clear that this form of cultural psychology has been framed by split foundationalist background ideas. Similarly, when sociocultural claims are made about the "primacy of social forces," or claims arise suggesting that "mediational means" (i.e., instrumental-communicative acts) constitute the *necessary* focus of psychological interest (see, e.g., Wertsch, 1991), the shadow of split foundationalist metatheoretical principles are clearly in evidence.

A recent example of a relational developmentally oriented *cultural standpoint* emerges in the work of Valsiner (1998b), which examines the "social nature of human psychology." Focusing on the social nature of the person, Valsiner stresses the importance of avoiding the temptation of trying to reduce person processes to social processes. To this end, he explicitly distinguishes between the "dualisms" of split foundationalist metatheory and "dualities" of the relational stance he advocates. Ernst Boesch (1991) and Lutz Eckensberger (1990, 1996) have also presented an elaboration of the relational cultural standpoint. Boesch's cultural psychology and Eckensberger's theoretical and empirical extensions of this draw from Piaget's cognitive theory, from Janet's dynamic theory, and from Kurt Lewin's social field-theory and argues that "cultural psychology aims at an integration of individual and cultural change, an integration of individual and collective meanings, a bridging of the gap between subject and object" (e.g., Boesch, 1991, p. 183).

In a similar vein, Damon (1988) offers a vision of the cultural standpoint in his discussion of "two complementary developmental functions, . . . the social and the personality functions of social development" (p. 3). These are presented by Damon as an identity of opposites. The social function is an act of integration serving to "establish and maintain relations with other, to become an accepted member of society-at-large, to regulate one's behavior according to society's codes and standards" (p. 3). The personality function is the function of individuation; an act of differentiation serving the formation of the individual's personal identity that requires "distinguishing oneself from others, determining one's own unique direction in life, and finding within the social network a position uniquely tailored to one's own particular nature, needs, and aspirations" (p. 3). Although others could also be mentioned as illustrative (e.g., Grotevant, 1998; Hobson, 2002), it should be noted in conclusion here that Erik Erikson (1968), was operat-

ing from exactly such a relational line of sight when he described identity as "a process 'located' *in the core of the individual* and yet also *in the core of his communal culture*" (p. 22).

As a final point, concerning syntheses and the view from the center, it needs to be recognized that a relational metatheory is not limited to three syntheses. For example, *discourse or semiotics* may also be taken as a synthesis of *person* and *culture* (Latour, 1993). In this case, biology and person are conflated and the biological/person and culture represents the opposites of identity that are coordinated by discourse.

In summary to this point, the argument has been made that metatheoretical principles form the ground out of which grow the concepts and methods of any domain of empirical inquiry. Split metatheory produces dichotomous understandings of the world and methods that rely exclusively on the analytic ideal of the reduction of psychological process and behaviors to fixed elements, followed by the additive linear causal recomposition of elements. Split metatheory has led to the creation of a broad array of antinomies that constrict empirical inquiry. Relational metatheory heals these splits by generating inclusive holistic understandings of the world, and methods that are inherently analytic-synthetic. The relational framework promotes a truly multidisciplinary, multimethod approach to inquiry in which each individual approach is valued not as a potentially privileged vantage point, but as a necessary line of sight on the whole.

Relational metatheory grounds the unified definition of development discussed earlier, and offers methods for unraveling many conceptual knots that impact on our exploration of developmental change. However, the abstract nature of relational metatheory requires that other isomorphic metatheories mediate between this level and the more circumscribed levels of both theory and empirical observation. Again, the notion of levels of analyses and levels of metatheory become critical to a full understanding of the impact of basic concepts on empirical inquiry. Currently, *developmental systems* constitutes the best example of a metatheory that is nested within relational metatheory. Developmental systems (Gottlieb, Wahlsten, & Lickliter, 1998; Lerner, 2002; Overton, 2003; Oyama, 2000), takes seriously the centrality of holism, activity, organization, change, and nonlinearity. This approach specifically conceptualizes the individual organism as an active self-organizing systems that develops through the co-action or transaction of individual parts—initially genes-environment—in a manner that is often nonlinear in nature. The nonlinear character of this growth means that as the system transforms, novel features and novel levels of functioning emerge, and these cannot be reduced to (i.e., completely explained by) earlier features. Thus, the genetic-environmental system transforms through action into the cellular-environmental system, and then into the organ-environmental system, and ultimately the person-environmental system. Further transformations of the person-environment system result in developmental changes in cognitive, affective, and motivational subsystems. Variants of the developmental systems metatheory are found in perspectives described by Thelen and Smith (1998) as "dynamic systems"; by Magnusson and Stattin (1998) as a "holistic person" approach; and by Wapner and Demick (1998) as a "holistic, developmental, systems-oriented" approach. Developmental systems metatheory operates close to the level of theory itself and sometimes merges with specifically theoretical concepts.

In a later section, an important metatheory that operates at a midlevel between relational metatheory and developmental system is described. This interrelated set of concepts is termed developmentally oriented embodied action metatheory. It functions to extend relational metatheory and further grounds several important developmental and developmentally relevant concepts including the nature and function of the systems and subsystems that become the central domain of developmental analysis. Before turning to this description, the next section examines development and evolution as these concepts are expressed in relational and split metatheories.

DEVELOPMENT AND EVOLUTION: RELATIONAL HISTORY AND RELATIONAL MODELS

Development and evolution have been indissociable complementary concepts throughout the history of developmental psychology. As Broughton (1981) pointed out, it was the American developmental psychology pioneer James Mark Baldwin "who first attempted a synthesis of philosophy and the life sciences through a description of progressive stage by stage intellectual development (Baldwin, 1897/1973) and its continuities and discontinuities with biological organization and adaptation (Baldwin, 1902/1976)" (p. 396). Baldwin's

concern with the complementarity of evolution and individual development led him to explorations of the relation between the genome and the phenotype, and specifically questions concerning how individual adaptations during the course of ontogenesis might impact on species evolution (1902/1976). An important outcome of this work was the proposal of a process termed "organic selection" (1895) and known later as the "Baldwin effect" (see Piaget, 1967/1971, 1974/1980; see also Cairns, Chapter 3, this *Handbook,* this volume), which offered a non-Lamarckian alternative to Darwin's split mechanistic process of natural selection. Broadly, organic selection refers to the possibility of a phenotypic adaptation coming to be replaced by a genetic mutation. Such a replacement runs counter to the classical Darwinian and neo-Darwinian gene centered position that the sole function of the environment is to select from what the genome provides.

In Europe, the work of another founder of developmental psychology, William Stern (1938), also presented a framework for a developmental psychology in which evolutionary and individual developmental processes were tightly interwoven: "In the concept of development lies not merely a bare sequence of states and phases, but *evolution*; preparation, germination, growth, maturation, and recession as a meaningful process that is by nature of an organized kind" (p. 30). Heinz Werner later carried this framework to North America in his *Comparative Psychology of Mental Development* (1940/1948). Here, and in other works, Werner articulated the complementarity of evolution and development through an insistence that developmental psychology entails a *comparative* approach to formal similarities as well as material and formal differences among ontogenetic, phylogenetic and other change sequences, as follows:

> Such a developmental approach rests on one basic *assumption,* namely, that wherever there is life there is growth and development, that is, formation in terms of systematic, orderly sequence. This basic *assumption,* then entails the view that a developmental conceptualization is applicable to the various areas of life science. . . . Developmental psychology does not restrict itself either to ontogenesis or phylogenesis. . . . (1957, p. 125)

Of all the developmentalists, who have articulated and emphasized the basic complementarity of individual development and evolution, it was Jean Piaget who most extensively explored this relation. Piaget's work is best known for its person-centered approach to conceptual development from infancy through adolescence. However, when Piaget turned his attention to process explanations of this and other forms of development he moved to a broad based epigenetic stance and there explored fundamental biological × psychological × environmental interactions. It was in this context that he produced two major works (1967/1971, 1974/1980) that grappled both empirically and conceptually with the genotype-phenotype relation. Based on his own empirical studies with the common snail, *Limnaea stagnalis,* Piaget, like Baldwin, became convinced of the inadequacy of the neo-Darwinian gene dominated explanation according to which a random (genetic) variation and natural (environmental) selection process is presumed to account for adaptations that occur both intra- and intergenerationally across the course of organic life. He similarly became convinced that a Lamarckian solution in which phenotypic adaptations come to have a direct impact on the genome was equally untenable. In place of both of these, Piaget eventually (1967/1971, 1974/1980) proposed a model of the "phenocopy." This model describes a mechanism whereby individual phenotypic adaptations indirectly impact the genome and ensure intergenerational transmission of some behavioral characteristics The model builds upon Piaget's own general conceptualization of the "equilibration" process, found in his writings on ontogenetic development, and on Baldwin's notion of organic selection.

The model of the phenocopy begins with a recognition that individual development includes the several levels of organization described earlier, as each interacts (i.e., interpenetrates) with its environment (i.e., levels of DNA, protein production, cell formation, tissue growth, organ formation, the organism as a whole, the organization of behavior, and ultimately, in the case of human development, affect, motivation, and cognition). The dynamic organized systems of behavior present at birth are not the direct reflection of some split-off biologically determined innate mechanism, but the product of an epigenetic process that grows these levels across the period of prenatal development. The model accepts Baldwin's notion of organic selection with respect to this ascending series. Variational products of lower (earlier) levels may be selected according to modifications produced at higher levels. For example, "the extremely complex internal processes of the germ

cell . . . may effectively allow, prevent, or modify the transmission of mutations arising within the DNA" (Piaget, 1974/1980, p. 51).

Piaget's unique contribution lies in the further relationally based proposal that, along with this ascending effect, there is a descending one in which a disequilibrium at higher levels may, in certain situations, cause disequilibrium at lower ones ultimately resulting in a genomic copy of the phenotype or "phenocopy." The preadapted action systems available at birth function in an environment that presents conflicts and obstacles, and the impact of these obstacles represents a system disequilibrium. Importantly, these environmental obstacles do not constitute a specific message sent back to the system; this would be the beginning of a Lamarckian solution. Rather, the sole function of disequilibrium is to feed back to the system that something has gone wrong and, thus, to set in motion reequilibration processes, which are represented as variational exploratory activity. Exploratory activity constitutes phenotypic variations and in many cases the adaptation that results from this variation has no generalized impact on the biosystem (e.g., the French have been speaking French for more than a thousand years, but there have been no suggestions that French is genetically transmitted). However, the disequilibrium may impact on lower levels of organization and cause further disequilibrium all the way down to the genomic level. The response to this descending disequilibrium will produce variational exploratory activity at each level impacted. If the disequilibrium reaches to the genomic level, the variants selected will ultimately represent a genetic copy of the phenotype.

In presenting the phenocopy model, Piaget (1974/1980) explicitly acknowledged the close connection between his own work on equilibration and modern theories of self-organizing systems (i.e., dynamic systems that resist disorder and transform random process into ordered structures; p. 110). It is not surprising that others operating from a contemporary developmental systems perspective have continued to argue for a relational reciprocity of development and evolution (e.g., Ingold, 2000; Oyama, 2000) and have continued to explore the genotype-phenotype developmental relation. Recently, Gottlieb (2002), after reviewing the selective breeding and early experience literature, proposed a three-stage model for the developmental-behavioral initiation of evolutionary change that is highly consistent with Piaget's. The first stage of Gottlieb's model entails changes in ontogenetic development (novel behavioral adaptations) occurring across generations and encouraging new environmental relations. In the second stage, which may or may not entail changes in structural genes, the new environmental relations evoke latent anatomical or physiological change, and in the final stage genetic changes occur. As Gottlieb (2002) points out, "It is important to observe that, in this theory, evolution has already occurred phenotypically at the behavioral, anatomical, and physiological levels before the third stage is reached. Hence, new variations and adaptations arise before they are selected for and are therefore not a consequence of natural selection" (p. 217).

In summary, from its origins and continuing in the work of various developmental systems approaches, developmental psychology has operated within a relational frame with respect to the conceptualization of development and evolution as a reciprocal complementarity. However, beginning in the 1990s with the emergence of so-called evolutionary psychology (Buss, 1999; Tooby & Cosmides, 1992) and later evolutionary developmental psychology (Bjorklund & Pellegrini, 2002) this complementarity was fractured by a split-off conceptualization that embraces a genetic determinism and an additive concept of interaction. In this split account, genetic programs established across the course of evolution determine behavioral variation, while culture selects the individual variants that constitute individual developmental adaptations. This split perspective on evolution and development arose out of earlier ethological and sociobiological approaches, but its fundamental concepts are grounded in neo-Darwinian metatheory. There have been a number of excellent critiques of the conceptual problems raised by nonrelational accounts of evolutionary and developmental evolutionary psychology (e.g., Lickliter & Honeycutt, 2003; Mameili & Bateson, in press; Rose & Rose, 2000). We now focus on the way that split neo-Darwinian metatheory comes to impact these and other areas of traditional developmental interest.

DEVELOPMENT AND EVOLUTION: SPLIT APPROACHES

Neo-Darwinian metatheory has been variously termed the *neo-Darwinian synthesis* and *the modern synthesis.* It emerged in the 1940s based on a marriage of the evolutionary position of Darwin, called classical Darwinism, and the genetics of Mendel. There is some irony to

the use of the term "modern" as the approach is now some 60 years old. It is well known that the core of the synthesis is the duality of *random variation* and *natural selection.* From the beginning, both for Mendel with respect to genetics and for Darwin with evolution, there was a rigid separation (i.e., split) between the *internal* and the *external.* For evolutionists, the statement: "Mutations are random with respect to their environment" meant that the processes that accounted for the variation between individuals were independent of the evolutionary process that selects individuals. For geneticists, the genotype constituted the internal state of the organism, and the phenotype constituted the outside or outward manifestation (see Figure 2.5).

Along with the split between inner and outer, the most important feature of the neo-Darwinian synthesis is that evolutionary *change* is defined in terms of variation in gene frequencies and *only* variation in gene frequencies. Thus, the metatheory establishes that *change is understood as variation, not transformation.* Transformational change is essentially written out of the story and treated as epiphenomenal. Within the metatheory, genes (or DNA, to be more precise) cause phenotypes by "supplying information," "instructions," or "programs." Genes themselves are thought of as packages of independent causes, or gene pools that exert their influence in a one-way outward causal flow of direction. This independent causal aggregate and the transmission of causes from this aggregate then results in the outward manifestation called the phenotype.

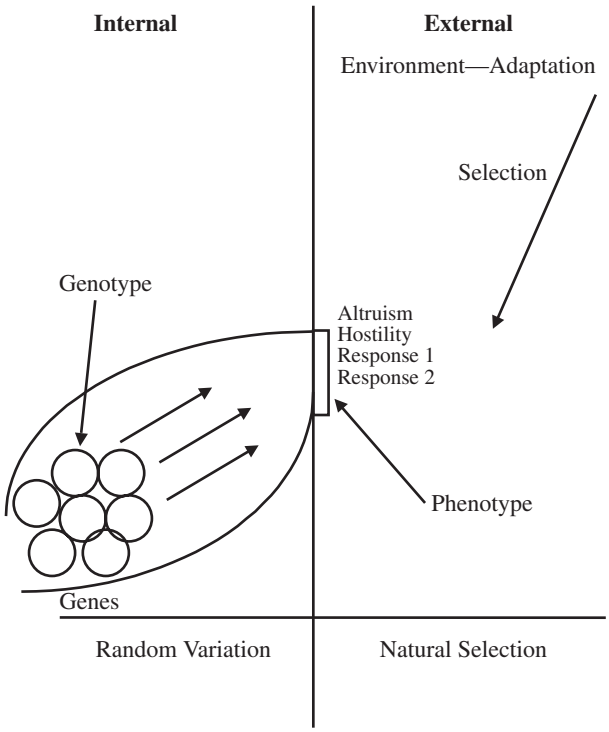

Figure 2.5 The split neo-Darwinian metatheory.

This metatheory has come to acquire a number of metaphors that support and enhance interpretations of split-off entities, fragments, aggregates, and linear unidirectional causality (see Nijhout, 1990; Oyama, 1989). Metaphors include the "bean bag" concept of the genome as independent packages, the notion that "instructions are transmitted," and the idea of a "program," "blueprint," or "instructions."

The *internal* aggregate produces random variation, but it is the *external* natural selection that determines the appearance of change. The *phenotype* constitutes the observed variability of behavior. The environment operates upon this variability as an *independent causal agent* to select those characteristics that promote survival. Two points need emphasis about this dualistic (i.e., split internal and external) understanding of causes. First, we have here the prototype for biological causes (internal) and social-cultural causes (external) as split, independent forces. Causality remains linear (additive) and unidirectional in the split model. When we tell the inside story, there is no reciprocal causation; causes simply operate independently and in a single direction, from internal toward external. The outside story replicates this; there is no reciprocal causation and the direction is now external toward internal.

The second point to note about the dualistic narrative of evolution as variation is the manner in which the concept of "adaptation" becomes formulated and established as a central feature of the external story (Gould, 1986; Lewontin, 2000). Adaptation is identified with "adjustment" and consequently refers to a *change designed to fit an independent context. Context* (i.e., social-cultural factors) selects those characteristics that best fit; hence, the central notion of competition and survival of the fittest.

In summary, the evolutionary metatheory described by the neo-Darwinian synthesis involves an internal aggregate gene pool that presents a package of solutions and an external environment that presents various problems to be solved (see Lewontin, 2000). This "adaptationist" program splits subject (genes) and object (environment) into isolated bits of reality and assigns chance variation to the former and contingent selection to the latter. The overall process is entirely contingent.

All elements—inside and outside—are fundamentally interchangeable, and any outcome could have been otherwise had other elements randomly appeared. At no point does any fundamental principle of organization enter the process; hence, all change is, in principle, reversible (Overton, 1994a).

There are many possible applications of this split neo-Darwinian metatheory to issues of developmental change. Those described below are selected to illustrate the breadth and depth to which this form of thinking has impacted on developmental issues, theory, concepts, and methodology.

Split Neo-Darwinian Metatheory: Developmental Applications

The first example of the impact of this split evolutionary metatheory, on developmental understanding is the famous/infamous nature-nurture issue. Although the neo-Darwinian metatheory did not generate the nature-nurture controversy (that had more to do with the original great splitters, Galileo and Descartes, who are discussed in a later section), it supports its continuance and limits "solutions" to attempts to put nature pieces and nurture pieces back together. The controversy is supported by the neo-Darwinian radical rupture of the whole into an inside (gene, biology) story that comes to be called nature, and an outside (social-cultural, experience) story called nurture. Once this split is confirmed as ontologically real, behaviors or characteristics (e.g., altruism, aggression, empathy, thinking, language) are explained as the causal outcome of one or the other, or some additive combination of the two. The controversy becomes the questions of *which one* fundamentally determines change, or *how much* does each contribute independently to determining change, or *how* does each contribute to determining change (Anastasi, 1958; Lerner, 1978; Overton, 1973).

The "solution" to the nature-nurture issue under this split metatheory requires choosing among several strategies designed to deal with combining and/or suppressing *independent pieces.* First, included among these strategies is *biological determinism,* which treats the outside story as epiphenomenal, and argues that the fundamental causes of behavior are given by the inside story. For example, this strategy argues that the capacity for violence is given by the genes (the real cause) and social-cultural events simply trigger the underlying biological capacity. *Social determinism,* the mirror image of biological determinism, is the strategy of treating the inside story as epiphenomenal, while arguing that the outside story provides the fundamental causes of behavior. The claim here is that there is sufficient genetic variability for either violence or gentleness, and social-cultural factors are the real cause of violent behavior. Both strategies usually decry the idea of dualism, but they deal with the dualism by suppressing the functional reality of one or the other sides of the neo-Darwinian narrative.

A third split nature-nurture strategy has been called *conventional interactionism* (Oyama, 1989; see also, Lerner, 1978; Overton, 1973). Dualism, although clearly a functional part of the scheme, is ignored by this strategy, and it is insisted that any characteristic is partially the effect of each factor. This strategy sometimes places the duality on a continuum and argues that various characteristics are more or less determined by one or the other factor (e.g., see Scarr, 1992). This is the quantitative additive compromise that was mentioned earlier with respect to split issues generally. In the final strategy, *bio/social interactionism,* dualism is *celebrated.* Generally, this approach makes claims that the biological sets the limits, or establishes "predispositions," or "constraints" for behavior and the social-cultural determines behavioral expression. This compromise is the most direct reflection of the neo-Darwinian metatheory of the nature of change (e.g., Karmiloff-Smith, 1991).

These four nature-nurture strategies do not exhaust the list of possible "solutions," nor are they necessarily mutually exclusive. Each tends at times to merge into another. However, neither the complexities of nature-nurture nor even the details of alternative nonsplit solutions are central here (see Overton, 2004a, for an extended discussion). Rather, the central point of emphasis is that the whole class of traditional solution strategies emerges because and *only* because of the acceptance of a particular metatheoretical story about the nature of things. This is the story in which "nature" (genetics, biology) is identified with an ontologically real *inside* called *nurture* that is radically split from an ontologically real *outside* called "nurture" (experience, social-cultural). If this conceptual distinction is rejected as an ontological description of "the Real," the controversies themselves evaporate.

A second example of the use of the neo-Darwinian metatheory as a template for understanding developmental phenomena emerges from the behaviorist literature. In this arena, several have noted (Oyama, 1989;

Skinner, 1984; Smith, 1986, 1990) that Skinner's model represented a direct application of the neo-Darwinian story. Skinner's operants had to originate from somewhere, but Skinner's behavioristic outside story of the subject (instrumental as opposed to expressive function of behavior) never required an articulation or elaboration on these internal origins. All that was required was the output of the inside neo-Darwinian story; the random variation of a set of operant (instrumental) responses. Given this base, Skinner's outside story can and does focus on natural selection or "selection by consequences" as presenting "the real" functional variables in the development of behavior.

More central to contemporary developmental psychological interests than Skinner's position is the work of Belsky, Steinberg, and Draper (1991), who used the neo-Darwinian metaphor as a frame for a developmental theory of socialization. Their strategy for explaining socialization has been to wed a social-biological approach to Bronfenbrenner's (1979) behavioral ecology. *Sociobiology* asserts the adaptationist strategic claim that natural selection favors behavioral strategies that increase fitness. Sociobiology also provides the authors with an inside story biologically grounded in "the modern view of evolution" (p. 663; i.e., the 1940s "modern" synthesis or neo-Darwinian synthesis). *Behavioral ecology,* alternatively, represents the outside story; the argument that behavior strategies are "contextually conditioned," shaped, or selected by the environment. "From sociobiology we take the maxim that natural selection tends to favor behavior that increases fitness. From *behavioral ecologists* we take the maxim that behavioral strategies that contribute to reproductive success are . . . contextually conditioned" (p. 648). And, "central to our theory is the notion drawn from modern evolutionary biology that humans . . . adjust their life histories in response to contextual conditions in a manner that will enhance reproductive fitness—or at least would have in the environment of evolutionary adaptation" (p. 663). The issue here does not entail the critique of this approach at either a theoretical or an observational level of discourse. The issue here concerns a recognition that this approach arises from a particular metatheory, and the consequences of accepting this metatheory, are different from those that follow from accepting another metatheory. This metatheory fosters split theoretical and observational understandings of the nature of developmental change and its explanation. The consequence of this split story is that only variability is allowed as fundamentally real developmental change, and explanation can occur only within the categories of "biological causes" and "social-cultural causes" (see Lewontin, 2000).

The investigation of mechanisms of development constitutes another important contemporary example of the neo-Darwinian metatheory of variational change and internal-external causes being applied to conceptually contextualize an important developmental psychological issue (see Hoppe-Graff, 1989; Sternberg, 1984 for a general discussions of developmental mechanisms). Siegler (1989, 1996; Siegler & Munakata, 1993) presented a scheme that represents hypothesized mechanisms of cognitive development as being analogous to several genes. Each mechanism produces alternative types (random selection), and the environment selects (natural selection) these types according to fitness criteria (see Figure 2.6).

For Siegler (1989), a mechanism of cognitive development is any "mental process that improves children's ability to process information" (p 353). This means that the developmental outcome (effect) of any mechanism

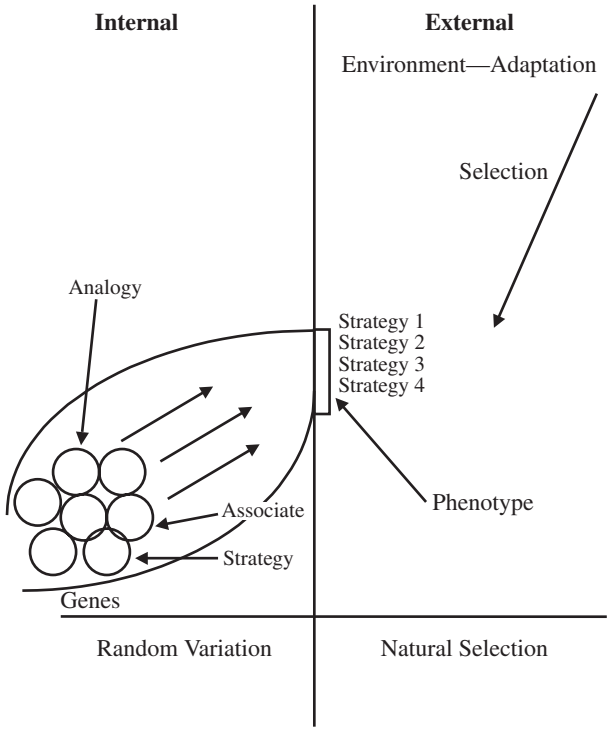

Figure 2.6 The neo-Darwinian metatheory and mechanisms of development (variational change).

(cause) is improvement in stored knowledge. Improvement here refers either to increases in amount of knowledge stored or to the effectiveness of the machinery that stores and accesses the knowledge. Thus, ultimately, development is defined in terms of stored knowledge. This in itself limits developmental change to variational change; there is no room here for transformational change as a fundamental type of change. To account for the change in stored knowledge, Siegler proposes five broadly conceived "mechanisms" of development: (1) synaptogenesis (a member of the broader class of neural mechanisms), (2) associative competition, (3) encoding, (4) analogy, and (5) strategy choice.

Each proposed developmental mechanism is understood as being analogous to an individual gene. Each is an internal packet with an outward flow of causality from genotype to phenotype. The strategy choice gene, to take one example of the five mechanisms (see Figure 2.6), causes variation in the phenotype. The result is variation in external behavior as in learning Strategy 1, Strategy 2, or Strategy 3, and so on. As a specific analogy, consider the idea of tail length in an animal. The human would have an innately prewired set of alternative strategies just as the rat would have a set of alternative genes for tail length (or technically, alleles at a particular locus).

Having presented the inside story of variational and *only* variational change, the outside story then comes into play for Siegler. The alternative strategies are conceived as being in competition for survival. The environment selects (i.e., causes) the strategy that is to survive, and that strategy is the one that best facilitates the processing of information and, hence, the building of stored knowledge. The rat might phenotypically appear with a tail length of 1″, 2″, or 3″ depending on which had been selected; individual children might come with Strategy 1, Strategy 2, or Strategy 3.

In summary, for Siegler, fast and effective knowledge acquisition defines human development and is explained by phenotypical behaviors, which are a result of underlying causal mechanisms that are built into the system. Considering knowledge acquisition, the phenotypical behavior, and the underlying mechanism as a totality constitutes both a description and an explanation of development. Siegler and Munakata (1993) have said: "The centrality of variation and selection within . . . change mechanisms does not seem coincidental. Multiple competing entities seem essential for adaptation to changing environments. Effective selection among the variants is essential for producing progressively more successful performance. Achieving these functions of variation and selection may be essential for any developing system" (p. 3).

In addition, Kuhn and her colleagues (D. Kuhn, Garcia-Mila, Zohar, & Andersen, 1995) have proposed a wide ranging cognitive position concerning the development of scientific reasoning that parallels Siegler's with respect to the exclusivity of variational change and adaptation. In their scheme, knowledge acquisition strategies, metacognitive competence, and metastrategic competence are presumed to be available in rudimentary forms in young children and constitute the elementary building blocks of scientific reasoning. These skills appear as intraindividual variability of behavior in problem solving, and development or change "appears as a gradual shift in the distribution of the use of a set of strategies of varying adequacy" (p. 9). White (1995), in commenting on this movement "toward an evolutionary epistemology of scientific reasoning" (p. 129) notes the striking similarity to the historical behavioral "scheme of trial-and-error learning proposed by Edward L. Thorndike (1898) at the turn of the century" (p. 134) and contrasts it with the Piagetian perspective that emphasizes the dialectic of transformational and variational change as codefining fundamental features of development (Overton, 1990):

> Instead of wide-sweeping structural changes in the logical engines available to the child, there are changes in cognitive *elements* that the child can call into play when confronted with a problematic situation. The changes are not wide sweeping. They are more local, particulate. Yet there is transfer. . . . The emergence of scientific reasoning depends on an orchestration of a number of cognitive *elements* that have to work together. *Change, as it occurs, is by no means irreversible.* (White, 1995, p. 135, emphasis added)

It needs to be emphasized again that, in the examples described, the type of change being identified as developmental follows directly from the neo-Darwinian metatheory as variational change and not transformational or morphological change. Siegler's proposed mechanisms of development, along with Kuhn's, Skinner's, the social biology/behavioral ecology, and socialization approaches, contemporary evolutionary psychology, and recent forays into developmental evolutionary psychology all describe change in which no

fundamental transformational novelty emerges. In each example, forms and the change of forms—changes in forms of thought from infancy to childhood, and to adolescence, or changes in forms of personality organization, or changes in emotional organization from global affect to differentiated specific emotions—are simply excluded from discussion or treated as epiphenomenal. In each of the neo-Darwinian generalizations, inside causes (nature) provide a variational base of behaviors, while outside causes (nurture) winnow down and shape that variation. Variation and the winnowing and shaping process constitute the definition and explanation of development within this story. Transformational or morphological change has simply been excluded from the fundamental story of development and treated as mere appearance.

Split Neo-Darwinian Metatheory: A Flawed Story of Change?

These several examples have been presented to demonstrate how split metatheory—specifically neo-Darwinian metatheory—can impact on the understanding and explanation of developmental change in various domains. Next, we turn to the question of the ultimate viability of this metatheory.

The split between variational change and transformational change that is a part of the neo-Darwinian story has created a broad paradox in the life sciences: On the one hand a significant number of psychologists have been turning to the neo-Darwinian story as a context within which to understand developmental change; on the other hand, many who work more directly in the fields of biological and evolutionary change complain that the neo-Darwinian story is outdated and deeply flawed because it fails to incorporate developmental change. More specifically, these critics argue that it is flawed because it omits the kind of developmental change defined as transformational change. These critics, from the fields of biology, evolutionary biology, evolutionary developmental biology, and anthropology include Brooks (1992; Brooks & Wiley, 1991), Edelman (1992), Gilbert (2003; Gilbert, Opitz, and Raff, 1996), Goodwin (1992), Gould (2000), Kauffman (1992, 1995), Ingold (2000), and Lewontin (2000). This same criticism has been articulated within the psychological community by a variety of developmental systems oriented investigators (e.g., Bateson, 1985; Gottlieb, 1992, Chapter 5, this *Handbook,* this volume; Kuo, 1967; Lehrman, 1970; Schneirla 1957; Tobach, 1981; Varela, Thompson, & Rosch, 1991).

These critics are not becoming anti-Darwinian or anti-evolutionary. They are simply articulating the need for modification and expansion of the neo-Darwinian story. Evolutionary biologists, developmental biologists, neurobiologists, geneticists, paleontologists, anthropologists, and psychologists speak in many different voices when they argue this point, but they uniformly agree on the following: Regardless of the level of analysis one chooses to explore, concepts of *organization, system, structure, or form—as well as the transformation of organization, system, structure, or form—must enter into a new evolutionary synthesis* in every bit as central a fashion as concepts of variation and selection enter the current narrative. Development—conceived as ordered changes in the form, organization, or structure of a system—must be directly integrated into the current narrative of variational change and selection.

Gilbert (2003), a developmental biologist, describes the origin of the exclusion of development (transformational change) from evolution:

> The developmental approach became excluded from the Modern Synthesis. . . . It was thought that population genetics could explain evolution, so morphology and development were seen to play little role in modern evolutionary theory. (p. 778)

Edelman (1992), a neurobiologist, goes on to articulate the dominant theme of most contemporary revisionist critics by arguing for the need to reintroduce the centrality of form and change of form (transformation) into an expanded neo-Darwinian narrative:

> The part of Darwin's program that needs most to be completed . . . is concerned with how animal form, tissue structure, and tissue function could have arisen from ancestors—the problem of morphologic evolution. (p. 48)

> Morphology—the shape of cells, tissues, organs, and finally the whole animal—is the largest single basis for behavior. (p. 49)

> To accomplish it [completing Darwin's program] we need to show how development (embryology) is related to evolution. We need to know how genes affect form through development. (p. 51)

Along with the criticism that there is more to the story of evolution than variational changes in gene frequencies, the revisionists argue against the interpretation of genes as independent split-off atomic entities,

and they call for a recognition that "genomic regulatory networks underlying ontogeny, exhibit powerful 'self-organized' structural and dynamical properties" (Kauffman, 1992, p. 153). As a consequence of recognizing the genome itself as a self-organizing system (i.e., an active form-changing organization), there is a call to "invent a new theory of evolution which encompasses the marriage of selection and self-organization" (Kauffman, 1992, p. 153; see also Varela et al., 1991).

Further, this group points out that evolutionary theory—as limited to random variation and natural selection—has become too sharply focused on the maintenance of diversity (i.e., focused on the reversible, and the cyclical) while ignoring the significance of the origin and developmental paths of diverse forms (i.e., the transformational, and the directional; Brooks, 1992; Lewontin, 2000).

Finally, the revisionists argue that the concept of adaptation to a split-off environment, as described by the neo-Darwinian metatheory of natural selection, severely limits understanding. They argue for a healing of the dualism of a split-off internal and external through a relational recognition that it is both the case that biological organisms construct their social-cultural world, and that the social-cultural world constructs biological organisms (Edelman, 1992; Lewontin, 2000).

Virtually all of the themes argued by contemporary evolutionary revisionists assert the need for an understanding that is relational in nature; an understanding where inside and outside, variation and transformation, biological and social-cultural as well as other fundamental splits are viewed as analytic distinctions, not ontological cuts in nature. This relational understanding yields distinctions that allow an investigator to stand at a particular line of sight and explore from that particular point of view without declaring that point of view to be "the real." An illustration of these themes in human ontogenesis is found in the contrast between the split-off adaptationist story found, for example, in Skinnerian theory and the social learning theories discussed earlier, and the relational picture of adaptation found in the work of Jean Piaget. Like Skinner (1984) and social learning theories, Piaget (1952) introduces adaptation as a fundamental and central theoretical concept. However, unlike these neo-Darwinian theorists, Piaget's concept of adaptation is always understood as the complement of a second central theoretical concept, organization. As with the modern evolutionary revisionists, Piaget stresses time and time again that *organization* (the form) and *adaptation* (the function) are two poles of the same relational matrix, two aspects of the same whole. It is neither that organization will ultimately be reduced to adaptation, nor that organization provides the variation and adaptation the selection. Novel organization emerges from processes of adaptation, but adaptation operates under the constraints of current organization. Organization and change of organization (transformational change) become the focus when inquiry is directed toward issues of emergent novelty, sequence, and irreversibility. Adaptation becomes focal as inquiry is directed toward issues of activity, process, and variation. Structure and function are not independent split-off either/or solutions to problems; structure and function, organization and activity, form and process, are alternative perspectives on the same whole.

In summary, the neo-Darwinian "modern synthesis" is a split metatheory that has consequences for developmental inquiry across a broad range of domains. As a narrative that speaks of variational change exclusively, it provides a conceptual context for, and reinforces, other narratives that would claim development is about variational change and *only* variational change, and that explanation is about biological causes and/or social-cultural causes. It is only within a relational metatheory that variation and transformation become indissociable complementarities and only within this metatheory do evolution and development return to the same complementary position.

DEVELOPMENTALLY ORIENTED EMBODIED ACTION METATHEORY

This section describes a metatheory that is consistent with relational metatheory but operates at a midlevel between relational metatheory and developmental system. This interrelated set of concepts is termed developmentally oriented embodied action metatheory. It functions to extend relational metatheory and further grounds several important developmental and developmentally relevant concepts including the nature and function of the systems and subsystems that become the central domain of developmental analysis

Embodiment

Several basic terms define a developmental oriented embodied action approach. Each term is associated with relational principles. For the moment, *embodiment* is the most central of these basic concepts, because

embodiment is a concept of synthesis that bridges and integrates biological, sociocultural, and person-centered approaches to psychological inquiry. Until recently, the trend of developmental inquiry over the past several decades had been moving toward ever increasing fragmentation of the object of study. Beginning in the early 1980s, the examination of human development aggressively promoted split and foundational approaches to inquiry, including variable oriented, discourse, modular, and domain specific inquiry. Each of these was advanced with claims that it presented the bedrock foundation from which scientific knowledge must grow. The result was that inquiry into human development was increasingly split into biologically determined, culturally determined, and bio-culturally determined behavior, innate modules of mind, situated cognitions, domain specific understandings, and communicative and instrumental functioning. What became lost in the exclusivity of these projects was the psychological subject as a vital integrated embodied center of agency and action. This is the embodied person—functioning as a self-organizing dynamic action system—expressively projecting onto the world, and instrumentally communicating with self and world, thoughts, feelings, wishes, beliefs, and desires. This is the embodied person who emerges from and transacts with the relational biological-cultural world, thereby developmentally transforming his or her own expressive and adaptive functioning and the world itself.

Embodiment is the affirmation that the lived body counts in our psychology. It is not a split-off disengaged agent that simply moves around peeking at a preformed world and drawing meaning directly from that world. It is not a set of genes that causes behavior nor a brain nor a culture. Behavior emerges from the embodied person actively engaged in the world. The concept of embodiment was first fully articulated in psychology by Maurice Merleau-Ponty (1962, 1963) and it represents a relational movement away from any split understanding of behavior as an additive product of biological and sociocultural determinants.

Embodiment is the claim that perception, thinking, feelings, desires—*the way we behave, experience, and live the world*—is contextualized by our being *active agents* with this *particular kind of body* (Taylor, 1995). The kind of body we have is a precondition for our having the kind of behaviors, experiences, and meanings that we have. As Johnson states, "Human beings are creatures of the flesh. What we can experience and how we make sense of what we experience depend on the kinds of bodies we have and on the ways we interact with the various environments we inhabit" (1999, p. 81).

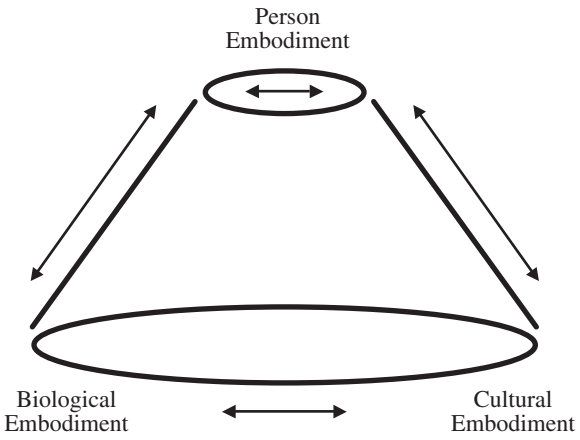

Figure 2.7 Embodied person, biology, culture.

As a relational concept embodiment includes not merely the physical structures of the body but *the body as a form of lived experience, actively engaged with the world of sociocultural and physical objects.* The *body as form* references the biological line of sight, the *body as lived experience* references the psychological subject standpoint, and the *body actively engaged with the world* represents the sociocultural point of view. Within a relational perspective, embodiment is a concept that bridges and joins in a unified whole these several research points of synthesis without any appeal to splits, foundationalism, elements, atomism, and reductionism (see Figure 2.7).

Biological Embodiment

Contemporary neuroscience has increasingly endorsed the significance of embodiment as an essential feature of the biological line of sight as it addresses psychological issues. For example, Antonio Damasio (1994, 1999)—exploring the neurological dimension of emotions—and Gerald Edelman (1992; Edelman & Tononi, 2000)—exploring the neurological dimensions of consciousness—along with Joseph LeDoux (1996)—exploring the neurological dimension of emotions—all support an embodied approach to biological-psychological inquiry and all argue that the cognitive, affective, and motivational systems and actions that constitute mind can no longer be thought of as the direct expression of genetic modularities (as nativists such as Steven Pinker, 1997, would claim), nor can they be thought of as a functionalist piece

of software, nor even as merely a function of brain processes. Rather, they argue, these meanings must be considered in a fully embodied context (see also, Gallese, 2000a, 2000b). As Damasio says:

> Mind is probably not conceivable without some sort of embodiment (1994, p. 234). And further, commenting on contemporary perspectives on mind, "This is Descartes' error: the abyssal separation between body and mind. . . . The Cartesian idea of a disembodied mind may well have been the source, by the middle of the twentieth century, for the metaphor of mind as software program . . . [and] there may be some Cartesian disembodiment also behind the thinking of neuroscientists who insist that the mind can be fully explained in terms of brain events [i.e., connectionism], leaving by the wayside the rest of the organism and the surrounding physical and social environment—and also leaving out the fact that part of the environment is itself a product of the organism's preceding actions." (1994, pp. 249–250)

Similarly, Edelman (1992) argues:

> The mind is embodied. It is necessarily the case that certain dictates of the body must be followed by the mind. . . . Symbols do not get assigned meanings by formal means; instead it is assumed that symbolic structures are meaningful *to begin with*. This is so because categories are determined by bodily structure and by adaptive use as a result of evolution and behavior. (p. 239)

Sociocultural Embodiment

From the cultural point of synthesis, social constructivists not committed to a split metatheoretical approach (e.g., Harre, 1995; Sampson, 1996) have come to embrace embodied action as a relational anchoring to the relativism of split-off discourse analysis. Sampson (1996) argues for "embodied discourses" as these "refer to the inherently embodied nature of all human endeavor, including talk, conversation and discourse itself" (p. 609; see also, Csordas, 1999; Ingold, 2000; Overton, 1997). Perhaps the most fully articulated contemporary employment of embodiment in a developmentally oriented cultural psychology is found in Boesch (1991). Boesch's presentation of *The I and the body* is a discussion of the centrality of embodiment for a cultural psychology. Thus, he states "The body, obviously, is more than just an object with anatomical and physiological properties: *it is the medium of our actions,* it is with our body that we both conceive and perform actions" (p. 312, emphasis added).

Person-Centered Embodiment, Action, and Development

The person-centered or psychological subject point of synthesis constitutes the standpoint that frames the major focus of any specifically psychological theory of development. This point of synthesis maintains a theoretical and empirical focus on the psychological processes and patterns of psychological processes as these explain the psychological subject's actions and the development of these actions in the world (see Figure 2.8–A). This approach to developmental inquiry requires the description of five critical interwoven concepts—*person, agent, action, experience, and person-embodiment.* Before detailing these concepts this person-centered standpoint needs to be briefly contrasted with what have been termed "variable" approaches.

Variable and Person-Centered Standpoints

Variable approaches focus inquiry on biological, cultural, and individual variables as these are understood to operate as predictors, correlates, risk factors, or antecedent causes of behavior. The distinction between this and a person-centered or child-centered standpoint is similar to that described some time ago by Block (1971), and more recently elaborated by Magnusson (1998; Magnusson & Stattin, 1998) and others (e.g., Cairns, Bergman, and Kagan, 1998; Hart, Atkins, & Fegley, 2003; NICHD Early Child Care Research Network, 2004; Robins & Tracy, 2003). As Magnusson has suggested, from a variable approach various individual

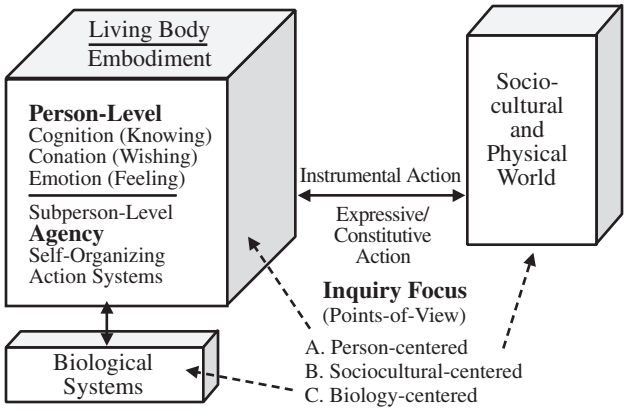

Figure 2.8 Embodied action: A relational approach to inquiry.

variables (i.e., "child factors," "child characteristics") and contextual environmental and biological variables are understood as the explanatory actors in the processes being studied (see Figure 2.9). From a person-centered standpoint, self-organizing dynamic action systems—which identify psychological mechanisms—operate as the main vehicles of explanation. Although variable approaches often suggest a split-off exclusivity, they can in fact be transformed into to yet another necessary point of view of relationally integrated inquiry. A variable-centered approach inquiry, aiming at the prediction of events, states, and movements, and a person-centered approach, aiming at explaining psychological processes and their transformation come into conflict only in the reductionistic case where one or the other is asserted as the exclusive foundational aim of inquiry. In this context, it is important to recognize that the complementarity here is one of aim and not one suggesting that variable inquiry is oriented to research methods and person-centered inquiry is oriented to conceptual context. Both approaches entail the translation of theory into the empirically assessable, and the translation of the empirically assessable into theory. Perhaps the clearest example of an important contemporary developmental theory that grounds itself within a variable tradition is found in Bronfenbrenner's bioecological model (Bronfenbrenner & Morris, 1998).

The single most important value of recognizing a person-centered standpoint as a necessary point of synthesis, along with the biological (Figure 2.8–B) and cultural (Figure 2.8–C) points of synthesis, is that it rescues psychology generally, and developmental psychology specifically, from becoming a mere adjunct to biology, culture, discourse, narrative, or computer science. *Psyche* initially referenced "soul" and later "mind," and if psychology is not to again lose its mind—as it did in the days of the hegemony of behaviorism—keeping the psychological subject as the center of action is a necessary guard against explanatory reduction to biology, culture, discourse, and so on.

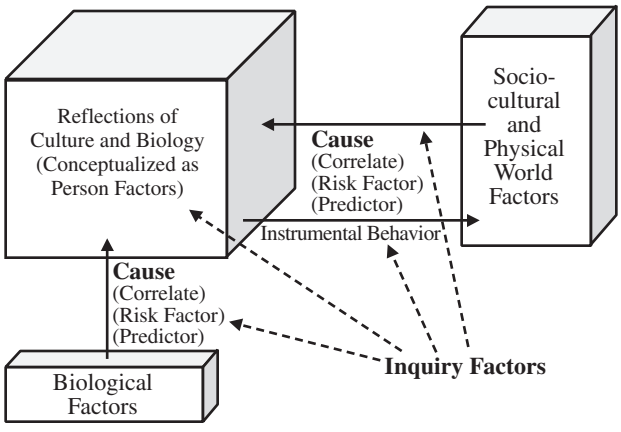

Figure 2.9 A variable approach to inquiry.

The second benefit that accrues to maintaining, a person-centered approach as a necessary point of view is that this perspective again highlights the fact that any act can be profitably understood—in a complementary bipolar fashion—as both *expressive-constitutive and as instrumental-adaptive.* Split or dichotomous approaches—especially split-off variable approaches—lead to the illusion that acts exhibit only adaptive-instrumental-communicative functions. A person-centered approach argues that any act may also be understood as an expression of an underlying dynamic organization of cognitive, affective, and conative meanings, and this expression operates to constitute the world as known, felt, and desired. Here, Bloom's work (Bloom & Tinker, 2001) on the development of language provides an excellent illustration of the power of conceptualizing language acquisition in the context of the expression of person-centered cognitive, affective, and conative-motivational meanings, rather than exclusively as an instrumental tool operating solely for communicative ends.

A third benefit derived from a person-centered point of view is that it provides the necessary context for the resolution of certain important problems related to our general understanding of psychological meaning. Specifically, a person-centered approach is a necessary frame for solving the so-called symbol-grounding problem. This is the question of how to explain that representational items (i.e., a symbol, an image) come to have psychological meaning (Bickhard, 1993). I return to this problem in a more detailed fashion later.

With these examples of some of the benefits of a child- or person-centered approach to developmental inquiry as background, it is possible to turn to a specific description of this metatheoretical approach, which entails the five critical interwoven concepts of *person, agent, action, experience, and person-embodiment.*

Person-Agent

Person and agent are complementary Escherian levels of analysis of the same whole (see Figure 2.8–A). The person

level is constituted by genuine psychological concepts (e.g., thoughts, feelings, desires, wishes) that have intentional qualities, are open to interpretation, and are available to consciousness (Shanon, 1993), or in other words have psychological meaning. The agent level—called the subpersonal level by some (Dennett, 1987; Russell, 1996)—here refers to action systems or dynamic self-organizing systems. "Schemes," "operations," "ego," "attachment behavioral system," and "executive function" are some of the concepts that describe these action systems.

Taken as a whole, the person-agent forms the nucleus of a psychological metatheory of mind. And, in this context, mind is defined as a self-organizing dynamic system of cognitive (knowings, beliefs), emotional (feelings), and conative or motivational (wishes, desires) meanings or understandings, along with procedures for maintaining, implementing, and changing these meanings. Importantly, it must be noted and underlined that a person-centered metatheory of mind is not an encapsulated cognition but a theory that includes emotions, wishes, desires, and cognition. Further, there is no question about where mind is located: Mind emerges from a relational bio-sociocultural activity matrix. In the present context, mind is a person-centered concept because the approach being described takes the *person standpoint.* As a person-centered concept, mind bridges naturally to both the biological (Figure 2.8–C) and the sociocultural (Figure 2.8–B).

Action, Intention, Behavior

Person-agency is the source of action and a person-centered approach establishes the framework for what has traditionally been termed an *action theory* (Brandstädter, 1998; Brandstädter & Lerner, 1999; Mueller & Overton, 1998a). At the *agent level,* where it is not necessary to limit a definition to the human organism, action is defined as the *characteristic functioning of any dynamic self-organizing system.* For example, a plant orients toward the sun. Weather systems form high and low pressure areas and move from west to east. Alternatively, human systems organize and adapt to their biological and sociocultural worlds. At the *person level,* action is defined as *intentional activity* (i.e., meaning giving activity). Intentionality, however, is not to be identified with consciousness: While all acts are intentional, only some intentions are conscious or self-conscious. In a similar fashion, intention is not to be identified solely with a symbolic level of reflection. Following Brentano (1973/1874), all acts, even those occurring at the most sensory-motor level of functioning intend some object.

Action is often distinguishable from *behavior,* as the action of the person-agent implies a *transformation* in the intended object of action, while behavior often simply implies movement and states (e.g., the classically defined "response" was understood as specific movement in space and time—a behavior—see von Wright, 1971, p. 199). As action, when the infant chews (act)—something that from a *sociocultural standpoint* is called a "basket"—the infant, from a *person-centered standpoint,* is transforming this part of her known world into a practical action—chewable. Piaget's cognitive developmental theory is a good example of a child-centered developmental action theory where the metatheoretical "action" becomes translated into specific theoretical concepts. Thus, Piaget's basic theoretical concepts of "function," "assimilation," "accommodation," "operation," "reflective abstraction," all reference action. And Piaget (1967) repeatedly affirms the centrality of action throughout his writings: "I think that human knowledge is essentially active. To know is to assimilate reality into systems of transformations. To know is to transform reality. . . . To my way of thinking, knowing an object does not mean copying it—it means acting upon it" (p. 15). "To know an object . . . is to act on it so as to transform it" (1977, p. 30). "Nothing is knowable unless the subject acts in one way or another on the surrounding world" (1980, p. 43).

Action serves at least three major functions in the development of mind (see Figure 2.1). First, *action expresses cognitive-affective-conative meaning.* It is important to recognize that meaning, like many other basic concepts, has relational complementary definitions that are determined by the standpoint being taken (Overton, 1994b). "I mean" and "it means" operate in a relational matrix. The former is concerned with person-centered meanings, the latter with sociocultural meanings and reference. From a person-centered standpoint, the focus of analysis is on "I mean" and secondarily on how "I mean" becomes associated with "it means." Considered in its expressive moment, action entails the projection of person-centered meanings, thus transforming the objective environmental world (i.e., an object point of view) into an actual world as known, felt, desired. World, here is another relational bi-polar concept. The *actual* world

is the world of meanings constructed by the person—the known world; the *environmental or objective* world is the world of reference, examined from a sociocultural standpoint.

The second function that action serves is the *instrumental function of communicating and adjusting person-centered meanings.* Communication, dialogue, discourse, and problem solving all call attention to the relational to-and-fro movement between the expression of the self-organizing system, and instrumental adaptive changes. Completely adapted (i.e., successful) action entails only the *projection* of meaning onto the world (e.g., If I intend this object before me to hold water as a cup, and successfully drink from it, no change occurs in my conceptual system). Partially adapted (i.e., partially successful) action results in exploratory action, or *variations* (e.g., If the intended cup leads to water leaking onto my shirt, I vary my actions such as putting my finger across a crack in the object). Exploratory action that is adaptive (e.g., The finger placement permits successful drinking) leads to reorganization of the system (transformational change) and new meanings (e.g., A cup is an object without open cracks).

Experience and Action. This general cycle of projected action, and exploratory variational action as the accommodation to encountered resistances, constitutes the third and most general function of action: *Action defines the general mechanism of all psychological development.* From a person-centered developmental action standpoint *all development is explained by the action of the subject.* However, this metatheoretical concept will be translated into specific theoretical concepts at the level of theory itself (e.g., Piaget's concepts of assimilation-accommodation and equilibration identify action mechanisms of development).

In claiming that action is the general mechanism of all development, it is necessary to recognize that within an action based perspective *action and experience are identical concepts.* As a consequence, the claim that action is the mechanism of development is identical to the claim that experience is the mechanism of development. All development occurs through experience. But in this definition it should be clear that experience as action excludes neither the biological nor the sociocultural. In fact, experience understood as action of the person-agent represents a synthesis of these two.

Experience is itself yet another concept that acquires alternative meanings depending on whether the focus is from the person-agent or the objective environmental standpoint. From each perspective, experience is identified as the interaction of the act and the environment (i.e., acts intend objects), but each has a distinct emphasis regarding the locus of this interaction. From the person-agent standpoint (Figure 2.8–A), *experience is the action of exploring, manipulating, and observing the world,* while from an environmental standpoint (Figure 2.8–C), *experience is an objective event or stimulus present in the context of the act.* As understood from the person-agent standpoint, when experience is described as a feeling, the reference here is the person-centered felt meaning of the observational, manipulative, and explorational action.

In the history of psychology, and especially developmental psychology, the complementarity of these usages has often been lost in a world of split metatheory. As a consequence, implicitly or explicitly, experience has frequently been identified with, and only with, the objective stimulus. When this privileging of the stimulus occurs it carries with it the split metatheoretical principle of investing the privileged concept with a causal power. Consider, for example:

> For Schneirla, experience referred to all stimulus influences that act on the organism throughout the course of its life. . . . Any stimulative influence, any stimulus that acts on the organism in any way, is a part of experience. (Lerner, 2002, p. 152)

Here, experience is both defined exclusively by the stimulus and the stimulus is conceptualized as causally acting on. The consequence of such split understandings is that they again draw us back into a fruitless nature-nurture debate in which "experience" become pitted against "innate" or against "biological maturation" as one of two competing alternative explanation of behavior; thus, empty questions such as "Does experience influence behavior and change?" "How much does experience count in adolescence?" rise to the fore. When, on the other hand, experience is conceptualized as the complementary "act-environment," these and all other nature-nurture questions disappear, being replaced by empirical explorations that examine acts in relation to their source (person-agent) or acts in relation to the environment (see Overton & Ennis, in press).

When experience is understood as entailing the developmental *action cycle* of projection-transformation (of the known world) exploration-transformation (of the system), experience also becomes the psychological

bridge between biological and cultural systems. There is no sense here of an isolated, cut off, solitary human psyche. Person-centered experience emerges from a bio-sociocultural relational activity matrix (see, for example, Gallese 2000a, 2000b; Suomi, 2000) and this experience both transforms the matrix and is transformed by the matrix. Person development is not a split-off nativism or environmentalism, or a split-off additive combination of the two. The neonate is a dynamic system of practical action meanings. These meanings represent the outcome of 9 months of the interpenetrating action of biology-environment, and this interpenetration stretches all the way down to DNA (Gottlieb, 2002; Lewontin, 2000). Finally, it cannot be repeated too frequently that to say that development is explained by experience does not deny that development is explained by biology and that development is explained by culture. What is denied is the absolute exclusivity of any of these standpoint explanations.

Development of Person-Agent

Psychological development of the person-agent entails the epigenetic stance that novel forms emerge through the interpenetrating actions of the target system, and the resistances the target system encounters in both the actual and objective sociocultural and physical environment. It is through interpenetrating actions that the system changes and becomes differentiated. But differentiation of parts implies a novel coordination of parts and this coordination itself identifies the emergence of novelty (see Figure 2.2). Thus, as suggested earlier, the neurological action system becomes differentiated through the interpenetrating actions of neurological-environmental functioning. This differentiation leads to a novel coordination or reorganization that eventually leads to the adapted level of conscious practical action found in the neonate. Consciousness is a systemic property of this emergent action system. The initial adapted practical consciousness is a minimum awareness of the meaning entailed by an act (Zelazo, 1996). Consciousness cannot be reduced to or "squeezed" out of lower stages, it is the result of a transformation. Similarly, further developmental differentiations and coordinations of actions—described as higher levels of consciousness—emerge through the interpenetrations of conscious action and the sociocultural and physical worlds it encounters (see Figure 2.2). Symbolic meaning and the symbolic representational level of meanings (Mueller & Overton, 1998a, 1998b) describes forms of consciousness that arise from the coordination of practical actions; reflective and transreflective (reflective symbolic understandings of reflective symbolic understandings) meanings describe further developmental advances in the coordination of action systems.

In summary, to this point the nucleus of a relationally informed person-centered developmental action metatheory of mind has been described, where mind is conceptualized as a dynamic self-organizing system of cognitive (knowings, beliefs), emotional (feelings), and conative or motivational (wishes, desires) meanings or understandings, along with procedures for maintaining, implementing, and changing these meanings. Mind, through expressive projections—transforms the world as known, and—through adaptive exploration—transforms itself (i.e., develops). However, this remains a nucleus and only a nucleus, because it lacks the critical necessary feature of embodiment.

Person-Agent Embodied Actions

Person-agency is the source of action, and action is the source of meaning; but this action itself is embodied. As discussed earlier, embodiment is the claim that our perception, thinking, feelings, desires—the way we experience or live the world—is contextualized by our being active agents with this particular kind of body. At the agent level, embodiment specifies the characteristic nature of the activity of any living system (e.g., the actual world of the fly is necessarily shaped by the nature of the fly's embodied acts). At the person level, embodiment affirms that—from the beginning—bodily acts constrain and inform the nature of intentionality (Margolis, 1987). Intentionality is not limited to a symbolic, reflective, or transreflective system of psychological meanings. Intentionality also extends to a system of psychological meanings that characterize practical embodied actions operating at the most minimum level of consciousness. These most basic meanings and all others "come from having a body with particular perceptual and motor capabilities that are inseparably linked" (Thelen, Schöner, Scheier, & Smith, 2001, p. 1). They arise—as Piaget repeatedly insisted—from the sensorymotor functioning that represents a concrete instantiation of embodied actions.

Varela et al. (1991) have sketched a general outline for an embodied theory of cognition. Sheets-Johnstone (1990) provides an evolutionary anthropological perspective on human embodiment and thought, and Santostefano (1995) has detailed the emotional and

cognitive dimensions of practical, symbolic, and reflective embodied meanings. Further, many who have studied psychopathology, from R. D. Laing (1960) to Donald Winnicott (1965) and Thomas Ogden (1986), argue that disruptions in the embodied actions of the person-agent are central to an understanding of the development of severe forms of psychopathology (see Overton and Horowitz, 1991).

At the level of practical actions (see Figure 2.2), Bermudez's (1998) work on the development of self-consciousness is central to an understanding of the impact of an embodied person conceptualization. Bermudez's fundamental argument is that late emerging forms of meaning found in symbolic and reflective consciousness develop from—and are constrained by—embodied self-organizing action systems available to the infant. Most important, these early systems entail person-level somatic proprioception and exteroception. As these person-centered processes interpenetrate the physical and sociocultural worlds, proprioception operates as the differentiation mechanism for the emergence of a self-consciousness action system, and exteroception operates as the differentiation mechanism for the emergence of an object-consciousness system. Hence, over the first several months of life a basic practical action associated with "me" and "other" develops, which in turn becomes transformed into the symbolic "me" and "other" of early toddlerhood. Thelen's (2000) work on the role of movement generally, and specifically "body memory," in infant cognitive functioning is another closely related area that illustrates the importance of embodiment at the level of practical actions.

Langer's (1994) empirical studies represent important demonstrations of the intercoordination of embodied action systems as these intercoordinations move development from the practical to the symbolic plane of meaning (see Figure 2.2). Earlier work by Held and his colleagues (e.g., Held & Bossom, 1961; Held & Hein, 1958) illustrates the significance of *voluntary* embodied action at all levels of adaptation. Goodwyn, & Acredolo (1993) research on the use of bodily gestures as signs expressing practical meanings in older infants suggests the expressive and instrumental value of embodied practical gesture. Other work has elaborated on the significance of bodily representations at the symbolic and reflective levels of meaning. For example, while the use of fingers for counting is well documented (Gelman & Williams, 1998), Saxe's (1981, 1995) research has shown cross-culturally that other bodily representations enter into counting systems. Further, earlier research by Overton and Jackson (1973) and more recently by Dick, Overton, and Kovacs (2005) has demonstrated that bodily gestures support emerging symbolic representations at least until the level of reflective meanings.

At the level of symbolic, reflective, and transreflective conceptual functioning (see Figure 2.2), the writings of Lakoff and Johnson (1999; see also, Lakoff, 1987) are well known for their detailed exploration of the significance of embodiment. For Lakoff and Johnson, embodiment provides the fundamental metaphors that shape meanings at all levels of functioning. In a parallel but distinct approach, Kainz (1988) has described how the basic laws of ordinary logic (i.e., the law of identity, the law of contradictions, and the law of the excluded middle) can be understood as emerging from the early embodied differentiation of self and other. Finally, Liben's (1999) work on the development of the child's symbolic and reflective spatial understanding presents a strong argument for an understanding of this development in the context of an embodied child rather than in the context of the disembodied eye that traditionally has framed this domain.

EPISTEMOLOGICAL-ONTOLOGICAL ISSUES

In broad outline, to this point the chapter has explored the nature of the concept of development and related concepts as they are grounded and sustained within a hierarchy of metatheories. The discussed metatheories—split, relational, embodied action, developmental systems—are themselves contextualized by metatheoretical concepts that operate at yet a higher level of discourse (see Figure 2.1). These are the *epistemological* (i.e., issues of knowing) and *ontological* (i.e., issues of reality) level of metatheory to which we turn next. The conceptual issues that are illustrated at these levels have evolved across the course of history, and any clear exposition of these issues itself necessitates an historical approach.

Metaphysics is the broad area of philosophical inquiry concerned with conceptual inquiry into the nature, origin, and structure of the world or "being." *Ontology* is the domain of metaphysics concerned with question of what constitutes the Real with a capital R (Putnam, 1987). *Epistemology* is about knowing, and its primary question concerns the validity of what and how we know. Understood relationally, epistemology is a narrative about how we know what is Real, and ontology is a narrative about the Real as we know it. Historically,

each domain has offered sets of alternatives in answer to its fundamental question. The basic epistemological candidates for yielding valid knowledge have been *reason and observation.* In the ontological domain, matter and form have been primary candidates for the Real. When matter is interpreted as bits, or elements, or uniform pieces, and form is taken as pattern, structure, or organization, then *uniformity and organization,* as the surrogates of matter and form respectively, are the candidates for what constitutes the Real. A related set of candidates for the nature of the Real concerns the assumed activity status of matter and form. The Real may be assumed to be fundamentally *inactive and unchanging,* or it may be assumed to be fundamentally *active and changing.* Thus, it is possible to conceptualize (a) an inactive and unchanging matter—a Newtonian favorite; (b) an active and changing matter—a pre-Newtonian understanding, as well as Einstein's post-Newtonian understanding of the nature of the physical world; (c) an inactive and unchanging form—a position often attributed to Plato; and (d) an active and changing form—Leibniz's monadology and Hegel's dialectic.

In discussing ontology and the Real, it cannot be too strongly emphasized that there is a critical distinction between the use of the term "real" in everyday commonsense life and the ontological. No one argues that there is a lack of reality or realness in the experienced everyday world. This is commonsense realism. Commonsense realism accepts the material existence of a real, actual, or manifest world and all ontological-epistemological perspectives treat people, and animals, and physical objects as having such a real existence. The ontological issue of the Real with a capital R (Putnam, 1987) is a very different issue. It concerns the idea of having a base or foundation from which everything else emerges. In this limited sense, the Real is defined as that which is not dependent on something else, or that which cannot be reduced to something else.

If we were to approach the issue from a split understanding, then matter and form would become a dichotomy. In this case, the assertion of *either* matter *or* form as the Real would privilege the former and marginalize the latter as reducible Appearance. Asserting split matter to be the Real yields a *materialist ontology.* Within this ontological position, form, pattern, organization, and ideas are cast as appearances that ultimately are assumed to find their source or origin in the foundational Real (i.e., matter). For example, when the concept "system," is used within this split ontological frame, it simply references the individual elements of matter such as neurons. Or, as a social example, "community" merely refers to the linear aggregate of individuals. Choosing split-off form as the foundational Real would assert an *idealist ontology.* In this choice elements, individuals, and bits, would achieve an identity only in the context of the pattern or form that would constitute the Real. Within this ontological context, "system" would be the foundational Real, and matter, such as neurons, a mere reflection of this Real. "Community" in this case would be foundational and "individuals" would be taken to be an expression of this form. When the narrative is split, as in these cases, the Real becomes an absolute foundation and this is referred to as *foundationalism or a foundationalist position.*

Plato and Aristotle and the Relational Developmental Tradition

For Plato and Aristotle, there were no radical splits between ontology and epistemology or between the alternatives in each domain. Each took the problem of knowing as his focus. Both reason and observation, and form and matter constituted an indissociable complementary matrix for understanding the world. Plato favored an epistemological emphasis on reason; Aristotle articulated more precisely the dialectical balance of reason and observation. Plato's point of view, or line of sight, began from the ontological significance of form or pattern described in his doctrine of Ideas. However, he admitted another line of sight, which was matter as a "formless, indefinite, substrate of things" (Stace, 1924). Aristotle emphasized the significance of the relational nature of form and matter. Form and matter were understood as dialectically related, as in Escher's *Drawing Hands.* Formless matter or matterless form were simply not possible. Aristotle maintained that only individual things exist, but "existence" did not imply a simple split-off matter. Existence implied matter in the context of the categories (forms) of space and time. Thus, existence was not the criterion of the Real; the relational form/matter constituted the Real. As Ross (1959) points out, " 'Matter' is not for Aristotle a certain kind of thing as we speak of matter in opposition to mind. It is a purely relative term—relative to form" (p. 76).

Plato and Aristotle also held a relational view of inactivity-fixity (termed "Being") and activity-change (termed "Becoming"). Plato is most widely known for his postulation of a realm of timeless forms (i.e., a realm of the unchanging). In modern times, this notion has cast Plato as the father of the search for "essences"

of nature and, thus, what has been called *essentialism* (see Mayr, 1982). Conceived in this split fashion, the fixed forms of essentialism constitute the conceptual grounding for contemporary nativist positions that interpret "structure" and "organization" as fixed and unchanging. It is unlikely, however, that Plato intended this split interpretation (Cornford, 1937; Lovejoy, 1936; Nisbet, 1969), as Plato himself specifically stated, "that *only* the divine is changeless; that the world of man and society is an incessant process of development and of becoming" (Nisbet, 1969, p. 308).

Aristotle's relational understanding of the nature of *being* (static, fixed, inactive, unchanging) and *becoming* (active, changing) is expressed in his concepts of the "potentiality" and "actuality" of individual things. The actuality of an object of inquiry (i.e., what the object is at a given moment) points to its being. The passage from potentiality to actuality points to the becoming of the object (Ross, 1959, p. 176; Wartofsky, 1968). Coming into being (i.e., becoming) constituted Aristotle's conceptualization of developmental change and—as in the unified definition of development elaborated earlier in this chapter—he emphasized both the transformational and variational nature of change as critical relational features of becoming. Aristotle referred to transformational change as "generation and destruction," and variational change "alteration" (Ross, 1959, p. 101–102). Despite the centrality of development (i.e., becoming) to his system, it is often suggested that Aristotle's ideas promoted an understanding of nature as a hierarchical organization of unchanging forms that later became celebrated as the *scala naturae* or "The Great Chain of Being" (Lovejoy, 1936). The attribution of this nonevolutionary and, hence, nondevelopmental view of nature to Aristotle confuses his ontological-epistemological stance with the proposal of a single possible biological classificatory system (Lovejoy, 1936, p. 58). Aristotle was the champion of a logic of classification, but the other side of the story is that he also recognized the dangers and limitations of any specific system of classification. Today, to characterize Aristotle as an antievolutionist who promotes a static conception of hierarchical forms (see Mayr, 1982) misses the relational character of Aristotle's work.

Modernity and the Rise of the Split Tradition

In the seventeenth century with the dawn of the modern age or "modernity," split metatheory began its historical journey. The story of modernity is defined both by a quest for absolute certainty of knowledge (Toulmin, 1990) and by an effort to expand individual freedom, especially freedom of thought. Building knowledge on rational and reasoned grounds, rather than on the grounds of authority and dogma, was understood as the key to each of these goals. The early protagonists who developed the basic story line were Galileo Galilei, and his physics of a natural world *disconnected* from mind; Rene Descartes, whose epistemology elevated disconnection or splitting to a first principle; and Thomas Hobbes, who saw both mind and nature in a vision of atomistic materialism. Of the three, Descartes was to have the greatest and most lasting impact on the formation of split metatheory.

Descartes major contributions entailed the introduction and articulation of *splitting and foundationalism* as core interrelated epistemological themes. As described earlier splitting is the formation of a dichotomy—of an exclusive either/or relationship—and foundationalism is claim that one or the other elements of the formed dichotomy constitutes the ultimate Real. Nature and nurture, idealism and materialism (form and matter), reason and observation, subject and object, constancy and change, biology and culture, and so on all can be—and under the influence of Cartesian epistemology are—thought of as split-off competing alternatives. Privilege the one as the Real—as the *foundation*—and it follows under a split interpretation that the other is marginalized as mere appearance or epiphenomenal.

The foundation here is the final achievement of absolute certainty and the end of doubt. The foundation is not a vantage point, standpoint, or point of view, and certainty and doubt are not dialectically related as an identity of opposites. Descartes's foundationalism describes *the* final fixed secure base. It constitutes an absolute, fixed, unchanging bedrock; a final Archimedes point (Descartes, 1969).

With splitting and foundationalism in place, the theme of *reductionism* was firmly planted in the history of this tradition, and virtually all change to the present day represents elaboration and variation of the idea that Appearance will ultimately be reduced to (i.e., explained by) the Real. "Eliminative reductionism," "ontological-reductionism," "property ontological-reductionism," "theoretical-reductionism," "definitional-reductionism," "causal reductionism," (Searle, 1992) "radical or leveling reductionism," "microreductionism," "smooth reductionism," "semantic reductionism" (Shanon, 1993), and

"biosociological reductionsim" (Bunge & Ardila, 1987)—while each making interesting and valuable discriminations to the plot line—add little to the theme (Overton, 2002).

Having literally invented *dualism* by splitting the Real into a Subject piece and an Object piece, Descartes—and all others who have since accepted the Cartesian categories—was faced with the problem of how to put the individual pieces back together again. If there is an absolute bedrock to nature and this bedrock is composed of individual elements, there must be a glue that can join the pieces into the appearance of wholeness. Descartes favored the solution called *interactionism,* a solution not unlike some of the "conventional" interactionist positions discussed earlier with respect to the nature-nurture issue. According to conventional interactionism any behavior is explained as the additive outcome of pure forms of fixed elements labeled nature and pure forms of fixed elements labeled nurture.

Empiricism, Materialism, and Objectivism

Cartesian splitting and foundationalism came to operate as a permanent background frame for modernity's split tradition. However, the specification of the *nature* of the ultimate foundation remained at issue. It was left to Hobbes and later empiricists to operate within the frame of subject split from object, mind split from body, ideas split from matter, and to build into this frame the materialist identification of *atomistic matter* as the ultimate ontological foundation—the Real. In the eighteenth century—a period called the Enlightenment—British empiricism arose as a protest against the rational and subjective elements found in Descartes—against both the "*I*" and the "*think*" of the famous "I think, therefore I am." In the epistemological writings of John Locke, George Berkeley, and David Hume, reason became split off from observation and *empiricism* arose as the doctrine that all knowledge originates in the senses (observation) and only the senses and, hence, all knowledge must ultimately be reducible to sense information (see Overton, 1998 for an extended discussion). This empiricist line of modernity continued to pursue the goal of building knowledge on rational and reasoned grounds, but the rational and reason came to be considered acquisitions, which in turn needed to be explained as arising from the senses and only from the senses. This forced monism operated to marginalize subjectivity, mind, or ideas, thereby creating *objectivism*; the belief that the ultimate material Reality exists as an absolute—independent of mind or knower (Searle, 1992). This constituted, as Putnam (1990) has said, an epistemological "God's eye view."

Objectivist matter thus came to constitute the ontological Real to which the manifold of commonsense experience would be reduced to arrive at the goal of science; a systematized body of *certain* empirical knowledge. Support for the materialist foundation arose and was further defined by Newton's contributions. Central among these was the redefinition of the nature of matter in a way that conceived of all bodies as fundamentally inactive. Prior to Newton, matter was understood as inherently active. Matter had been conceived in terms of the relation of being (static, fixed) and becoming (active, changing). Newton, however, through his concept of inertia, split activity (becoming) and matter (being) and redefined matter as inactivity (Prosch, 1964).

The redefinition of bodies as inert matter, and the assumption of the atomicity of matter (i.e., bodies are ultimately aggregates of elemental matter that is uniform in nature, and in combination, yields the things of the world), were basic for Newton's formulation of his laws of motion. However, they were also ideas that a later generation generalized into a metaphysical worldview that identified the nature of the Real as fixed inert matter and *only* fixed inert matter. This "billiard ball" or "mechanistic" worldview entailed "the notion that basically everything . . . was made up of small, solid particles, in themselves inert, but always in motion and elasticitly [sic] rebounding from each other, . . . and operating mechanically" (Prosch, 1964, p. 66). Within this split worldview, all human psychological processes, including the cognitive (perception, thought, reasoning, memory, language), the affective (emotions), and the conative (motivation, wishes, desires), were necessarily reduced to a bedrock of sensations. Associations were used as the glue designed to explain how from these simple sensations it would be possible to have the complex ideas, emotions, and desires that are apparent in commonsense understanding.

With these themes at hand—*splitting, foundationalism, materialism, objectivism*—it was a short epistemological step to the formulation of a complete scientific methodology termed "mechanical explanation" that with relatively minor modifications has extended to the present day as the basic methodology of neopositivism and later instrumentalism, conventionalism, and functionalism. This notion of explanation is discussed in a later section on methodology.

While the eighteenth century empiricists focused their enquiry primarily on cognitive issues ("complex ideas") in the nineteenth century, the Utilitarian philosophy of Jeremy Bentham, passed down through James and John Stuart Mill, and Alexander Baine, sought an extension of the empiricist doctrine by applying the Newtonian paradigm to the explanation of actions, values, morals, and politics (Halevy, 1955). The *experimental* psychologies of Wundt and Titchener grew from this ground, followed by the functionalist perspectives of Angell, Carr, Woodworth, and, ultimately, behaviorism and multiple forms of neobehaviorism, including learning theories and social learning theories of development. With behaviorism, "stimuli" and "responses" came to replace the earlier "sensations" as bedrock explanatory concepts.

In the twentieth century, the split tradition continued operating as a metatheory for various domains of inquiry, including developmental inquiry. In philosophy, the tradition extended its influence in the articulation of Anglo-American analytic philosophy. As the name suggests, analytic philosophy has continued to maintain the Cartesian split categories and to the present day, in various surrogate forms, pursue the analytic ideal of finding the "atoms," or absolute bedrock foundational elements of knowing (Rorty, 1979). The British line of this approach located its foundationalism in the analysis of "ordinary language." The American line pursued the same goal in the "neutral data language" and "observation sentences" of neopositivism, elaborated in the writings of Moritz Schlick, Roudolf Carnap, Gustav Bergmann, Herbert Feigl, Carl Hempel, A. J. Ayer, and the "earlier" Ludwig Wittgenstein (of the *Tractatus Logico-Philosophicus*).

Modernity and the Elaboration of Relational Metatheory

As British empiricism followed its route of splitting and foundationalism, the German modern period continued to elaborate relational epistemological and ontological issue. At the forefront of the German Enlightenment stands Leibniz's grand synthesis of a universal mathematics and a metaphysics of individuality (Gadamer, 1993). For Leibniz, epistemology as the universal, the knowing of the Subject, was joined in a relational matrix with ontology as the particular, the being of the Object. The twentieth-century philosopher, Ernst Cassirer (1951) captures this fundamental relational quality of Leibniz's work when he asserts that "the central thought of Leibniz's philosophy is therefore to be looked for neither in the concept of individuality nor in that of universality. These concepts are explicable only in mutual relationship; they reflect one another" (p. 33).

Leibniz

With ontology as the line of sight, Leibniz, a contemporary of Locke, refused to split off being from becoming. Activity and ceaseless change were fundamental to the nature of the Real. In his concept of substance, Leibniz substituted a "pluralistic universe" in place of Descartes's dualism and Locke's materialist monism. Leibniz's "monad" is the fundamental unit of this universe. The monad " 'is' only in so far as it is active, and its activity consists in a continuous transition from one new state to another as it produces these states out of itself in unceasing succession. . . . Never is one of these elements just like another; never can it be resolved into the same sum of purely static qualities" (Cassirer, 1951, p. 29). "In Leibniz's philosophy an inalienable prerogative is first gained for the individual entity. The individual no longer functions as a special case, as an example; it now expresses something essential in itself. . . . Every individual substance is not only a fragment of the universe, it is the universe itself seen from a particular viewpoint. And only the totality of these unique points of view gives us the truth of reality" (Cassirer, 1951, pp. 32–33).

From an epistemological line of sight, if substance is in "continuous transition from one state to another," then understanding entails the rational discovery of the rule of this transition and the laws according to which it occurs. This is Leibniz's rationalism. It differs significantly from Descartes's in that there is no return to God as the imprinter of these universal ideas, nor is reason split from observation. Universal ideas as rules and laws, and particular experiences as observations, are relational or co-relational. Knowing may begin in observation, but observation proceeds in the context of some system, idea, or form. Analysis is not suppressed in Leibniz's system; it occupies a significant place in his thought. However, analysis is not privileged over synthesis; all analysis implies a whole or synthetic aspect according to which the analysis proceeds. Cassirer (1951) points out that, for Leibniz, the "concept of the *whole* has gained a different and deeper significance. For the universal whole, which is to be grasped can no longer be reduced to a mere sum of its parts. The new whole is organic, not mechanical; its nature does not consist in the sum of its parts but is presupposed by its parts and con-

stitutes the condition of the possibility of their nature and being" (p. 31).

The Leibnizian tradition is a relational tradition, and it emerged, as Cassirer suggests, from an organic understanding of the nature of events and the nature of knowing. Thus, it was within an emerging organic worldview that specific features of the relational ontological-epistemological ground came to be articulated. The significance of the legacy of the Leibnizian relational tradition for developmental inquiry is—like the significance of the legacy of the Newtonian split tradition—severalfold. First, it established a distinct rationale for the proposal that knowing necessarily proceeds from a "point of view" or line of sight. The importance of perspective or point of view is traceable to Plato (Kainz, 1988), but Leibniz gave it a central significance by embedding it in the relational context of parts to whole. *Point of view* does not imply an unrestrained relativism as it sometimes seems to suggest in contemporary usage. A "point of view" within the Leibnizian tradition, only becomes a point of view as it is embedded with other points of view within a broader context. For example, Subject and Object become "points of view" only within a broader organic unity that joins the two within a relational matrix. Without this unity, they are simply isolated elements and the application of the phrase "point of view" is quite meaningless.

In the postmodern era of contemporary Continental philosophy, point of view continues to exert a strong influence through the concept of "horizon" of understanding or inquiry. The notion of horizon appears in the works of Nietzsche and Husserl, but it has been most fully developed in the hermeneutics of Hans-Georg Gadamer (1989). A *horizon* is the entire range of understanding that can be generated from a particular vantage point. Achieving a horizon entails placing something in the foreground or what is termed the process of *foregrounding,* a methodological principle that is inherently relational in nature. Whatever is foregrounded must be foregrounded from something else. Consequently, foregrounding makes visible this other that is joined with it in a relational matrix. With respect to developmental inquiry, for example, to "foreground" the subject is to recognize the object; to foreground the expressive is to recognize the instrumental, or to foreground the transformational is to recognize the variational. It is the reciprocity of horizons, or what is termed the *fusion of horizons* that ultimately constitutes truth in such a relational system. The situation here is similar to the familiar reversible figure of the vase-person. From one vantage point, we foreground, and, thus, acquire the horizon of two faces turned toward each other. The two faces become a legitimate object of inquiry, moving toward a full achievement of this horizon. From another vantage point, a vase is foregrounded and a different horizon is acquired. Both horizons yield legitimate objects of study; yet, both are parts of the one whole, and that whole constitutes the fusion of horizons.

Other developmental implications of the Leibnizian relational tradition follow from the principle that activity, change, and organization are as fundamental as stability, fixity, and uniformity. Activity-stability, change-fixity, and organization-uniformity compose the bipolarities, or relative moments, of the ontological-epistemological relational matrix. This became the principle of *Becoming* in philosophical and developmental inquiry (Overton, 1991b). As suggested earlier, it contrasts directly with the Newtonian-Humean tradition of split off *Being,* where activity, change (other than random variation), and organization are treated as ultimately reducible Appearances.

The principle of Becoming, whose origins are traceable to the pre-Socratic works of Anaximander and Heraclitus (Wartofsky, 1968), takes, as its line of sight, activity, change, and organization as necessary and nonreducible features of the cosmos (Allport, 1955; Nisbet, 1969). In the eighteenth century, Becoming was generalized from Leibniz's ontology to an understanding of man, society, and nature.

In 1725, Giambattista Vico attacked the static view of human nature and proposed that changes of society are the reflection of the imminent and necessary development of the human mind. In 1755, Kant, in his *General History of Nature and Theory of the Heavens,* applied the notion of Becoming to the material world, and maintained that this world continuously evolves in a systematic and ordered fashion. And from 1784 on, in a series of four volumes, Johann Gottfried Herder extended the idea of Becoming to include nature, living species, and human society alike (Toulmin & Goodfield, 1965).

Hegel

In the late eighteenth and early nineteenth centuries, the most influential figure to advance the principle of Becoming was G. W. F. Hegel (1770–1831). For Hegel, history was a necessary dynamic process of growth, defined as expressive-transformational change. The nature of this change was defined by the dialectic (see earlier discussion), a process through which concepts or fundamental

features of a system *differentiate* and move toward *integration.* This process, suggests a grounding for understanding change as directional. In split understandings, there must always be a controversy over whether change is best characterized as *either* cyclical (variational) *or* directional (transformational). Within the dialectical context, this dichotomy is resolved through recognition that the polarities of thesis-antithesis constitute the cyclical dimension of change. However, such cycles are never closed, as they would be in a circle. When a circle is opened a bit, it does not return precisely to its starting point. As a consequence, with the continuation of activity, the open cycle forms a spiral (the synthesis or integration). With the repetition of spirals, a direction is formed (see Overton 1994a, 1994c).

In the nineteenth century, the principle of Becoming was extended in the works of social theorists such as Comte, Marx, and Spencer and in the writings of biologists such as Wolff, Goethe, and von Baer. And James Mark Baldwin (1895, 1897/1973) first formulated a developmental psychology specifically in terms of dialectical categories. As Broughton (1981) points out, "his [Baldwin's] . . . orientation came to be tempered with a Hegelian view of dialectical progress through qualitatively distinct levels of consciousness" (p. 399; see also, Freeman-Moir, 1982).

In the twentieth century, Heinz Werner (1948, 1957) drew his own theoretical approach from the dialectical feature of the principle of Becoming. In this context, he proposed the orthogenetic (normal development) principle as a universal explanatory principle, or law, of transformational change. The *orthogenetic principle* asserts that "whenever there is development it proceeds from an initial state of relative globality and lack of differentiation to a state of increasing differentiation, articulation, and hierarchic integration" (1957, p. 126). But Werner was not alone among twentieth-century developmentalists in constructing metatheoretical and theoretical understandings framed by the dialectic of Becoming. Piaget, for example, draws from the same image in laying out the metatheoretical grounding for his "*equilibration*" explanation of human transformational development: "These global transformations . . . gradually denote a sort of law of evolution which can be phrased as follows: assimilation and accommodation proceed from a state of chaotic undifferentiation to a state of differentiation with correlative coordination" (Piaget, 1954, p. 352). Similarly, Vygotsky (1978) maintains that development is best characterized as "a complex dialectical process characterized by periodicity, unevenness in the development of different functions, metamorphosis or qualitative transformation of one form into another" (p. 73).

It is significant also that these three major developmentalists of the last half of the twentieth century—Piaget (Piaget & Garcia, 1991, p. 8), Werner (Werner & Kaplan, 1963, p. 11) and Vygotsky (1978) all considered development to be change entailing a spirality that emerges from cycles and yields direction (see Figure 2.6). As Vygotsky noted specifically with respect to higher psychological functions, "Development, as often happens, proceeds here not in a circle but in a spiral, passing through the same point at each new revolution while advancing to a higher level" (p. 56).

Along with classical developmental theorists like Werner, Piaget, and Vygotsky, dynamic theorists, both from the British object-relations (e.g., Fairbairn, 1952; Winnicott, 1965) and the ego psychology schools (Erikson, 1968) have found the core dialectical Becoming notions of "activity," "differentiation," and "integration" central for understanding both normal and pathological human ontogenesis (Overton & Horowitz, 1991).

This discussion has focused on the historical impact of the Leibnizian-Hegelian tradition as it advanced and articulated the principle of Becoming. More broadly, the philosophical grounding of the relational developmental tradition was progressively elaborated from Leibniz to Kant to Hegel, and it was Kant's own contribution that simultaneously both advanced and retarded this process. Kant's line of sight was epistemological, and because knowing is a human activity, his focus was on the human conditions necessary for knowledge. Hume, after splitting reason (mind) from observation, had come to argue that valid (universal and necessary) knowledge cannot be found in the observational world, which yields only the particular and the contingent. Kant agreed, but adopting a relational stance, he argued that this fact does not lead to the dismissal of valid knowledge. Rather, it simply demonstrates that if contingent knowledge is a feature of the observational world, then valid knowledge must be a feature of thought, of mind.

Kant

Arguing from the relational perspective, Kant maintained that both valid and contingent knowledge are essential aspects of human experience (i.e., both the universal and the particular, the necessary and the contingent are features of human experience). Consequently, the question was not—as assumed in the

Newtonian-Humean split tradition—whether it was possible to have valid knowledge. The central question became the conditions of mind that had to be assumed to produce the experienced valid knowledge. Kant began the description of these conditions with the presupposition that reason-thought-concepts form a relational matrix with observation-intuitions-perceptions. This affirmation of the Leibnizian relational tradition—itself often described as Kant's (1781/1966) attempt to reconcile rationalism and empiricism—is nowhere better articulated than in the famous relational aphorism ascribed to him: "Concepts without percepts are empty, percepts without concepts are blind." This often repeated aphorism is a variant of Kant's actual "Thoughts without contents are empty, intuitions without concepts are blind. . . . The understanding cannot see, the senses cannot think. By their union only can knowledge be produced" (p. 45).

From this overarching relational commitment, Kant presented a philosophical sketch of human cognition that further affirmed both the activity and organization features of the Becoming tradition. Kant's description of mind basically entailed three interrelated dynamic system components. Because Kant did not split structure and function, these dynamic systems are sometimes examined from the structural perspective and are called "faculties" and "forms." At other times, they are examined from the functional perspective and called "powers" or "activities": First, sense data or content is transformed into *a priori* categories of space and time according to the *forms of intuition* or forms of perception. Second, perceptions become synthesized in terms of *a priori categories of understanding*. The categories of understanding (e.g., existence, reality, causality, necessity) operate as a base level rule system that orders percepts according to the very features that Hume had dismissed (e.g., necessity, causality, reality, existence). Third, the *imaginative faculty* characterizes the activity of mind as it functions to synthesize perceptions and categories into objects of knowledge; "There exists therefore in us an active power for the synthesis of the manifold which we call imagination. . . . This imagination is meant to change the manifold of intuition into an image" (1781/1966, p. 112).

In addition to these three basic components of mind, Kant described a faculty of "judgment." Judgment is the active process that applies knowledge—gained through intuition, understanding, and imagination—to the practical world. This scheme of the relation between knowledge and the accessing and application of that knowledge became the background for a later cognitive developmental distinction between the development of a cognitive competence and the development of procedures for accessing and applying that competence (Chandler & Chapman, 1994; Overton 1990, 1991a; Overton & Dick, in press).

Kant and the Phenomena-Noumena Split

Although this sketch of human cognition is grounded in the relational, two additional features of Kant's position are inconsistent with the relational developmental tradition: Kant's Cartesian split of phenomena and noumena, and that Kant considered the categories and forms of intuition to be fundamentally unchanging. *Noumena* were described as "things-in-themselves," or objects and events independent of any representation of the object or event. *Phenomena* were described as representations of objects and events as they are known by the knower. For Kant, these spheres were split. The thing-in-itself was disconnected from knowing, and knowing was disconnected from the thing-in-itself. A direct consequence of this split is that the (person) point of view became a privileged position, in the same way that the Newtonian-Humean tradition had made the point of view a privileged position.

One broad impact of this Kantian split for developmental inquiry is that it came to form the background logic for the nativist side of the nature-nurture debate, just as the Newtonian-Humean split formed the background logic for the nurture side. This nativism—whether with respect to Chomskyian (1975) explanations of language (see Jackendoff, 1994; Overton, 1994b; Pinker, 1997), or with respect to other contemporary forms of neo-nativism (e.g., Astuti, Solomon, Carey, 2004; Baillargeon, 1993; Karmiloff-Smith, 1991; J. M. Mandler, 1992; Spelke & Newport, 1998)—presents a picture of the human mind as a set of innate rules, untouched by history and culture; an inversion of the empiricist tradition, which presents a picture of history and culture, untouched by the human mind.

Hegel's Relational Developmental Reconciliation of Mind and Nature

Hegel resolved Kant's split and moved his static categories back into a more fully coherent relational developmental context. Hegel (1807, Introduction) began his work from the position that there could be no detached thing-in-itself, just as there could be no detached knowing-in-itself. Rather, the world of knowing and

the world of actual objects operated within the same dialectical relational matrix as other fundamental categories. This is the meaning of his well-known relational aphorism: "What is reasonable [the known] is actual [the object] and what is actual is reasonable" (Hegel, 1830, p. 9). Like Kant and others who held this line of thought, Hegel took the a subject, person centered, or phenomenological point of view. However, for Hegel, the world of actual objects and events became a dialectical feature of this perspective.

In his *phenomenology* (i.e., the study of experience) of mind (i.e., of the subject), Hegel distinguished two features or "moments" of consciousness: (1) the *moment of knowledge* (i.e., knowing, thinking, "notion") and (2) the *moment of truth* (i.e., the actual or object). At any point, these moments may not stand in a harmonious relationship, as when what one thinks to be the case (moment of knowledge) turns out to be in error with respect to the actual world (moment of truth). In this dialectic history comes to play a central role, and knowledge becomes developmental, as when there is a lack of correspondence between these two moments then "consciousness must alter its knowledge to make it conform to the object" (Hegel, 1807, p. 54). Thus, while Kant maintained that knowing is action that remains static in its form, Hegel held knowing to be action that transforms itself across time.

In Hegel, the Kantian stable and fixed features of mind became fluid and changing, or as Hundert (1989) points out, Kant's metaphor of mind as "a steel filing cabinet" became replaced by a metaphor of organic growth. This metaphor of organic growth then assumes the position as background that sustains and promotes future thinking from a relational-developmental perspective. The metaphor is evident in the relational concepts of "differentiation" and "integration" that emerge from the dialectic, and Hegel's description of the development of knowledge that he presents in the first pages of his *Phenomenology,* stands as a prototype for the developmental organic vision:

> The bud disappears in the bursting-forth of the blossom, and one might say that the former is refuted by the latter; similarly, when the fruit appears, the blossom is shown up in its turn as a false manifestation of the plant, and the fruit now emerges as the truth instead. These forms are not just distinguished from one another, they also supplant one another as mutually incompatible. Yet at the same time their fluid nature makes them moments of an organic unity in which they not only do not conflict, but in which each is as necessary as the other; and this mutual necessity alone constitutes the life of the whole. (Hegel, 1807, p. 2)

The Hegelian image of growth according to active processes of system differentiation and integration contrasts sharply with the Kantian image of fixed, *a priori* given active systems. A number of contemporary domains of developmental inquiry reflect the legacy of these traditions. For example, the Kantian metaphor of mind as a fixed "steel filing cabinet" provides background support for contemporary approaches to developmental inquiry that offer the digital computer as their guiding model of the nature of mind. The computer image itself fixes an understanding of the nature of cognitive-affective processes, change, and persons. The reality that emerges from this metaphor portrays cognitive development as either a simple increase in representational content (Scholnick & Cookson, 1994), which this machine "processes," through various linear causal mechanisms, or as an increase in the efficiency of the computational machinery itself (Siegler, 1989, 1996; Sternberg, 1984). In this picture, there is no room for the expressive-transformational change found in the works of Hegelian oriented investigators such as Piaget, Werner, Erikson, Bowlby, and others

The Kantian-Hegelian contrast also grounds and sustains an important debate in the domain of affective development among those who begin from a shared understanding that "emotions are not 'stimuli' or 'responses' but central, organizing features of personality and behavior" (Malatesta, Culver, Tesman, & Shepard, 1989, p. 5). Moving from this shared subject or person centered point of view that takes expressive change as the domain of developmental inquiry, a Kantian group (e.g., Ekman, 1984; Izard, 1977; Izard and Malatesta, 1987) and a Hegelian group (e.g., Lewis 1993; Sroufe, 1979) set off on different paths concerning how best to characterize the affective development of the child. The Kantians argue for the adequacy of models that describe the infant as having a number of "discrete" basic emotions innately available. The Hegelians argue that a more adequate description suggests that the infant begins affective life—as well as social and cognitive life—as a relatively undifferentiated action system that becomes differentiated and reintegrated through operating on the actual world. Malatesta et al. (1989) capture the psychological translation of the Hegelian framework with respect to Sroufe's work: "Affects begin as undifferentiated precursor states of distress and nondistress

and differentiate into specific emotions only gradually. Differentiation occurs in a stage-like way as a function of major developmental reorganizations" (p. 11).

The debate over the form of emotional development is paralleled by a debate about the nature of the relationship between cognitive and emotional development. This debate is also framed by split and relational positions. The split positions assert that conceptual boundaries are cuts of nature. The relational developmental position understands them as moments of functioning. As Santostefano (1995) points out, "Cognition and emotion will remain segregated as long as investigators view the boundary as real and the domains as opposites, either independent of each other (e.g., Zajonc, Pietromonaco, & Bargh, 1982), parallel and interacting with one another (e.g., Leventhal, 1982) or with one dominating the other (e.g., Izard, 1982; G. Mandler, 1982)" (p. 63).

Phenomenological Constructivism and Realism

The Hegelian reconciliation of mind and nature established the conceptual base for a particular type of constructivism that is probably best referred to as phenomenological constructivism. *Constructivism* is broadly the position that the activity of mind necessarily participates in the construction of the *known* world. Constructivism is an epistemological position that affirms the necessity of the constitutive dimension of the person in *all* knowing. Constructivism is usually contrasted with *Realism,* which is the epistemological claim that the world as known is a direct reflection of a mind-independent world. For the realist, perception of this world is direct, without the mediating activity of mind (see, for example, Gibson, 1966, 1979). *Phenomenological constructivism* is the position that the mind constructs the world as known, but the known world is a co-actor in the process of construction. Following Hegel, there are alternative object worlds, and it is important to be explicit about whether inquiry is focusing on the subject's object world—inquiry explores phenomenological constructivism—or the physical-cultural object world—inquiry explores implications of the settings within which phenomenological constructivism occurs. Hilary Putnam (1987) clearly captures the sense of phenomenological constructivism: "My view is not a view in which the mind makes up the world. . . . If one must use metaphorical language, then let the metaphor be this: the mind and the world jointly make up the mind and the world" (p. 1). Phenomenological constructivism best characterizes Piaget's (1992) writings, as he suggests when he declares himself, "neither empiricist nor a priorist but rather constructivist or partisan of dialectic as a source of novelties" (p. 215).

Object relations as a family of theories of human development, along with Erikson's ego theory and the cognitive-affective theories of Piaget and Werner, all focus their inquiry on the psychological development of the individual or the person. However, phenomenological constructivist inquiry may take as its point of view either this constructive process or the correlation between this process and cultural-biological objects. Thus, within phenomenological constructivism, as within the broader relational framework, theories of *intrapsychic* development and theories of *interpersonal* development do not necessarily conflict. Consider, Piagetian intrapsychic and Vygotskyian interpersonal approaches to development. The development of individual intrapsychic dynamic organizations has been the Piagetian focus of inquiry, but a good deal of Piaget's own investigations concerned the role of the interpersonal-cultural context (Carpendale & Mueller, 2004; Overton, 2004b; Piaget, 1995; Youniss & Damon, 1992). The sociocultural interpersonal process has been the Vygotskian focus; yet, Vygotsky's writings demonstrate a significant interest in intrapsychic dynamic organizations of the person. van der Veer and Valsiner (1994) argue that it is inaccurate to depict Piaget and Vygotsky as irreconcilable opponents, as Piaget and Vygotsky did not differ about the development of "personal-cognitive (and affective) structures" (p. 6) and there is an "actual closeness of the basic personalistic (i.e., person centered) standpoints of both . . . [that] has gone without attention" (p. 6). As a consequence of both their reciprocal interests and their metatheoretical closeness, Piaget and Vygotsky can reasonably be offered as alternative poles of a broadly unified approach to developmental inquiry: Piaget's intrapsychic inquiry functions in the context of the Vygotskian interpersonal action, as Vygotsky's interpersonal inquiry functions in the context of the Piagetian intrapsychic action.

Hermeneutics: Gadamer and the Relational Developmental Tradition

Hans-Georg Gadamer (1976, 1989, 1993) in Europe, along Charles Taylor (1979, 1985, 1991, 1995) in North America, illustrate contemporary forms of the Leibnizian-Hegelian relational developmental philosophical tradition. Although both Gadamer and Taylor

reject features of the Hegelian system (e.g., the dogmatic notion that history must proceed according to the dialectic), each draws from and extends Hegel's notions of the relational, the developmental, and the centrality of action as both expressive-constitutive and instrumental-communicative. Both also contributed to an understanding of the centrality of embodiment; Gadamer in his existential grounding of the hermeneutic and Taylor in his explicit discussions of embodiment.

Broadly, hermeneutics is the theory or philosophy of the interpretation of meaning. Its heritage goes back to a classical period when the hermeneutic task involved the discovery of the meaning of sacred texts. Schleiermacher made important formative contributions during the Romantic period. Vico and Droysen later added a historical dimension to the problem of interpretation, and Dilthey, in his *Critique of Historical Reason* at the turn of the twentieth century developed the method of *verstehen* (understanding) as a methodology for the human sciences (Bleicher, 1980).

Gadamer's hermeneutic approach has been labeled "universal hermeneutics" or "philosophical hermeneutics" (as distinct from Habermas's "critical hermeneutics" to be discussed in a later section). As heir of the hermeneutic tradition, Gadamer (1989) elaborates upon the method of *verstehen* (see the relational developmental methodology section of this chapter), but it goes beyond a methodology to present a broad philosophical position that seeks to answer the question: "How is understanding possible?"

The Hermeneutic Circle: Transformational Change. The *hermeneutic circle*—a reaffirmation of the Leibnizian-Hegelian holism of the unity of parts to whole—constitutes the *fundamental background condition for all understanding* from a hermeneutic point of view. Understanding moves forward from preunderstanding to understanding in a circular movement. The whole—whether a text that requires understanding, or some general phenomenon of inquiry, such as human development—is initially approached with the meanings, or "prejudices" that constitute common sense. These are the initial meanings of what hermeneutics terms the *preunderstanding*. These anticipatory meanings—called *the horizon of a particular present* (Gadamer, 1989, p. 306)—are projected onto the phenomenon of inquiry. As a consequent, they form an early stage in understanding. However, the object of inquiry is not merely a figment of projection but is itself an internally coherent whole; thus, the object of inquiry reciprocally operates as a corrective source of further projections of meaning. Through this circle of projection and correction understanding advances, and the notion of an advance or progression is appropriate here because the hermeneutic circle is never a closed circle, and represents—following Hegel's dialectic—the open *cycle* whose action creates a continuing directional spirality to knowing. "The circle is constantly expanding, since the concept of the whole is relative, and being integrated in ever larger contexts always affects the understanding of the individual part" (Gadamer, 1989, p. 190).

The hermeneutic circle has formed the conceptual context for several features of developmental inquiry. When inquiry is focused on the transformational nature of ontogenetic change, the hermeneutic circle becomes the conceptual context for the Piagetian theory of assimilation-accommodation, as the action mechanism of change. *Assimilation* constitutes the projection of expressive meanings (i.e., affects, perceptions, cognitions) onto a world being constituted. *Accommodation* constitutes the action of correction, as assimilation yields partial success-partial failure. Psychological development necessarily proceeds from some organization (sensory motor, representational, reflective) that constitutes preunderstanding, and this is projected to constitute the world as experienced. But this projection meets the demands of a world with its own structure, and action corrects itself in anticipation of further projection.

When inquiry is focused on defining the *scientific nature* of developmental inquiry, then the hermeneutic circle articulates the relational scientific logic called "abduction" or "retroduction." This concept and its place in a relational metamethod will be detailed in the methodology section of this chapter.

In claiming the hermeneutic circle as the core precondition for understanding, Gadamer follows Heidegger, by grounding the concept in the existential world (1989, p. 293). Through this grounding (a) epistemology and ontology are joined as relative moments in the whole of understanding, and (b) understanding is identified as both relational (the reciprocity of the interpreter and tradition) and variational-transformational (the oscillating movement of part and whole leads to changes in the form of the individual and tradition).

The hermeneutic circle, as the precondition for understanding, owes an obvious debt to the Leibnizian-Hegelian holistic tradition. Gadamer acknowledges this debt, and identifies himself as "an heir of Hegel." However, this kinship is defined most significantly when Gadamer articulates the specific conditions for under-

standing; for here he endorses the Hegelian "dialectic of the universal and concrete as the summation of the whole of metaphysics" (Gadamer, 1993, p. 51).

The preservation and renewal of the dialectic of universal and concrete—the transcendental and the immanent—defines the core of Gadamer's approach. Here *universal and concrete stand in a dialectic relationship,* an identity of opposites. Each is granted an ontological reality.

The Marxist Split Tradition

Karl Marx was an early admirer of Hegel and an heir to the Leibnizian-Hegelian tradition. His work affirmed the centrality of both activity and the dialectic. However, and most importantly, Marx elevated the material world to an absolute privileged position as *the* source of thought. In this move, Marx reasserted a split tradition. Marx's *dialectical materialism* thus became another foundationalist position similar to the Newtonian-Humean tradition in that both appeal to a mind-independent material world as the absolute bedrock of the Real.

Social and Biological Constructivism

The Marxist split tradition became the ground for a second type of constructivism, *social constructivism.* If the material world is elevated to a privileged ontological status, then this world of instrumental-communicative social relations, and *only* this world, provides the base for building the categories of thought. Once the categories of thought are acquired from the split-off social world, the person projects these socially instilled categories back onto the world, and, in this sense, constructs the known world. Hence, social constructivism is the constructing of the known world from an instrumental-communicative social relations foundation and *only* from this foundation. This position was later elaborated by the pragmatist George Herbert Mead under the rubric of "social behaviorism" (Mead, 1934). Vygotsky, who was writing at about the same time as Mead, has come to be viewed as the father of the social constructivist movement—probably because Vygotsky's writings were initially "discovered and propagated by small groups of 'progressive' young Marxists who saw his work as providing, among other things, a foundation for a criticism of the prevailing tendency to attribute individual failure and success to genetic endowment" (van der Veer & Valsiner, 1994, p. 5).

When Vygotsky is placed in a social constructivist framework, there is no rapprochement between he and Piaget—between the interpersonal and the intrapsychic. When located in this frame, his work becomes more closely aligned with the Gibsonian (Gibson, 1966, 1979) realist ecological position. In this context, the person's "intentions" become reduced to instrumental acts that change through a Darwinian-like selection process in accordance with the affordances of the environment for action (Reed, 1993; Rogoff, 1993).

Social constructivism, as a split position, tends to not even address phenomenological constructivism. Instead, social constructivism places itself in a dichotomous, either/or relationship with yet a third variety of constructivism, *biological constructivism.* Biological constructivism emerges from the Kantian split. It involves the claim that the person cognitively-affectively constructs the world as known, but that genetic endowment determines the fundamental nature of the person who does the constructing. Scarr (1992) nicely illustrates biological constructivism. She maintains, on the one hand, that "reality" is constructed by experience, and thus, it is "not a property of a physical world" (p. 50). On the other hand, she asserts that "*genotypes drive experiences.* . . . In this model, parental genes determine their phenotypes, the child's genes determine his or her phenotype, and the child's environment is merely a reflection of the characteristics of both parents and child" (p. 54). The biological and social constructivist confrontation, as it turns out, is yet another manifestation of the split nature-nurture dichotomy.

The Marxist split tradition has continued to exert a strong contextual influence over both the interpretation of Vygotsky's approach, and, more broadly, the interpretation of the relationship between the intrapsychic and the interpersonal. The Marxist tradition has been elaborated, and these elaborations often function as the epistemological-ontological ground for conceptualizing the interpersonal and social-cultural features of development. Jurgen Habermas's "critical theory" represents the most carefully and fully articulated contemporary elaboration of the Marxist split tradition.

Habermas and the Marxist Split Tradition

In a negative sense, the core of Habermas's work is the denial of any possible centrality of the expressive-constitutive subject as a point of reference. As McCarthy points out, "the key to Habermas's approach is his rejection of the 'paradigm of consciousness' and its associated 'philosophy of the subject' in favor of the through-and-through intersubjectivist paradigm of 'communicative' action" (1993, p. x). Habermas himself

considers this move to an exclusive privileging of the instrumental-communicative to be a "paradigm-change," which leaves behind any vestige of Cartesian "subjectivism" or "metaphysics of subjectivity" (Habermas, 1993b, p. 296). From this position, Habermas (1991, 1992) analyzes favorably George Herbert Mead's "social behaviorism" as furthering the same paradigm shift, and he attacks "the moral point of view" taken by expressive-constitutive oriented developmental investigators such as Kohlberg because here "issues of moral cognition take precedence over questions of practical orientation" (1993a, p. 121).

In a more positive vein, Habermas attempts to locate all the traditional dialectical tensions between subject-object, self-other, and reason- observation *within* the domain of communication and social practice (McCarthy, 1991). If this conceptualization functioned as a point of view thereby allowing another point of view that located the same tensions within the expressive-constitutive subject, it would constitute a powerful perspective from which to explore the instrumental-communicative features of development. However, Habermas insists that the dialectical tensions *must be located in the instrumental-communicative realm, and only in the instrumental-communicative realm.* This insistence on exclusivity, undercuts the potential of the position by perpetuating a split that ultimately unnecessarily constrains developmental inquiry.

Culture and Development in Split and Relational Metatheories

The Marxist split tradition has, in recent times, been an influential background for the study of culture and development. Wertsch (1991) highlights this in his "cultural" approach to development. He begins his broadly synthetic account by setting a contrast between developmental inquiry that focuses on "the universals of mental functioning" and his own focus on "sociocultural specifics." However, rather than continuing this contrast of the universal and the particular—the transcendent and the immanent—in a relational context, Wertsch explicitly establishes the Marxist ontological agenda, and casts Vygotsky and Luria solidly in this tradition, by stating:

> In pursuing a line of reasoning that reflected their concern with Marxist claims about the *primacy of social forces* [emphasis added], Vygotsky and his colleagues . . . contended that many of the design features of mediational means [instrumental activity] originated in social life. As stated by Luria (1981), "in order to explain the highly complex forms of human consciousness one must go beyond the human organism. One must seek the origins of conscious activity and 'categorical' behavior not in the recesses of the human brain or in the depths of the spirit, but in the external conditions of life. Above all, this means that one must seek these origins in the external processes of social life, in the social and historical forms of human existence" (p. 25). (Wertsch, 1991, p. 33–34)

The Marxist split tradition then becomes the bridge between Vygotsky and M. M. Bakhtin (1986) whose contribution was a conception of meaning and language that is thoroughly external to the expressive-constitutive subject (Kent, 1991), as follows:

> Both Vygotsky and Bakhtin believed that human communicative practices give rise to mental functioning in the individual. . . . They were convinced that "the social dimension of consciousness is primary in time and in fact. The individual dimension of consciousness is derivative and secondary" (Vygotsky, 1979, p. 30). (Wertsch, 1991, p. 13)

However, in Wertsch's estimation Vygotsky failed to sufficiently pursue the Marxist tradition, for given that Vygotsky was "interested in formulating a Marxist psychology, he made precious little mention of broader historical, institutional, or cultural processes" (1991, p. 46). Consequently, Wertsch draws on Habermas's (1984) account of instrumental-communicative action, and moves beyond Vygotsky to Bahktin's contribution, to pursue the general claim that "mediational means emerge in response to a wide range of social forces" (1991, p. 34).

Shweder's (1990) approach to culture and development is another contemporary illustration of the background influence of the Marxist split tradition (see also Cole, 1995, 1996; Miller, 1996; Rogoff, 1990, 1993). However, in proposing an outline for a "cultural psychology," he follows a more Habermas-like strategy by locating the dialectic tension of subject and culture necessarily in the realm of instrumental, thereby denying any reality to the fully embodied expressive subject. In Shweder's presentation, the universal, the transcendent, the ideal, and the fixed are explicitly denied any fundamental reality (1990, p. 25); thus, a dichotomy is established that privileges the particular, the immanent, the practical, and the relative. As a result, when Shweder (Shweder & Sullivan, 1990) identifies the subject or person of his subject-culture inquiry, it explicitly is not, nor could it be, the universal or ideal subject

found in some domains of cognitive-affective and personality research. Shweder explicitly excludes this subject, and instead offers the "semiotic subject" characterized by instrumental rationality and instrumental intentionality only. The final result is little different than a straight forward Skinnerian (1971) position or frame in which it is permissible to consider "higher mental processes" only to the extent that they are understood as being defined by a specific repertoire of instrumental responses correlated with specific stimuli. Similarly, for Shweder, "rationality" and "intentions" are defined as instrumental problem solving behaviors that are correlated with cultural contexts.

When the Marxist tradition is the ground for developmental inquiry, as in these illustrative examples, activity is central—as action is central in the Leibnizian-Hegelian relational tradition. However, it is important to keep in focus the fact that activity, in the Marxist tradition, is necessarily restricted to the instrumental-communicative. When Rogoff (1993) discusses cognition—as Sweder discusses intentions or Bakhtin discusses language and meaning—it becomes restrictively defined as "the active process of solving mental and other problems" (p. 124). The Leibnizian-Hegelian tradition accepts both this instrumental action, and expressive mental action as relational moments. But when Rogoff addresses the expressive, she first reframes it as a static formulation and then rejects it as a "cognition as a collection of mental possessions" (p. 124). The result of splitting off the expressive subject, is that Rogoff's own "relational" approach is a relation between the instrumental-communicative subject and cultural contexts. This she presents as an approach, which permits the consideration of "individual thinking or cultural functioning as foreground without assuming that they are actually separate elements" (p. 124). This is correct, but the assumption of "separate elements" has already been made in the background, and the unwanted element of this assumption has already been suppressed.

The expressive-instrumental Leibnizian-Hegelian tradition of the centrality of action is illustrated in a number of action theories that focus on the role of culture in human development (see Oppenheimer, 1991 for a review). However, a particularly rich account is found in the work of E. E. Boesch (1991). As Eckensberger (1989) points out:

> Bosech begins with the notion that any action and any goal has two dimensions or aspects: one . . . is *the instrumental aspect,* that an action is carried out instrumentally in order to reach a goal. For example, one takes a hammer to drive a nail into the wall. There is, however, a second aspect in any action, which Boesch calls the *subjective-functional aspect* [the expressive-constitutive]. Here, the driving of the nail may have the subjective-functional meaning that one feels proud of being able to do so, one may also enjoy it, or it may even be related to feelings of rage. In any case, the action of nailing receives a meaning beyond its instrumental purpose. (p. 30)

From this base, Boesch (1980, 1991, 1992) and Eckensberger (1989, 1990, 1996) formulate the beginnings of a developmentally oriented cultural psychology that is more inclusive than those founded in the Marxist tradition. Boesch's system and Eckensberger's extension of this system draw from Piaget—whom Boesch calls the first action theorist—as well as from Janet's dynamic theory, psychodynamic theory, and Kurt Lewin's field-theory. Elaborating on the relational theme of expressive-constitutive/instrumental-communicative action they argue for a cultural psychology that aims at an integration of "cultural and individual change . . . individual and collective meaning systems . . . [and one that] should try to bridge the gap between objectivism and subjectivism" (Eckensberger, 1990).

Inclusive relational developmental models of the individual and culture are not limited to the European continent. For example, as described earlier, Damon (1988, 1991; Damon & Hart, 1988), presents the outline of just such an approach in his discussion of "two complementary developmental functions, . . . the social and the personality functions of social development" (1988, p. 3). Moving within the broader Leibnizian-Hegelian concepts of differentiation and integration, Damon presents the interpenetration of the two functions as an identity of opposites. Furth (1969), also explicitly presented a relational view of social development in which "self and other as isolated entities are denied in favor of relations" (Youniss, 1978, p. 245), and this perspective has been the continuing focus of Youniss and his colleagues (e.g., Davidson & Youniss, 1995; Youniss & Damon, 1992). This relational perspective has most recently been expanded in the literature on infant development (Mueller & Carpendale, 2004; Hobson, 2002) through a focus on the contrast between individualist (split) and relational approaches to the origin and nature of social development:

> The basic tenet of the relational framework is that the self always already lives within a social world and is always already immersed in relations with other. These relations

> are not established in the mind of the individual, but in common space through interaction and dialogue. . . . Neither self nor other are primary. Rather self and other are sustained by particular interactive relations, and it is within and through these relations that concepts of self and other evolve. (Mueller & Carpendale, 2004, p. 219)

Pragmatism

A final epistemological-ontological tradition that requires a brief exploration to establish a grounding for an inclusive understanding of development is the American pragmatism of Pierce, James, and Dewey. Pragmatism's fundamental postulates cohere as a contextualist worldview (Pepper, 1942) that draws on many Leibnizian-Hegelian themes, including holism, action, change, and the dialectic. The focus of these themes is located on the *instrumental* rather than the expressive pole of the relational dialectic. If Gadamer and Taylor (see also Ricoeur, 1991) can be said to represent the phenomenological perspective of the relational developmental philosophical grounding, then pragmatism, particularly the work of James and Dewey, can be read as representing the instrumental perspective.

Putnam (1995) describes *holism* as one of the chief characteristics of James' philosophy. This holistic commitment leads to an "obvious if implicit rejection of many familiar dualisms: fact, value, and theory are all seen by James as interpenetrating and interdependent" (p. 7). James (1975) addresses virtually all the traditional dichotomies of split-off traditions, and he, along with Dewey (1925), argue for a relational interpenetrating understanding of universal-particular, inner-outer, subject-object, theory-practice, monism-pluralism, and unity-diversity. Although affirming the ontological reality of the dialectic of interpenetration, the stress and the focus of pragmatism is, however, on the particular, the outer, object, practice, pluralism, and diversity.

Epistemologically, pragmatism repudiates the foundationalism of an ultimate fixed object of knowledge, and insists on the connection of knowledge and action. Knowledge arises out of action, out of particular practices or *praxis*. In this respect, James and Dewey differ little from Habermas, Gadamer, Bahktin, and Taylor. Rather than specifically elaborating the notion of dialogue as the mediator of knowing (expressive and instrumental), the concept of experience carries this function in pragmatism. Experience manifests its relational dialectical as well as its embodied character in being what James terms a "double-barrelled" (1912, p. 10) concept. "It recognizes in its primary integrity no division between act and material, subject and object, but contains them both in an unanalyzed totality" (Dewey, 1925, pp. 10–11). *Experience* refers to *both* the action of the subject (i.e., the subject's embodied active exploration, active manipulation, and active observation of the object world) *and* the object world's active impingement on the subject. "It includes *what* men do and suffer, *what* they strive for . . . and endure, and also *how* men act and are acted upon" (p. 10). For purposes of empirical investigation, analysis separates this integrity into two points of view, and hence two different analytic meanings. However, the empirical question is not whether experience is truly one or the other. The question is how each form of experience contributes to the understanding of human development.

Change and novelty are also basic to the pragmatists position. However, the focus of change in pragmatism is on the variational rather than transformational. Similarly, novelty is the new variant rather than the emergent level of organization found in transformational change. This focus is due in part to pragmatism's Darwinian evolutionary commitment ("Darwin opened our minds to the power of chance-happenings to bring forth fit results if only they have time to add themselves together," James, 1975, p. 57) along with the commitment to the joint relation of the instrumental and adaptation.

Pragmatism's focus on variational change and variational novelty, also follow from a preference for pluralism and diversity over unity (James, 1975, p. 79). In the discourse of pragmatism, and especially in James' writings, concepts of "unity," "order," "form," and "pattern" tend to be interpreted as denoting the fixed and unchanging, in the sense of an Absolute Transcendentalism (James, 1975, p. 280) or an essentialism. When this is the horizon of understanding, change in fact necessarily becomes restricted to the sphere of diversity. If it is only in the sphere of diversity and pluralism that there is "some separation among things, . . . some free play of parts on one another, some real novelty or chance" (p. 78), then change must be restricted to this sphere. For pragmatism, it is in the sphere of pluralism and diversity that "the world is still in process of making" (p. 289).

The suggestion, that pragmatism can be read as representing the instrumental perspective of the relational developmental philosophical grounding falters upon this restrictive identification of unity with the static and fixed, and of diversity with the active and changing. In

the broad relational developmental tradition, activity and change are not split off and thus encapsulated. Unity and synonyms of unity—including "the universal," "the transcendent," "order," "system," "form," "pattern," "organization," and "structure"—have been understood throughout the Leibnizian-Hegelian tradition as ontologically active and changing. As emphasized throughout this chapter, the Leibnizian-Hegelian tradition grants the same ontological reality to diversity and synonyms of diversity—including "the concrete," the "immanent," "disorder," "plurality," "content," and "function." From the expressive and transformational point of view within this tradition, structures function (act) and change and self-organizing systems operate (act) and change. From the instrumental and variational point of view within this tradition, action is variational (diversity, plurality, and individual differences) and changing.

A related problem concerns the ambivalent posture that pragmatism takes toward the notion of order or unity itself. If implicit, in the writing of the pragmatists, it is clear, and explicit, in Stephen Pepper's (1942) distillation of the presuppositions of the pragmatists that disorder or diversity is a fundamental category of pragmatism-contextualism. However, because pragmatism offers itself as not denying any category that has a practical value ("I call pragmatism a mediator and reconciler. . . . She has in fact no prejudices whatever," James, 1975, p. 43), it cannot deny order, unity, organization, pattern, or structure. Pragmatism does, however, approach these concepts from a certain distance and distrust. Most important, in some readings pragmatism tends to interpret order and unity as an end to be attained, rather than as a legitimate ontological real. In this case, order is *treated,* if not directly conceptualized, as Appearance. Such a reading of pragmatism splits the dialectical relation between the transcendent and the immanent or unity and diversity found in both Gadamer and Taylor. When this split occurs, pragmatism takes on the flattened character suggested in the postmodern approach of Richard Rorty. As the philosopher Thomas McCarthy (1991) points out, "Rorty's epistemological behaviorism is a variant of the contextualism common to most postmodernist thinkers" (p. 20). It entails "a radically contextualist account [that] . . . amounts to flattening out our notions of reason and truth by removing any air of transcendence from them" (p. 14–15).

This split reading of pragmatism is not necessarily canonical however. Pepper, in a work following his well-known *World Hypotheses,* acknowledges the significance of *integration* in contextualism. He argues relationally that the integration the pragmatist should stress "is an integration of conflicts" (1979, p. 411); hence, a dialectical integration. He also warns the contextualist against the danger of an overemphasis on the contingent, the accidental, and the variable. For Pepper, the contextualist has been "so impressed with evidences of historical change and cultural influences and the shifting contexts of value that he cannot easily bring himself to accept any degree of permanence" (p. 414). Pepper chides the constricted contextualist by arguing that "there is much more permanence in the world than the contextualist admits" (p. 414). Similarly, Hilary Putnam has elaborated an extensive contemporary relational reading of pragmatism. Putnam sometimes refers to this reading as "internal realism" and sometimes as "pragmatic realism" (1987, 1990, 1995). In either case, the—"realism" is the commonsense realism discussed earlier—neither the Realism of mind (idealism), nor the Realism of world (materialism). The "internal" and "pragmatic" features of his system assert the position of a pragmatism that includes both the expressive and the instrumental.

Finally, that pragmatism need not be read as a split tradition, which suppresses order and change of form, can even be gleaned from the writings of one of the founders of pragmatism:

> There is in nature . . . something more than mere flux and change. Form is arrived at whenever a stable, even though moving, equilibrium is reached. Changes interlock and sustain one another. Whenever there is this coherence there is endurance. Order is not imposed from without but is made out of the relations of harmonious interactions that energies bear to one another. Because it is active . . . order itself develops. It comes to include within its balanced movement a greater variety of changes. (Dewey, 1934, p. 14)

If pragmatism is read as joining order to disorder, and joining activity and change to both structure and function as this quote from Dewey and the work of Putnam and others suggest, then pragmatism enlarges the philosophical grounding of the relational developmental tradition, and it enlarges the field of developmental inquiry. Illustrations of the impact of this expanded grounding of pragmatism are found, for example, in Damon and Hart (1988) with respect to social development, Nucci (1996) on moral development, and in the works of Varela et al. (1991) and Wapner and Demick

(1998) for cognitive development. Piaget (1985)—considering the relation between his earlier investigations of operational knowing (expressive-transformational) and contemporary explorations of procedural knowing (instrumental-variational)—found in this new arena "a possible synthesis of genetic structuralism, the focus of all of our previous work, with the functionalism found in the work of J. Dewey and of E. Claparede" (p. 68).

The aim of this section has been to establish a broad epistemological-ontological grounding for an inclusive understanding of development as formal (transformational) and functional (variational) changes in the expressive-constitutive and instrumental-communicative features of behavior. This has been done by following the historical thread of the Leibnizian-Hegelian tradition and noting the locations where this thread splits-off toward exclusivity. Ultimately, the illustrations given do not aim to categorize particular writings. Rather, they suggest the consequences that follow for the domain of developmental inquiry when a particular path is taken. In the concluding section, the epistemological-ontological grounding, the relational developmental metatheory, developmental systems, developmentally oriented embodied action metatheory and the integrative concept of development become the interwoven context for a discussion of the nature of the scientific understanding and explanation of developmental phenomena. This section centers on issues of methodology, where methodology is understood broadly as metamethods for empirical scientific inquiry. Methods, in the narrow sense of specific techniques for designing, conducting, and evaluating empirical research, are considered within the context of alternative methodologies.

In an important sense, the discussion to the present point has constructed our developmental landscape, and populated it with certain types of psychological subjects (expressive-instrumental), who change in certain ways (transformationally-variationally), and act in a biological-cultural world that both creates and is created by them. Now, the task is to inquire into how best to investigate the changing character of these persons and this world. This is the task of methodology.

METHODOLOGY: EXPLANATION AND UNDERSTANDING

The focus to this point has been developmental inquiry as a broad-based knowledge-building activity. Now, we turn more specifically to developmental psychology as an empirical science. The historical dialogue has arrived at a common agreement that whatever else it may be, any empirical science is a human activity—an epistemological activity—with certain broad orientations and aims. The historical dialogue has further led to common agreement that the most general aim and orientation of empirical science is the establishment of a *systematic* body of knowledge that is tied to observational evidence (Lakatos 1978b; Laudan 1977; Nagel, 1979; Wartofsky, 1968). Any empirical science aims at building a *system* of knowledge that represents *patterns* of relations among phenomena and processes of the experienced world. These patterns constitute explanations of the phenomena and processes under consideration. Further, to be properly empirical, the explanations must have implications that are *in some sense* open to observational-experimental assessment.

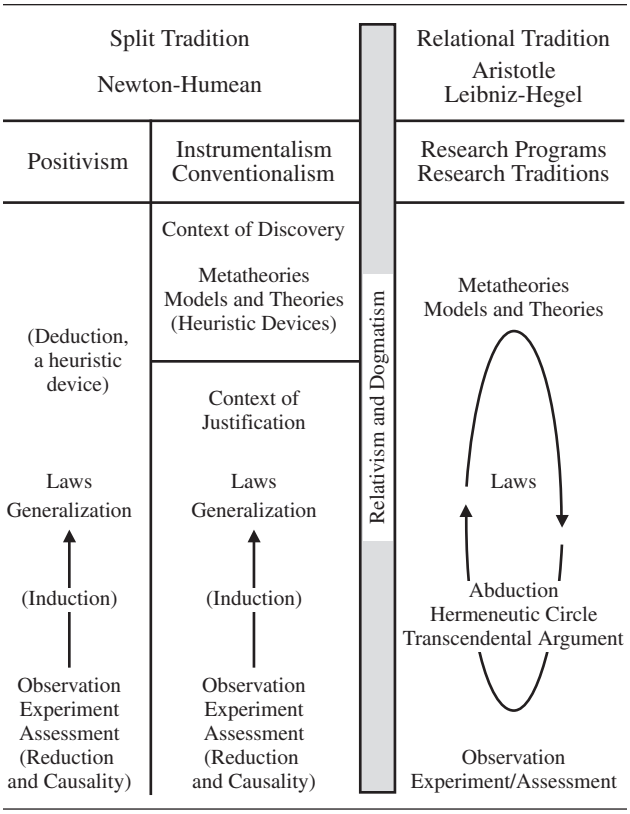
If science aims toward order, it begins in the flux and chaos of the everyday experience that is often termed common sense (see earlier discussion of commonsense level of observation, Figure 2.1, and see also, Nagel, 1967, 1979; Overton, 1991c; Pepper, 1942; Wartofsky, 1968). As the philosopher Ernst Nagel (1967) has described it, "All scientific inquiry takes its departure from commonsense beliefs and distinctions, and eventually supports its findings by falling back on common sense" (p. 6). This commonsense base is what Gadamer refers to as the "anticipatory meanings" of preunderstanding (see earlier discussion of the hermeneutic circle).

For the science of developmental psychology, this starting point includes actions that are commonly referred to as perceiving, thinking, feeling, relating, remembering, valuing, intending, playing, creating, languaging, comparing, reasoning, wishing, willing, judging, and so on. These actions, and the change of these actions, as understood on a commonsense level of experience or discourse (see Figure 2.1), constitute the problems of developmental psychology. They are problems because, although they represent the stability of practical everyday life, even the most meager reflection reveals they appear as inconsistent, contradictory, and muddled. Refined, critically reflective theories and metatheories, including systems, embodiment, cultural, biological, information processing, Piagetian, Gibsonian, Vygotskian, Eriksonian, Chomskyian and the rest, all represent attempts to explain (i.e., to bring order into) the contradictory, inconsistent, muddled features of these various domains of inquiry.

There is little disagreement among scientists, historians of science, and philosophers of science about where science begins—in common sense and the contradictions that show up when we begin to examine common sense—and where it leads—to refined theories and laws that explain. Science is a human knowledge building activity designed to bring *order and organization into the flux of everyday experience.* Disagreement emerges only when the question is raised of exactly how, or by what route, science moves from common sense to refined knowledge. *This issue—the route from common sense to science—constitutes the methodology of science.* Historically, two routes have been proposed, and traveled. One emerges from the Newtonian-Humean split epistemological-ontological tradition. Those who follow this route are directed to avoid interpretation, and to carefully walk the path of observation and *only* observation. On this path, reason enters *only* as an analytic heuristic; a tool for overcoming conflicts by generating ever more pristine observations, free from interpretation. The second route emerges from the Leibnizian-Hegelian relational tradition. Those who follow this route are directed toward a relational dialectical path on which interpretation and observation interpenetrate and form an identity of opposites. On this path, interpretation and observation, become co-equal complementary partners in conflict resolution.

The following discussion discusses these two pathways (see Overton 1998 for a more extensive historical discussion). We begin from the Newtonian split tradition of mechanical explanation and move to a contemporary relational methodology. This evolution of these scientific methodologies including the empiricist variants of positivism, neopositivism, instrumentalism, and conventionalism as well as relational metamethod is outlined in Table 2.1.

TABLE 2.1 Scientific Methodologies



Split Mechanical Explanation

Mechanical explanation continues the splitting process by dichotomizing science into two airtight compartments, *description and explanation.* There are three steps to mechanical explanation. The first is considered descriptive and the second two are considered explanatory.

Step 1: Reduction Description

The first step of mechanical explanation entails addressing the commonsense object of inquiry and *reducing* it to the absolute material, objective, fixed, unchanging, foundational elements or atoms, that are, in principle, directly observable. Terms like *reductionism, atomism, elementarism, and analytic attitude,* all identify this step. In psychology, for many years the atoms were "stimuli" and "responses." Today, they tend to be "neurons" and "behaviors" or "contextual factors" and "behaviors" or "inputs" and "outputs"—the story line changes, but the themes remain the same within this metamethod. In keeping with the framework of empiricism and materialism, the broad stricture here is to ultimately reduce all phenomena to the visible.

Briefly, consider one impact of this first step on developmental inquiry. Immediately, "transformational change," "stages" of development, and the "mental organizations," or "dynamic systems" that change during development become suspect as being somehow derivative because they are not directly observable. At best under this storyline, transformations, stages, and mental organization can only function as summary statements for an underlying more molecular really Real. The drive throughout this step is toward the ever more molecular in the belief that it is only in the realm of the molecular

that the Real is directly observed. This is particularly well illustrated in the recent enthusiasm for a "microgenetic" method (e.g., D. Kuhn et al., 1995; Siegler, 1996) as a method that offers "a *direct* means for studying cognitive development" (Siegler & Crowley, 1991, p. 606, emphasis added). In this approach an intensive "trial-by-trial analysis" reduces the very notion of development to a molecular bedrock of visible behavioral *differences* as they appear across learning trials.

It is important to recognize that the aim of Step 1 is to drive out interpretations from the commonsense phenomena under investigation. Under the objectivist theme, commonsense observation is error laden, and it is only through ever more careful *neutral* observation that science can eliminate this error, and ultimately arrive at the elementary bedrock that constitutes the level of "facts" or "data" (i.e., invariable observations).

Step 2: Causal Explanation

Step 2 of mechanical explanation begins to move inquiry into the second compartment of compartmentalized science—*explanation.* Step 2 consists of the instruction to find the invariant relations among the elements described in Step 1. More specifically, given our objects of study in developmental psychology—behavior and behavior change—this step directs inquiry to locate antecedents. These antecedents, when they meet certain criteria of necessity and sufficiency, are termed "causes" and *the discovery of cause defines explanation within this metamethod.* The antecedents are also often referred to as *mechanisms,* but the meaning is identical.

This is another point at which to pause and notice an important impact of metatheory. Because of the particular metatheoretical principles involved, the word "explanation" comes to be defined as an antecedent-consequent relation, or the efficient-material proximal cause of the object of inquiry. Further, science itself comes to be defined as the (causal) explanation of natural phenomena. It is critically important to remember here that Aristotle had earlier produced a very different metatheoretical story of scientific explanation. Aristotle's schema entailed *complementary relations* among four types of explanation rather than a splitting. Two of Aristotle's explanations were causal in nature (i.e., antecedent material and efficient causes). Two, however, were explanations according to the pattern, organization, or form of the object of inquiry. Aristotle's "formal" (i.e., the momentary pattern, form or organization of the object of inquiry) and "final" (i.e., the end or goal of the object of inquiry) explanations were explanations that made the object of inquiry *intelligible* and gave *reasons* for the nature and functioning of the object (Randall, 1960; Taylor, 1995). Today, the structure of the atom, the structure of DNA, the structure of the solar system, and the structure of the universe are all familiar examples of formal pattern principles drawn from the natural sciences. Kinship structures, mental structures, mental organization, dynamic systems, attachment behavior system, structures of language, ego and superego, dynamisms, schemes, operations, and cognitive structures are familiar examples of formal pattern principles drawn from the human sciences. Similarly, reference to the sequence and directionality found in the Second Law of Thermodynamics, self-organizing systems, the equilibration process or reflective abstraction, the orthogenetic principle, or a probabilistic epigenetic principle, are all examples of final pattern principles (Overton, 1994a).

Both formal and final pattern principles entail interpretations that make the phenomena under investigation intelligible. Both, within the Aristotelian *relational* scheme, constitute legitimate explanations. However, within the *split* story of mechanical explanation, as guided by reductionism and objectivism, formal and final principles completely lose any explanatory status; explanation is limited to *nothing but* observable efficient (i.e., the force that moves the object) and material (i.e., the material composition of the object) causes. At best, within the mechanical story, formal and final principles may reappear in the descriptive compartment as mere summary statements of the underlying molecular descriptive "Real" discussed in Step 1. In this way, transformational change and dynamic psychological systems become eliminated or marginalized as necessary features of developmental inquiry.

Step 3: Induction of Interpretation-Free Hypotheses, Theories, Laws

Step 3 of mechanical explanation installs *induction* as the foundational logic of science. Step 3 instructs the investigator that ultimate explanations in science must be found in fixed unchanging laws, and these must be inductively derived as *empirical generalizations* from the repeated pristine observations of cause-effect relations found in Step 2. Weak generalizations from Step 2 regularities constitute interpretation-free "hypotheses." Stronger generalizations constitute interpretation-free theoretical propositions. Theoretical propositions joined

as logical conjunctions (and connections) constitute interpretation-free theories. Laws represent the strongest and final inductions.

Deduction reenters this story of empirical science as a split-off heuristic method of moving from inductively derived hypotheses and theoretical propositions to further empirical observations. In twentieth-century neopositivism, a "hypothetico-deductive method" was introduced into the Newtonian empiricist metamethod but this it was simply another variation on the same theme. The hypothesis of "hypothetico" has nothing to do with interpretation, but is simply an empirical generalization driven by pristine data that then served as a major premise in a formal deductive argument. Similarly, when the mechanical explanation termed "instrumentalism" moved away from the hypothetico-deductive stance to the employment of models, models themselves functioned merely as the same type of interpretation-free heuristic devices (see Table 2.1).

Another important variation on this same theme was the so-called covering law model of scientific explanation. This was introduced as a part of neopositivism by Carl Hempel (1942) and became the prototype of all later explanations formulated within this metatheory. According to the covering law model, scientific explanation takes a deductive (i.e., formal) logical form; particular events are explained when they are logically subsumed under a universal law or law-like statement (i.e., a highly confirmed *inductive empirical generalization*; Ayer, 1970; Hempel, 1942). The covering law model was particularly important for developmental inquiry because it treated historical events as analogous to physical events in the sense that earlier events were considered the causal antecedents of later events (Ricoeur, 1984).

Here, then, is the basic outline of the quest for absolute certainty according to the Newtonian and later empiricist stories of scientific methodology: Step 1, reduce to the objective (interpretation-free) observable foundation. Step 2, find the causes. Step 3, induce the law. As noted, variations appear throughout history. In fact, it would be misleading not to acknowledge that "probability" has replaced "certainty" as the favored *lexical item* in the story as it is told today. Induction is itself statistical and probabilistic in nature; however, this change represents a change in style more than substance, as the aim remains to move toward 100% probability, thereby arriving at certainty or its closest approximation. This type of fallibilistic stance continues to pit doubt against certainty as competing alternatives rather than understanding doubt and certainty as a dialectical relation, framed by the concept of *plausibility*.

Positivism and Neopositivism

Since its origin in the eighteenth century, mechanical explanation has been codified in several forms as specific methodologies or metamethods. Each of these represents a variation on the theme, but none of them have changed the basic theme itself. In the middle of the nineteenth century, mechanical explanation began to be formalized into a general strategy designed to demarcate empirical science from nonscience. It was at this time that the "age of metaphysics" came to an end. The ending was defined by philosophy's turning away from imperialistic dogmatic applications of broad philosophical systems, and directing its reflections toward what were called the "positive" sciences. Auguste Comte, writing a history of philosophy at the time, coined the term "positivism" when he described a division of three ages of thought: an early theological age, a metaphysical age that was just passing, and an age of positive science (see Gadamer, 1993; Schlick, 1991). The positive sciences were understood as those that located inquiry in the "given" or "positive." This positive sphere was identified as the sphere of "experience" rather than a sphere of the transcendental *a priori.* However, under the continuing influence of the "silent" metaphysics of the Newtonian-Humean tradition of empiricism and materialism, the "given" of experience became defined, not as commonsense observations or a commonsense level of discourse, but as observations that had been purified (i.e., reduced) of all interpretative features (i.e., reduced to "data" and more specifically, a type of data termed "sense data"). Thus, the positive sciences came to be those that were grounded in the Newtonian methodology, and positivism came to consist of the rules that further codified that methodology (see Table 2.1).

Following Comte, positivism was articulated across the remainder of the nineteenth century and into the early twentieth century by John Stuart Mill, Richard Avenarius, and Ernst Mach. In the 1920s and 1930s, what came to be termed neopositivism assumed a new posture in the philosophical work of the Vienna Circle, composed of such principal figures as Moritz Schlick, Rudolf Carnap, Herbert Feigl, Gustav Bergmann, Otto Neurath, Kurt Godel, and A. J. Ayer (see Smith, 1986). This "logical" positivism—which Schlick preferred to call "consistent empiricism" (1991, p. 54)—grew in the

context of the legacy of the Newtonian-Humean tradition that was now coming to be called analytic philosophy. At this point, analytic philosophy was taking its "linguistic turn" away from traditional epistemological questions of how the Real is known and replacing these with questions of what it means to make the language claim that the Real is known. In this context, logical positivism concerned itself not with knowing the Real but with the nature of statements that claim to know the Real (Schlick, 1991, p. 40).

Logical positivism focused on the reductionist and inductive features of Newtonian mechanical methodology. These were presented as the descriptive features of science, and as they go hand in hand with (causal) explanation as formulated in the covering law model, science from a positivist point of view is often characterized as the *description and explanation of phenomena.* This reductionistic focus ultimately led to the articulation of two complementary criteria for the demarcation of science from nonscience (Lakatos, 1978a, 1978b; Overton, 1984). First, a proposition (e.g., a hypothesis, a theoretical statement, a law) was acceptable as scientifically meaningful *if, and only if,* it could be reduced to words whose meaning could be directly observed and pointed to. "The meaning of the word must ultimately be *shown,* it has to be *given.* This takes place through an act of pointing or showing" (Schlick, 1991, p. 40). The words "whose meaning could be directly observed" constituted a *neutral observation language*—completely objective and free from subjective or mind-dependent interpretation. Thus, all theoretical language required reduction to pristine observations and a neutral observational language. Second, a statement was acceptable as scientifically meaningful *if, and only if,* it could be shown to be a strictly inductive generalization, drawn directly from the pristine observations. Thus, to be scientifically meaningful, any universal propositions (e.g., hypotheses, theories, laws) had to be demonstrably nothing more than summary statements of the pristine observations themselves (see Table 2.1).

Although logical positivism was formulated primarily within the natural sciences, its tenets were exported into behavioral science through Bridgman's (1927) "operationalism." The reductionism of positivism culminated in A. J. Ayer's (1946) "Principle of Verifiability." According to this principle, a statement is scientifically meaningful to the extent that, in principle, there is the possibility of direct experience (pristine observation) that will verify or falsify it. Bridgman's operationalism extended this principle by not only setting the criteria of scientific meaning, but also identifying the specific nature of this meaning: Within operationalism, the meaning of a scientific concept resides in the application of the concept (i.e., in the definition of the concept in operational or application terms).

Neopositivism reached its zenith in the 1940s and 1950s, but ultimately both the friends and the foes of positivism recognized its failure as a broad demarcationist strategy. It failed for several reasons:

1. It became clear, as demonstrated in the work of Quine (1953) and others (e.g., Lakatos, 1978b; Popper, 1959; Putnam, 1983), that rich theories are not reducible to a neutral observational language.
2. There was a demonstrated inadequacy of induction as the method for arriving at theoretical propositions (Hanson 1958, 1970; Lakatos, 1978a; Popper, 1959).
3. It became evident that the covering law model that it introduced was highly restricted in its application (Ricoeur, 1984) and faulty in its logic (Popper, 1959).
4. It was recognized that there are theories that warrant the attribution "scientific" despite the fact that they lead to no testable predictions (Putnam, 1983; Toulmin, 1961).

Instrumentalism-Conventionalism

With the failure of neopositivism, there arose out of the Newtonian-Humean tradition a revised methodology called *instrumentalism* or *conventionalism* (Lakatos, 1978b; Laudan, 1984; Kaplan 1964; Overton, 1984; Pepper, 1942; Popper, 1959). This demarcationist strategy accepted the failure of reductive-inductive features of positivism and admitted the introduction of theoretical interpretation as an irreducible dimension of science (see Table 2.1). However, metatheories, theories, and models were treated as mere *convenient or instrumental heuristic devices for making predictions.* Thus, theories in instrumentalism were restricted to the same predictive function that formal deductive systems (the covering law model) performed in neopositivism. Popper (1959) added a unique dimension to instrumentalism through the claim that theories and models should become acceptable in the body of science, *if and only if,* they specify observational results that, if found, would disprove or falsify a theory.

Instrumentalism opened the door for interpretation to reenter science but hesitated in allowing it to become a full partner in the scientific process of building a systematic body of knowledge. The movement to a dialecti-

cally defined full partnership of interpretation and observation required a radical change; one that would (a) abandon the splitting and foundationalism that had established pristine observation as the exclusive final arbiter of truth and (b) free up the notion of scientific explanation that was fossilized by this splitting and foundationalism. This move to a Libnizian-Hegelian relational alternative path from common sense to refined scientific knowledge emerged in the 1950s and it continues to be articulated today.

The concepts that constitute this relational methodology arose from diverse narrative streams including analytic philosophy, the history and philosophy of the natural sciences, the philosophy of behavioral and social sciences, and hermeneutics. Despite their often complementary and reciprocally supportive nature these narratives have frequently failed to connect or enter into a common dialogue. Yet, their cumulative effect has been to forge at least the outline of an integrated story of scientific methodology that moves beyond the split Cartesian dichotomies of natural science versus social science and explanation versus understanding, observation versus interpretation, and theory versus data.

Here briefly are some of the central characters in the 1950s emergence of this new metamethod: The later Ludwig Wittgenstein (1958)—whose seminal book *Philosophical Investigations* was first published in 1953—represented analytic philosophy, and he was followed by his pupil Georg Henrik von Wright and later Hilary Putnam. Hans-Georg Gadamer (1989)—whose *Truth and Method* was first published in 1960—represented the hermeneutic tradition and later came Jurgen Habermas, Richard Bernstein, and Paul Ricoeur. Steven Toulmin (1953)—whose *Philosophy of Science* was published in 1953—and N. R. Hanson (1958)—whose *Patterns of Discovery* was published in 1958—represented the natural sciences. They were later followed by Thomas Kuhn, Imre Lakatos, Larry Laudan, and, most recently, Bruno Latour. Elizabeth Anscombe (1957)—whose *Intention* was published in 1957, as were William Dray's (1957) *Laws and Explanation in History,* and Charles Frankel's (1957) *Explanation and Interpretation in History,* represented the social sciences as did Peter Winch (1958) and Charles Taylor (1964).

Relational Scientific Methodology

The story of the development of an integrated relational methodology of the sciences is obviously detailed and complex (see Overton, 1998, 2002). I outline its main features by focusing primarily on some of the major contributions of several of these central figures. These include Wittgenstein (1958) and *Philosophical Investigations,* Gadamer (1989) and *Truth and Method,* Hanson (1958) and *Patterns of Discovery,* von Wright (1971) and *Explanation and Understanding,* and Ricoeur (1984) and *Time and Narrative.*

Wittgenstein and Gadamer provide the basic scaffolding for the construction of this relational methodology. Wittgenstein's fundamental contribution entailed opening the door to the recognition that it is a profound error to treat the activities of science as providing veridical descriptions of a foundational Real. More positively, Wittgenstein's contribution lies in his suggestion that science is the product of some of the same human actions that underlie the conceptual constructions of our "form of life" or our *lebenswelt.* Gadamer's contribution was a systematic demonstration that this move beyond objectivism and foundationalism did not necessitate a slide into relativism.

Hanson's (1958) analysis of the history of the physical sciences was significantly influenced by Toulmin and by the Wittgenstein of *Philosophical Investigations.* In this work, Hanson drew three conclusions about the actual practice of the physical sciences as distinct from the classical rules described by neopositivism and instrumentalism. Hanson's conclusions themselves articulate a blueprint for the new relational methodology. The conclusions were: (a) There is no absolute demarcation between interpretation and observation, or between theory and facts or data. This was captured in his now famous aphorism "all data are theory laden." (b) Scientific explanation consists of the discovery of patterns, as well as the discovery of causes (see also Toulmin, 1953, 1961). (c) The logic of science is neither a split-off deductive logic, nor a split-off inductive logic, but rather, the logic of science is abductive (retroductive) in nature.

Interpretation and Observation

Hanson's first conclusion, that "all data are theory-laden," became the core principle of the new relational methodology: If there is a relational reciprocity between observation and interpretation, then the analytic idea of reducing interpretation to a foundational observational level makes no sense. In place of the analytic reductionism described in Step 1 of mechanical explanation, relational methodology substitutes a complementarity of analysis and synthesis. Analysis and the analytic tools of empirical science are reaffirmed in this principle, but there is a proviso that it simultaneously be recognized

that the analytic moment always occurs in the context of a moment of synthesis, and that the analysis can neither eliminate nor marginalize synthesis.

This feature of the new relational methodology was further supported and extended by two features of Gadamer's "philosophical hermeneutics." The first was his insistence that the alternating to-and-fro motion exhibited in play presents a favorable ontological alternative to Cartesian foundationalism. It is this ontological theme of to-and-fro movement that grounds and sustains the relational methodology. As a consequence, scientific activity—regardless of whether that activity is in the natural or the behavioral or the social sciences—becomes grounded in the to-and-fro (Escherian left hand-right hand) movement of interpretation-observation.

Gadamer's second contribution consists of his articulation—following Heidegger—of the hermeneutic circle described earlier. In this articulation, the hermeneutic circle comes to describe the basic *form* of how interpretation and observation move to and fro; that is, the cycle that opens to a spiral describes the basic structure of the new scientific methodology.

Inquiry moves in a circular movement from phenomenological commonsense understanding of an object of inquiry to the highly reflective and organized knowledge that constitutes scientific knowledge. The whole—the general field of inquiry, such as human development—is initially approached with the meanings or "prejudices" that constitute both commonsense observations and background presuppositions including metatheoretical assumptions. These anticipatory meanings are projected onto the phenomenon of inquiry. As a consequent, they form an early stage in inquiry. However, the object of inquiry is not merely a figment of projection, but is itself an internally coherent whole; the object of inquiry reciprocally operates as a corrective source of further projections of meaning. In this circle, interpretation identifies what will ultimately count as observations, and observations determine what will count as interpretation. To paraphrase Kant, interpretation without observations is empty; observation without interpretation is blind.

Through this circle of projection (interpretation) and correction (observation; Escherian left hand-right hand) inquiry advances; the circle remains open and constitutes a spiral. It was the dialectic cycle of interpretation and observation that later grounded Thomas Kuhn's (1962, 1977) notion of interpretative *paradigms* in the natural sciences and Lakatos's (1978a, 1978b) and Laudan's (1977, 1984, 1996) later discussions of the centrality of ontological and epistemological background presuppositions in any *research program* or *research tradition* (see Table 2.1).

Causality and Action Patterns

Hanson's second conclusion—that pattern and cause have always operated as explanations in the physical sciences—subverts the split stories of a clear-cut line of demarcation between the natural and social sciences. If natural science inquiry has—throughout the modern period—centrally involved both pattern and causal explanation, then understanding and explanation need not be dichotomous competing alternatives. Pattern or action-pattern explanation (Aristotle's formal and final explanation), which entails intention and reasons, and, causal explanation (Aristotle's material and efficient explanation), which entails necessary and sufficient conditions, here become relational concepts (Escherian left hand-right hand). Explanation then—defined as "intelligible ordering" (Hanson, 1958)—becomes the superordinate concept that joins dynamic patterns and cause. In place of detached causes described in Step 2 of mechanical explanation, relational methodology thus substitutes this concept of intelligible ordering.

The challenge within this relational methodology is to establish a justifiable coordination of the two modes of explanation. Von Wright (1971) presents a richly detailed and complex effort in this direction, and Ricoeur (1984) later builds upon and expands this effort. Both focus on explanation in the behavioral and social sciences. Von Wright and Ricoeur each suggest that the coordination be made along the lines of an internal-external dimension. Internal here refers to the domain of the psychological person-agent or psychological action system. External refers to movements or states. Following from a critical distinction made earlier by Anscombe (1957), any given behavior can be considered internal under one description and external under another description. Thus, any specific behavior may be, to quote von Wright (1971) "intentionalistically understood as being an action or otherwise aiming at an achievement, *or* . . . as a 'purely natural' event, i.e. in the last resort, muscular activity" (p. 128).

Within this framework, causal explanations—understood as Humean causes defined by the logical independence or contingency relationship between cause and effect—account for external movements and states. Action-pattern explanation (i.e., action, action systems, intention, reason) accounts for the meaning of an act.

On a moment's reflection, the situation described here is quite clear. Imagine the following behavior of two figures: Figure A moves across a space and a part of Figure A comes into contact with Figure B. In this situation, we have states and movements, and causal explanation is quite appropriate. The intervening states that identify the movement can readily be considered a series of sufficient and necessary conditions leading to the last state in the series. This can be easily demonstrated via various experimental designs.

While this explanation could be satisfactory if the figures were inorganic objects, the situation changes when the figures are identified as persons. In this latter case, it is unlikely that you will be satisfied with the causal explanation because you have been given no real psychological sense of the meaning of these movements. If, however, after identifying the figures as people you further learn that the movement of Figure A to B is the action of a man who walks across the room and caresses his wife's cheek, explanation begins to operate in the context of action, intention, reasons, and broadly meaning. The two moments of explanation—causal explanation, on the one hand, and action-pattern explanation, on the other—explain different phenomena. They have distinct referents; *movement and states* in causal explanation and *meaning* in action-pattern explanation. Because they have different referents—different *explananda*—they are compatible. However, they don't replace each other. Action isn't a cause of movement, it is a part of movement. Cause cannot explain action, action is required to initiate movement.

There are a number of implications that can be drawn from this analysis of the coordination of explanatory types. One is that it demonstrates that, in principle, it is not possible to explain phenomena of consciousness via brain or neurobiological explanations. Consciousness is internal as defined above; consciousness is about psychological meaning and must be explained by actions-pattern explanation. The brain is external, it is about states and movements, not psychological meaning. Neurobiological causal explanation complements action-pattern explanation, but can never present "the mechanism" of consciousness.

A second important implication is that when one again considers the distinction between person-centered and variable inquiry, it becomes clear that action-pattern explanations are the focus of the former and causal-explanations the focus of the latter. Piaget's theory, for example, represents a person-centered theory. "Person" (child-adult), "agent" (system, i.e., the "epistemological subject"), "action," "embodiment," and "intention" are core concepts that identify Piaget's focus on development. Piaget implicitly recognized the coordination of explanatory types and focused his efforts on explanation via formal action-pattern (schemes, operations) and final action-pattern (the equilibration process, reflective abstraction). Many, if not all, of the misunderstandings of Piagetian theory that Lorenço and Machado (1996) have articulated are derived from the fact that attacks on Piaget theory have invariably come from those who remain locked into the neopositivist story of exclusive causal explanation.

There are other implications to be drawn from a relational coordination of explanatory types, but a most important question that arises is that of exactly how action pattern explanation is operationalized. Students from their first science courses are trained in experimental methods designed to sort out the causal status of variables. When it can be shown, under controlled conditions, that an added variable (antecedent, independent variable) reliably leads to the behavior of interest (consequent, dependent variable), this demonstrates that the variable is the sufficient cause of the event. This provides the rationale for training and enrichment experiments often found in developmental psychology. If it can be shown, under controlled conditions, that when a variable is subtracted or removed and the event does not occur, the variable is the necessary cause of the event. This provides the rationale for deprivation experiments. Correlations are also discussed in this context, and while it is made explicit that correlation isn't causation, the same message treats correlation as a step in the direction of causal explanation.

But inductees into scientific methods receive little instruction concerning action-pattern forms of explanation, except perhaps to be told from an implicit neopositivist or instrumentalist perspective that it would be inappropriate speculation. To understand how action-pattern explanations can be made in a legitimate scientific fashion, it is necessary to turn to Hanson's third conclusion about the actual operation of science.

Abduction-Transcendental Argument

Hanson concluded that neither split-off induction nor split-off deduction constitutes the logic of science. Each of these enters the operation of science, but Hanson argued that the overarching logic of scientific activity is abduction. Abduction (also called "retroduction") was originally described by the pragmatist philosopher Charles Sanders Pierce (1992). In a contemporary version

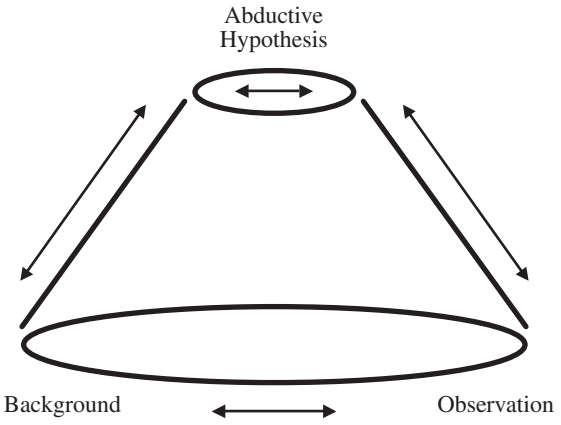


Figure 2.10 The abductive process.

this logic is termed "inference to the best explanation" (Fumerton, 1993; Harman, 1965). Abduction operates by arranging the observation under consideration and all background ideas (including all metatheoretical principles and theoretical models) as two Escherian hands (Figure 2.10). The possible coordination of the two is explored by asking the question of what, given the background ideas, must necessarily be assumed to have that observation. The inference to—or interpretation of—what must, in the context of background ideas, necessarily be assumed, then constitutes the explanation of the phenomenon. This explanation can then be assessed empirically to ensure its empirical validity (i.e., its empirical support and scope of application). An important relational feature of this logic is that it assumes the form of the familiar hermeneutic circle by moving from the phenomenological level (the commonsense object) to explanation and back in an ever-widening cycle that marks scientific progress (see Figure 2.11). The difference between this and the earlier described hypothetical-deductive explanation is that in abduction all background ideas, including metatheoretical assumptions, form a necessary feature of the process, and the abductive explanations themselves become a part of the ever widening corpus of background ideas.

The basic logic of abduction operates as follows:

1. Step 1 entails the description of some highly reliable phenomenological observation (O is the case).
2. For step 2, with O as the explanandum, an inference or interpretation is made to an action-pattern explanation (E). This results in the conditional proposition "If E is the case, then O is expected."
3. Step 3 entails the conclusion that E is indeed the case.

Examples of this abductive action-pattern explanation—or more specifically the one I describe next—are found

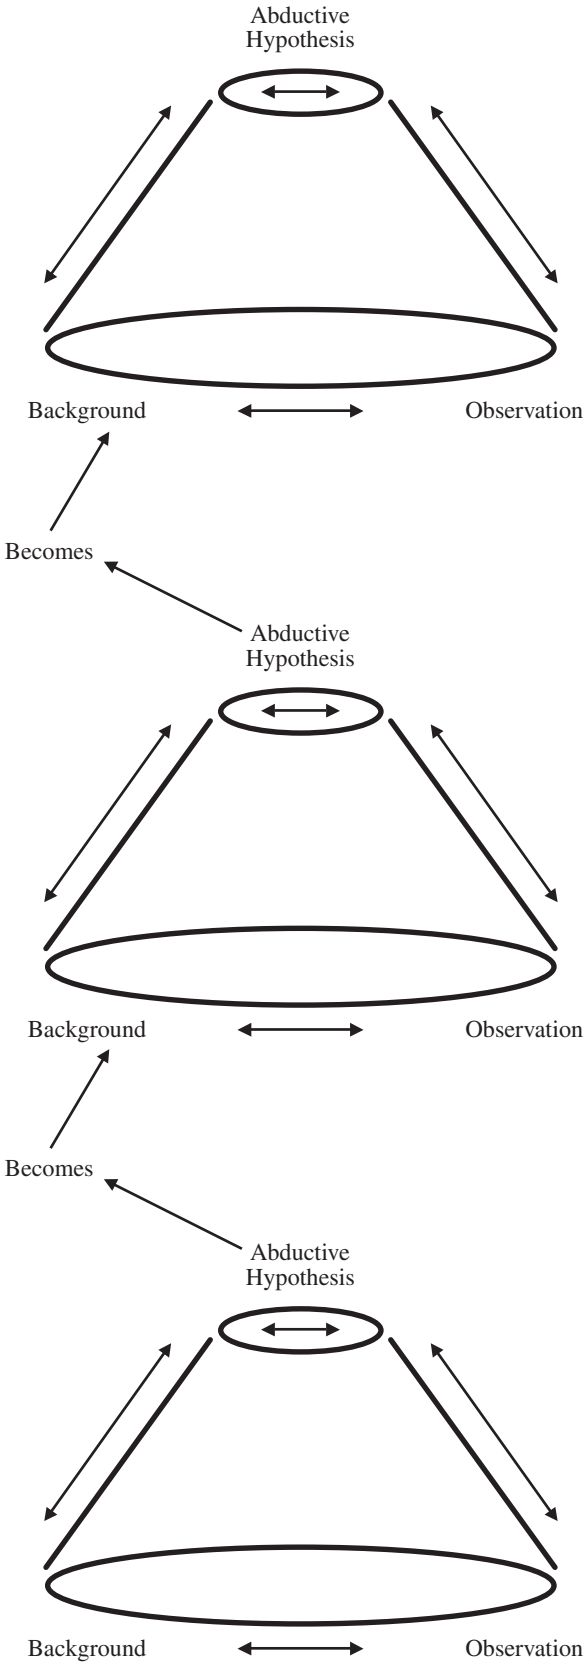

Figure 2.11 Scientific progress through abduction.

in virtually any psychological work that assumes a centrality of emotional, motivational, or cognitive mental organization. Piaget's work is particularly rich in abductive explanation. Consider the following example:

> There is the phenomenal observation (O) that it is the case that certain persons (i.e., children generally beyond the approximate age of 7 years) understand that concepts remain quantitatively invariant despite changes in qualitative appearances (conservation).
>
> Piaget then infers (E) a certain type of action system having specified features including reversibility (concrete operations). Thus, the conditional "If (E) concrete operations, then (O) conservation, is what would be expected."
>
> And the conclusion, given the O, "Therefore, concrete operations explains the understanding of conservation."

As Fumerton (1993) points out, it is obvious that if the conditional in Step 2 is read as material implication, the argument would be hopeless as it would then describe the fallacy of the affirmed consequent (i.e., the circle would be closed and it would represent a form of vicious circularity). Quite correctly, Fumerton recognizes that the "If . . . then" relation asserts some other sort of *connection.* Specifically, the connection is one of meaning "relevance" between E & O, where relevance is defined in terms of the intelligibility of the relation between E and O (Overton, 1990).

There must also be criteria established that would allow us to choose among alternative Es, the "best" E. But this is no major hurdle because many of the traditional criteria for theory or explanation *selection* that have been available can, with profit, be used here. These criteria include scope of the explanation; the explanation's depth, coherence, logical consistency; the extent to which the explanation reduces the proportion of unsolved to solved conceptual and/or empirical problems in a domain (Laudan, 1977); and the explanation's empirical support and empirical fruitfulness. Note here that scope, empirical support, and fruitfulness themselves bring the circle back to the observational world and thus keeps the cycle open. Action-pattern explanation or theory, in fact, determines what will count as further observations and the empirical task is to go into the world to discover whether we can find these observations. Thus, the cycle continually moves from commonsense observations and background presuppositions to action-pattern explanations, returning then to more highly refined observations and back again to explanation.

A form of abduction was brought to prominence by Kant and has recently been elaborated by Charles Taylor (1995; see also Grayling, 1993; Hundert, 1989) and used in the arena of cognitive development by Russell (1996). This is the *transcendental argument* and its form is:

1. (We) have a (reliable) phenomenological experience with characteristic *A.*

2. (We) could not have an experience with characteristic *A* unless mind has feature *B.*

3. *Therefore,* mind necessarily has feature *B.*

The transcendental argument is designed to answer the how possible questions (von Wright, 1971) with respect to consciousness or the organization of mind. Given some highly reliable phenomenological observation or phenomenological experience, like conservation, what must we necessarily assume (i.e., what kind of action-pattern explanation) about the nature of our consciousness or the nature of mind? What are the necessary conditions of intelligibility? Again, we begin with the explanandum, make a regressive argument to the effect that a stronger conclusion must be so if the observation about experience is to be possible (and being so, it must be possible). And this then leads to the stronger conclusion.

This then is the answer to the question of how one does pattern explanation in the behavioral and social sciences. The procedure for doing action-pattern explanation is found in abduction and the rules of the transcendental argument, and in the criteria that establish a particular abductive-transcendental explanation as the best or most plausible of alternative explanations. Rozeboom (1997) provides a richly detailed operational analysis of this process along with practical advice on statistical and research strategies associated with the process.

In conclusion, there is much more to the story of the new relational methodology. Much of this story is detailed in the elaboration of research methods and measurement models as the specific techniques for designing, conducting, and evaluating the empirical inquiry that adjudicates the best explanations, where these explanations may assume the various shapes of transformational, variational, expressive, instrumental, normative, and individual difference features of developmental change. The work of Rozeboom (1997) is an example, but there are a number of others who have been active in pursuing new tools for modeling and assessment of these diverse features of development. Even beginning to list these would be the work of a new chapter and, consequently, I mention only an excellent summary discussion of some of these new tools found in the work of Fischer and Dawson (2002).

Within this relational context, where interpretation and observation function as a complementary identity of

opposites, the broad issue of the validity of our scientific observations also becomes a central issue. Validity has always been a concern of scientific methodology, but in the split understanding of science, validity had nothing to do with interpreted meaning. In that story, validity became a content issue dependent to a great degree on the outcome of experimental design. In the relational story, the validity of our scientific observations, or what Messick (1995) terms "score validity," becomes a complementary process involving, on the one Escherian hand, the distinctive features of construct validity as it involves interpretative meaning, and, on the other Escherian hand, content validity as it involves denotative meaning (see Overton, 1998 for an extended discussion).

CONCLUSIONS

This chapter has explored background ideas that ground, constrain, and sustain theories and methods in psychology generally, and developmental psychology specifically. An understanding of these backgrounds presents the investigator with a rich set of concepts for the construction and assessment of psychological theories. An understanding of background ideas in the form of metatheories and metamethods also helps to prevent conceptual confusions that may ultimately lead to unproductive theories and unproductive methods of empirical inquiry. The ideas in the chapter are presented in the context of Hogan's (2001) earlier mentioned comment:

> Our training and core practices concern research methods; the discipline is . . . deeply skeptical of philosophy. We emphasize methods for the verification of hypotheses and minimize the analysis of the concepts entailed by the hypotheses. [But] all the empiricism in the world can't salvage a bad idea. (p. 27)

The ideas in this chapter are also presented in the service of ultimately proving wrong Wittgenstein's (1958) comment that "in psychology there are empirical methods and conceptual confusions" (p. xiv).

CHAPTER 3

The Making of Developmental Psychology

ROBERT B. CAIRNS and BEVERLEY D. CAIRNS

This chapter is an introduction to the ideas, people, and events that have guided scientific activity in developmental psychology over the past century. Its preparation has been facilitated by several recent publications on the history of developmental psychology. The views of the past held by active researchers are reflected in chapters of the edited volume, *A Century of Developmental Psychology* (Parke, Ornstein, Rieser, & Zahn-Waxler, 1994). The contributors are, with few exceptions, currently involved in contemporary research. Secondary commentaries can provide useful guides and interpretations, but there is no substitute for consulting original

sources. To that end, a reprint series containing historically significant original articles and volumes has been prepared by Wozniak (e.g., 1993, 1995).

Other recent volumes include the contributions of professional historians and others who are not enmeshed in current empirical debates of the discipline (e.g., Broughton & Freeman-Moir, 1982; Elder, Modell, & Parke, 1993). In addition, the social relevance and the making of the discipline in U.S. society have been told expertly by Sears (1975) and White (1996). Any single overview—including this one—can tell only part of the story.[1]

Adopting the convention used in the previous *Handbook of Child Psychology,* 20 years must lapse before a contribution or event qualifies as historical. Two decades constitute approximately one generation in the life of our science. This rule makes the task manageable and sharpens the focus on the events of the past.

DEVELOPMENT AND HISTORY

It is mildly ironic that an area committed to the study of the origins and development of behavior and consciousness traditionally has shown little interest in its own origins and development. In the great handbooks of the field, the first five (Carmichael, 1946; Murchison, 1931, 1933; Mussen, 1970) did not include historical overviews; in the 1983 edition of this volume, this state of affairs was changed when two chapters on history were included (Borstlemann, 1983; Cairns, 1983). The earlier reluctance to look to our past, though regrettable, is understandable. If substantive progress is to be made in new empirical research, it will be won by those who look ahead rather than backward. There are also institutional and economic limits on scholarship where journal space is precious, and historical reviews and comments are afforded low priority. The upshot is that contemporaneous research articles tend to bypass the work and insights of earlier investigators. This neglect of the past has been correlated with a more general tendency to give short shrift to competing findings, concepts, and interpretations. Such shortcomings in scholarship, if unchecked, can undermine real progress in the discipline.

Historical accounts are neither static nor immutable. As new information about the nature of developmental phenomena becomes available, perspectives on earlier events may shift in emphasis and interpretation. Similarly, as new findings and issues emerge, prior relevance can be reevaluated and viewed in a fresh light. The rediscovery of J. M. Baldwin's contributions is a case in point. With the increased interest in integrative concepts of cognitive, moral, and social development, it was perhaps inevitable that researchers should rediscover the intellectual foundation for developmental studies provided by Baldwin. A direct line of influence has been drawn between the concepts of J. M. Baldwin and those of Jean Piaget, L. S. Vygotsky, H. Wallon, and L. Kohlberg (see Broughton & Freeman-Moir, 1982; Cairns, 1992; Valsiner & van der Veer, 1993). The construction of the intellectual history of a science is necessarily an ongoing enterprise.

One point of consensus is that developmental psychology has its own distinctive history, which is associated with but independent of the history of experimental or general psychology. The year 1979—one century after Wundt established a psychology laboratory at the University of Leipzig—was the centennial of scientific psychology (Hearst, 1979). The assignment involves a modest fiction, since even a casual reading of the literature of the day indicates that the enterprise of modern psychology was already well under way in 1879 in the laboratories of Helmholtz, Fechner, Weber, Lotze, James, and Galton (Littman, 1979).

Looking backward, it might seem inevitable that the study of behavioral development should have emerged as the focal problem for the new science of psychology. Several of the founders of the discipline approached the subject matter of psychology from a developmental per-

[1] Professor Robert Cairns died on November 10, 1999. This chapter is based on the chapter written by Professor Cairns for the 5th edition of the *Handbook of Child Psychology* (1998) and was amended by Beverley D. Cairns and Richard M. Lerner. As was true for the 1998 version of the chapter, the present version owes much to two earlier chapters that Professor Cairns wrote on the history of developmental psychology (Cairns, 1983; Cairns & Ornstein, 1979) and to several people who contributed to the preparation of the earlier works: Beverley D. Cairns, Peter A. Ornstein, Robert R. Sears, William Kessen, Ronald W. Oppenheim, Alice Smuts, Lloyd Borstlemann, Robert Wozniak, Philip R. Rodkin, Kimberly Davidson, and the staff of the Center for Developmental Science.

spective, and the genetic theme was influential in philosophical and biological thought in the late nineteenth century. Alfred Binet in France, William Preyer and William Stern in Germany, Herbert Spencer and George J. Romanes in England, and several U.S. psychologists (from G. Stanley Hall and John Dewey to James Mark Baldwin and John B. Watson) agreed on the fundamental viewpoint of development, if little else. What is the fundamental viewpoint? Watson, who is often depicted as an opponent of the developmental approach, indicated that developmental methods require the continuous observation and analysis "of the stream of activity beginning when the egg is fertilized and ever becoming more complex as age increases" (1926, p. 33). For Watson, the developmental approach was:

> [the] fundamental point of view of the behaviorist—viz. that in order to understand man you have to understand the life history of his activities. It shows, too, most convincingly, that psychology is a natural science—a definite part of biology. (p. 34)

Nor was the kernel idea of development a new one for biological science or for psychology. It had guided the work and thinking of physiologist Karl von Baer (1828) and those who followed his early lead in the establishment of comparative embryology. It was also a basic theme in the earliest systematic statements of psychology (Reinert, 1979).

But not all of the founders of the new science subscribed to the developmental perspective or the assumption that psychology was a definite part of biology. Some of the most influential—including Wilhelm Wundt himself—had a different view. Noting the difficulties that one encounters in efforts to study young children in experimental settings, Wundt argued that "it is an error to hold, as is sometimes held, that the mental life of adults can never be fully understood except through the analysis of the child's mind. The exact opposite is the true position to take" (1907, p. 336).

Even the father of child psychology in America, G. Stanley Hall, relegated developmental concerns to minor league status in the new psychology. In the inaugural lectures at Johns Hopkins, Hall (1885) followed his mentor Wundt in holding that psychology could be divided into three areas: (1) experimental psychology, (2) historical psychology, and (3) the study of instinct. The study of children and adolescents was assigned to historical psychology, which included as well the study of primitive people and folk beliefs. Instinct psychology dealt with those processes and behaviors that were considered innate, thus encompassing much of what is today called comparative and evolutionary psychology. Of the three divisions, Hall considered experimental psychology to be the "more central and reduced to far more exact methods." These methods included the use of reaction time, psychophysical procedures, and introspection to examine the relations between sensation and perception. Historical and instinct psychology necessarily relied on observational and correlational methods, hence were seen as less likely to yield general and enduring principles. Hall's divisions were consistent with the proposals of numerous writers—Auguste Compte, John Stuart Mill, Wilhelm Wundt—who called for a second psychology to address aspects of human mind and behavior that were based in the culture (Cahan & White, 1992; Wundt, 1916). In Hall's account, the second psychology was a second-class psychology.

The division between experimental and developmental psychology has proved to be remarkably durable—but that is getting ahead of the story. The main point is that developmental issues could have been nuclear concerns for the new science, but they were not. They have not even played a significant role in the history of experimental psychology (see Boring, 1929/1950).

There is also consensus that the initiation of the scientific study of children represents the convergence of two forces, one social and the other scientific. The scientific background is the primary focus of this chapter, and our principal attention is given to the intellectual and empirical foundations of the discipline.

But there were also social and political roots. Sears (1975) observed, in his classic chapter titled "Your Ancients Revisited," that:

> By the end of the [nineteenth] century, there had developed a vaguely cohesive expertise within the professions of education and medicine, and the origins of social work as a helping profession were clearly visible. During the first two decades of the twentieth century, these professions began relevant research to improve their abilities, but their main influence on the future science was their rapidly expanding services for children in the schools, hospitals, clinics, and social agencies. This expansion continued after World War I, and it was in the next decade, the 1920s, that scientists from several nonprofessionally oriented ("pure science") disciplines began to join the

> researchers from the child-oriented professions to create what we now view as the scientific field of child development. But like the engineering sciences which evolved from physics and chemistry, child development is a product of social needs that had little to do with science qua science. . . . The field grew out of *relevance.* (p. 4, author's emphasis)

Whether it is viewed as a creation of social forces or as an inevitable outcome of open scientific inquiry, developmental psychology was established as a separate research discipline only within the past century. However, its scientific roots in biology extend back at least an additional 100 years. It was then that fundamental questions on the origin of life, species transmutation, and individual development began to generate empirical investigations.

BIOLOGICAL ROOTS: EMBRYOLOGY AND EVOLUTION

A strong case could be made that the early scientific roots of developmental psychology are to be found in embryology and evolutionary biology rather than in experimental psychophysics. Two core ideas in nineteenth-century biological thought directly shaped developmental psychology and require attention: (1) K. E. von Baer's developmental principle and (2) C. R. Darwin's evolutionary theory.

THE DEVELOPMENTAL PRINCIPLE

Karl Ernst von Baer (1792–1876) ranks as one of the great original biologists of the nineteenth century, alongside Curvier, Lamarck, and Darwin (Hamburger, 1970). Born in Estonia, of German ancestry, he did his pivotal work on anatomical development at Würzburg and Königsberg. The pioneer of comparative embryology, von Baer discovered the human ovum and the notochord (the gelatinous, cylindrical cord in the embryo of vertebrates around which, in higher forms, the backbone and skull develop). More relevant to this chapter, von Baer generalized beyond his empirical work in embryology and anatomy to enunciate general principles on the fundamental nature of ontogenetic change (von Baer, 1828–1837). He proposed that development proceeds, in successive stages, from the more general to the more specific, from relatively homogeneous states to increasingly differentiated hierarchically organized structures.

Although von Baer himself considered his developmental proposals to be revolutionary, they initially received only modest attention. After a bout of extreme fatigue, disappointment, and disillusionment, von Baer moved to Russia in 1834 and became librarian of the Academy of Science in St. Petersburg. Later, he was appointed leader of a Russian Arctic expedition where he conducted geographical, botanical, and biological research relevant to evolution and development. At the end of his career, he returned to Estonia, the country of his birth, and served as president of the University of Tartu.

Von Baer's developmental principles may seem commonplace to modern students; his general axioms are mentioned in introductory chapters of texts on biological and cognitive development. But when the ideas were first proposed, they challenged the then-dominant explanations for how development proceeds. Two views vied for prominence throughout most of the nineteenth century: (1) preformism and (2) epigenesis (Gould, 1977). Preformism held that developmental transformations were illusions because the essential characteristics of the individual had already formed at the beginning of ontogenesis. Only the size and relations of the parts to each other changed, and their essential properties were preset and predetermined. Although preformism is dismissed nowadays as drawings of a miniaturized adult in the womb, the concept of a homunculus is not essential to the model (Gould, 1977).

What was basic to preformism was the idea that development could bring about changes in the shape and relationships among organs, but development fails to bring out new or novel properties. Hence, stability and predictability from embryogenesis and infancy to adulthood was expected, if one's measurement tools were adequate. Absurd? Perhaps, except that the proposals do not appear entirely unreasonable if one considers parallels in modern genetic theory, where genes endure unchanged even though the organisms that they create do not. Moreover, particular alleles are assumed to be associated with the ontogeny of specific structural and behavioral characteristics. At another level, modern developmental researchers often assume that the primary traits and dispositions—such as attachment and aggression—develop and become stabilized during the interchanges of infancy and early childhood. These dispositions and the internal-

ized models thus generated may be transformed over development into age-appropriate expression, but not in underlying type.

The other major nineteenth-century approach to development was epigenetic. Novelties were brought about through progressive transformations in development. But what determines the course of the transformations and, ultimately, the nature of the finished product? The earlier vitalistic answer—*entelechy,* the Aristotelian vital force—was no longer acceptable to most nineteenth-century epigeneticists. Among other problems, the teleological answer looked to be an admission of ignorance. But without developmental regulation and direction, what would prevent growth from occurring willy nilly into diverse and monstrous forms? The concept of epigenesis-as-developmental-transformations could not stand alone. It required additional assumptions to account for the sequential properties of development and its orderly nature (von Bertalanffy, 1933; Gould, 1977).

This theoretical void was filled in nineteenth-century biology by the recapitulation concept prominent in *Naturphilosophie,* a significant philosophical movement in Germany. Recapitulation bound together the two main forms of organic creation, ontogeny (individual development) and phylogeny (species development), into a single framework. In embryonic development, organisms are assumed to pass through the adult forms of all species that had been ancestral to them during evolution. Organisms in embryogenesis experience a fast-forward replay of evolutionary history. With this predictable and orderly progression, novel features may be added only in the terminal or mature phases of development. This concept, labeled the "biogenetic law" by Ernst Haeckel (1866), was enormously influential in nineteenth-century biology. The recapitulation hypothesis also provided the biological metaphor for Hall's account of adolescence and S. Freud's original formulations of repression and psychosexual stages (Sulloway, 1979, pp. 198–204, 258–264).

In opposition to prominent biologists of his day, von Baer argued that recapitulation was based on faulty observations and romanticism rather than logic. In his own research, he found that organisms of related species were indeed highly similar in anatomy during their early stages of embryonic growth. However, contrary to the expectations of the recapitulation interpretation, species-typical differences appeared early in the course of development, not only in its final stages. Moreover, the organization at successive stages seemed to uniquely fit the organism for its current circumstances. It was not merely the mechanical repetition of earlier ancestral forms, as implied by the recapitulation model (de Beer, 1958). To sharpen the epigenetic account, von Baer (1828–1837) offered four laws by which development could be described:

1. The general features of a large group of animals appear earlier in the embryo than the special features.
2. Less general characteristics are developed from the more general, and so forth, until the most specialized appear.
3. Each embryo of a given species, instead of passing through the stages of other animals, departs more and more from them.
4. Fundamentally, therefore, the embryo of a higher animal is never like a lower animal, but only like its embryo.

Von Baer held that development was a continuing process of differentiation and organization; hence, novelties could arise at each stage, not merely the terminal one. When this embryological principle was later applied to structures, actions, thoughts, and social behaviors (e.g., Piaget, 1951; Werner, 1940/1948), it produced far-reaching consequences. The conclusion proposed in 1828 was that developmental processes demand rigorous study in their own right; they cannot be derived from analogies to evolution.

Although von Baer was recognized as a leading embryologist, his generalizations on the nature of development were not immediately accepted. They were inconsistent with broadly held beliefs in biology, and von Baer's rejection of the Darwinian account of evolution probably did not help matters. Despite compelling empirical and comparative evidence, for most of the nineteenth century von Baer's developmental generalizations fared poorly in open competition with the recapitulation proposal.

Von Baer's developmental ideas were not entirely ignored in his time, however. It was in Carpenter's (1854) influential physiological textbook that Herbert Spencer discovered von Baer's formulation of the developmental principle. Spencer (1886) wrote that von Baer's work represented "one of the most remarkable indications of embryology" and stated:

> It was in 1852 that I became acquainted with von Baer's expression of this general principle. The universality of law had ever been with me as a postulate, carrying with it a correlative belief, tacit if now avowed, in unity of method throughout Nature. This statement that every plant and animal, originally homogeneous, becomes gradually heterogeneous, set up a process of coordination among accumulated thoughts that were previously unorganized, or but partially organized. (p. 337)

Spencer's work, in turn, inspired the genetic epistemology of James Mark Baldwin and his successors, including Jean Piaget. Von Baer's other line of influence on psychology appears in animal behavior and comparative psychology through the work of Z.-Y. Kuo, Schneirla, and Carmichael in the twentieth century. The modern dynamic systems model, transactional theory, developmental psychobiology, and developmental science have von Baer's principle of development as a kernel concept (e.g., see Lerner, Chapter 1; Thelen & Smith, Chapter 6, this *Handbook,* this volume). Moreover, time and timing are central in von Baer's formulation, consistent with modern concepts of critical periods in embryogenesis and sensitive periods in behavior development, and with the concepts of neoteny and heterochrony in behavioral evolution (Cairns, 1976; de Beer, 1958; Gottlieb, 1992; Gould, 1977).

There have been some major revisions, of course. The developmental principle identified a key feature of epigenesis—homogeneity giving way to heterogeneity through progressive differentiation, then integration into reorganized structures—but it did not solve the problem of how development is directed. In his writing, he remained vaguely teleological, a position that seemed consistent with *Naturphilosophie* but out of line with his rigorous experimental work and careful theoretical analysis. Leaving the directionality issue open-ended invited continued application of the recapitulation proposition. The puzzle of directionality in embryological development took almost 100 years to solve (von Bertalanffy, 1933).

EVOLUTION AND DEVELOPMENT

"To what extent and in what manner has the work of Charles Darwin influenced developmental psychology?" (Charlesworth, 1992, p. 5). In answering his question on Darwin's impact, Charlesworth concludes that the influence is much less direct and much weaker than has been traditionally accepted. He finds only few direct links to Darwinian propositions or to evolutionary theory in modern developmental psychology. This is regrettable because:

> Darwin's contribution and its current elaborations can enhance developmental research, whereas the latter can assist the former by putting its hypotheses to competent test. (p. 13)

It should be noted that Charlesworth's conclusion on the modest impact of evolutionary theory on developmental psychology is at variance with other judgments in the literature. For example, Kessen (1965) credited Darwin with dramatically changing our concept of children and childhood. This effect, according to Kessen (1965), was both direct (through Darwin's published observations of his infant son) and indirect (through the profound impact of evolutionary ideas on the developmental contributions of Preyer, J. M. Baldwin, Hall, and Taine). A similar conclusion is expressed by Wohlwill (1973), who tracks three lines of Darwinian influence on developmental thought through Baldwin, Preyer, and S. Freud.

The proposition regarding the impact of Darwin depends in large measure on how broadly or narrowly Darwin's influence is defined. As observed above, the study of individual development is rooted in embryology, not in evolution. In her overview of the history of embryology, Jane Oppenheimer (1959) observes that the methods and concepts of embryological science owe little to the concepts of evolutionary biology. Moreover, von Baer himself explicitly rejected the Darwinian construction of evolution.

The picture becomes blurred, however, with Haeckel's (1866) wedding of ontogenetic and evolutionary concepts in the recapitulation principle. Haeckel was an enormously influential advocate of Darwinian evolution in the second half of the nineteenth century, and his influence is strongly represented in Preyer (1882/1888–1889) and Hall (1904). Moreover, a direct line can be drawn from Darwinian commentaries on the evolution of the emotions and intelligence to the work of comparative psychologists Romanes (1889) and Morgan (1896), and from these pivotal figures in the late nineteenth century to the foundation of modern comparative work on psychobiological integration and concepts of learning. The importance of evolutionary themes is told by Sigmund Freud himself (1957). It is also a core message in Sulloway's (1979) intellectual biography that was aptly titled, "Freud, Biologist of the Mind."

Those aspects of Darwin's evolutionary theory that have had only a modest influence on developmental psy-

chology concern its strong implications for the heritability of behavior and the evolution of behavioral propensities. At least one modern model of sociobiology views ontogenetic variation as "developmental noise" (Wilson, 1975). This is because sociobiological emphasis is on (a) variations in structures of societies, not variations in individual life histories, and (b) the biological contributors to those variations in group structures, including the genetic determinants of aggressive behaviors, altruism, and cooperation. As in the logic of Wundt, immature expression of these phenomena in individuals is seen as ephemeral and individualistic; genetic and evolutionary forces may be viewed more clearly when they are aggregated across persons into societal structures (see Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume).

In contrast, evolutionary concepts have had a major impact on research in comparative studies of development in animals from the mid-nineteenth century to the present. In England, Douglas Spalding (1873) reported the remarkable effects of early experience in establishing filial preferences in newly hatched chicks. His experimental demonstrations seemed to confirm that phyletic and ontogenetic influences must operate in tandem, that the young animal was predisposed to form preferences during a period of high sensitivity shortly after hatching, and that the experiences that occurred then were especially effective in the rapid establishment of preferences.

George John Romanes, a young scientist who had the confidence of Darwin, was impressed by Spalding's demonstrations and, with him, emphasized the early formation and plasticity of behavior within the framework of its evolutionary foundation. More generally, Romanes's analysis of the stage-paced development of sexuality and cognition served as a basic text for the two most important theorists in developmental psychology, Sigmund Freud and James Mark Baldwin. *Mental Evolution in Man* (Romanes, 1889) was one of the most annotated books in Freud's library, and Sulloway (1979) suggests that it provided inspiration for Freud's later emphasis on the early appearance of infantile sexuality. In accord with recapitulation theory, Romanes had placed the onset of human sexuality at 7 weeks. J. M. Baldwin (1895), for his part, gives explicit credit to Romanes and Spencer as providing inspiration and direction to the work embodied in his *Mental Development in the Child and the Race.* It should also be observed that Romanes, whose aim was to clarify the evolution of the mind and consciousness, is also regarded as the father of comparative psychology (Gottlieb, 1979; Klopfer & Hailman, 1967).

Studies of behavioral development in nonhumans were also rapidly becoming a focal concern in North America. The Canadian physiologist, Wesley Mills, offered an especially clear statement of the need for developmental studies in a *Psychological Review* paper that appeared in 1899. In the article, Mills took E. L. Thorndike (1898) to task for his narrow view of how experimental analyses can contribute to understanding animal learning and intelligence.

For Mills, the notions of ecological validity and biological constraints on learning would not be unfamiliar ideas. In a remarkable passage, Mills (1899) outlines a strategy that anticipates the importance of understanding development in context. He wrote:

> Were it possible to observe an animal, say a dog, from the moment of its birth onward continuously for one year, noting the precise conditions and all that happens under these conditions, the observer being unnoticed by the creature studied, we should, I believe be in possession of one of the most valuable contributions it is possible to make to comparative psychology. This would imply not one, but several persons giving up their whole time, day and night, by turns, to such a task. As yet, but very imperfect approaches have been made to anything of the kind; nevertheless, such as they have been, they are the most valuable contribution thus made, in the opinion of the present writer, and the more of such we have the better.
>
> If to such a study another were added, in which the effect of altering conditions from time to time with the special object of testing the results on an animal or animals similarly closely observed from birth onward, we should have another most valuable contribution to comparative psychology; but experiment on animals whose history is unknown must, in the nature of the case, be very much less valuable than in such an instance as that just proposed. (p. 273)

However convincing Mills's proposals may appear in retrospect, E. L. Thorndike completed the work, and experimental methods won the battle of the day and, for the most part, the war of the century. By the next generation, experimental studies of learning in animals and children were dominated by Thorndikian short-term, nondevelopmental experimental designs, at least in the United States. It should be noted, in Thorndike's defense, that the main point of his experimental laboratory work, first described in *Animal Intelligence* (1898, p. 1), was to clarify "the nature of the processes of association in the animal mind." It was, in effect, the study of

animal consciousness and the role that representation plays in learning methods. Thorndike's statement of the "law of effect" proved to be enormously influential.

In summary, thoughtful investigators of development in nonhuman animals have been concerned with evolutionary and ontogenetic issues and how they are interrelated. The focus was reflected in the work of Romanes (1889), Morgan (1896), and Mills (1898) in the latter part of the nineteenth century, and in the work of Z.-Y. Kuo (1930), Schneirla (1959), Tinbergen (1972), and Hinde (1966) in the mid-twentieth century. This dual concern, along with the research on animals and young humans that it has stimulated, has helped establish the conceptual and empirical foundations for a fresh developmental synthesis. Whether Darwinian thought has been influential for modern developmental psychology depends on which evolutionary ideas are evaluated and which aspects of developmental psychology are examined.

THE EMERGENCE OF DEVELOPMENTAL PSYCHOLOGY (1882–1912)

Developmental studies flourished *despite* the influence of traditional psychophysical laboratories rather than because of it. The study of behavioral and mental development was going full steam in the 1890s. By mid-decade, genetic or developmental psychology had its own scientific journals (*L'Année Psychologique,* 1894; *Pedagogical Seminary,* 1891, later to be renamed the *Journal of Genetic Psychology*), research institutes (Sorbonne, 1893; Clark University, 1890), influential textbooks (e.g., *The Mind of the Child,* 1982; *L'Évolution Intellectuelle et Morale de l'Enfant,* 1893; *Mental Development in the Child and the Race,* 1895), professional organizations (e.g., Child Study Section of the National Education Association, 1893; Société Libre pour l'Étude Psychologique de l'Enfant, 1899), and psychological clinic (University of Pennsylvania, 1896). As early as 1888, Hall was able to refer to the "nearly fourscore studies of young children printed by careful empirical and often thoroughly scientific observers" (Hall, 1888, p. xxiii). The field had advanced so far that it was christened with a name—Paidoskopie—to emphasize its newly won scientific independence (Compayré, 1893). Happily, the activity survived the name.

There is, however, no strong consensus on which year should serve as an anchor for developmental psychology's centennial. The problem is that the area is now sufficiently diverse so that one can point to several landmark dates, depending on which movement or which pioneer one wishes to commemorate. The founding of the child development research institute at Clark University and the establishment of the journal *Pedagogical Seminary,* by Hall, were clearly of signal importance for the area. But to celebrate Hall's contributions over those of Alfred Binet can hardly be justified. Binet, at almost the same time, was laying the foundations for modern experimental child psychology at the Sorbonne and establishing *L'Année Psychologique* as a prime source for developmental publications. Perhaps the dilemma may be eased by recognizing that these major advances were themselves beneficiaries of a zeitgeist that seems to have begun about 1880 and gained significant momentum with the publication of William Preyer's *The Mind of the Child* in 1882/1888–1889.[2]

The book has been called "the first work of modern psychology" (see Reinert, 1979), providing "the greatest stimulation for the development of modern ontogenetic psychology" (Munn, 1965).

Not everyone agrees with these high evaluations of Preyer's work or of its originality (see, for instance, Bühler, 1930; Kessen, 1965; and below). Nonetheless, Preyer's book served as a powerful catalyst for the further study of development in psychology and in biology, and 1882 seems to be a reasonable date for us to begin this story of the development of modern developmental psychology. In addition to Hall and Binet, two other persons—James Mark Baldwin and Sigmund Freud—contributed much to the molding of the area. The nature and extent of their contributions are the main focus of this section.

Embryos and Infants

When *The Mind of the Child* was published, William T. Preyer (1841–1897) intended it to be only the first in-

[2] There is some ambiguity about the actual publication date of *The Mind of the Child.* In the preface to the second edition, Preyer tells us that "the first edition of this book appeared in October, 1881" (p. xvi). That seems straightforward enough, but the publication date of the original German work was 1882. The discrepancy apparently arose because of the lag between the time when the author signed off the Preface (in Jena, October 6, 1881) and the time the finished book was actually published. Similar ambiguity surrounds the traditional assignment of 1879 as the founding of Wundt's laboratory; it was an ongoing enterprise at the time, and William James claimed priority anyway.

stallment of a more comprehensive study of the nature of development. He completed the project 4 years later, with publication of *The Special Physiology of the Embryo* (Preyer, 1885). That these two contributions were not translated together and studied as a unit is a pity, for, in Preyer's mind, the issues to which they were addressed were mutually dependent and complementary. Preyer assumed that the methods and concepts applicable to embryological study could be applied with advantage to behavioral study, and that investigations of the one would support and complement investigations of the other. Why then two books? As Preyer (1882/1888–1889) explains it:

> I proposed to myself a number of years ago, the task of studying the child, both before birth and in the period immediately following, from the physiological point of view, with the object of arriving at an explanation of the origin of separate vital processes. It was soon apparent to me that a division of the work would be advantageous to its prosecution. For life in the embryo is so essentially different a thing from life beyond it, that a separation must make it easier both for the investigator to do his work and for the reader to follow the expositions of the results. I have, therefore, discussed by itself, life before birth, in the "Physiology of the Embryo." (p. ix)

Preyer completed work on both phases of the project, embryogenesis and postnatal development, in a significant number of species (including humans). It is almost true that his feat has yet to be matched by another single investigator.

What drew Preyer to the study of development in the first place? That question cannot be answered definitively, but we do know that he was trained in physiology in Germany and, with others of his generation, came under the spell of Ernst Haeckel's vision of the unity of science and the centrality of development in evolution and life. Preyer recognized that the scientific program of modern biology would be incomplete without a careful analysis of human development from conception through maturity, and that such a program would necessarily be interdisciplinary. As he put it, such prenatal and postnatal observations "are necessary, from the physiological, the psychological, the linguistic, and the pedagogic point of view, and nothing can supply their place" (1882/1888–1889, pp. 186–187). Beyond Preyer's appreciation that intellectual and scholarly breadth were required for the productive study of children, he established methodological standards for the enterprise. The procedures that he endorsed, and followed, belied the proposition that children, even immature and unborn ones, could not be studied objectively and with profit.

Preyer was not the first person to undertake detailed observations of his offspring for scientific purposes. A professor of Greek and philosophy at the University of Marburg, Dietrich Tiedemann (1748–1803), had earlier employed the method, and his 1787 monograph *Observations on the Development of Mental Capabilities in Children* (Murchison & Langer, 1927), seems to have been the first known published psychological diary of longitudinal development in children, according to Reinert (1979). In the 100 years between Tiedemann and Preyer, several studies appeared, some of which were sufficiently free of parental bias and distortion from other sources to be considered useful scientific contributions (Reinert, 1979, has an informative account of this work).

An article by Charles Darwin played an important role in stimulating further interest in the endeavor. In 1877, it appeared in the new psychological journal *Mind,* having been triggered by the appearance, 2 months earlier, of a translation of H. Taine's (1876) parallel observations in the immediately preceding issue. Darwin's article was based on 37-year-old notes he made during the first two years of one of his sons. Although inferior to the other reports in terms of systematicity of observation and depth of reporting, Darwin's contribution served to legitimize the method and promoted research with children.

The methodological standards that Preyer established for himself are admirable, even by today's criteria. He reports that he "adhered strictly, without exception," to the following rules:

- Only direct observations were cited by the investigator, and they were compared for accuracy with observations made by others.
- All observations were recorded immediately and in detail, regardless of whether they seemed uninteresting or "meaningless articulations."
- To the extent possible, observations were unobtrusive and "every artificial strain upon the child" was avoided.
- "Every interruption of one's observation for more than a day demands the substitution of another observer, and, after taking up the work again, a verification of what has been perceived and noted down in the interval."

- "Three times, at least, every day the same child is to be observed, and everything incidentally noticed is to be put upon paper, no less than that which is methodically ascertained with reference to definite questions" [*The Mind of the Child* (1882/1888–1889), vol. 2, pp. 187–188].

In brief, most problems of observation and categorization were anticipated by Preyer, including those of reliability and observer agreement.

How Preyer chose to organize his findings is almost as interesting as his methods and findings. For Preyer, the mind of the child, like Gaul, can be divided into three parts: (1) senses, (2) will, and (3) intellect. Because his knowledge about the comparative development of vision, hearing, taste, smell, touch, and temperature perception was surprisingly broad, many—but not all—of Preyer's (1882/1888–1889) generalizations on the "Development of Senses" were on target. A few of his statements were demonstrably wrong. For instance, he wrote "the normal human being at birth hears nothing" (p. 96). Preyer arrived at an opposite (and correct) set of conclusions on the capabilities of various nonhuman species to hear at birth. In light of the care and precision of most of the observations, it's puzzling that Preyer made such an elementary error. In retrospect, we may speculate that a primary flaw was theoretical rather than methodological. Preyer's conclusions on neonatal incompetence were colored by his general assumption that human beings were less mature at birth than were species ancestral to them (i.e., neoteny). This was not the first time, nor the last, that strongly held hypotheses about the nature of children led to erroneous conclusions, despite disconfirming empirical evidence.

The "Development of Will" provided an informative and informed analysis of the onset of such patterns as sitting, grabbing, pointing, standing, and other motoric acts. But Preyer was looking for more than a behavioral inventory: He hoped to find out how the pattern arose. For instance, "deliberate" pointing seemed to arise from the early action of abortive "seizing" or "grabbing," and only at about 9 months of age did "pointing" gain the capacity to signal to others the child's wants and needs. Among other things, he concludes: "The first deliberate intention-movements occur only after the close of the first three months" (p. 332). Preyer thus found, in the study of the development of movement patterns, reflexes, and other actions, a possible clue to the systematic analysis of the onset of intentionality.

The third part of *The Mind of the Child,* "Development of Intellect," includes the consideration of language comprehension and production as well as the development of social cognition, including the concept of the self. Preyer's discussion proceeds, with uncommonly good sense, from a description of the onset of landmarks of language development to an attempt to determine when the notion of "ego," or the self, develops. For Preyer, it occurs when the child can recognize "as belonging to him the parts of his body that he can feel and see" (p. 189). Whatever the other merits of that proposal, it permits Preyer to undertake a series of observations and mini-experiments on the matter. One section deals with the ability of children to respond to their reflections in a mirror; another, with the uses and misuses of personal pronouns by young children.

In addition to his study of infancy and early childhood, Preyer left another legacy to modern developmentalists, *The Special Physiology of the Embryo* (1885). To complete his analysis of the "origin of separate vital processes," Preyer conducted experiments and made observations on the embryos of invertebrates, amphibia, birds, and various mammals. Some of these observations—on the prenatal development of sensory and motor functions—have only recently been confirmed and extended using modern techniques. In line with recent interpretations of early development, Preyer concluded that (a) integrated, spontaneous motor activity was antecedent to the development of responsiveness to sensory stimulation, and (b) motor activity may provide the substrate for later mental, emotional, and linguistic performance. Because of his pioneering studies, he is acknowledged to be the father of behavioral embryology (Gottlieb, 1973).

Preyer has sometimes been depicted as the prototypic methodologist—careful, precise, compulsive, and pedestrian. On this score, Karl Bühler (1930) writes that *The Mind of the Child* was "a remarkable book full of interesting and conscientious observations, but poor in original ideas" (p. 27) and that "Preyer himself was no pioneer in psychology" (p. 27). Others have echoed the exact words, along with the sentiment that his book was more like a developmental psychophysiology than a developmental psychology (Reinert, 1979).[3]

[3] Did cultural stereotypes play a role in the evaluation of *The Mind of the Child?* For instance, Compayré (1893) called the book a "monument of German assiduousness." Mateer (1918) remarked (in the context of comparing Frenchman Peréz's

Has Preyer's empirical reputation outrun his theoretical contribution to developmental psychology? The answer depends in part on what aspects of theory one chooses to focus on. Preyer's main concern in preparing both *Mind of the Child* and *Special Physiology* was the clarification of a basic issue of development: the relations between ontogeny and phylogeny of behavior, and how these two processes influenced each other. His categorization of the dates of onset was *not* an end in itself, to develop a behavioral timetable. Rather, his aim was to establish the lawful sequence of development of sensory and cognitive systems so that meaningful generalizations could be drawn between species and among systems in development.

Hence, for Preyer (1882/1888–1889), one key theoretical issue was how to reconcile competing claims of the "nativists" and the "empiricists" in the origin and perfection of the "vital processes" of behavior and thought. As far as human vision (or other sensory processes) was concerned, he concluded that "my observations show that . . . *both parties are right*" (vol. 1, p. 35, emphasis added). In a discussion that constitutes an early model for the developmental landscape of C. H. Waddington (1971), he speculates that "The brain comes into the world provided with a great number of impressions upon it. Some of these are quite obscure, some few are distinct" (vol. 2, p. 211). Through experience, some of the pathways are obliterated, and others are deepened.

Lest Preyer be written off as a naïve nativist, it should be added that his position was closer to the bidirectional approach of modern developmental psychobiology than to the innate ideas of Immanuel Kant. Drawing on studies of the comparative anatomy of the brain as well as cross-species comparisons of behavior, he concluded (1882/1888–1889) that there is feedback between experience and normal structural development in the brain. He offered a foresightful statement of the bidirectional structure-function hypothesis, reaching the conclusion that "*The brain grows through its own activity*" (vol. 2, p. 98, emphasis added). How then does the individual contribute to his or her own development? Preyer's answer was clearly speculative, but it followed the same line of reasoning that is reflected in the structure-function bidirectional proposals offered in the next century by developmental psychobiologists and modern neurobiologists. (See also Brandtstädter, Chapter 10; Gottlieb et al., Chapter 5, this *Handbook,* this volume.)

The theoretical import of Preyer's behavioral timetable comes into focus when viewed in the context of Haeckel's biogenetic law. Its key assumption was that human maturation was *accelerated* with respect to ancestral species. That is, as noted earlier, in this concept humans are presumed to pass through the several stages of development more rapidly than the species from which they were derived, so that evolutionary "novelties" and distinctively human characteristics appear at maturity, not in infancy. To be tested, the view required precise information about the relative rates of maturation; hence, the need for exactness in plotting the onset of particular behaviors. But Preyer was not a biogenetic apologist. He offered the compelling hypothesis that humans' maturation rate was retarded relative to ancestral species, an idea that ran counter to the accepted version of recapitulation. Human beings should enjoy a longer (not shorter) period of immaturity than their closest phyletic relatives. Accordingly, in most "vital processes" and behavior, there should be relatively greater plasticity in development and opportunities for learning for children than for nonhuman animals (vol. 1, pp. 70–71, 1882/1888–1889). This is essentially an early statement of behavioral neoteny: The relatively slower rate of maturation should be an advantage in making for an extended period of curiosity, flexibility, and adaptability in human beings (see also Fiske, 1883). Echoes of his theoretical interpretations can be found in modern studies of ontogenetic-phyletic relations (e.g., Cairns, 1976; de Beer, 1958; Mason, 1980) and the bidirectionality of structure-function relations (e.g., Gottlieb, 1976; Z.-Y. Kuo, 1967).

Tracing the heritage that Preyer left for developmental study, we find that he set high standards for scientific observation of behavioral development. Though not unflawed, his observations were carefully recorded and sanely written. For those who followed him, Preyer embedded the study of children in the framework of biological science, and he demonstrated how interdisciplinary techniques could be employed. Beyond the methodological message, there was a theoretical one. Preyer was a man of his times, evolutionary in outlook and committed to the clarification of the relations between ontogeny

"logical, brilliant style" with that of Preyer) that: "The French write brilliantly and convincingly but their technique is apt to be at fault. They seem to hit intuitively upon right premises and conclusions, although their data may be unconvincing or scanty. The German work is more stolid, more convincing in its facts but less inspiring in application" (p. 24).

and phylogeny, between nature and nurture. Surprisingly, he was perhaps as influential in embryology as in developmental psychology. Through his work, talented young men and women were recruited to experimental embryology (including Hans Spemann, who identified "critical periods" and "organizers" in embryological development). Perhaps most important, Preyer demonstrated, by his successful integration of experimental studies of human and nonhuman young, that the investigation of behavioral development could be as much a scientific enterprise as a social, humanistic movement. Happily, other colleagues in America and Europe understood the message.

Memory and Intelligence

In an article on the scientific contributions of Alfred Binet (1857–1911), Siegler (1992) observes: "It is ironic that Binet's contribution should be so strongly associated with reducing intelligence to a single number, the IQ score, when the recurring theme of his research was the remarkable diversity of intelligence" (p. 175). That is only one of the ironies in Binet's work and life. Another is that he was arguably the greatest French psychologist of his day; yet, he was unable to obtain a professorship in France. Moreover, the intelligence test that he developed with Simon, which was intended to provide guides on how "to learn to learn," has been used over the past century as a basis for classifying children and adults into intellectual categories that are presumed to be constant over life.

Statements about historical priority and influence are delicate matters, but among non-French observers there is no serious debate over the claim that Alfred Binet was France's first significant experimental psychologist.[4] What makes his work of special importance for this chapter is that he was the premier early experimental child psychologist whose observations extended beyond the laboratory. The results have been far-reaching. Jenkins and Paterson (1961) observed, "Probably no psychological innovation has had more impact on the societies of the Western world than the development of the Binet-Simon scales" (p. 81). Given the influence of this procedure identified with Binet's name, it is understandable, yet regrettable, that his other contributions to developmental psychology have gained so little attention. As it turns out, it took experimental child psychology some 70 years to catch up with some of Binet's insights on cognition and the organization of memory.

Throughout his career, Binet was characterized by an independence of thought and action, starting with his introduction to psychology. It was his third choice in careers, after he had dropped out of law school and medical training (Wolf, 1973). In 1879/1880, Binet began independent reading in psychology at the Bibliothèque Nationale in Paris. Curiously, he selectively avoided experimental psychology (the Wundtian version) by reading little or no German, and he took no trips to Leipzig. Shortly after he began work in psychology, he published his first paper, a useful discussion of experiential contributions to the psychophysics of two-point tactile discrimination. For research training, Binet affiliated himself with the distinguished neurologist, Jean Martin Charcot, at the Salpêtrière (a noted Paris hospital). Over a period of seven years, Binet collaborated with Charcot and Charles Féré in studies of hypnotism and its expression in normal persons and in the patient population. Binet's introduction to "experimental methods" thus was some distance removed from the then-acceptable laboratory procedures. His apprenticeship in research led to some spectacular controversies, with young Binet in the middle of the fray. The problem was that certain phenomena reported by the Salpêtrière group defied credibility—for example, that the effects of hypnotic suggestion migrate from one side of the body to the other by virtue of electromagnetic influences (a very large magnet was used in demonstrations). Attempts to replicate the phenomena elsewhere proved unrewarding. As it turned out, the research procedures followed by Binet and Féré were remarkably casual, and they gave scant attention to the possible suggestibility of their subjects or of themselves (see Siegler, 1992).

An absurd idea? In light of our present knowledge about the brain and hypnotism, it was a thoroughly naïve proposition. But this is the stuff out of which discoveries are made. Féré shortly afterward (1888) became the first investigator to discover that emotional changes were correlated with electrical changes in the human body. Naïve or not, he is credited with discovering the resistance method of measurement and developing the

[4] But not France's first child psychologist. Peréz (1851/1878) published his *The First Three Years of the Child* several years before Preyer's *The Mind of the Child* (1882/1888–1889). The two authors covered the same ground, but, as Reinert (1979) indicates, Peréz was generally considered to be the more imaginative and Preyer the more methodical.

first statement of arousal theory (Thompson & Robinson, 1979, p. 444).

While he was at the Salpêtrière, Binet's research skills were simultaneously being sharpened in the embryological laboratory of E. G. Balbiani. He became acquainted firsthand with the rigorous procedures of biological research and the then-current concepts of evolution, development, and genetics. This work culminated in 1894 with his being awarded a doctorate in natural science from the Sorbonne and his appointment as Director of the Laboratory of Physiological Psychology at the same institution. In that year, Binet also founded and edited *L'Année Psychologique,* co-authored two books (one dealing with the determinants of the extraordinary memory feats of chess masters and calculators; the other, a critical treatment of the methods and approaches of experimental psychology), and published 15 articles. Among the articles were studies of the psychology of aesthetics, suggestibility, the nervous system of invertebrates, perception in children, and studies on the development of memory. Only one year's work? No, because some of the studies had been ongoing over the previous 2 to 3 years; yes, because his publication list was just as impressive in 1895 as in 1894. This pattern was maintained until his death in 1911; except that, later in his career, he also wrote and supervised plays that were produced in Paris and London (Wolf, 1973).

Prolificacy can be embarrassing if one hasn't much to write about. That seems not to have been a problem for Binet, due in large measure to his "very open, curious, and searching" mind. Binet was so described when, prior to completing his doctorate, he was named laureate by the Moral and Political Academy of the Institute of France (Wolf, 1973). Although he began his research training in the library, he soon became committed to the task of expanding the empirical foundations of the area in ways that seemed novel if not heretical. He early rejected the conventional methods of experimental psychology (as it had been practiced in Leipzig and Baltimore) as being narrow and misleading. On introspective experiments, he wrote, in his *Introduction to Experimental Psychology:*

> Subjects go into a little room, respond by electrical signals, and leave without so much as a word to the experimenter. . . . With the three choices only—"equal," "greater," or "less"—they often seem to set up the results of the experiments in advance. Their aim is simplicity, but is only a factitious one, artificial, produced by the suppression of all troublesome complications. (Binet, Phillippe, Courtier, & Henri, 1894, pp. 28–30)

Nor was he impressed by the large-scale studies by Hall and his students, who used the questionnaire methodology. On the latter, Binet (1903) wrote:

> The Americans, who love to do things big, often publish experiments made on hundreds or even thousands of persons. They believe that the conclusive value of a study is proportional to the number of observations. That is a myth. (p. 299)

These hardly were the sorts of comments that would endear him to his U.S. and German colleagues, and Howard C. Warren, one of the more generous reviewers, reciprocated by "confessing to a feeling of disappointment when it is considered what even a short book like this might have been" (Warren, 1894).

What Binet had to offer psychology was a pragmatic, multimethod, multipopulation approach to the problems of behavior. Instead of relying merely on introspection and psychophysiological experimentation, Binet thoroughly dissected behavioral phenomena. To explore memory, for instance, he varied the nature of the stimuli (memory for figures and for linguistic material; memory for meaningful sentences versus individual words), the subjects tested (chess masters and superior "calculators" who performed on the stage; normal children and retarded children), measures employed (free recall, recognition, physiological measures of blood pressure, and electrical activity), type of design (large group samples, individual analysis over long-term periods), and statistics employed. Through it all, Binet selected designs, procedures, and subjects with a purpose, not merely because they were available. To investigate imagination and creativity, he studied gifted playwrights and explored new techniques (inkblots, word association, and case history information).

Such methodological catholicism is not without pitfalls. He was open not only to new discoveries but to new sources of error. In his day, he received high praise and devastating criticism for his work, and both seemed earned. The early studies were vulnerable: Binet was in the process of learning a trade for which there were, as yet, no masters. He came out on the short end of a devastating exchange on the "magnetic" nature of hypnotism (Siegler, 1992), and there was equally justified

criticism by H. S. Jennings (1898–1899) on Binet's interpretations of his studies on the psychic life of the lower beasts. S. Franz (1898), a student of J. M. Cattell, took him to task for the quality of his statistical presentation in a series of studies on the relation between cognition and physical measures in children. Florence Mateer (1918) doubtless had Binet in mind when she commented that "the French write brilliantly and convincingly but their technique is apt to be at fault" (p. 24). Such errors—and the attitudes they fed—unfortunately masked the fundamental brilliance of Binet's work. Though shy in personal demeanor, Binet as a scientist was not a timid man; he was outspoken, and his criticism of naïve generalizations and wrongheaded conceptualizations placed him at odds with beliefs held by then-dominant leaders of the discipline. He published what he believed, and seems to have judged the long-term gains to be worth the short-term costs to his career and influence.

Binet reported demonstrational studies of memory and perception that he had conducted with his two young daughters. The work was extended in succeeding years not only with his children (through adolescence) but also with diverse subjects and areas of memory. Along with his collaborators, notably Victor Henri, the work was extended to persons who were extraordinarily talented or retarded. Because Binet operated on the working assumption that the study of normal processes was the key to understanding special talents or deficits, his laboratory also made a major investment in the analysis of memory in normal children, adolescents, and adults. Binet was highly sensitive to the need for convergent analyses that intersect on a common problem. He argued in 1903 that "our psychology is not yet so advanced" that we can limit our analyses to information obtained in the laboratory; rather, complex intellectual functions are best understood in studies of persons "whom we know intimately, to relatives and friends."

Binet did not, however, disdain large-scale research designs; he simply believed that they were insufficient *in themselves* to tell the full story about the nature of memory processes. In collaboration with Henri, he conducted a remarkable series of studies on memory development that involved several hundred children.

In one of their analyses, Binet and Henri (1894) found that the children reconstructed material into chunks of information that were meaningful to them. It should be noted that this idea of active reorganization has now returned to occupy the attention of "modern" views of memory and recall (e.g., Paris, 1978). In the words of Binet and Henri, as translated by Thieman and Brewer (1978):

> The children have a tendency to replace a word from the spoken text when the word appears in a rather lofty style, with another word with which they are better acquainted, and which they encounter more often in their own conversation. Their act of memory is accompanied by an act of translation. (p. 256)

How Binet and his colleagues chose to follow up this experimental work is instructive. Noting that other researchers might do things differently, Binet embarked on an intensive study of "superior functions" in relatives (namely, his two adolescent daughters) and friends. Binet did not give up on experimental designs so much as he extended their boundaries by conducting experiments on persons whose histories and characteristics were known intimately to him. For Binet, the key to unlocking the secrets of intelligence involved not only mapping its outline in large-scale studies but also making a detailed tracing of its internal features in individual analysis. This movement back and forth—from a focus on individuals to a focus on large samples, then back to individuals—was a distinctive and deliberate research strategy.

Attention to two or three children, rather than to a single individual or to large samples, inevitably leads one to a focus on the differences among them. So it was with Binet. He was not the first psychologist to be curious about differences among persons and their assessment and explanation. Francis Galton had earlier used sensory discrimination tests to assess differences in basic abilities. The rationale for such tests was stated succinctly by Galton (1883): "The only information that reaches us concerning outward events appears to pass through the avenue of our senses; and the more perceptive the senses are of difference, the larger is the field upon which our judgment and intelligence can act" (p. 27).

In other words, modest differences at the level of sensation would be directly reflected in "complex" cognitive functioning, or would be multiplied. A similar rationale (and research strategy) was recommended by the U.S. psychologist, James McKeen Cattell, in an article entitled "Mental Tests and Measurement" (1890). Specifically, Cattell proposed that mental measurement should employ several tests of "basic" sensory and motor abilities, including assessments of color discrimination, reaction time, and other standard psychophysical

procedures. Other experimental psychologists—including Joseph Jastrow at Wisconsin, Hugo Munsterberg at Freiberg, and J. A. Gilbert at Yale and Iowa (1894, 1897)—concurred.

Characteristically, Binet and Henri (1895) took an approach that was radically different from that of their U.S. and German colleagues. It was, however, wholly consistent with the conclusions they had arrived at in their earlier studies of memory development; namely, it was absurd to focus on elementary units of memory as opposed to a recall for ideas and meaning. Furthermore, from Binet's studies of individuals, it seemed clear that great differences could be observed among persons of "higher" mental functions, including language skills, suggestibility, commonsense judgments, and imagination. Binet and Henri (1895) thus argued for a methodological strategy that was precisely opposite to that of Galton and Cattell:

> The higher and more complex a process is, the more it varies in individuals; sensations vary from one individual to another, but less so than memory; memory of sensations varies less than memories of ideas, and so on. The result is that if one wishes to study the differences between two individuals, it is necessary to begin with the most intellectual and complex processes, and it is only secondarily necessary to consider the simple and elementary processes. (p. 417)

Although "complex processes" are more difficult to measure than simple ones, less precision is required because individual differences in complex functions are much greater than in elementary ones. The more fundamental problem that Binet and Henri identified is that it is easier to separate the intellect into its parts than it is to put the elements together and create a functioning, competent whole. The greatest challenges arise not in the initial assessment of sensory elements but in determining how they should be *combined* to predict intellectual performance. How should the components be appropriately weighted, and what is the nature of the process by which sensations are translated into cognitions? The solution that Binet and Henri offered was a wholly pragmatic one: Bypass the recombination problem and assess the complex functions directly. Given this simplifying solution, Binet and Henri outlined a programmatic approach to the assessment of individual differences that was completed 10 years later.

The child study movement in France directly contributed to the eventual development of workable mental tests. Soon after the formation of the *Société Libre pour l'Étude Psychologique de l'Enfant* (Society for the Psychological Study of the Child), Binet was invited to become a member and he shortly became a leading voice in its activities and publications. The *Société* not only prodded the Ministry of Public Instruction to think constructively about the needs of retarded children, but was also influential in having a commission appointed to set up special classes. Binet, as a leader of the Société, was appointed to the commission. It was not entirely coincidental, then, that he was invited to develop tests for identifying children who could benefit from special instruction, and the results of the work were reported in a series of articles in *L'Année Psychologique* in 1905 (Binet & Simon, 1905) and later extended (Binet, 1908, 1911). Although the articles offered guidelines for assessment in each of three areas (medical, educational, psychological), their greatest attention was given to psychological tests. The 30 tests of the 1905 scale followed the outline offered by Binet and Henri (1895) some 10 years earlier, except some procedures—including the suggested use of inkblots to study imagination—were omitted and new techniques were borrowed from other investigators—among them, Ebbinghaus's incomplete sentence technique (1897) and Jacobs's (1887) "memory for digits" test.

Although most of the basic concepts of intelligence test construction were reflected in the initial scale (e.g., multiple tests arranged in order of difficulty, various areas of competence tested, age standardization, and external validation), the refinement of the scale so it could be used productively with normal children required extensive further revision. The task was begun by Binet (1908, 1911) and completed by U.S. developmental psychologists, notably Goddard (1911) and Terman (1916). Despite the magnitude of their achievement, Binet and Simon (1905) were fully aware of the limitations of the technique as well as its promise. They wrote in conclusion:

> We have wished simply to show that it is possible to determine in a precise and truly scientific way the mental level of an intelligence, to compare this level with a normal level, and consequently to determine by how many years a child is retarded. Despite the inevitable errors of a first work, which is of a groping character, we believe that we have demonstrated this possibility. (p. 336)

They had indeed.

Binet eschewed identification as a theorist, even declining initially to offer a definition of intelligence, "a problem of fearful complexity." He added, in 1908:

> Some psychologists affirm that intelligence can be measured; others declare that it is impossible to measure intelligence. But there are still others, better informed, who ignore these theoretical discussions and apply themselves to the actual solving of the problem. (p. 163)

Despite his disinclination to define intelligence, Binet was not hesitant to take a strong stand on the nature of intellectual functioning and its determinants. The design of the tests themselves reflects the assumption that the aim was to diagnose different levels of functioning, not to assess the child's "faculty" for thought. Consistent with this functional view of cognitive processing, Binet argued that one of the test's primary virtues would be to identify children who needed to "learn to learn." For Binet, intellectual adaptation reflected dynamic, ever-changing processes that underwent constant modification and reorganization; hence, he focused on the ways that these processes become organized over time, and their "plasticity and extendibility" (1909/1978, pp. 127–128). On this score, he proposed a program of "mental orthopedics" that should be followed to enhance cognitive functioning. In *Les Idées Modernes sur les Enfants* (1909/1978), Binet specifically deplores the notion that "the intelligence of the individual is a fixed quantity" and protests the idea as "brutal pessimism" (p. 126). Ironically, exactly the opposite assumption fueled the enthusiasm of most U.S. translators for the test, along with the conviction that this "fixed quantity" is hereditarily determined, and a child's "true score" can be identified within limits of sampling error.

How can we summarize Binet's primary contributions to understanding development? Beyond his specific insights on psychological phenomena, three fundamental advances may be attributed to this remarkable scientist. The first concerns the insight that the assessment of individual differences in higher-order cognition requires a molar rather than a molecular strategy. In retrospect, the idea seems to make a good deal of sense, but it was embraced by U.S. psychology only after the research of Binet and Simon made the conclusion inescapable. After all, it seems intuitively obvious that precise, microanalytic experimental methods *should* be superior to molar, complex ones in predicting everyday behavior. The idea dies slowly, and it is alive and well today in the study of social development. As with cognition, recent molecular analyses of social interactions appear to fare less well in prediction and classification than do molar assessments of the same phenomena. Exactly why molar techniques have an advantage continues to be a matter of debate, and Binet's analysis may still be the key.

A second contribution is related to the first. For Binet, the "two sciences of psychology," described later by Cronbach (1957), were both essential. Binet pioneered both experimental child psychology and the study of individual differences. His stance on the matter is embodied in the methodological credo: "To observe and experiment, to experiment and observe, this is the only method that can obtain for us a particle of truth" (Binet, 1904/1973, p. 293). As Binet saw it, problems inevitably arise when the two basic methodologies are divorced. If questions are raised that cannot be settled by experimentation, then they should be dismissed "since they are not susceptible to the sole criterion of certainty" that modern psychology can accept.

One other, more general legacy requires comment. Beyond the other pioneers in the field, Binet was one of the first to provide convincing evidence for the proposition that a *science* of human development was possible. He understood the complexity of the problem, but he persevered in the attempt to help developmental psychology "become a science of great social utility" (Binet, 1908). Binet demonstrated that an empirical science of behavioral development in humans was within grasp, if the investigator maintained a profound respect for the information yielded from the dual methods of observation and experimentation.

THE NEW PSYCHOLOGY IN THE UNITED STATES

In leading the organization of the new science of psychology in the United States, Hall (1844–1924) had no peer. In his long career, he proved to be an effective and durable advocate, writer, and spokesman for psychology and for children in the United States. The story of Hall's career has been expertly told by Ross (1972) and White (1992), with the latter providing fresh insights on Hall's role in science and social policy. Born in Massachusetts, Hall was a minister, professor of philosophy, experimental psychologist, child psychologist, educational psychologist, university president, and

leader of the child study movement. He was also a premier figure in U.S. psychology: the first professor of psychology in the United States (at Johns Hopkins, 1883) and the first president of the American Psychological Association (1891). As is the case with truly effective teachers, Hall had great enthusiasm and tolerance for ideas, and he was a master at conveying his enthusiasm to others. He had a large vision for psychology and its destiny in creating better persons and a more perfect society.

But how did he fare as a scientist and a theorist in the light of history? In the previous edition of the *Handbook,* this chapter concluded that Hall had a large influence on the growth and organization of the new psychology in the United States, and that he provided a foundation for the scientific study of children and adolescents. It was concluded that Hall's own research contributions were modest and his theoretical proposals were flawed by being too tightly woven to the informed beliefs of his day and too loosely linked to empirical data. The grand vision of the science that he offered had only modest substance. After spending several years carefully sifting the evidence, Sheldon White (1992) has arrived at a radically different conclusion regarding Hall's contributions. He observes:

> Recent writings usually picture Hall as a functionary and figurehead, condense his ideas into a few slogans, quote criticisms of his work by his often rivalrous peers, and effectively concede Hall his administrative trophies while ignoring most of what he had to say. (p. 33)

Some did listen to what Hall had to say because, like Mark Hopkins, his mentor at Williams College, he was a masterful teacher (White, 1992). Lewis Terman, Arnold Gesell, and E. C. Sanford were strongly influenced by Hall in their graduate training at Clark University. John Dewey, James McKeen Cattell, and Joseph Jastrow took courses from Hall at Johns Hopkins. Others—including Earl Barnes, who initiated investigations of children at Leland Stanford Junior University in the 1890s—were attracted to Hall's method and perspectives through the child study movement (Goodwin, 1987; Zenderland, 1988). These scientists helped shape the face of twentieth-century psychology in the United States.

Hall's introduction to developmental psychology occurred in 1880, when he returned to the United States from postdoctoral study in Europe with Wundt. He brought with him from Germany the "questionnaire method" to study "the contents of children's minds." The method was initially aimed at helping teachers learn what concepts children had available at the time that they entered school. The procedure involved asking children brief questions about their experiences and about the meaning of words—for example, "Have you ever seen a cow?" or "Where are your ribs?" The answers were scored right or wrong, and the percentage correct was used to describe groups of children, not individuals. Rural children were compared with city ones, boys with girls, Black children with White ones, and so on. The questionnaire method, at least in terms of the kind of questions asked, was a precursor of later general aptitude tests of general information and vocabulary. In Hall's core investigation, children just entering school in Boston were asked some 134 questions, such as those given above. Data collection was voluminous but haphazard; about half of the protocols from the 400 children tested had to be eliminated.

In commenting on this research, White (1992) writes:

> The questionnaire work was methodologically weak, to be sure, but the methodological regulations psychology subsequently put into place have probably been excessively restrictive. Hall's questionnaires asked people to give narrative accounts of children's behaviors in everyday situations, and this kind of approach is becoming more popular nowadays. (p. 33)

The point is well taken. Educators were impressed by Hall's vision of how scientific research had the potential to revolutionize educational practices (Hall, 1883, 1891). Zenderland (1988) suggests that the main impact of the child study movement on psychology was to pave the way for the acceptance of clinical psychology.

Hall's opportunity to shape the direction of psychology in the United States came when he was offered the first professorship in psychology in the United States, at Johns Hopkins University in 1884. He had been selected over C. S. Peirce and G. S. Morris—no modest competition. Peirce is viewed by many to be the preeminent U.S. philosopher, and Morris was a "brilliant lecturer" (White, 1992). Following the general model established by Wundt at Leipzig, Hall set up a teaching laboratory at Hopkins and recruited to it several young persons who were later to play a formative role in the development of the science. In the first laboratory course, the students included John Dewey, James McKeen Cattell, Joseph Jastrow, and E. H. Hartwell. With the support and encouragement of Johns Hopkins president D. Gilman, Hall also established the first psychological journal in

the United States, the *American Journal of Psychology.* On the basis of his success at Hopkins, Hall was offered in 1889 the opportunity of shaping a university himself by serving as first president of Clark University. Hall remained at Clark until his death in 1924, and established there a tradition of developmental study that remains strong today.

In the spirit of *Naturphilosophie,* Hall applied the biogenetic law to all aspects of human development. For Hall, the implications for the education, rearing, and religious instruction of children were manifold. He warned about the hazards of "unnatural" and "artificial" constraints on learning and early development, and expressed disdain for parents and teachers who attempt to instruct children rather than permitting their natures to unfold. According to Hall's view of recapitulation, behaviors, like morphological structures, follow an invariant course of development that has been determined by ancestral evolutionary progression. Interference with that natural process would be detrimental, and likely to bring about a stunting of growth or "developmental arrest."

Hall's biogenetic framework led him to a focus on the phenomena of adolescent development. In behavior, the fast-forward replay of ancestral psychological characteristics ended in adolescence, and the individual became free to superimpose distinctive and individual talents on the predetermined developmental sequence. Hence, it should be the stage of greatest plasticity and possibility for change. As Hall (1904) put it:

> While adolescence is the great revealer of the past of the race, its earlier stages must be ever surer and safer and the later possibilities ever greater and more prolonged, for it, and not maturity as now defined, is the only point of departure for the super anthropoid that man is to become. (vol. 2, p. 94)

Hall's designation of adolescence as the time when the child begins a fresh set of tracks was optional. Other recapitulation theories propose that the adding on of unique features occurs in the early postnatal period, or even prenatally (see Gould, 1977, for an informed discussion of the matter). Convinced that the adolescent period was the nuclear one for the fulfillment of human potential, Hall (1904) prepared a two-volume compendium entitled *Adolescence: Its Psychology and Its Relations to Physiology, Anthropology, Sociology, Sex, Crime, Religion, and Education.* The book offered a broad sweep of citations from philosophical, physiological, anthropological, religious, and psychological sources. Where the data fell short, Hall offered speculative evolutionary and moralistic interpretations. The product was impressive in scope and uneven in logic and scientific rigor.

But it was often on target. Some of the insights and discussions appear remarkably modern in content if not in tone. On social cognition and developmental changes in attitudes, Hall (1904) wrote:

> Children's attitude toward punishment . . . tested by 2,536 children (ages 6–16) showed also a marked pubescent increase in the sense of the need of the remedial function of punishment as distinct from the view of it as vindictive, or getting even, common in earlier years. There is also a marked increase in discriminating the kinds and degrees of offenses; in taking account of mitigating circumstances, the inconvenience caused others, the involuntary nature of the offense and the purpose of the culprit. All this continues to increase up to sixteen. (vol. 2, pp. 394–395)

Similarly, in a discussion of moral reasoning, Hall (1904) concluded: "Thus with puberty comes a change of view-point from judging actions by results to judging by motives" (vol. 2, p. 394). The statement was also based on empirical data using a reformed version of the questionnaire method. In this context, Hall cites Schallenberger's study (1894) on the development of moral judgments:

> From one thousand boys and one thousand girls of each age from six to sixteen who answered the question as to what should be done to a girl with a new box of paints who beautified the parlor chairs with them with a wish to please her mother, the following conclusion was drawn. Most of the younger children would whip the girl, but from fourteen on the number declines very rapidly. Few of the young children suggest explaining why it was wrong, while at twelve, 181, and at sixteen, 751 would explain. The motive of the younger children in punishment is revenge; with the older ones that of preventing a repetition of the act comes in; and higher and later comes the purpose of reform. With age comes also a marked distinction between the act and its motive and a sense of the girl's ignorance.[5] (vol. 2, pp. 393–394)

[5] Twenty-two thousand subjects? Not really. Schallenberger's (1894) article in the *Pedagogical Seminary* actually reported the responses of 3,434 girls and boys who were 6 to 16 years of age. The misinterpretation arose because Schallenberger transformed their responses to proportional scores, then multiplied by 1,000 to permit comparisons between age-sex groups. Nonetheless, a sample of 3,434 boys and girls is

Adolescence thus is "the stage when life pivots from an autocentric to an heterocentric basis" (vol. 2, p. 301).

So far, so good, except Hall had the misfortune of discovering the biogenetic law at about the time that the new generation of biologists was discarding it. If evolution and recapitulation ranked high on Hall's psychological priorities, then morality and religion ran a close second. The linkages came about in ways that were not always immediately obvious but that seemed to represent his faith in the psychic "continuity throughout the universe" (vol. 2, p. 208).

How does one evaluate Hall's contributions to developmental psychology? It is almost true to say that they were unique. Kessen (1965) provides a perceptive and succinct summary: "There have been diggers in the sand pile of child study since him, but in a sense, Hall has had no descendants—only heirs" (p. 151). More recently, White (1992) concluded that Hall made three significant contributions:

1. Hall provided a "first cooperative 'normal science' of child development" through his questionnaire program. The point is that the questionnaires, although limited as scientific instruments in the ways that Hall employed them, had great potential for describing children's lives in natural context.
2. Hall viewed social participation as a catalyst for internal organization, and thereby provided a "social-biological" conception of childhood.
3. Hall was guided by the need "to arrive at a scientific synthesis on the one side and practical recommendations on the other."

Related to the third point, one contribution should not be overlooked because it has potentially large implications for both developmental theory and intervention models. Hall focused on adolescence because he believed it was a period of great vulnerability and the time when novel actions and beliefs were established and consolidated, for good or for ill. In his view, infants and children were more or less buffered, a belief shared by his student Arnold Gesell (see below). Although Hall's reasoning about recapitulation was clearly off base, his intuitions about developmental plasticity in adolescence were inventive and provocative.

Hall also expanded the boundaries of the academic discipline and stimulated fresh approaches to it. Of special importance was his pivotal role in the organization and support of the activities of the child study movement in America, including the Child Study Section of the National Education Association.

In his scientific role, Hall was more an importer and translator of scientific methods and theories than he was a creator of them. In addition to the questionnaire method and the biogenetic law, Hall helped bring Wundtian experimental procedures and Preyer's volume on *The Mind of the Child* (Hall wrote the foreword to the U.S. translation) to the United States. He also helped change the face of U.S. psychology when, in 1909, he arranged a meeting between Sigmund Freud and his lieutenants (C. G. Jung, A. A. Brill, E. Jones, and S. Ferenczi) and the most prominent psychologists in North America. This meeting was held to commemorate the 20th anniversary of the founding of Clark University, and it is generally viewed as a key event in the acceptance of psychoanalysis in North America at a time when Freud felt ostracized by the European scientific establishment. In the same year, Clark University presented an honorary degree to William Stern, another significant pioneer in the establishment of developmental psychology. Throughout his career, Hall remained open to new and fresh approaches, and he promoted efforts to make psychology more useful and relevant to society.

In sum, Hall was a remarkable teacher and catalyst for the field. Some of the most significant areas of developmental study—mental testing, child study, early education, adolescence, life-span psychology, evolutionary influences on development—were stimulated or anticipated by Hall. Because of shortcomings in the methods he employed and the theory he endorsed, few investigators stepped forward to claim Hall as a scientific mentor. His reach exceeded his grasp in the plan to apply the principles of the new science to society. Psychology's principles were too modest, and society's problems were too large. Perhaps we should use a fresh accounting to judge Hall's contributions, one that takes into account the multiple facets of his influence on individuals, the discipline, and society. The audit would reveal that all of us who aspire to better the lot of children and adolescents can claim him as a mentor.

MAKING DEVELOPMENTAL THEORY

Any account of the scientific study of cognitive and social development must take note of the singular contributions of James Mark Baldwin (1861–1932). His role as an

impressive in any era, especially before the invention of computers, electric calculators, and mechanical pencils.

intellectual leader of the emergent discipline is now well established. Baldwin's *Mental Development in the Child and the Race* (1895) was one of the first attempts to construct a genetic epistemology within the framework of the "new psychology" (Broughton & Freeman-Moir, 1982; Cairns & Ornstein, 1979; R. H. Mueller, 1976). The companion volume, *Social and Ethical Interpretations of Mental Development* (J. M. Baldwin, 1897/1906), was the first systematic effort by a psychologist to use developmental ideas to bridge the gap between the study of social institutions (i.e., sociology) and the study of individual functioning (i.e., psychology).

Recent scholarship has compared Baldwin's proposals with those of Jean Piaget. In this regard, Wozniak (1982, p. 42) writes:

> Baldwin proposed a biosocial, genetic theory of intelligence, a theory of mind in the broadest sense, which was conceptually far ahead of his time. This theory contained within it, en germe, many of the most important concepts of the biological theory of intelligence and of the genetic epistemology which Piaget was to develop.

Other studies show direct lines of descent of key ideas and concepts expressed by Baldwin to those commonly associated with Piaget and Vygotsky (Broughton, 1981; Cahan, 1984; Valsiner & van der Veer, 1988; Wozniak, 1982). But it would be a mistake to view Baldwin's thinking only through a Piagetian or Vygotskian lens. Baldwin's distinctive ideas on evolutionary epistemology, cross-generational transmission of developmental accommodations, the dynamics and social embeddedness of personality, and the dual genesis of cognition are sufficiently provocative to demand study in their own right.

Baldwin is less of a "shadowy figure" now than he was just 20 years ago (Broughton & Freeman-Moir, 1982, p. 2). Baldwin was born in 1861 in Columbia, South Carolina, and died in 1934 in Paris. Following undergraduate training in philosophy and psychology, and a year of advanced study in Europe (including a semester in Leipzig with Wilhelm Wundt), Baldwin completed a doctorate at Princeton University in 1888. In the 4 years that he was on the faculty at the University of Toronto, he founded an experimental laboratory and began a research program on "infant psychology." The results of this work, which were published in the journal *Science* 100 years ago, dealt with the ontogeny of movement patterns, handedness, color vision, suggestibility, and research methodology (J. M. Baldwin, 1890, 1891, 1892, 1893). These findings provided the empirical basis for his first major work on mental development.

From the beginning, Baldwin was more a theoretical psychologist than an experimental one. He employed research findings to illustrate theoretical principles rather than to systematize empirical phenomena. Primary in Baldwin's thinking was the "conviction that no consistent view of mental development in the individual could possibly be reached without a doctrine of the race development[6] of consciousness—that is, the great problem of the evolution of mind" (Baldwin, 1895, p. vii). In this conviction, he followed the theoretical lead of Herbert Spencer in philosophy and George John Romanes in biology, and the empirical lead of Wilhelm Preyer and Alfred Binet. After this intensive but brief involvement with the experimental investigation of infants, Baldwin returned to issues of psychological and evolutionary theory, historical commentary, editorial activities, and philosophical construction and systemization. The study of development was no longer an empirical activity for him, but questions of psychological genesis remained at the core of his theoretical and philosophical speculations.

He was a key figure in the organization of psychology as a science, the establishment of three of its basic journals (*Psychological Review, Psychological Bulletin,* and *Psychological Abstracts*), and the founding of two major departments of psychology (at the University of Toronto and Princeton University) and the reestablishment of a third (at Johns Hopkins University). He served as one of the first presidents of the American Psychological Association when he was only 36 years of age. He won the highest honors available to psychologists in his day, including the Gold Medal of the Royal Academy of Denmark and the first honorary Doctorate of Science degree awarded by Oxford University. It is now generally acknowledged by those who have reviewed the record that Baldwin stands alongside William James, John Dewey, and C. S. Peirce as one of the primary intellectual forces involved in the founding of U.S. psychology as a science.

Metaphysics and Development

In an excellent analysis of the structure of Baldwin's thought, Wozniak (1982) writes, "Baldwin had deep intellectual roots in the 'mental philosophy' tradition

[6] *Race development* is one of the unconventional expressions employed by Baldwin. Race in this context refers to variations across the human species. In effect, cross-cultural studies of the development of cognition are required to complement studies of individual development in humans.

which dominated American higher education during the nineteenth century" (p. 13). Yet, he early gained a respect for the emerging biological and behavioral sciences, and the possibility that there might be a scientific explanation for the origin of knowledge and the perception of reality. At the outset of his career, Baldwin explicitly oriented his empirical and theoretical work toward a synthesis of metaphysics and psychological science (Wozniak, 1982, p. 14). In the early 1890s, he became convinced that genetic study must be the central theme for the synthesis of reason and reality.

Throughout the remainder of his career, "the great topic of development itself" (J. M. Baldwin, 1895, p. x) dominated his work and thinking. In his day, Baldwin expanded the application of genetic concepts in three emergent disciplines—psychology, evolutionary biology, and sociology—and in one established discipline—philosophy. Baldwin's own scientific life illustrates his view that cognitive development is not limited to childhood. As Wozniak (1982) observes:

> Baldwin was himself subject of a series of intellectual transformations. So great, in fact, are the differences in conceptual structure and content among his major books . . . that one wonders if perhaps there might not have been three Baldwins at work: a mental philosopher (roughly to 1889), an evolutionary psychologist (approximately 1889–1903), and an evolutionary epistemologist (1903–1915). (p. 14)

Although Wozniak's characterization of the marked intellectual transitions in Baldwin's career seems accurate, Baldwin appears to have moved beyond scientific psychology even before the turn of the century, coincident with his work on the *Dictionary of Philosophy and Psychology.* Given the scope and complexity of Baldwin's work, any brief summary is likely to be misleading. Shortcomings in the following account may be corrected by consulting more complete analyses including Wozniak (1982), on the intellectual origins of genetic epistemology; R. H. Mueller (1976) and Valsiner and van der Veer (1988), on the relations between psychology and sociology; and Cahan (1984), on the comparison of the genetic psychologies of Baldwin and Piaget. In addition, various chapters in the previous edition of the *Handbook of Child Psychology* (Mussen, 1983) attempt to place Baldwin's contributions into contemporary and historical context (Cairns, 1983; Harter, 1983; Sameroff, 1983). Then there are the voluminous writings of Baldwin himself, including 21 books and more than 100 articles. Baldwin's own thoughtful summary of his life's work is perhaps the best place to begin (Baldwin, 1930).

Mental Development and Social Ontogeny

The two works of Baldwin that have proved most stimulating to modern developmental psychologists are *Mental Development in the Child and the Race* (Baldwin, 1895), and *Social and Ethical Interpretations of Mental Development* (Baldwin, 1897/1906). The earlier book presented Baldwin's attempt to formulate a "genetic epistemology." In individual development, a key mechanism for bringing about growth in the "cognitive scheme" is the "circular reaction." This invention of Baldwin's is linked to concepts of learning that appeared later and explained how experience could become internalized into habit through recurrent self-stimulation or imitation. A consideration of ontogenesis challenged the then-dominant idea that consciousness was "a fixed substance, with fixed attributes" (Baldwin, 1895, p. 2). He writes with respect to the static conceptions of traditional approaches:

> The genetic idea reverses all this. Instead of a fixed substance, we have the conception of a growing, developing activity. Functional psychology succeeds faculty psychology. Instead of beginning with the most elaborate exhibition of this growth and development, we shall find most instruction in the simplest activity that is at the same time the same activity. Development is a process of involution as well as of evolution, and the elements come to be hidden under the forms of complexity which they build up. . . . Now that this genetic conception has arrived, it is astonishing that it did not arrive sooner, and it is astonishing that the "new" psychology has hitherto made so little of it. (1895, p. 3)

In Baldwin's eyes, development proceeds from infancy to adulthood through stages, beginning with a reflexive or physiological stage, continuing through "sensorimotor" and "ideomotor" stages, and progressing to a stage of symbolic transformations (Baldwin, 1895). Only in the most advanced stage do "syllogistic forms come to have an independent or a priori force, and pure thought emerges—thought, that is, which thinks of anything or nothing. The subject of thought has fallen out, leaving the shell of form" (Baldwin, 1930, p. 23). From its earliest formulation, Baldwin's stage theory of mental development focused attention on process as much as on structure. Many of the terms that he employed—"accommodation," "assimilation," "imitation,"

"circular reaction"—are commonplace in today's textbooks, although it cannot be assumed that Piagetian meanings are necessarily the same as Baldwinian ones.

Social and Ethical Interpretations in Mental Development: A Study in Social Psychology (Baldwin, 1897/1906) appeared only 2 years later. This book is the first work by a U.S. psychologist on social-cognitive development in childhood; it is also the first volume in English that includes "social psychology" in its title (R. H. Mueller, 1976). In this work, the cognitive-stage model is extended to issues of social development, social organization, and the origins of the self. Baldwin (1895) felt that the essential issues of social psychology had been neglected because of the void that existed between the concepts of psychology and sociology:

> And it is equally true, though it has never been adequately realized, that it is in genetic theory that social or collective psychology must find both its root and its ripe fruitage. We have no social psychology, because we have had no doctrine of the *socius.* We have had theories of the ego and the alter; but that they did not reveal the socius is just their condemnation. So the theorist of society and institutions has floundered in seas of metaphysics and biology, and no psychologist has brought him a life-preserver, nor even heard his cry for help. (p. ix)

In social development, there is a "dialectic of personal growth" that progresses from an egocentric receptive stage to a subjective one and, eventually, to an empathic social stage. In Baldwin's (1897/1906) scheme:

> The development of the child's personality could not go on at all without the modification of his sense of himself by suggestions from others. So he himself, at every stage, is really in part some one else, even in his own thought of himself. (p. 30)

Consistent with his emphasis on developmental processes of the self rather than static structures, personality is not fixed by early experience or by genes. Accordingly, "personality remains after all a progressive, developing, never-to-be-exhausted thing" (p. 338). Actions are fluid, dynamic, and responsive to the immediate setting. In Baldwin's (1897/1906) view:

> [The child's] wants are a function of the social situation as a whole. . . . His wants are not consistent. They are in every case the outcome of the social situation; and it is absurd to endeavor to express the entire body of his wants as a fixed quantity under such a term of description as "selfish," or "generous," or other, which has reference to one class only of the varied situations of his life. (p. 31)

The self becomes progressively and inevitably accommodated to others and to the traditions of society. This "social heredity" is mediated through imitation and the operation of an internal circular reaction. From each relationship, there emerges a refined sense of oneself and of others. "The only thing that remains more or less stable is a growing sense of self which include both terms, the ego and the alter" (Baldwin, 1897/1906, p. 30).

Sociogenesis

One other primary developmental concern of Baldwin involves the relations between nature and nurture and the cross-generational transmission of modifications in individual development. In light of the metaphysical synthesis that guided Baldwin's thinking, it was entirely fitting for him to argue that the nature-nurture dichotomy falsely "supposes that these two agencies are opposed forces" and that it fails to entertain the possibility that "most of man's equipment is due to both causes working together" (Baldwin, 1895, p. 77). Evolutionary adaptations and developmental accommodations operate toward the same goals, although they are established over vastly different time intervals. Extending this analysis to the problem of how this synchrony is established and maintained, Baldwin (1895) wrote:

> It is clear that we are led to relatively distinct questions: questions which are now familiar to us when put in the terms covered by the words, "phylogenesis" and "ontogenesis." First, how has the development of organic life proceeded, showing constantly, as it does, forms of greater complexity and higher adaptation? This is the phylogenetic question. . . . But the second question, the ontogenetic question, is of equal importance: the question, How does the individual organism manage to adjust itself better and better to its environment? . . . This latter problem is the most urgent, difficult, and neglected question of the new genetic psychology. (pp. 180–181)

Beginning in his first developmental volume (Baldwin, 1895) and continuing through *Development and Evolution* (Baldwin, 1902), Baldwin expanded on his view of the cross-generational transmission of behavior tendencies through "organic selection." He proposed that "accommodations" that occur in the lifetime of the individual could be transmitted to the next generation in

the form of "adaptations" of the species by means of the process that he labeled "organic selection" (Baldwin, 1895, p. 174). The essence of the idea was that ontogenetic accommodations can serve to direct the course of evolutionary change. How was it accomplished? On this matter, there remains debate on exactly what processes were implicated (e.g., Gottlieb, 1979, 1987; Piaget, 1978; Vonèche, 1982). Baldwin was clearly reaching for a developmental mechanism of directed selection that would supplement the Darwinian concept of natural selection, without invoking "the Lamarckian factor" (i.e., the inheritance of acquired characteristics). Over the years, Baldwin sharpened this concept (J. M. Baldwin, 1930). The proposal became known in biology as the "Baldwin effect" (Cairns, 1983; Gottlieb, 1979), despite Baldwin's large debt to the crisp logic of C. L. Morgan (1896, 1902).

Toward a Critical Evaluation

Since the modernity of Baldwin's theory has become acknowledged, it has seemed reasonable to evaluate its adequacy by modern standards. Certain shortcomings in coherence and expression appear in a cursory examination of his books; other problems demand the examination of the work of Baldwin's contemporaries. Doubtless the most important measure of his theory has to do with its effects on subsequent investigators, including those in the present generation.

Perhaps because of his openness to novel conceptions, Baldwin sometimes evolved the meaning of basic concepts in the theoretical models that he proposed. The relativity of his ideas to time and context renders any static description of his theory misleading. It also confounds comparisons that may be made with his contemporaries and apparent intellectual heirs, including Piaget and Vygotsky.

Baldwin's work illustrated another premise of his theoretical perspective—that an individual undergoes the "constant modification of his sense of himself by suggestions from others" (1897/1906, p. 30). On this score, his early work in mental philosophy was heavily influenced by the metaphysical view of Scottish commonsense philosophy in general and the intuitional realism of James McCosh, his mentor at Princeton (R. H. Mueller, 1976; Wozniak, 1982). During the second period, his research laboratory owed much to the prior work of Preyer, Binet, and Shinn. Similarly, his conceptions of "organic selection" seemed to have drawn much from the work of Morgan (1896) and Osborn (1896). In the work on genetic logic and precision of philosophical definition, Baldwin drew on contemporaries William James and C. S. Peirce in his conception of the task and its execution. Baldwin typically was generous in acknowledging these influences, and thereby highlighted his own distinctive insights and creativity.

Baldwin's writing style and organization were uneven. On some issues, as is illustrated by some quotes in this chapter, he was incisive, powerful, and challenging. He could also, however, be obtuse. William James, one of the few U.S. psychologists who remained friendly with Baldwin, gently remarked, "This article (like much of its author's [Baldwin's] writing) is in places deficit in perspicuity" (James, 1894, p. 210). Other critics were less generous. James Sully, an important British experimentalist and a contemporary of Baldwin, began and ended a review of *Mental Development in the Child and the Race* with the following comments:

> This is a book which presents special difficulties to the reviewer. One looks on a biological work—for such Professor Baldwin's work seems to be quite as much as a psychological one—for arrangement, structure, organic form: in the present case one is struck almost at first glance by the apparent absence of these attributes. And the first impression is by no means dispelled as one begins to read. . . .
>
> To sum up my impression of Prof. Baldwin's book. It seems to me in many respects fresh and stimulating. On the other hand, in what looks like an over-straining after originality apparent newness of conception often turns on closer examination to be but newness of phrasing. *When new ideas are put forward one misses for the most part an impartial and thorough-going confronting of theory with fact.* (1896a, pp. 97, 102–103, italics added)

Unclarity was not limited to this first volume. In comparing Baldwin's discussions of social development with those of C. H. Cooley (1902), Sewney (1945) indicated that "Cooley presented his views in a language that is lucid and readable, and free of the confusing and jumbled terminology that fills the writings of Baldwin" (p. 84). R. H. Mueller located an unpublished journal in which Cooley himself had the following comments on Baldwin's style and motivation:

> A great fault with strenuous writers like Baldwin is that in their eagerness to produce they do not allow time enough for their imaginations to grow naturally and thoroughly

> into the mastery of a subject. They force it, and so impair its spontaneity, its sanity and humanness. What they write may be stimulating, consecutive, attractive for a time, but it is not food to live on. A style like this Goethe calls mannerism or "*das manirierte*." If you wish to produce anything of lasting value, you see to it that the subject matter, the truth, is the first interest of your mind, not your books, your essay, yourself as discoverer and communicator of truth. (R. H. Mueller, 1976, p. 250)

A modern reviewer, otherwise sympathetic to Baldwin, indicated that "there is much in Baldwin's work that is unfinished and confusing" (Broughton, 1981, p. 402). Examples of the unfinished business included theoretical discontinuities in Baldwin's social theory, and internal inconsistencies in the description of stages.

Baldwin's style may have been more than an inconvenience for readers. It permitted him to reform explanations and concepts so that one and the same term could take on fresh nuances or alternative meanings, depending on its context. Imprecision in presentation thereby promotes projection in interpretation. Perhaps this explains the considerable dispute as to what exactly was meant by Baldwin in his use of such terms as *organic selection, imitation,* and *genetic method.*

Baldwin tended to incorporate new ideas into his own developmental view, and he did not always appear to be sensitive to possible contradictions between the new and the old. Baldwin seems to have benefited greatly from Josiah Royce and William James in his concepts of the social self (Valsiner & van der Veer, 1988). He also introduced some of the ideas of Osborn (1896) and Morgan (1896) in his revision of the concept of "organic selection." It was, however, a process of assimilation, not imitation. Most of the ideas were transformed when they became incorporated into a genetic framework. This long-term pattern of intellectual reformulation and reconstruction may account for why Baldwin invented new terms for old ideas and was particularly sensitive to the issue of intellectual priority and ownership. In his eyes, the concepts were new inventions. Priority and recognition were especially important for Baldwin, and this concern may help explain his haste to publish.

To illustrate, consider the concept of *organic selection.* The aim of the concept was clear from the beginning: to link the accommodations that occur in the life history of the individual to the adaptations that occur in the life history of the species. But the identification of the precise mechanisms has proved to be something of a projective test. This is due in part to the assimilation by Baldwin of the terms and logical argument outlined by C. Lloyd Morgan (1896). In a brief but brilliant essay on this matter, reprinted as an appendix in Baldwin's volume on *Development and Evolution,* Morgan (1902) refers to the collaboration of individual modification in development and adaptive variation in phylogenesis as *coincident variations.* The concept of coincident variation was incorporated into Baldwin's account of organic selection, but it was unclear when he accepted the important corollary that there were no direct connections between specific individual experiences in ontogeny and specific variations in phylogeny. Eventually, Baldwin did clarify the concept (Baldwin, 1930).

All this is to say that the contributions of Baldwin did not arise independently of the rich intellectual context in which he lived and drew inspiration. Consistent with his model of social-cognitive development, the influences were bidirectional. There is now ample evidence that a large number of investigators in four disciplines were challenged by Baldwin's proposals and conceptions on development. In his commitment to the concept of development and its systematic application, Baldwin was more persuasive, thoughtful, and persistent than any of his peers, including Hall. He envisioned a new *genetic science* (Baldwin, 1930).

Lawrence Kohlberg deserves credit—more than any other psychologist of the present generation—for having brought the attention of U.S. psychologists to the theoretical contributions of Baldwin. Before Kohlberg's (1969) classic article on social cognition, there was scant recognition among modern developmental psychologists of the extent to which Baldwinian insights have persisted in the discipline. Kohlberg himself studied Baldwin's work independently in graduate school to establish a theoretical framework for his investigation of ethical and moral development. It is therefore fitting that the primary book on Baldwin's theory should be edited by two of Kohlberg's former students (Broughton & Freeman-Moir, 1982) and that Kohlberg's chapter in that volume contained some of its most noteworthy passages. His essay provides a succinct answer to the question: What are the real differences between Baldwin's and Piaget's theories? Kohlberg (1982) writes:

> In the end, the fundamental distinction between Baldwin's moral psychology and Piaget's is that Piaget's psychology has no self. Piaget starts with an ego knowing objects, but

> knowing them first egocentrically. Development is a progressive movement toward objectivity. In contrast, for Baldwin all experience is experience of a self, not just of a bodily and cognitive ego. This means first that central to the self is not cognition but will. Second, it means that from the start experience is *social* and reflective. The child's sense of self is a sense of will and capacity in the relation of self to others. The individual is fundamentally a potentially moral being, not because of social authority and rules (as Durkheim and Piaget thought) but because his ends, his will, his self is that of a shared social self. (pp. 311–312)

It is also an integrative self. Baldwin (1897/1906) himself indicated: "In spite of the large place which I assign to Imitation in the social life, I should prefer to have my theory known as the 'Self' or the 'Self Thought' theory of social organization" (p. xviii).

Baldwin's theoretical work anticipated much of Piaget's theory of cognitive and moral development. Piaget's use of Baldwin's distinctive terms—from circular reaction and cognitive scheme to accommodation, assimilation, and sensorimotor—point to a direct line of intellectual descent. More importantly, as Cahan (1984, p. 128) has observed, "the goals, genetic approach, and epistemological assumptions underlying Piaget's inquiry into cognitive development found explicit statement around the turn of the century in Baldwin's work." The mediational linkages from Baldwin are readily identified. From 1912 to his death in 1934, Baldwin's primary residence was in Paris. His work was well regarded in French intellectual circles in general, and by Pierre Janet in particular. As Piaget wrote to Mueller (1976, p. 244):

> Unfortunately, I did not know Baldwin personally, but his works had a great influence on me. Furthermore, Pierre Janet, whose courses I took in Paris, cited him constantly and had been equally very influenced by him.

There is also a written record in the pattern of Piaget's citations of Baldwin. Curiously, these references appeared in works that were published very early (1923/1926) or very late (1978) in Piaget's career.

It would be a mistake to infer that Piaget's theory was simply a revision of Baldwin's original. As Broughton (1981) and Cahan (1984) have observed, the differences are as great as the similarities. In addition to the insightful distinction made by Kohlberg, there is a large difference in the scientific styles of the two investigators that, in turn, gave rise to marked differences in the content of their approaches. Baldwin used the methods and analyses of experimental psychology to illustrate developmental theory. He learned early that the methods of experimental psychology were inadequate to evaluate the developmental theory that he was constructing. Given this dilemma, he chose to abandon the scientific issues and address the philosophical ones.

Piaget, alternatively, was trained in biology rather than philosophy. As an empirical scientist, he employed observations to understand phenomena rather than merely demonstrate principles. Piaget was challenged to invent methods appropriate to the empirical issues he sought to comprehend. The clinical method of direct observation and the creation of developmentally appropriate tasks provided him with the tools for revising, extending, and evaluating his proposals. They also permitted others to assess the replicability of the phenomena and determine the adequacy of the theory. More important, the objective tracking of phenomena over time permitted Piaget and those who followed his lead to arrive at insights that were not self-evident to experimentalists or armchair observers. The insights, in turn, contributed to the vitality of Piaget's developmental model.

Despite the shortcomings in Baldwin's theoretical system and empirical work, his proposals have nonetheless exercised a large direct and indirect influence on developmental theorists in the twentieth century. As Valsiner and van der Veer (1988) document, there are direct connections between Baldwin's (1897/1906) concepts of the development of the self in social context and George H. Mead's (1934) symbolic interactionism, on the one hand, and L. S. Vygotsky's (1962) propositions on the social-contextual origins of personality, on the other. Baldwin's work was the common denominator, since neither Mead nor Vygotsky referred to the other directly. The Valsiner and van der Veer (1988) analysis is consistent with independent evidence that (a) Baldwin's work had a significant influence on C. H. Cooley as well as Mead, in formulations of symbolic interactionism; and (b) Baldwin's influence on Vygotsky was mediated primarily through Janet's writings. Valsiner and van der Veer (1988) point out that the assimilation of Baldwin's influence was selective. On the one hand, Cooley (1902) and Mead (1934) tended to discard the developmental features of Baldwin's self theory. On the other hand, Vygotsky (1962) preserved both

the ontogenetic focus and the social dynamics of Baldwin's system.

In addressing the issue of what lasting significance Baldwin's developmental concepts may have for the science, we first must ask why they vanished from psychology in the first place. The primary explanation was that Baldwin's theoretical formulations were out of line with the ideas and empirical trends that were to dominate the new U.S. psychology of the early twentieth century. The new psychology was to be dominated by models that either denied the importance of cognition or diminished the importance of development beyond infancy. Moreover, his developmental concepts of the mind and of social processes required research methods that were simply not available to the discipline. The further Baldwin went beyond the study of infancy, the more speculative and removed from data he became. But the fulfillment of his aim—the building of a science of development—demanded a continuing tension between a drive for system and a drive for evidence. As Quine (1981) has observed:

> If either of these drives were unchecked by the other, it would issue in something unworthy of the name of scientific theory: in the one case a mere record of observations, and in the other a myth without foundation. (p. 31)

Baldwin lacked the cadre of colleagues and students to help him translate his developmental ideas into an empirical science. Without adequate methodologies, he became increasingly removed from the validation and correction of his ideas, and, like William James before him, became increasingly drawn to philosophy and away from the empirical issues of developmental psychology.

There were other factors that various writers have felt were important in limiting his influence: (a) his writing style failed to inspire confidence in the validity of his ideas; (b) he failed to produce students who might have continued his work (i.e., in the 5 years that he was at Johns Hopkins, no students completed the doctoral program in psychology); and (c) his severe embarrassment in a personal scandal that became public led to abrupt termination from his academic position at Johns Hopkins in 1909. After that incident, he spent little time in the United States, and his name seems to have been virtually blacklisted by the next generation of psychologists. Each of these events may have contributed to the regression and submersion of Baldwin's concepts in U.S. psychology. Ironically, Baldwin's forced move to Paris may have facilitated the acceptance of his concepts. European psychologists tended to be more receptive to developmental concepts and methods than their U.S. counterparts.

Beyond these contributing factors, the unfinished business in Baldwin's agenda was to create methods, techniques, and analyses that are appropriate for developmental study. Piaget and Vygotsky, who helped establish those methods and revised their concepts in the light of their results, had an enormous impact on modern developmental thinking. Recent methodological critiques have suggested that the systematic study of developmental processes requires not only different statistics, but also different research designs and different ways to organize empirical observations (Cairns, 1986; Valsiner, 1986; Wohlwill, 1973). Furthermore, it was explicit in Baldwin's proposals that the task of disentangling development-in-context was necessarily an interdisciplinary activity that extends beyond the traditional boundaries of psychology. Sully (1896a) was probably correct when he observed that Baldwin's *Mental Development in the Child and the Race* was as relevant to biology as it was to psychology. And R. H. Mueller (1976) was likely accurate when he noted that Baldwin's *Social and Ethical Interpretation of Mental Development* was as relevant to sociology as to psychology.

The broader point is that Baldwin may have failed in his larger goal even if he had written more precisely, recruited more students, and died of old age in Baltimore rather than Paris. He would have failed because he had envisioned a science different from any that could be accommodated by the new psychology. It appears that many of the obstacles that precluded the adoption of developmental concepts into the psychology of the 1890s remain in place.

What might we conclude about James Mark Baldwin? Beyond whatever shortcomings may have existed in his writing and teaching, and beyond whatever honors he coveted and disappointments he endured, he ultimately succeeded in reaching the part of the goal that was within his grasp. He had insight and vision to describe developmental ideas that continue to inspire and challenge after 100 years.

DEVELOPMENTAL PSYCHOPATHOLOGY

Sigmund Freud (1856–1939) stood in curious relationship to the founding of developmental psychology. Un-

like the other investigators covered in this section, Freud published no empirical research on behavioral development: He observed few children in a clinical setting, and none in a traditional experimental design. Yet, psychoanalysis has emerged as one of the more important influences—if not the most important—for developmental psychology in the twentieth century. Further, the early acceptance of psychoanalysis in the United States and elsewhere was due in part to the enthusiasm of Hall. As Freud (1926/1973) himself described the emergence of the psychoanalytic movement:

> In 1909, Freud and Jung were invited to the United States by G. Stanley Hall to deliver a series of lectures on psychoanalysis at Clark University, Worcester, Mass. From that time forward interest in Europe grew rapidly; it showed itself, however, in a forcible rejection of the new teachings, characterized by an emotional colouring which sometimes bordered upon the unscientific. (vol. 18, p. 720)

Hall recognized a novel developmental idea when he saw one. His promotion of psychoanalysis occurred at a time when it was suffering rejection in Europe and obscurity in North America. Freud's (1910) lectures at Clark, published in Hall's *American Journal of Psychology,* remain one of the most lucid and succinct presentations of psychoanalysis by its founder.

Born in Moravia and raised in Vienna, S. Freud as a student showed the catholicity of interests that was to appear in his mature work. Though anatomy and physiology were his primary areas of concentration, he was greatly impressed by the work of Darwin and Haeckel, on the one hand, and by the ideas of British associationist John Stuart Mill, on the other. After completing medical studies, Freud engaged in neurobiological research for several years, initiating, among other things, a phyletic-ontogenetic analysis of the fetal brain and the mapping of sensory neural tracts. Freud's early physiological publications were well received, and he achieved international recognition as a highly promising researcher and methodologist.

The mid-1880s constituted a turning point in his career when he decided to practice neurology, in part for economic considerations, according to E. Jones (1953). To further his training in this specialty, Freud won a fellowship to study in Paris with the renowned neurologist, J. M. Charcot. From October 13, 1885, until February 28, 1886, Freud thus worked in the facilities at the Salpêtrière and, presumably, shared some of the same interests as Alfred Binet. Apparently both young men were attracted by Charcot's demonstrations of the interrelations between physical symptoms and the mind, including the use of hypnotism in the remission of hysteric symptoms and in probing the "unconscious" mind. Binet, characteristically, was the first of the two to publish on issues of sexual perversions and their origins. In a remarkable yet almost forgotten paper titled "*Le Fétichisme dans l'Amour,*" Binet (1887) described the ease with which sexual attractions and impulses could be associated with neutral objects, and the "abnormal" could be brought about by normal mechanisms of associative learning. In this paper in an early volume of the *Revue Philosophique,* Binet anticipated three of the major themes identified with psychoanalysis; namely, (1) the continuity between mechanisms that regulate normal and abnormal behaviors and emotions, (2) the significance of sexuality in psychopathology, and (3) the essential lawfulness of human behavior.

Returning to Vienna, Freud began his neurological practice, leading to a collaboration with Josef Breuer in the writing of *Studies in Hysteria* (1895/1936). When Freud substituted free association and dream analysis for hypnotism in reaching the unconscious, psychoanalysis was invented.

Might Binet's concepts of unconscious have contributed to the psychoanalytic movement? In a remarkable passage in Breuer and Freud (1895/1936), we find:

> The continuation of the hysterical symptoms which originated in the hypnoid state, during the normal state, agrees perfectly with our experiences concerning posthypnotic suggestions. But this also implies that complexes of ideas incapable of consciousness co-exist with groups of ideas, which function consciously; that is to say, there is a *splitting of the psyche.* . . . It seems certain that this too can originate without hypnoidism from an abundance of rejected ideas which were repressed, but not suppressed from consciousness. *In this or that way here develops a sphere of psychic existence, which is now ideationally impoverished and rudimentary, and now more or less equal to the waking thoughts, for the cognition of which we are indebted above all to Binet and Janet.* (p. 188, emphasis added)

One reason that the Binet-Janet-Freud linkage has been heretofore overlooked may be that A. A. Brill failed to include this section in his earlier English translation of *Studies in Hysteria* (i.e., before 1936). A mere oversight? Perhaps, but Sulloway (1979) proposes a less benign interpretation of selective recall and biased citations in psychoanalysis. He asks, "Why is the history

of intellectual revolution so often the history of conscious and unconscious attempts by the participants to obscure the true nature and roots of their own revolutionary activity?" (p. 6). His answer is that there "generally exists a powerful underlying tension between the forward-looking orientation of the would-be discoverer and the backward-looking orientation of the historian" (p. 7). Innovation, novelty, and discovery are the stuff out of which new scientific movements are created. There is strong temptation to ignore or denigrate research and researchers who threaten the illusions of novelty or validity—despite a commitment of the scientist to balanced and thorough scholarship. Although psychoanalysis illustrates this temptation, it hardly constitutes a unique case in the past of developmental psychology.

As Freud (1926/1973) has pointed out, psychoanalysis "in the course of time came to have two meanings: (a) a particular method of treating nervous disorders and (b) the science of unconscious mental processes, which has also been appropriately described as 'depth psychology' " (p. 720). Psychoanalysis, the theory, involves strong assumptions about the development and evolution of personality that psychoanalysis, the method and therapy, does not. Why did psychoanalysis-as-theory emerge as a developmental one?

One answer would be that it was demanded by the data. The roles of, say, infant sexuality and the primacy of early experiences would be seen as having been revealed by the use of psychoanalysis-as-method. A second possibility, not incompatible with the first, is that Freud may have been intellectually prepared to focus on the formative nature of ontogenetic events by virtue of his research training and experience in neurobiology. Recall that Freud had, in his physiological work, undertaken analyses of embryogenesis. Finally, broader intellectual-scientific forces appear to have been at work. As Gould (1977) and others have noted, parallels to the then-contemporary evolutionary developmental assumptions seem to be liberally represented throughout psychoanalytic thought. That Freud should draw on biological approaches in the formulation of his theory of personality and psychopathology seems entirely reasonable, in light of his scientific training in the area.

Contrary to the view that Freud employed physics as the basic model for psychoanalysis, the theory seems more analogous to the biological thought of the day than to either "physical" or even "medical" models. Hence, certain psychoanalytic propositions appear to be immediately parallel to Darwinian-Haeckelian proposals on development and evolution. These include: (a) the never ceasing intrapsychic struggle and competition among instincts for survival and expression; (b) the psychoanalytic focus on two immanent motivational forces that figure importantly in evolution-instincts that bring about reproduction (sexual, libido), and instincts that bring about selection and destruction (aggression, Thanatos); (c) the assumed preestablished progression of the stages of ontogenesis that parallel the stages of phylogenesis, hence the appearance of sexual expression in human infancy; and (d) the notion of developmental arrest or fixation, an idea introduced into recapitulation theory to account for fetal teratology, whereby "monsters" would be produced if the ancestral stages of phyletic evolution were not permitted to be sequentially produced in individual development.

Later, in *Moses and Monotheism* (1939), Freud makes his debt to the biogenetic law explicit. As we have already seen, the primary U.S. psychological recapitulationist, Hall, recognized the fundamental harmony of his ideas on development and evolution with those of psychoanalysis.

The methodological legacy of psychoanalysis requires comment. Freud's main endeavor in life, according to Freud himself, was "to infer or to guess how the mental apparatus is constructed and what forces interplay and counteract it" (E. Jones, 1953, vol. 1, p. 45).

The inferences on development and infantile experiences were colored, in large measure, by statements and reconstructed memories of his adult neurotic patients. It was a narrow data base, hardly adequate to construct a theory of normal development. But Freud had an advantage that most other theorists of his day (and these days) did not have: He, like Binet, was permitted the opportunity to study complex processes in "persons whom we know intimately." Psychoanalysis thus evolved from the exhaustive observation of single individuals over a long-term period, including Freud's own self analysis. Theory construction and its evaluation thus proceeded on an idiographic basis, following a research strategy not unlike the method he found effective in his earlier physiological studies.

If the contributions of investigators who employed the idiographic method are any indication—Preyer, Binet, Baldwin, Lewin, Piaget—then the procedure seems not wholly without merits. But there are pitfalls. While Binet argued that it was necessary to work back and forth—verifying and testing one's hypotheses at both levels of

analysis—Freud eventually expressed a disdain for systematic experimental work, and the validity of the results it produced. For instance, in response to what seemed to be the experimental demonstration of repression in the laboratory, Freud observed: "I cannot put much value on these confirmations because the wealth of reliable observations on which these assertions rest makes them independent of experimental verification" (cited in Shakow & Rapaport, 1964, p. 129). Freud had earlier held that the rejection of psychoanalytic teachings had been for "emotional" and "unscientific" reasons. Here the suggestion appears to be that they should be accepted on the same grounds. In time, the validity of psychoanalytic assertions came to be evaluated by dogma, not by data. That's a pity on two counts. First, the history of developmental research indicates that Freud was correct in holding that idiographic methods are no less "scientific" than are nomothetic ones, though the more enduring advances have occurred when the two methods have been coupled. Second, the scientific status of the entire area was compromised when it became permissible to denigrate the value of a conclusive empirical observation or experiment if it happened to be in conflict with a kernel hypothesis.

In any case, psychoanalysis has thrived for 100 years in science and society. Its direct impact upon the health and social sciences and literature cannot be overestimated. As a scientific orientation, the breadth of its roots in the evolutionary-developmental thought of Darwin and Haeckel, on the one hand, and the psychological associationism of J. S. Mill and British empiricism, on the other, made it especially susceptible to hybridization. For example, psychoanalysis-as-theory was as readily married to the hypothetico-deductive behavioral model of C. Hull as it was to the ethological theory of K. Lorenz and N. Tinbergen. Both syntheses—social learning theory and attachment theory—have proved to be exceedingly influential in developmental research, a matter that we revisit.

One kernel assumption that has made psychoanalysis particularly attractive to developmentalists has been its focus on the very early years as formative and determinative. The events of infancy and early childhood are presumed to provide the foundation for adult personality and psychopathology. This broad assumption demands research on infancy and early childhood and on the events that occur in the familial relationships. Ironically, the assumption also implies that the events that occur later in ontogeny—during childhood and adolescence and early adulthood—are necessarily less plastic and malleable, hence less critical for understanding personality and psychopathology. Psychoanalysis is a developmental theory, up to a point. Hence, childhood is seen as the "latency" period, and adolescence is viewed as a period of activating the propensities and conflicts of the earliest years. The goal of much research in this tradition has been to demonstrate that there are strong continuities from infancy and the preschool period throughout childhood, adolescence, and early adulthood.

There is a formal similarity between psychoanalysis and most of its descendant theories—including object relations theory and attachment theory—in that the principal dynamic processes of development are restricted to the earliest years. Once these personality dispositions and structures become established and fixed, other nondevelopmental processes come into play. Under very special circumstances, such as psychoanalytic therapy, later interventions are possible. As Fenichel (1945) observes, the transference relationship in psychoanalysis is seen as a reconstructive psychiatric intervention where the fixations and conflicts of infancy and childhood are relived and repaired.

The broader point is that psychoanalysis and its descendant models implicate developmental processes—reciprocal interaction, bidirectionality, behavioral plasticity, biobehavioral organization—only up to a critical point in ontogeny. In the usual case, this point is infancy or very early childhood. These developmental processes become less active and less relevant, and the personality structures and dispositions that they produced govern the nature and quality of the individual's adaptations throughout the life course.

OTHER TRENDS IN SCIENCE AND SOCIETY

Psychoanalysis clearly played the leading role in setting the agenda for future studies of developmental psychopathology, but other, nearly forgotten forces were operating to link psychology and society. One notable event, particularly relevant to child study, was the opening of the first psychological clinic in the United States. It was founded in 1896 at the University of Pennsylvania under the direction of Lightner Witmer, a former student of Wundt and Cattell.

The aim of Witmer's work was to assist in the diagnosis and treatment of children with school problems,

and to apply the principles of the newly established science to everyday concerns. What were those principles? In Witmer's view, the study of children required a multidisciplinary approach, and from the beginning he brought together different professions, including social workers, physicians, and practicing psychologists. In the absence of a treatment model, he created one. Although the clinic was essentially a local Philadelphia operation, it grew and prospered under Witmer's leadership, and a journal, the *Psychological Clinic,* was founded to describe its activities. The concept of an applied psychology, as well as a clinical psychology, caught on, and one of the students from Witmer's group at Pennsylvania, Morris Viteles, led the way in the establishment of industrial psychology in America (Viteles, 1932).

Developmental Theory

From 1900 forward, when theoretical activity in developmental psychology was on the wane in the United States, it began to thrive in Europe. Following the impetus provided by Preyer, developmental work in German-speaking countries expanded, with the young William L. Stern (1871–1938) playing a leading role. Stern was instrumental in extending the theoretical and institutional foundations of the new science in Germany from the turn of the century through the early 1930s (Kreppner, 1992). In 1909, he was sufficiently prominent in the discipline that he was awarded an honorary degree from Clark University.

Kreppner (1992) has recently argued that Stern should be viewed as the peer of Preyer, Binet, Freud, Hall, and Baldwin as a pioneer in developmental psychology. Remembered in U.S. psychology mostly for his proposal that the mental ages could be converted into an intellectual quotient (J. Peterson, 1925; Stern, 1911, 1914)—a transformation that was designed to equate intelligence scores across chronological ages—little systematic recognition has been given to his fundamental role in establishing three areas of psychology as scientific disciplines: (1) differential psychology, (2) personality psychology, and (3) developmental psychology. Stern's influence is seen in the ideas on development that he generated, in the institutions he created, and in the students whom he influenced, including Heinz Werner and Martha Muchow.

Although he completed his dissertation with Hermann Ebbinghaus, Stern saw early that the study of human development required a unified perspective (Kreppner, 1992). In this regard, Binet and Henri (1895) had earlier confronted the dualism between elementarism and holism in understanding children's cognitive functioning and problem solving. In the same spirit:

> [Stern criticized] the view that psychological elements are carriers of psychological forces . . . a person's actions are defined not by single elements but by the entire structure of environment, person, and person-environment interaction. Thus, a wholistic view was one of the fundamental bases from which Stern constructed his person-oriented theoretical framework. (Kreppner, 1994, p. 317)

Consistent with the dialectic philosophy, Stern described the tug-of-war between personal dispositions and environmental constraints in development. This brings up the issue of how plastic or malleable are actions in ontogeny. The individual is a complex unit that is not entirely determined by the forces within or the forces without. In this regard, Stern wrote:

> This is the fact of personal plasticity or malleability, a domain of intentional education or unintentional influences of the milieu. This domain is narrower than many empiricists might be aware of. For the person is not only a passive recipient of the environmental forces impinging on him, but he is also reacting to these forces. The way he shapes and keeps a kind of plasticity is not only a symptom of the conflict between activity and passivity, it is also a tool for overcoming it: It is a mirror which is a weapon at the same time. (W. Stern, 1918, pp. 50–51, quoted from Kreppner, 1994, p. 318)

But it should be recalled that a dialectical systems perspective is not necessarily a developmental perspective. Stern's dual interest in development and individual differences presents a dilemma. The inclusion of developmental change in any discussion of characteristics of the self—traits and types—adds fresh complications. The theoretical task is to resolve the tension between changing, adaptable features that promote fresh adaptations, and enduring, permanent features that provide for predictable individual differences. On this score, the proposal of the IQ ratio held age constant and focused on individual differences; it represented the differential assessment, nondevelopmental side of Stern's thinking. His students represented both features of Stern's thought, from the nondevelopmental representations of topographical theory (Lewin, 1935) to the thoroughly developmental concepts of mental development and symbolic transformation in Werner (1940/1948).

His influence extended even beyond the boundaries of recent retrospectives. Through the work of Gordon Allport, Stern's ideas became prominently represented in the classic volume *Personality* (Allport, 1937). Stern's strong influence is seen in Allport's concepts of the holistic nature of personality organization and functioning, and idiographic and nomothetic models. In the study of individual differences, Stern literally wrote the book, authoring one of the first systematic texts on differential psychology (1911), a volume that is still admirable in its precision and clarity.

After establishing and directing the Psychological Institute at Hamburg University, Stern was expelled from Germany in 1933 by the Nazi regime. He came to the United States in 1934, was appointed in the Department of Psychology at Duke University, and died in Durham, North Carolina, in 1938. As in the case of J. M. Baldwin, his ideas have survived, but his name recognition temporarily lapsed.

Child Study

In France, developmental work progressed in brilliant leaps in education and became bogged down in the universities. Binet himself was rejected in his three attempts to secure an academic appointment as chairs became open at the Sorbonne and the Collége de France. He died without having been named to a professorship in France, despite his preeminent role in the establishment of psychology as an empirical science. Binet's founding of a laboratory for the experimental study of educational problems inspired E. Claparéde's establishment of the J. J. Rousseau Institute in Geneva.

In England, James Sully (1896b) and William Drummond (1907) produced influential textbooks on psychology and on development, although there was relatively little novel research being conducted on children (but see McDougall, 1906–1908). In this regard, Mateer (1918) observed that "on the whole English contributions to child study, in so far as it deals with the child of preschool age, have been imitative rather than original and very scanty in number" (p. 28). Additionally, the contributions of Hall were being brought back to Europe whence they had originated. The British Child Study Association, in England, and the Society for the Psychological Study of the Child, in France, were two of the more influential groups modeled after Hall's U.S. association. Comparable developments were occurring in Italy, Russia, Denmark, and Portugal, but these events were relatively remote from the mainstream of ongoing developmental work and thinking. They soon were to become less remote with the importation by Mateer (1918) of classical conditioning methods for studying learning in infants and children.

From 1890 onward, North America joined Europe as a primary center for the scientific study of children. Millicent Shinn's "Notes on the Development of a Child" appeared in 1893 and led to a renewed interest in individual studies. At the time, her replication and extension of Preyer's method was considered to be a "masterpiece" (Mateer, 1918).

Development and Education

The work of Binet, Hall, and Stern has underscored the intimate linkage between basic developmental research and educational practice. These investigators became psychologists, however, and they focused on developmental phenomena in their research and their writings on education. It was a different course with John Dewey. Cahan (1994) notes in her review of Dewey's contributions to the science:

> Education was Dewey's most enduring, comprehensive, and synthetic philosophical problem and the one for which he became best known. His interest in education "fused with and brought together what might otherwise have been separate interests—that in psychology and that in social institutions and social life." (p. 146)

Influenced by the neo-Hegelianism of George S. Morris and W. T. Harris, on the one hand, and the pragmatism of C. S. Peirce and William James, on the other, Dewey evolved a distinctive view of education that focused on the social circumstances of the child. The dialectic between the child and the environments in which he or she lived and adapted was key to understanding the nature of development. In this framework, schools became the natural settings for the study of development.

Dewey held that the experiences of children in school could prepare them to develop those intellectual and moral virtues that would establish a better society (Dewey, 1916). How is this to be achieved? According to Dewey, the subject matter of education should not be imposed by the agenda of the adult but should be drawn from the child's immediate environment and from the child's current interests. The task then would be to begin with the child's needs and concerns, not the teacher's.

Sound familiar? These ideas were in the air in the early decades of the twentieth century. The Baldwin-Piaget concepts of accommodation and assimilation were first cousins to the idea that there is a "constant reorganizing and restructuring of experience" (Dewey, 1916, p. 82). So are the views of Stern that "the way [the child] shapes and keeps a kind of plasticity is not only a symptom of the conflict between activity and passivity, it is also a tool for overcoming it." Vygotsky's "zone of proximal development" captures a similar concept. These interwoven ideas owe much to Hegelian idealism and the emergent, developmental assumptions with which it has been associated.

At the level of theory, Dewey created a framework for conceptualizing development and education rather than providing a tightly knit model to guide teaching practices. There are ambiguities, however, in how the transition is made from theory to practice. For example, the idea of a "restructuring of experience" does not provide prescriptive rules on how challenging the task must be, or how much assistance and drill the child should be given.

In a review of Dewey's work and thought, Cahan (1994) emphasized that Dewey considered education to be an opportunity for society to reformulate itself, and that "the school is cast as a lever for social change" (p. 163). This central theme was expressed early by Dewey (1899) in a lecture at the University of Chicago:

> The obvious fact is that our social life has undergone a thorough and radical change. If our education is to have any meaning for life, it must pass through an equally complete transformation. . . . The introduction of active occupations, of nature study, of elementary science, of art, of history; the relegation of the merely symbolic and formal to a secondary position; the change in the moral atmosphere, in the relation of pupils to teachers—of discipline; the introduction of more active, expressive, and self-directing factors—all these are not mere accidents, they are necessities of the larger social evolution. . . . To do this means to make each one of our schools an embryonic community life, active with types of occupations that reflect the life of the larger society, and permeated throughout with the spirit of art, history, and science. When the school introduces and trains each child of society into membership within such a little community, saturating him with the spirit of service, and providing him with instruments of effective self-direction, we shall have the deepest and best guarantee of a larger society which is worthy, lovely, and harmonious. (pp. 43–44)

Hence, educational theory "becomes political theory, and the education is inevitably cast into the struggle for social reform" (Cremin, 1964, p. 118). In Dewey's framework, there is an explicit fusion among the science of human development, educational applications, social reform, and morality. Viewed in historical perspective, Dewey's work and vision may be seen as yet another legacy of his former teacher at Johns Hopkins, Hall.

THEMES OF THE FOUNDATIONAL PERIOD

The emergence of modern developmental psychology in the late nineteenth and early twentieth centuries was hardly a coherent, systematic enterprise. For instance, Dewey's broad philosophical view of development and the embryological concepts of von Baer and evolutionary constructs of Darwin seemed to live in different lands. Considered as a whole, developmental work and theory were diverse, vigorous, contentious, fresh, and, in many instances, brilliant. Despite the lack of unanimity in method and theory, certain themes seemed to capture the attention and guide the work of these early developmental investigators. Seven themes of general significance were:

1. The ontogeny of consciousness and intelligence.
2. Intentionality and the correspondence between thought and action.
3. The relations between evolution and development.
4. The nature-nurture debate.
5. The effects of early experience and when development ceases.
6. Moral development.
7. How the science may contribute to the society.

Knowledge and Consciousness

"Theory of the mind" concepts are hardly new for developmentalists. Indeed, for both comparative and developmental investigators, the origins of consciousness and the development of knowledge were the major empirical concerns in the formative period of the science. The main business of comparative psychology, in the view of Romanes (1884), was to investigate the continuity of consciousness and intelligence from animals to man. To

establish the linkage, it was necessary to undertake studies of animal consciousness and of animals' apparent "intelligent" adaptations to the varied circumstances of life. Why continuity? For Romanes, continuity would demonstrate that human beings were on the same continuum as animals in the evolutionary scheme. Using information brought to him from varied and informal sources, Romanes collected anecdotes on how various beasts (dogs, chickens, spiders, cats) demonstrated high levels of intelligence in their adaptations, and transmitted this knowledge to descendants through Larmarckian mechanisms of hereditary transmission.

Here C. Lloyd Morgan entered the scene. Recall that Morgan's major contribution to developmental and evolutionary thought was his elegant refutation of the concept of hereditary transmission of acquired characteristics, a variation of which Baldwin labeled "organic selection" (Klopfer & Hailman, 1967; Morgan, 1896, 1902). The logic of his argument against Larmarckianism extended beyond psychology and beyond behavior.

Morgan was also instrumental in helping establish some limits on the projection of higher-order cognitive processes to lower organisms. Initially a skeptic about interpreting the mental status of nonhuman animals, he formulated a canon (or criterion) by which such attributions may be permissible. Now known as *Morgan's Canon,* it reads "In no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the outcome of the exercise of one which stands lower in the psychological scale" (Morgan, 1894/1903, p. 53). In its assumption that the "psychic facility" of nonhuman animals can be qualitatively different from those of human beings, Morgan's criterion helped put a break on the more blatant forms of nineteenth-century anthropomorphism (see also Schneirla, 1966). As a by-product, it invited a shift from a focus on animal consciousness to a focus on animal behavior, including analyses of the roles of biophysical and chemical processes within the organism and physical and social forces without.

The shift was nontrivial. By 1906, H. S. Jennings entitled his magnificent study of the activities of paramecia as "The *Behavior* of Lower Organisms." Earlier, Binet's work on infusoria and other lower beasts was labeled, "The *Psychic Life* of Micro-Organisms" (emphases added). Through Jennings and J. Loeb, the shift in focus paved the way for J. B. Watson's behaviorism (1914) and, ironically, the denial of consciousness. In the article, "How Lloyd Morgan's Canon Backfired," Costall (1993) proposes that "C. L. Morgan argued that the behavior of animals and humans could only be treated in intentionalist terms; his Canon was an attempt to stem anthropocentrism but has been consistently misunderstood" (p. 13; see also Wozniak, 1993). Whatever might have been Morgan's own intentions, he played a pivotal role in extending accounts of behavioral development in animals and children beyond mentalism and anthropomorphism. This was a critical step if developmental research was to be promoted from the second-class status that it had been assigned by Wundt (1907) and Hall (1885).

Questions on the origin of knowledge were also central for early developmentalists. Not only were child psychologists concerned with "the content of children's minds" (Hall, 1891), but with how the content got into the mind. Preyer gave primary attention to the establishment of the senses, language, and cognition, and Binet and Baldwin early focused on experimental studies of childhood perception, discrimination, and memory. J. M. Baldwin's (1895, 1915) developmental theory on the origins of knowledge arose in part from an admixture of the speculations of the post-Kantian and the evolutionary views of Herbert Spencer and G. J. Romanes on stages in consciousness and cognition.

At its root, however, were observations of infants that provided empirical substance to the ideas of reflexive, sensorimotor, and ideomotor adaptations. Baldwin's mature theory of "genetic epistemology" was, essentially, a theory of the mind. It was based for the most part on intuition and the framework that had been established by predecessors in philosophy and biology. It seems no mere coincidence that the dominant concern with cognition and intelligence gave rise to the most robust empirical tests and the most reliable experimental methods of the period.

The Relations between Thoughts and Actions

Although the problem of consciousness was the major theme, questions of the linkages between thoughts and actions lagged not far behind. At what point in ontogeny do "willful" acts arise, and what is the relationship among consciousness and intention and action at any stage of development? These related questions were explored by virtually all early developmental investigators,

but, again, with different emphases and different conclusions. Binet and Freud, in part because of their experience with hypnotism and their exposure to the work of Charcot, were concerned with the role of unconscious processes in the direction and control of behavior, both normal and pathological. Binet's (1892) studies of alterations of personality dealt with the effects of unconscious forces, and Breuer and Freud (1895/1936) made motivation and unconscious control the central theme of psychoanalytic theory. On this score, one of the more interesting observations from this period is the discovery of the linkage between Binet's and Freud's views of unconscious processes. Similarly, Baldwin (1897/1906) considered how conscious acts, with practice and time, become unconscious, and how awareness and intentionality develop in step with cognitive development. Nonetheless, the study of "intentionality" posed formidable methodological problems that were not solved (although Preyer launched an early assault on the problem in his studies of infants).

Ontogeny and Phylogeny

How may development be defined: in terms of the ontogeny of individuals, or the ontogeny of the species? Developmental psychology was born in the wake of the biological revolution created by the formulation and widespread adoption of the Wallace-Darwin theory of species origins. The challenge to produce a similarly powerful theory of individual genesis was felt by biologists and psychologists alike. The initially popular candidates for such a general developmental theory were unfortunately limited.

Doubtless the most influential early developmental theory was the "biogenetic law." Virtually all early important developmental writers were recapitulationists of one sort or another. Adoption of the recapitulation perspective did not, however, preclude consideration of alternative or supplementary views. On this score, the delayed maturation hypothesis of Preyer and the Baldwin-Morgan-Osborne proposal on organic selection represented efforts to solve the puzzle of how development could contribute to evolution as well as the reverse.

The "biogenetic law" collapsed shortly after the turn of the century, when the cornerstone assumption of recapitulation was discredited in biology (Gould, 1977). Embryological studies indicated that morphological steps in development could not be simply accounted for in terms of ancestral analogs. Even in embryogenesis, morphology was adaptive to the special conditions that prevailed and, as von Baer had earlier argued, development was appropriately described in terms of early differentiation of structures in ways that became increasingly distinctive for the species. The idea that evolutionary modifications and developmental adaptations are mutually supportive has been repeatedly offered, from the proposals of Morgan and Baldwin to those of modern ethology and developmental psychobiology. To be sure, the recapitulation doctrine was wrongheaded, but the issues to which it was addressed remain fundamental for the science.

Nature and Nurture

A related but separable matter concerns the extent to which an individual's behavior and propensities reflect the operation of experiences as opposed to an inborn, heritable potential. The "nature-nurture" problem, as labeled by Galton (1871), continues to tantalize developmental theorists. Positions on this matter were as diverse then as they are now. Virtually all writers of this early period paid at least lip service to the proposal that it was not an "either/or" proposition but a question of how the two influences were fused in the course of development.

A variety of methods were employed for the study of "natural" influence on behavior. Preyer, for instance, assumed that the actions that develop in the absence of training must reflect the operation of innate factors in the infancy of an individual child. Galton, in a nomothetic approach, placed emphasis on the information to be obtained from pedigree studies, familial and twin comparisons, and selective breeding in animals. Along with Karl Pearson, he developed new statistical tools for the evaluation of covariation and correlation, and these fit neatly with the metric scale of intelligence. They also invited the partitioning of variance into heritable and environmental sources, a technique that also provided the foundation for modern quantitative behavioral genetics and a century of controversy.

When Does Development End?

All early developmentalists, by definition, assumed that experience played a role in the establishment and maintenance of basic systems of behavior, emotion, and cognition. There were radical differences among them regarding *when* they considered experience to be relevant, since timing made all of the difference in the

world (see Elder, Chapter 16, this *Handbook,* this volume). For Hall, individual experience played a major role in adolescence; early experience was virtually irrelevant because evolutionary forces laid the course for development up through adolescence. For Freud, it was just the opposite: Infancy was key; he assumed very early development to be basic in laying the foundations for adult behavior. Beyond infancy and early childhood, the person resisted enduring changes (except under psychoanalytic treatment). For Preyer, it was embryogenesis. And for Baldwin, personality development was a continuing, never-to-be-exhausted process over the life course, so turning points could occur throughout ontogeny.

When the details of timing and plasticity of development were left unspecified, investigators could talk past each and share a happy illusion that they referred to the same issues and outcomes. A basic premise of psychoanalytic theory is the strong hierarchical assumption that very early experiences are foundational for the thoughts, actions, and relations that follow. Psychoanalytically oriented writers could be radical developmentalists, but only for one phase of the life course. Once the personality structures, motives, and "working models" become established, focus was given to the processes of maintenance, not those of establishment and change. Investigators in a Baldwinian life-course perspective could look to events that occurred over ontogeny.

In the absence of longitudinal information on the behavioral adaptations of human beings, there was no adequate basis for selecting or rejecting these theoretical assumptions about the timing and functions of early experience. Although Mills (1898) called for systematic longitudinal study, it took a half-century before this method was systematically explored, and still another 90 years before it became a method of choice.

Morality and the Perfectibility of Humans

The concern with intentionality and willfulness can be viewed as part of a broader question of ethics: How can science help understand how human perfectibility may be achieved and imperfections avoided? This core issue was clearly pervasive in the moral psychologies of Tetens and Carus, and it was also a matter of no little import for Spencer, Hall, Baldwin, and several others of the era. A goal shared by many of them was to formulate a developmental science, which, in its highest application, would supplement—or supplant—religion.

By 1900, the key empirical finding—that stages existed in the "development of moral judgments"—had been established; in that, older children gave greater weight to the motivation and intentions of a transgressor than did younger children. Similarly, striking age-developmental differences were obtained in the level of abstraction of the "moral judgments," and in the extent to which older children as opposed to younger (12 to 16 years versus 6 to 10 years) took the point of view of the offender. These generalizations were drawn from voluminous questionnaire studies, based on the responses of thousands of children at each age level (e.g., Hall, 1904; Schallenberger, 1894). The methodology, but not the conclusions, was severely criticized at home and abroad. On matters of moral conduct, J. M. Baldwin's proposals adumbrated both Hartshorne and May on the specificity of moral conduct, and the proposals of Kohlberg on the development of the self and moral reasoning.

Social Applications

The application to the needs of society presented both opportunities and problems. To promote the application of "scientific" principles to rearing and educating children, child study movements arose in America, and similar efforts were initiated on the continent and in England. The problem was that scientific principles were in short supply. On this point, William James noted, in *Talks with Teachers* (1900), that "all the useful facts from that discipline could be held in the palm of one hand." Not everyone, including Binet and Hall, agreed with James. Then, as now, the temptation was great to go beyond commonsense beliefs in writing about children.

The ideas and claims of some early developmentalists had political ramifications as well. One of the outcomes was the establishment and rapid growth of the eugenics movement, with Francis Galton as its intellectual leader and the protection of superior genes as its goal in England. One by-product of "Social Darwinism" was the importance attached to the newly devised metric scale of intelligence and the belief that it would permit rapid identification of innate, stable differences in talent. A movement in Germany, promoted by Haeckel (1901), carried a message of biological ethnic superiority and led to dark political goals.

There was also a very bright side to the application of developmental principles and ideas (see Sears, 1975). Persons concerned with the science tended to act as

child advocates, lending their prestige to the passage of child labor laws, the revision of elementary and secondary school curricula, and the promulgation of child-centered rearing and control practices. The discipline may not have directly benefited from these efforts, but the welfare of children did. Then there was the enormous impact that John Dewey's concepts of human development had on teaching and schooling practices. The field moved ahead to consolidate its claim to be an empirical science as well as a progressive social movement.

In summary, the modern study of behavioral development had an auspicious beginning as a vigorous, multidisciplinary undertaking that was pregnant with new ideas, fresh approaches, and novel developmental methods. To the founders, the resolution of the basic problems of development seemed within grasp. Perhaps they were, but that early promise was not to be fulfilled, at least not for another half-century.

THE MIDDLE PERIOD (1913–1946): INSTITUTIONALIZATION AND EXPANSION

One-third of the twentieth century, from 1913 to 1946, encompassed two world wars, an economic depression of unprecedented depth and duration, the rise to world power of two new political-economic systems, and unspeakable horrors of mass destruction and genocide. These events affected the course of all intellectual and scientific work undertaken during the period, and developmental psychology was no exception.

Paradoxically, some of the events that had tragic worldwide consequences served to enrich and broaden the discipline. World War I brought attention to the advantages and potential of psychological assessment, particularly intelligence testing. It also sent the primary U.S. developmental theorist, James Mark Baldwin, to France, where he enjoyed greater influence than he had had in his own country. World War II contributed toward the establishment of psychology as a profession as well as a science. The U.S. prosperity enjoyed in the 1920s was directly translated into liberal support for the discipline by private foundations and state funds. Likewise, the depression of the 1930s and early 1940s effected a massive withdrawal of funds and, concomitantly, a drop in the level of research activity on developmental problems.

Nazi persecution in the 1930s brought to the United States a cadre of brilliant theorists from Europe. Some, including Kurt Lewin, Fritz Heider, and Heinz Werner, gained an opportunity to change the direction of modern social psychology and to keep alive the developmental concept. For others, including Karl Bühler and William Stern, the exodus was a tragedy wherein their talents and achievements were virtually unappreciated and ignored. And what directions might the study of social development have taken if Charlotte Bühler had been permitted to remain safe and free at her Institute in Vienna rather than becoming an adjunct faculty member in Los Angeles?

Beyond societal and political influences, there was much to be accomplished within the area. There was an immediate need to extend the methodological boundaries of the discipline to permit systematic investigation of the several issues claimed by its investigators and theorists. Hence, the formulation of ways to translate ideas into research operations remained a first task. Virtually all substantive issues required attention, from social, cognitive, and sensorimotor analyses to the study of language, moral development, and psychobiological changes. In the 1920s, with the widespread granting of funds that were specifically assigned to support studies of children, there was an explosive increase in empirical research.

In the establishment of its empirical foundations, the enterprise of child and developmental psychology became segregated into separate subareas, topics, and theories. No single model, not even behaviorism, was broad enough to encompass and provide direction for the activities of researchers. The fragmentation stimulated efforts to put the field back together again through the publication of handbooks (which served to summarize the diverse investigations) and the founding of development-centered journals and scientific societies. But in the absence of a compelling and coherent general theory of development, the subareas of developmental investigation and thought evolved along separate trajectories. The story of the main events and ideas of this period is perhaps best told by recounting the progress made in the several areas of inquiry—from mental testing and moral development to language and thought and developmental psychobiology. That is the strategy adopted in this section, beginning with some comments on the institutionalization of U.S. developmental psychology and ending with a brief review of some major theoretical ideas of this period.

INSTITUTIONS AND DEVELOPMENT

The child study movement led by Hall in the 1880s and 1890s bore fruit some 20 years later. Child study associations had been established in one form or another in all regions of the country. Collectively, they formed a potent movement for child advocacy. In 1906, an Iowa housewife and mother, Cora Bussey Hillis, proposed that a research station be established for the study and improvement of child rearing (Sears, 1975). Her argument was simple but compelling: If research could improve corn and hogs, why could it not improve the rearing of children? The campaign to establish a Child Welfare Research Station at the University of Iowa was eventually successful. The Iowa unit was established in 1917 and its research-laboratory school opened in 1921.

The Iowa facility—along with a comparable research unit that opened shortly afterward at the Merrill-Palmer Institute in Detroit—became the model for child development institutes that were to spring up across the United States and Canada in the 1920s and 1930s. Because one of the main functions of the institutes was dissemination of information about children, various publications were established, ranging from university monograph series (at Iowa, Columbia, Minnesota, Toronto, and Berkeley) and journals (*Child Development, Child Development Monographs*) to handbooks (Murchison, 1931, 1933) and magazines (*Child Study, Parents Magazine*). Most of the institutes also awarded advanced degrees, thereby helping to create a new professional workforce. The graduates found placements in university teaching and research positions, as well as in a wide range of applied settings. An interdisciplinary organization, the Society for Research in Child Development, was established in 1930 to provide a forum and a framework for scientific contributors to the discipline (Frank, 1935).

The story of this "golden age" for the study of children in the United States has been told expertly by two of its participants (Sears, 1975; Senn, 1975), so only an overview is required here. New funds from diverse private and governmental sources were made available to researchers in child development. Among the more notable contributors were the individual sponsors of the Fels and Merrill-Palmer child study institutes, along with various special-mission projects (i.e., Terman's study of gifted children, by the Commonwealth Fund; the study of the effects of motion pictures on children, by the Payne Foundation; the causes of morality, by the Institute for Religious and Social Education).

But in terms of sheer impact on the field, the Laura Spelman Rockefeller Memorial (LSRM) must be acknowledged as having the greatest influence. Through LSRM funds, major centers for research were established at three universities (California, Columbia, Minnesota). Substantial support was awarded to the existing institutes at Yale and Iowa, and smaller-scale research centers were created at the University of Michigan and in Washington, DC. Studies of personality and child development at Vassar, Sarah Lawrence, and Teachers College (Columbia) also shared in the Rockefeller support. And that's not all. Under the general direction of Lawrence Frank, the Rockefeller funds provided support for individual research projects (including C. Bühler's pioneering investigations) and made possible the establishment of the national Child Study Association (see *Child Study,* vols. 1 to 3). Such liberal support for child study provided stimulation for ongoing work at Stanford, Harvard, Toronto, and Cornell. All in all, the effect was to confirm Binet's observation that Americans like to do things big.

To summarize in detail the specific activities and accomplishments of these institutes from 1920 to 1940 is beyond the scope of this review. At midstream, Goodenough (1930b) provided an informative coverage of the work and accomplishments during a period of great activity. Each institute soon evolved its own "personality" in terms of methods employed and problems addressed. The issues that the institutes tackled should illustrate the point.

1. *Mental testing.* Virtually all of the institutes were committed, at some level, to clarifying the problems of intelligence assessment and how individual differences in test performance came about. By the late 1930s, studies at Iowa on the effects of enrichment on intelligence test performance had appeared, and longitudinal work on the stability and change of IQ had begun at Fels and Berkeley. Anderson (1939) at Minnesota offered a provocative theory of the continuity of intellectual functions, based on the extent to which early tests assessed functions that overlapped with those assessed in later tests. The faculty at Stanford, headed by Lewis Terman and Quinn McNemar, strongly contested any strong claims on the malleability of intelligence (Minton, 1984).

2. *Longitudinal study.* Most thoughtful developmental psychologists recognized the need for gaining adequate information about behavior and development over a significant portion of the life span. But the lack of resources inhibited such long-term, large-scale investigations of behavior and cognition. Here is where the institutes were invaluable. Two of the institutes—Berkeley and Fels—launched systematic longitudinal investigations. The work complemented the already initiated study by Terman at Stanford.

3. *Behavioral and emotional development.* The study of children's fears and how they arise was undertaken at Columbia, Johns Hopkins, Minnesota, California, and Washington University (St. Louis). This work, essentially an extension of the projects launched by Watson and his collaborators at Johns Hopkins (see below), dealt with the problems of how emotions arise in ontogeny and how fears are learned and unlearned (Jersild, Markey, & Jersild, 1933; M. Jones, 1931).

4. *Growth and physical maturation.* The early work of the Iowa group was concerned with the study of children's physical development, including the care and feeding of children (Baldwin & Stecher, 1924). Similarly, Arnold Gesell's institute at Yale led the way in establishing graphs of normal development for use in identifying instances of aberrant behavior or developmental disorders (see below). The Fels Institute early established a tradition for clarifying the relations between physical and behavioral development, leading to, among other things, significant advances in assessment and diagnosis of psychosomatic relations.

5. *Research methods.* John Anderson and Florence Goodenough at Minnesota, Dorothy S. Thomas at Columbia, and H. McM. Bott at Toronto recognized the need for more adequate observational research methods (see Anderson, 1931; Bott, 1934; Goodenough, 1929; D. S. Thomas, 1929). But the methodological work was not limited to observational techniques. Goodenough (1930a) continued to explore alternative and flexible methods for personality and intellectual assessment (including her Draw-a-Person test), and these workers led the way in ensuring that high levels of statistical sophistication would be employed in research design and analysis. Dorothy McCarthy at Minnesota and Jean Piaget at the J. J. Rousseau Institute began their influential studies of the origins of children's language and thought.

This is a mere sampling of the major concerns and issues. Without detracting from the intellectual and scientific quality of the work completed, it should be noted that few major theorists were associated with the newly founded institutes. There were some notable exceptions to this generalization, including Jean Piaget at the Rousseau Institute and, in the 1940s, Kurt Lewin and Robert Sears at Iowa. For the most part, the institutes were devoted to the pragmatic problem that Mrs. Hollis had identified, "How can we improve the way that children are reared?" The area soon learned that it had neither methods nor theories adequate to the task. The institutes focused on devising more adequate methods, leaving the primary theoretical work to others.

MENTAL TESTING

In the eyes of many developmentalists in the 1920s and 1930s, the major obstacle to establishing a credible science of child psychology was not theoretical so much as it was methodological. Given Binet's insights on and career-long devotion to the matter, it seems altogether fitting that he, along with his collaborators, engineered the most significant methodological advance of the first half-century of the science. Whatever may be the flaws and shortcomings of the Binet-Simon method of intellectual assessment, it provided the tool that was required for the precise study of children's development, and for the translation of cognitive events into quantifiable units. The test opened the door for comparisons of significant psychological dimensions across ontogeny, and for the analysis of individual differences among persons. It also provided a reliable method for addressing the major themes that had been identified in the first era of the field, including the problems of nature-nurture, early experience, continuity of consciousness, and the predictability of behavior and cognition.

Goddard (1911) deserves credit for having been the first to bring the Binet-Simon scale to the United States, but Lewis M. Terman and his colleagues at Stanford University were key in extending the use of intelligence tests in the United States and worldwide through their revision of the Binet-Simon scales. The Stanford-Binet individually administered tests helped establish clinical psychology as a separate profession in clinics, schools, the military, and industry, fulfilling one of Binet's visions (J. Peterson, 1925).

Like other students of Hall who gravitated toward educational psychology, Terman's initial academic appointment at Stanford was in the School of Education.

Formerly a school principal, Terman had a long-standing interest in the problems of individual differences in the classroom. He selected as his dissertation project the comparison of seven bright and seven dull boys on various measures (Terman, 1906). He had been acquainted with Binet's work since his research for his undergraduate thesis at Indiana University, and, given his background and the Barnes-associated tradition at Stanford for large-scale study, it seemed entirely in character that Terman should attempt an extensive standardization of the Binet-Simon scales (on some 1,000 California schoolchildren; Terman, 1916). Among other improvements to the scale, Terman adopted a suggestion by William Stern that any child's performance could be expressed in terms of an Intelligence Quotient (IQ). In his commitment to observation and standardization, Terman proved to be a worthy successor to Binet. The Americanized version of the test was an almost immediate success. The method was widely adopted and the essential idea was used to construct group tests to meet the needs of the military (in screening recruits for World War I) and the schools to sort out highly gifted or retarded children (Goodenough, 1954).

This is not the place to attempt a comprehensive account of the testing movement; useful histories of mental testing, through 1925, can be found in J. Peterson (1925) and K. Young (1924), and more recent accounts can be found in Goodenough (1954), and Carroll and Horn (1981). Three comments on mental testing and its relation to developmental psychology are in order, however.

First, the method paved the way for systematic comparisons across time, across persons, and across conditions. This was a necessary step toward the conduct of longitudinal studies of human behavior. It also provided the tool for comparing persons of different backgrounds, races, and environmental experiences, thereby permitting the researcher to address anew the problems of heredity and environmental influence. The study of the effects of early experience on IQ was explored by Sherman and Key (1932), by Wheeler (1942), and by the Iowa group led by Skeels and Wellman (Skeels, 1966; Skeels, Updegraff, Wellman, & Williams, 1938). In addition, the procedure was applied in ways not anticipated by its innovators. For instance, Kamin (1974) reported the tests were used as a screening device for immigrants to the United States—a practice that was hardly appropriate, given the diverse backgrounds of the persons being tested and the conditions of assessment. The device proved to be an exceedingly powerful tool for categorization and for differentiation of cognitive abilities.

Second, this comment concerns the relation of the testing movement to the rest of psychology, especially the rest of developmental psychology. Interest in the use of the procedure as a research device initially rode a wave of enthusiasm, followed by a period of neglect. When experimental studies of how performance on intelligence tests could be modified were conducted in the 1930s, it became clear that increments of one or more standard deviations (e.g., 10 to 20 IQ points) were not uncommon and could be brought about in a relatively brief period (4 to 16 weeks; see H. E. Jones, 1954, for a review of this work). In addition, Sherman and Key (1932) demonstrated that a negative correlation was obtained between IQ and age among children living in culturally deprived Appalachia. Such findings raised questions about the environmental contributions to IQ scores, and much debate about the nature and meaning of the findings followed (see McNemar, 1940; Minton, 1984). A parallel controversy arose over the interpretation of twin data, and the implications of findings from the tests of monozygotics, dizygotics, and other types of siblings for the inheritance of intelligence. The issues subsided, without clear resolution, in the late 1930s, then came to the forefront again some 30 years later.

Third, the method of intelligence testing did not give rise to a coherent theory of the development of intelligence. The theoretical debates centered mostly around matters of test structure and statistical analysis (e.g., whether a single factor could account for the variance or whether two or multiple factors were required) and whether the results of the experimental tests were being properly interpreted. There was a significant gap between the emerging theories of cognition (following the model of Baldwin and Piaget) and the methods of assessment being employed. Neither Piaget nor Baldwin are mentioned in Goodenough's (1954) comprehensive chapter on "mental growth." The gap was not unprecedented: A parallel problem could be found between the methods of social interactional assessment and the theories of personality and social learning patterns (see below). But the test procedures proved their worth in education and in the marketplace, even though they could not be readily integrated into the existing body of psychological theory. Hence, the testing movement evolved and prospered outside the mainstream of developmental psychology (Dahlstrom, 1985).

LONGITUDINAL STUDIES

According to Wesley Mills (1899), the discipline needed (a) longitudinal studies of individual organisms from birth to maturity, and (b) systematic experimental manipulations of the long-term conditions for development. Without that information, one could scarcely hope to achieve a firm grasp of the processes of development, whether nonhuman or human. Because the major hypotheses about development were concerned at their root with these processes, one would have thought that longitudinal studies would have been given the highest priority in the new discipline. They were not. Perhaps the practical difficulties in mounting life-span projects in humans seemed too formidable, or the investment and risks seemed too great. For whatever reasons, the information available about longitudinal development by the end of the first period of the area's history was either sketchy (e.g., Binet's study of his two daughters) or subjective and retrospective (e.g., psychoanalytic interviews). But, on this fragmentary information, the most influential psychoanalytic and behavioristic theories of cognitive and personality development were formulated, and few data were available to assess their implications or correct their shortcomings.

One of the obstacles for longitudinal study—the need for measurement—seemed to be solved by the development of a reliable device for the metric assessment of cognitive abilities. That advance was sufficient for Lewis M. Terman, who perfected the instrument and pioneered the first large-scale longitudinal study of behavioral-cognitive characteristics in 1921. He selected 952 boys and girls in California, from 2 to 14 years of age, who achieved a test score of 140 IQ or above. This group comprised the brightest children (in terms of test performance) who could be found in a population of about a quarter-million (Terman, 1925). His initial aim seems to have been the planning of educational procedures for gifted children. As it turned out, the sample provided the core group for follow-up studies that continued through most of the twentieth century. At several stages in childhood and early adulthood, these "gifted" children-cum-adults were reassessed, with the behavioral net widened to include personality characteristics, life accomplishments, and social adaptations. Later, their spouses and children were included in the study, and each group of subjects was followed through the 60th year of life (Sears, 1975). Despite shortcomings in the original design (e.g., absence of a matched nongifted control or comparison group), the data provide a rich yield of development through the life span. Overall, the work constitutes one of the major achievements of the science in its first century, incorporating the efforts of three of its most influential figures (Binet, Terman, & Sears).

Another factor that had inhibited longitudinal studies was the need for research institutes that would survive as long as their subjects. That problem was solved in the 1920s by the formation of the several child research institutes across the United States. Soon afterward, longitudinal projects were initiated at Berkeley, Fels Institute, Minnesota, and Harvard. Initially, smaller short-term projects were undertaken to investigate particular issues. Mary Shirley (1931, 1933a, 1933b), for instance, completed a 2-year-long investigation of the motor, emotional, and social development of infants. In contrast to the cross-sectional studies of Gesell, her longitudinal work permitted her to identify particular sequences in growth and change.

Experimental intervention studies of the sort that Mills (1899) had called for in animals were undertaken with children. Myrtle McGraw's (1935) work with Jimmy and Johnny, twins who were given different training experiences, is one of the better instances of the use of what Gesell called the "co-twin" control procedure. By providing "enrichment" experiences prior to the normal onset of basic motor functions, McGraw was able to demonstrate that experiences can facilitate the appearance and consolidation of climbing and other movement patterns. The "enriched" twin continued to show a modest advantage over the control twin, even though age and associated growth greatly diminished the apparent gains (see Bergenn, Dalton, & Lipsitt, 1994, for a more detailed account of McGraw and her contributions). Along with these well-known works, a large number of lesser-known investigations were addressed to the same issues, using short-term longitudinal interventions to influence intelligence test performance (e.g., Hilgard, 1933) and motor skills (e.g., Jersild, 1932).

These studies of longitudinal development were limited to children, at least in the initial stages. What about development beyond childhood? Since the early investigations of Quetelet, there had been few attempts to address directly the problems of developmental change during maturity. The exceptions are noteworthy because they provide part of the foundation for contemporary emphasis on the study of development over the entire life span of human experience. One of the first texts on

aging was produced by Hall (1922), shortly before his death. Later in the same decade, Hollingworth (1927) published a text on development over the whole life span, and some 12 years later, Pressey, Janney, and Kuhlen (1939) extended the coverage.

The database for these extensions to developmental issues over the life span was meager, at best. Surprisingly little research on behavioral development in adolescence was stimulated; perhaps Hall's major work gave the appearance that all of the important questions were already answered. One of the more interesting studies of this age group was reported by Bühler (1931), who analyzed the diaries of some 100 adolescents. In describing this work, Bühler (1931) writes:

> Intimate friendship is by all authors, considered as a characteristic of adolescence, not of childhood. The same is true of that love or devotion which one calls *hero-worship.* This is also considered as a very characteristic feature of puberty. Charlotte Bühler studied, on the basis of adolescents' diaries, the distribution and types of hero-worship during puberty. Her collection of about one hundred authentic diaries contains contributions from different countries, different milieus, and different age groups. . . . There are German, Austrian, American, Czech, Swedish, and Hungarian diaries in this collection. Statistics show that the average age at which girls begin to write diaries is thirteen years and eight months, while the average age for boys is fourteen years and eleven months. In all of the girls' diaries either a "crush" or a flirtation plays a role, sometimes both. The period of the "crush" is from thirteen years and nine months to seventeen years. The boys' diaries show a larger variety of types of friendship. In the place of the "crush," a devoted admiration for a leader or for a girl, or often for an older woman, plays a role. (p. 408)

Diaries provided an innovative substitute for prospective longitudinal data, providing an account of the adolescent's most intimate thoughts, concerns, hopes, and wishes. But it also had certain hazards, with the problems of selection paramount (e.g., who keeps a diary, what is selectively omitted or recorded). Because of its inherently private nature, the method has few safeguards against fraud. On this score, Sigmund Freud wrote a laudatory introduction to the published version of a diary that, upon critical examination, proved to be a fake. It is a modest irony that the young Cyril Burt (1920–1921) exposed the fraud. Some 50 years later, Kamin (1974) and others raised questions about biases and the accuracy of data in Burt's own work on twins reared apart. Despite the pitfalls, diaries continued to provide a potentially rich source of information about the beliefs, attitudes, and conflicts of adolescents.

Given the amount of time, effort, and funding required for these longitudinal studies, what could be said about their payoffs by mid-century? Were they worth the investment? The early returns indicated that the highest levels of predictability were obtained when the assessment procedures had previously established reliability and utility (i.e., intelligence and physiological measures). In social and personality characteristics, however, individual differences appeared to be demonstrably less stable over time. Because the longitudinal work was, for the most part, atheoretical, except for an implicit belief in the long-term stability of human characteristics, the early findings posed serious problems for interpretation. Were the methods and measures at fault, or was the theoretical framework itself to blame? It took research another half-century to answer this question.

BEHAVIORISM AND LEARNING

At about the time that World War I began in Europe, U.S. psychology underwent an internal upheaval. John B. Watson (1878–1957) called behaviorism a "purely American production" (1914, p. ix). Its essential message—that the study of humans, animals, and children required the objective methods of natural science—was of fundamental importance, but it was hardly novel. Others close to Watson, including his mentors in behavioral biology (Jacques Loeb and H. S. Jennings) and his colleagues in psychology (e.g., K. Dunlap), had expressed similar ideas. But none had presented the argument with the persuasiveness and flair that Watson did in person and in print. As Watson (1914) put it:

> Psychology as the behaviorist views it is a purely objective experimental branch of natural science. Its theoretical goal is the prediction and control of behavior. Introspection forms no essential part of its methods, nor is the scientific value of its data dependent upon the readiness with which they lend themselves to interpretation in terms of consciousness. The behaviorist attempts to get a unitary scheme of animal response. He recognizes no dividing line between man and brute. The behavior of man, with all of its refinement and complexity, forms only a part of his total field of investigation. (p. 1)

For Watson, there was an essential unity in animal and human psychology. The methodological differences that trifurcated the discipline for Hall and divided it for Wundt were not valid; the study of children, animals, and adult human beings could be reduced to the same behavioral, noncognitive techniques. Moreover, Watson called for a pragmatic psychology, one that could be applied in society and useful in everyday affairs. Watson liberalized psychology by holding, in effect, that the science could apply itself to any problem of life and behavior.

Watson was originally trained in comparative psychology and heavily influenced by biologist Jacques Loeb, who was "concerned with explaining animal behavior in terms of physiol-chemical influences and without the use of anthropomorphic, psychic, or mentalistic terms" (Jensen, 1962, p. x). His explanatory concept of "tropism" was borrowed from studies of plants, where stimulus-directed movement occurs, say, toward sunlight. At the same time, another behavioral biologist, H. S. Jennings, agreed with Loeb on the need for objective analysis, but he also emphasized the "complexity and variability of behavior in lower organisms and the importance of internal factors as determinants of behavior" (Jensen, 1962, p. x). How Loeb—Watson's mentor at Chicago, and Jennings—Watson's senior colleague at Johns Hopkins—outlined many of the essential ideas of behaviorism is a fascinating story that has been brilliantly documented by D. D. Jensen (1962; see also Pauly, 1981).

Watson's contributions to development evolved through two stages: empirical and theoretical. Consider first his methodological and research contributions to developmental study. Consistent with his vision, Watson set about to demonstrate the relevance of purely behavioral procedures to the study of human behavior. He began his work with newborn infants and the analysis of the conditioning of emotional reactions (Watson & Morgan, 1917; Watson & Rayner, 1920). Watson was well prepared for the task; by mid-career, he had been recognized as one of America's leading researchers in comparative and physiological psychology (Buckley, 1989; Horowitz, 1992).

Why did Watson choose to work with infants? Given the methodological outline of behaviorism, would it not have been as appropriate to begin with adolescents or adults? Watson provided the answer himself in his "lifechart" of human activities, where he asserted that "to understand man," one must begin with the history of human behavior (1926). He saw personality as being shaped by learning experiences from birth onward. Innate reflexes and inherent emotions provided the substrate, and conditioning and learning mechanisms permitted the elaboration of emotions and behavior in development. Personality thus was the outcome of a hierarchical structure, and discrete learning experiences provided the essential building blocks. The conditioning of early emotions—love, fear, or rage—provided the foundation for all that followed. In his stress on emotions and early experience, Watson seems to have been influenced directly by Freud (as Watson suggested in 1936, in his autobiographical statement), as well as by other views of personality current in the day (including McDougall's, 1926, theory of sentiments). In any case, the study of emotional development in infancy became the focus for Watson's experimental and observational work from 1916 to 1920. Because of his work, Watson (along with E. L. Thorndike) was credited in an early *Handbook of Child Psychology* as having initiated experimental child psychology (Anderson, 1931, p. 3). Binet was overlooked again.

The infant work was conducted in the laboratories and newborn nursery at Johns Hopkins Hospital from 1916 through 1920; it was interrupted by Watson's service in World War I and terminated by his being fired from Hopkins in 1920. The series involved controlled observation of stimuli that elicit emotional reactions in infants (Watson & Morgan, 1917), a systematic attempt to catalogue the behavior responses present at birth and shortly afterward (Watson, 1926), and the experimental conditioning and manipulation of fear reactions (Watson & Rayner, 1920).

Although Watson's conditioning studies were only demonstrational and would hardly deserve publication on their methodological merit, they proved to be enormously influential. Following the lead of the more extensive and careful work of Florence Mateer (1918) and of the Russian investigator N. Krasnogorski, who first reported in 1909 the conditioning of salivation in children (see Krasnogorski, 1925; Munn, 1954; Valsiner, 1988), Watson boldly attacked the problem of the conditioning of emotions in infancy in the "case of Albert." What was impressive about this work was the finding that fear was conditioned and, once established, resisted extinction and readily generalized. As M. C. Jones (1931) pointed out, "conditioned emotional responses" differ from earlier demonstrations of reflexive conditioning in that there was one obvious discrepancy: "Whereas the conditioned reflex is extremely unstable, emotional responses are often acquired as the result of one traumatic experience and are pertinacious even in

the absence of reinforcement" (p. 87). According to Watson (1928), "guts can learn", and they seemed to have excellent memories. He wrote, "This proof of the conditioned origin of a fear response puts us on a natural science grounds in our study of emotional behavior. It yields an explanatory principle which will account for the enormous complexity in the emotional behavior of adults" (p. 202). Conditioned emotional responses, whether in the form of the "CER" of B. F. Skinner and W. K. Estes (1944), the "two-factor theory of anxiety" of Solomon and Wynne (1953), or the "learned helplessness" concept of Maier, Seligman, and Solomon (1969), have continued to play a significant if enigmatic role in neobehavioral accounts of personality and development.

Although Watson himself completed no further scientific investigations, his experimental studies with infants were taken up by students and colleagues through the 1920s and early 1930s (see M. C. Jones, 1931). Mary Cover Jones (1924) explored the problem of the extinction of emotional reactions, demonstrating how experimentally produced fears could be "undone." H. E. Jones (1930) clarified the short-term stability of the response (not great after 2 months). Later, experimental psychologists investigated the possibility of neonatal (e.g., Marquis, 1931; Wickens & Wickens, 1940) and fetal (Spelt, 1938) conditioning, along with extensive studies of early motor learning. Watson's work also stimulated the development of observational methods to assess children's behaviors, on the one hand, and the establishment of the family of behavioristic theories of learning, on the other (e.g., Guthrie, 1935; Hull, 1943; Skinner, 1938; Tolman, 1932).

This brings us to Watson's theory of psychological development, which grew both more extreme and more expansive the further he became removed from data in time and space. As Watson's ideas on child development became elaborated, it seemed clear that he considered all emotions—not merely fear and rage—to be obstacles for adaptive behavior and a happy life. Among other things, he campaigned, in his influential best-seller, *Psychological Care of Infant and Child* (1928), against too much mother love. The child, he said, would become "honeycombed" with affection and, eventually, would be a social "invalid" wholly dependent on the attention and responses of others. Love, like fear, can make one sick to the stomach.

Despite such rhetoric, Watson's books carried a deadly serious message for the 1920s and 1930s. Science could lead to improved and efficient ways to rear children, and if mothers and children could be liberated from each other early in the child's life, the potential of both would be enhanced. This "modern" view of child rearing was predictably controversial, attracting both converts and devastating criticism. Along with his emotionally cool view of personality, Watson became increasingly extreme in his environmentalism. Although he was developmental in his approach, Watson downplayed the role of psychobiological factors in personality after birth, considering learning to be the key mechanism for the pacing and stabilizing of behavior development from birth to maturity. Biology was important, of course, but only as it established potential for learning. In the absence of evidence on the long-term effects of early experience or longitudinal studies of human development, Watson was skating on extremely thin ice. To his credit, he said so (1926, p. 10). But Watson was in no position to obtain corrective or confirming data; except for occasional part-time teaching at the New School, in New York, and a lecture series at Clark University, he had dropped out of academia and out of scientific research in 1920.

Watson nonetheless became a symbol for a scientific approach to child rearing during the 1920s and 1930s through his popular magazine articles (e.g., in *Harper's* and *Atlantic Monthly*). His views extended into education, pediatrics, psychiatry, and child study, where the stress on the acquisition of habits and avoidance of emotions became translated into prescriptions for behavioristic child rearing. A cursory review of these materials reveals virtually no empirical citations, except for references to the demonstrational studies that Watson conducted or loosely supervised. It should be noted, however, that Watson's advice for mothers to adopt a psychologically antiseptic approach toward their children had not been original with him. In physician Emmet Holt's *The Care and Feeding of Children,* a best-seller since its first edition in 1894, the same guidance had been given on the evils of kissing children ("Tuberculosis, diphtheria, syphilis, and many other grave diseases may be communicated in this way"; Holt, 1894/1916, p. 174) or playing with babies ("They are made nervous and irritable"; Holt, 1984/1916, p. 171). Watson didn't offer fresh guidance so much as new reasons. In the book promotion in 1928, Watson was described as "America's greatest child psychologist" (Buckley, 1989, fig. 15).

What might have happened if Watson had remained involved in empirical research? We can only guess that his statements would have been more closely tied to facts rather than speculations, and that his views about

child rearing would have become less idiosyncratic and less extreme (see Buckley, 1989). But, as we have indicated elsewhere, certain problems remained at the heart of his system (Cairns & Ornstein, 1979). Beyond the behavioristic model of an emotionless and mindless child, perhaps the most salient weakness in Watson's view was the assumption that development was a mechanistic process that could be reduced to fundamental units of learning. Seemingly all behavior was learned, from birth onward, and the earliest experiences were the most basic. This was a peculiar and unnecessary position for a behaviorist to take. Although Watson early claimed psychology was "a definite part of biology," his view of development was nonbiological and nonorganismic. Learning is an essential process in development, but it is not the only process.

Experimental studies of learning in children did not begin and end with Watson. Another influential line of research followed the lead of E. L. Thorndike in studies of verbal learning and in the analysis of the "law of effect" and different reward and punishment contingencies (see J. Peterson, 1931, for a review of relevant studies). The work followed not only the laboratory analogues used by Thorndike (following Binet & Henri, 1895, and Ebbinghaus, 1897), but also within-classroom manipulations of the efficacy of different kinds of reward-punishment feedback (e.g., Hurlock, 1924). The studies of learning and memory were, for the most part, divorced from conditioning research in infants and animals, studies of mental testing, and investigations of language and thought. Areas of inquiry that might be seen as potentially fitting together to form a developmental view of cognition instead evolved separately, each toward its own distinctive methodology, concepts, and discipline affiliation. It would be another 50 years before serious attempts were made to bring them back together (see Carroll & Horn, 1981; Ornstein, 1978).

MATURATION AND GROWTH

While Watson served as the spokesman for behaviorism and environmentalism in child development, Arnold Gesell (1880–1961) was gaining stature as an advocate of the role of growth and maturation in behavior. Trained at Clark University in the early 1900s, Gesell absorbed Hall's vision of the significance of child study, the importance of biological controls in behavior, and the practical implications of child research, particularly for education. After earning his PhD degree, Gesell worked initially in schools and curriculum (as did most of the Clark graduates in developmental psychology in that period). He returned to complete an MD degree at Yale, then founded a child study laboratory in 1911, which permitted him to extend the tradition of W. Preyer and M. Shinn. Gesell (1931, 1933) early demonstrated himself to be an innovative and careful methodologist. He was one of the first to make extensive use of motion pictures in behavioral analysis and to explore the advantages of using twins as controls in experimental studies (i.e., one twin is subjected to the experimental manipulation, the other serves as a maturational control).

In 1928, Gesell published *Infancy and Human Growth,* a remarkable report on several years of study of the characteristics of infancy. According to Gesell, one of his aims was to provide "objective expression to the course, the pattern, and the rate of mental growth in normal and exceptional children" (p. viii). The other aim was theoretical, and the last section of the book takes on "the broad problem of heredity in relation to early mental growth and personality formation . . . and the significance of human infancy" (p. ix).

Gesell (1928) was characteristically thorough in dealing with both problems, and his normative tables and descriptions of how *Baby Two* (2 months old) differs from *Baby Three* and *Baby Nine* ring true to the contemporary reader. On basic characteristics of physical, motor, and perceptual development, children showed reasonably constant growth and age-differentiation. If the infants selected did not, as in a couple of instances, they may be substituted for by more "representative" ones. All in all, the business of establishing appropriate norms was seen as an essential part of his medical practice and the practical issues of diagnosis. As Gesell later described it:

> [The clinical practice] has always been conducted in close correlation with a systematic study of normal child development. One interest has reinforced the other. Observations of normal behavior threw light on maldevelopment; and the deviations of development in turn helped to expose what lay beneath a deceptive layer of "obviousness" in normal infancy. (Gesell & Amatruda, 1941, p. v)

Gesell and his associates established definitive norms for growth and behavioral change in the first 5 years of life, in a series of exhaustive and detailed reports (e.g., Gesell & Amatruda, 1941; Gesell & Thompson, 1934, 1938).

Few psychologists nowadays regard Gesell as a theorist. That is a pity, for his contributions might have provided a useful stabilizing influence during a period that became only nominally committed to "developmental" study. "Growth" was a key concept for Gesell. But what did he mean by growth? Horticultural terms have long been popular in describing children (a classic example being Froebel's coining of "kindergarten"). But Gesell was too astute to become trapped in a botanical analogue; he recognized human behavioral and mental growth as having distinctive properties of its own. He wrote:

> Mental growth is a constant process of transformation, of reconstruction. The past is not retained with the same completeness as in the tree. The past is sloughed as well as projected, it is displaced and even transmuted to a degree which the anatomy of the tree does not suggest. There are stages, and phases, and a perpetuating knitting together of what happens and happened. Mental growth is a process of constant incorporation, revision, reorganization, and progressive hierarchical inhibition. The reorganization is so pervading that the past almost loses its identity. (1928, p. 22)

What does this lead to? For Gesell, it led to a new perspective on the relations between heredity and environment. Similar to what Preyer had written some 50 years before, Gesell (1928) concluded:

> The supreme genetic law appears to be this: All present growth hinges on past growth. Growth is not a simple function neatly determined by X units of inheritance plus Y units of environment, but is a historical complex which reflects at every stage the past which it incorporates. In other words we are led astray by an artificial dualism of heredity and environment, if it blinds us to the fact that growth is a continuous self conditioning process, rather than a drama controlled, *ex machina,* by two forces. (p. 357)

These are not the only similarities to the interpretations offered by earlier students of infant development. Recall Preyer's analysis of infancy, and the functions of the extended immaturity of children for the plasticity of behavior. The concept of neoteny was elegantly restated by Gesell, along with a fresh idea on the social responsiveness that is unique to humans:

> The preeminence of human infancy lies in the prolongation and deepening of plasticity. There is specific maturation of behavior patterns as in subhuman creatures; but this proceeds less rigidly and the total behavior complex is suspended in a state of greater formativeness. This increased modifiability is extremely sensitive to the social milieu and is constantly transforming the context of adaptive behavior. In the impersonal aspects of adaptive behavior of the nonlanguage type (general practical intelligence) there is a high degree of early correspondence between man and other primates. This correspondence may prove to be so consistent in some of its elements as to suggest evolutionary and even recapitulatory explanations. But transcending, pervading, and dynamically altering that strand of similarity is a generalized conditionability and a responsiveness to other personalities, to which man is special heir. This preeminent sociality exists even through the prelanguage period, long before the child has framed a single word. Herein lies his humanity. (1928, p. 354)

As a rule, Gesell stood close to his data. When he ventured away, he was drawn irresistibly back to the facts that had been meticulously collected and to his belief in the curative effects of maturation. He felt strongly that the understanding of the properties of growth qua growth would be the key to unlocking the central dilemmas of psychology. The same year that Watson offered his polemic on the role of early stimulation in child rearing, Gesell offered the counterposition on the invulnerability of the infant to experience. He wrote:

> All things considered, the inevitableness and surety of maturation are the most impressive characteristics of early development. It is the hereditary ballast which conserves and stabilizes the growth of each individual infant. It is indigenous in its impulsion; but we may well be grateful for this degree of determinism. If it did not exist the infant would be a victim of a flaccid malleability which is sometimes romantically ascribed to him. His mind, his spirit, his personality would fall a ready prey to disease, to starvation, to malnutrition, and worst of all to misguided management. As it is, the inborn tendency toward optimum development is so inveterate that he benefits liberally from what is good in our practice, and suffers less than he logically should from our unenlightenment. Only if we give respect to this inner core of inheritance can we respect the important individual differences which distinguish infants as well as men. (1928, p. 378)

The infant is more robust than he appears, in that he is buffered by psychobiological fail-safe systems and driven by an "inborn tendency toward optimum development." The message is a general one, issued by one who observed the remarkable commonalities in infant growth

as it progresses, inevitably, from the stage of the neonate to the 1st year and beyond.

Does this inborn inertia apply to all features of infant growth—to mental development as well as personality and social development? On this matter, Gesell drew a distinction between the mechanisms that control cognitive and social growth. In the latter instance—social growth—the essential determinants were the social matrix present in the "web of life" and the "conditioned system of adaptation to the whole human family." Sound Watsonian? Not really, for Gesell is closer to the transactional views of James Mark Baldwin than to the unidirectional ones of behaviorism and its emphasis on the parental shaping of children. Gesell (1928) wrote:

> All children are thus, through correlation, adapted to their parents and to each other. Even the maladjustments between parent and child are adaptations in a psychobiological sense and can only be comprehended if we view them as lawfully conditioned modes of adaptation. Growth is again the key concept. For better or for worse, children and their elders must grow up with each other, which means in interrelation one to the other. The roots of the growth of the infant's personality reach into other human beings. (p. 375)

In effect, maturational changes demand interactional ones, and the nature of the resolution reached between the child and others at each stage is the stuff out of which personality is built. Gesell offers here the outline for a psychobiological theory of social development.

Where did the theory go? Not very far in Gesell's work, for it remained in a bare outline form, with scant data to back it up. Like Baldwin before him, Gesell did not have the methods (or perhaps the desire) to continue to explore the dynamic message implicit in this psychobiological view of social interactions. That is doubly unfortunate, for his views on social development were at least as reasonable and no more speculative than those of Watson. If enunciated more fully, they may have provided explicit guides for his next-door colleagues in the Institute of Human Relations when they set about to fabricate the first version of social learning theory. Some 40 years later, the essential model was explicated by Bell (1968) and Bell and Harper (1977), using surprisingly similar models and metaphors.

In speaking of Gesell's legacy, Thelen and Adolph (1992) comment on some of the paradoxes in Gesell's work:

> His devotion to maturation as the final cause was unwavering, yet he acted as though the environment mattered, and his work contains threads of real process. He believed in the individuality of the child but chose the dictates of the genes over the whims of the environment. He wanted to liberate and reassure parents but may only have added to the arsenal of parental guilt. (p. 379)

In retrospect, Gesell's views may seem paradoxical only because we fail to respect the distinctions that he made. A key distinction is that social interactions of children are more likely than motor and sensory structures to be impacted by experience; hence, there is a "generalized conditionability and a responsiveness to other personalities, to which man is special heir." Gesell did not assume the primacy of early experience; rather, the infant is buffered because "the inborn tendency toward optimum development is so inveterate that he benefits liberally from what is good in our practice, and suffers less than he logically should from our unenlightenment." This is a powerful message, consistent with the earlier pronouncement from Hall on adolescence. At the least, it indicates that investigators should look beyond infancy for the formative effects of experience, particularly the effects in "responsiveness to other personalities."

Gesell was a pioneering investigator who understood the totality of the organism. He also understood that experiential factors must be considered in any systematic developmental account. Although he appreciated the multiple ways that environmental events could influence behavior, he declined to assign them priority in accounting for the development of basic motor, sensory, and emotional systems.

Other investigators recognized the role of age-related biological changes in the development of behavior, and their relations to the occurrence of basic changes in emotional, cognitive, and social patterns. For example, M. C. Jones (1931), in discussing the development of emotions, remarks that a wariness or fear of unfamiliar persons tends to emerge in the second half of the 1st year of life (from 20 weeks to 40 weeks; see Bayley, 1932; Washburn, 1929). Jones notes that this phenomenon appears in the absence of any apparent pairing of the stranger with some external noxious stimulus; hence, it would not fit very well with the Watsonian view of the conditioned elaboration of fear or of love. Other developmental mechanisms must be at work.

Why the relative popularity of experimental demonstrations of fear and its conditioning and extinction, as opposed to careful longitudinal studies of the development of the phenomena subsumed by fear? M. C. Jones's (1931) answer was insightful and doubtless cor-

rect: "Because training and practice are more readily subject to laboratory proof, we have at times minimized the importance of the less accessible intraorganismic factors" (p. 78).

The availability of funding and staffing for the major child development institutes permitted the support of significant studies of maturation and growth at Teachers College (Columbia), Berkeley, Iowa, Minnesota, and Fels Institute. Among the more notable studies was that of Mary Shirley at the University of Minnesota. To extend Gesell's cross-sectional observations, Shirley conducted a longitudinal investigation of motor, emotional, and personality development over the first 2 years of life with 25 infants, and published the results in a comprehensive three-volume work (Shirley, 1931, 1933a, 1933b). Similarly, the Shermans at Washington University (St. Louis), McGraw (1935) at Teachers College, and K. M. B. Bridges at Montreal completed useful studies of growth-related changes in infants and young children.

SOCIAL AND PERSONALITY DEVELOPMENT

In a review of studies of social behavior in children, Charlotte Bühler (1931) gave an American, Will S. Monroe, credit for having completed the first studies of "the social consciousness of children." Monroe's work, published in German (1899), reported a number of questionnaire studies dealing with various aspects of social development. For instance, children were asked what sort of "chum" they preferred, what kinds of moral qualities they found in friends, and what their attitudes were about punishment, responsibility, and discipline. Monroe's work was not, however, the first published set of studies on these matters. Earl Barnes of Stanford (who had been Monroe's teacher) had earlier edited a two-volume work (*Studies in Education;* 1896–1897, 1902–1903) that had covered the same ground, reporting a reasonably comprehensive set of questionnaire studies of social disposition. Margaret Schallenberger (1894), for instance, had been at Stanford and was a student of Barnes at the time she completed the report discussed earlier on age-related changes in the social judgments of children. In the 1890s, questionnaires were being circulated to teachers throughout the country, through the various state child study associations (in Illinois, South Carolina, Massachusetts), and literally thousands of children were being asked brief questions about their social attitudes, morals, and friendships. Hall from time to time would include questionnaires in the *Pedagogical Seminary,* and would ask readers to submit the results to him.

Because of the shortcomings in the method, ranging from haphazard sampling procedures to problems in nonstandard administration and scoring of questions, the questionnaire studies were hardly models of scientific research. Nonetheless, certain age-related phenomena were sufficiently robust to appear despite the methodological slippage; hence, the earlier cited conclusion by Schallenberger about the reliance of young children on concrete forms of punishment, with reasoning and empathy playing roles of increasing importance in early adolescence. These findings were given wide circulation in Hall's *Adolescence,* and provided the empirical substrate for some of the more useful sections of that work. In time, the criticisms took effect, and after about 10 to 15 years of questionnaire studies, the method was no longer a procedure of choice. As Bühler notes, "little was done in the decade after Monroe made this first start in the direction of developmental social psychology," and, she concludes, the studies failed because of "the lack of a systematic point of view" (1931, p. 392).

Following a hiatus in work on social development, another method was introduced for studying the social behavior of infants and children in the mid-1920s. It was essentially an extension of the "objective" or "behavioral" procedures that had been used in the investigation of individual infants and young animals. Almost simultaneously, reports of behavioral studies appeared in child study institutes in Vienna, New York (Columbia), Minnesota, and Toronto. Somewhat earlier, Jean Piaget had recorded the naturalistic verbal exchanges among young children (Piaget, 1923/1926). Five of the first eight *Child Development Monographs* from Teachers College (Columbia) were concerned with the methods and outcomes obtained by the behavioral assessments of social patterns (Arrington, 1932; M. Barker, 1930; Beaver, 1930; Loomis, 1931; D. S. Thomas, 1929). Dorothy S. Thomas, who co-authored with sociologist W. I. Thomas *The Child in America* (1928), seems to have spearheaded this attempt to apply "the methodological scheme of *experimental sociology* to children." In addition to the work of Thomas and her colleagues, insightful methodological papers on the procedure were published by Goodenough (1929, 1930a) at Minnesota and Bott (1934) at Toronto. Charlotte Bühler should herself be credited with having pioneered the controlled experimental observations of infants, and she seems to have been the first investigator to have completed an

"experimental study of children's social attitudes in the first and second year of life" (Bühler, 1931).

Observational studies from 1927 to 1937 generated almost as much enthusiasm as earlier questionnaire studies. They were based on the assumption that the stream of behavior could be classified into particular behavior units, and that these units could be submitted to the statistical analyses previously developed for the treatment of experimental and test data. Careful attention was given to the basic issues of observation, including observer agreement, code reliability, stability of measures, various facets of validity and generality, and statistical evaluation. The issues attacked by the method ranged from the mere descriptive and demographic—including size and sex composition of groups as a function of age (Parten, 1933) and nature of play activities (Challman, 1932)—to studies of the natural occurrence of aggression (e.g., Goodenough, 1931) and reciprocal patterns of interchange (Bott, 1934). By 1931, Bühler was able to cite some 173 articles, many of which dealt directly with the observation of children's social behavior patterns. In the following 5 to 10 years, an equal number of studies was reported, some of which are now recognized as having laid the foundation for work taken up again in the 1970s (e.g., Murphy, 1937). In terms of method, the reports were on a par with the current generation of observational analyses of social interchanges.

What theoretical ideas were associated with these behavioral methods and to what extent was there a "systematic" point of view? There was, as it turns out, as little theoretical guidance for this work as for the earlier questionnaire studies. The work was behavioral, but it was not concerned with developmental processes, either learning or psychobiological. J. M. Baldwin had virtually been forgotten (save for some exceptions, e.g., Piaget, 1923/1926). Given D. S. Thomas's (1929) aims and background, it is mildly surprising that the procedures at Columbia were not more intimately linked to the sociological models of Cooley, Mead, and Baldwin. Perhaps that conceptual extension was part of the general scheme, but it failed to materialize in the work completed at Teachers College or at the other child institutes. As it turned out, the research focused on the immediate determinants of the actions and interactions of children, but scant information was gained about their relationship as to how interactions are learned or modified, or what they mean for longer term personality development.

If there were any theoretical underpinnings for the research on interactions and social development, the model seems to have been drawn either from a belief in the importance of growth and maturation, or from a commitment to the enduring nature of personality types, as determined by genetic, constitutional, or early experience factors. In this regard, Bühler (1931) classified infants into three types, depending on their reactions to social stimulation. "These types were called the socially blind, the socially dependent, and the socially independent behavior" (1931, p. 411). Socially blind children don't pay much attention to the actions and reactions of other persons; instead, they take toys, play, and move about without regard for the other child. The socially dependent child, on the other hand, is "deeply impressed by other's presence and activities; . . . he observes the effect of his behavior on the other and carefully watches the other's reactions." The socially independent child "is one who—though aware of the other's presence and responsive to his behavior—yet does not seem dependent on him, is neither intimidated nor inspired" (1931, p. 411). Bühler sees these dispositions as being independent of home and rearing conditions; hence, they are "primary" dispositions. Retests of the children (who were 6 to 18 months of age) suggested to Bühler that these types were relatively stable, but she adds the caveat that, "it remains to be seen, of course, whether these pioneer observations will be confirmed by other authors" (1931, p. 411).

In retrospect, the interactional studies were estranged from the issues being debated by the dominant theories of the day—psychoanalytic, learning, cognitive—and few seemed willing to attempt to bridge the theoretical or empirical gaps. As it turned out, the data did find a useful service in the practical areas of nursery school management and the training of young teachers. Because the findings were either ignored or deemed irrelevant by those concerned with major psychological theories of development, the method and its concerns passed from the scene, temporarily.

MORAL DEVELOPMENT

The perfectibility of humans and the establishment of a higher moral order had been a continuing concern for developmentalists. Although questionnaires on children's beliefs and attitudes toward transgressions and punishments were useful, they had obvious shortcomings as scientific instruments. In the 1920s and 1930s, work on these issues continued, but with a self-conscious appreciation of the limits of the techniques that were available. Nonetheless, there were substantive

issues to be addressed and real-life problems to be solved, and it seemed entirely reasonable to expect that the investigators of moral development would be ingenious enough to meet the challenge (see V. Jones, 1933). Out of this need arose three major advances in the study of moral development: (1) the use of short-term experimental manipulations in the assessment of honesty and prosocial behaviors; (2) the employment of observations of naturally occurring rule-making and moral judgments; and (3) the refinement of attitudinal questionnaires that might be employed in the assessment of particular experiences.

The demonstration of the utility of short-term experimental procedures with school-age children has an unusual background, at least in comparing what the sponsors had hoped to learn and what they actually got. Hugh Hartshorne was a professor in the School of Religion at the University of Southern California, and Mark May was a psychologist at Syracuse University when they were recruited to Columbia University by the Institute of Social and Religious Research to conduct a multiyear project on how Sunday schools, churches, and religious youth groups could better do their job. E. L. Thorndike was a guiding force in the initiation and interpretation of this research. If physical science could solve problems for the society, why could not behavioral science help solve some of the moral and ethical issues that had arisen?

The project was an ambitious one: to analyze the effects of various institutions of the society on moral behaviors, and to determine how the institutions could improve their performance. At the outset, Hartshorne and May recognized that they must solve the problem of the assessment of moral and ethical behaviors. Following a critique of then-available questionnaire and rating procedures, Hartshorne and May concluded that a fresh approach to the study of values and character was required. They wrote: "Although recognizing the importance of attitude and motive for both social welfare and individual character, as ordinarily understood, we realized that in any objective approach to ethical conduct we must begin with the *facts of conduct*" (1929, vol. 3, pp. 361–362). Accordingly, the investigators developed a battery of tests and experimental settings designed to yield information about honesty, helpfulness and cooperation, inhibition, and persistence. The best known measures are the brief experimental assessments of deceit (permitting the misuse of answer sheets, peeping, and other forms of cheating, all of which were monitored in sly ways by the experimenter). They also devised various sociometric techniques, including a "Guess Who" procedure to assess peer reputation. The results of this work and the authors' interpretation on the relative specificity of moral conduct have been widely discussed. For our purposes, it is sufficient to note that this was one of the first studies to be conducted of short-term experimental manipulations of social behavior in school-age children. In addition, the authors offered a courageous theoretical statement on how ethical conduct is acquired (via Thorndikian learning principles). It was not exactly what the sponsoring agency had expected, or wanted. The Executive Secretary of the sponsoring Institute of Social and Religious Research wrote apologetically in the foreword:

> To lay minds this volume, at first glance, may seem overloaded with matter that has little to do with moral and religious education—a medley of tests and statistics and a paucity of clear directions as to building character. Such readers might profitably reflect that these preliminary processes are inevitable if character education is ever to emerge from guesswork into a science. Medical and surgical science had to follow a similar road to advance from magic and quackery. (Hartshorne & May, 1929, vol. 2, p. v)

Hartshorne and May had concluded that traditional religious and moral instruction have little, if any, relationship to the results of experimental tests of honesty and service to others.

With questionnaire procedures generally in disfavor by the 1920s, the essential problem of how to quantify attitudes remained. L. L. Thurstone, a pioneering quantitative psychologist at the University of Chicago, was recruited by the Payne Foundation to determine the effects that moviegoing had on the social attitudes and prejudices of children. The assignment provided Thurstone the opportunity to develop a new technology for the assessment of moral/ethnic attitudes. In a series of studies, Thurstone and his colleague, R. C. Peterson (Peterson & Thurstone, 1933), introduced new methodologies for gauging the effects of specific motion pictures on attitudes toward national/ethnic groups. They used a pre- and posttest design, coupled with a 5-month follow-up test (post-posttest). Although these studies seem to be little known to contemporary writers, Thurstone himself (1952) considered them to be highly influential for his development of an attitude assessment methodology. Moreover, the work provided a wholly convincing demonstration of the strong effects that certain films had in decreasing, or increasing, racial and religious prejudice. In some cases (such as the inflammatory *Birth of a Nation*),

the unfavorable racial attitudes induced by viewing the film were detected 5 months later. This study was an admirable forerunner to the research of the 1960s and 1970s concerned with the effects of television (see also, V. Jones, 1933).

A major advance was pioneered by Jean Piaget in his assessments of moral reasoning (Piaget, 1932/1973). Piaget's clinical method—observing the actions of individual children and carefully recording their responses—permitted him to identify changes in the children's employment of rules and their origins. Although the procedure shared the self-report properties of questionnaires, his observations and direct inquiries permitted a more precise identification of the standards being invoked idiosyncratically by the children. Again, the impact of Piaget's reports seems to reflect in large measure the theoretical significance of his interpretations.

THE DEVELOPMENT OF LANGUAGE AND COGNITION

From 1924 onward, the problem of how language and thought develop attracted the attention of the brightest talents of the discipline. Some of them—including Jean Piaget and L. S. Vygotsky—were concerned with language as a vehicle for understanding how thought patterns develop in the child. Others focused on language as a phenomenon in itself, with attention given to the "amazingly rapid acquisition of an extremely complex system of symbolic habits by young children" (McCarthy, 1954).

The comprehensive review articles by Dorothy McCarthy that span this period provide an excellent overview of the era (McCarthy, 1931, 1933, 1946, 1954). At one time or another, virtually all major developmental investigators have been drawn to the study of language development, and so were some nondevelopmentalists as well. The intimate relationship that exists between language and thought was brought brilliantly to the attention of psychologists by Jean Piaget in a small book that he published to report the results of his new functional approach to the study of language development. Piaget's study of language breathed fresh life into one of the oldest questions of the area: How do thought, logic, and consciousness develop? Language was a mirror to the mind, for Piaget; it was to be used to reflect the nature and structure of the mental schemas that gave rise to verbal expressions. In this work, Piaget seems to have been explicitly guided by J. M. Baldwin's view that the young child proceeds in his thought to progressively discriminate himself from nonself. The major empirical marker for this shift in thinking was movement from egocentric speech to socialized speech. Piaget wrote:

> "Egocentric" functions are the more immature functions, and tend to dominate the verbal productions of children 3–7 years of age, and, to a lesser extent, children 7–12 years. In this form of speech, a child does not bother to know to whom he is speaking nor whether he is being listened to. He talks either for himself or for the pleasure of associating anyone who happens to be there with the activity of the moment. This talk is ego-centric, partly because the child speaks only about himself, but chiefly because he does not attempt to place himself at the point of view of his hearer. Anyone who happens to be there will serve as an audience. (1923/1926, p. 9)

Socialized speech, where the child "really exchanges his thoughts with others, either by telling his hearer something that will interest him and influence his actions, or by an actual interchange of ideas by argument or even by collaboration in pursuit of a common aim" (p. 9–10), does not emerge until about age 7 or 8, and the process is not complete until 11 or 12 years of age. Later in the same volume, Piaget linked egocentricism to the child's tendency to personalize thought:

> [Without the ability to "objectify" one's thinking,] the mind tends to project intentions into everything, or connect every thing together by means of relations not based on observation . . . the more the ego is made the center of interests, the less will the mind be able to depersonalize its thought, and to get rid of the idea that in all things are intentions either favourable or hostile (animism, artificialism, etc.). . . . Ego-centrism is therefore obedient to the self's good pleasure and not to the dictates of impersonal logic. It is also an indirect obstacle, because only the habits of discussion and social life will lead to the logical point of view, and ego-centrism is precisely what renders these habits impossible. (1952, pp. 237–238)

In other words, Piaget shares with both Baldwin and Freud the assumption that the child's concept of reality and logic develops from contact with the external world, emerging from an amorphous sense of the self. It is not insignificant that, in the foreword to *The Language and Thought of the Child* (1923/1926), Piaget stated:

> I have also been deeply impressed by the social psychology of M. C. Blondel and Professor J. M. Baldwin. It will likewise be apparent how much I owe to psychoanalysis, which

> in my opinion has revolutionized the psychology of primitive thought. (pp. xx–xxi)

The method employed by Piaget and the concepts he embraced stimulated almost immediate worldwide attention and controversy. In McCarthy's thorough reviews of the empirical data that bore on this question (including her own), she (1931, 1933, 1946, 1954) traced the evolution of a huge literature on the matter. Strict interpretation of Piaget's categories suggested that, over a wide variety of populations and settings in which young children were observed, seldom did the proportion of egocentric remarks exceed 6% to 8%. Moreover, the negative evidence came not merely from studies of children in the United States; an equally convincing set of disconfirming investigations emerged from studies of Chinese (H. H. Kuo, 1937), Russians (Vygotsky & Luria, 1929), and Germans (Bühler, 1931). After identifying what was meant by the concept of egocentric as opposed to socialized speech, C. Bühler (1931) wrote:

> It is agreed, however, among other authors, for example, William Stern and David and Rosa Katz—that this result is due to the special conditions of life in the "Maison des Petits" in Geneva, where Piaget's work was done. The Katzes (1927) emphasize, in opposition to Piaget, that even the special relationship of the child to each of the different members of the household is distinctly reflected in the respective conversations. This is surely true of all the dialogues they published. (p. 400)

This was a key point for Bühler, who had just spent several years of her life demonstrating the quality and nature of the social patterns of children in infancy and early childhood. She had conclusively shown the truly "social" nature of their behaviors. Note that Bühler attributes the discrepant findings to the contextual-relational specificity of Piaget's initial observations. Piaget seemed to accept that explanation, at least for the time being. In the foreword to the second edition of *The Language and Thought of the Child* (1923/1926), he wrote:

> [Our] original enquiries dealt only with the language of children among themselves as observed in the very special scholastic conditions of Maison des Petits de L'Institut Rousseau. Now, Mlle. M. Muchow, M. D. Katz, Messrs. Galli and Maso, and M. A. Lora [Luria], after studying from the same point of view children with different scholastic environments in Germany, Spain, and Russia, and especially after studying children's conversations in their families, have reached results which, on certain points, differ considerably from ours. Thus, while the little pupils show in their conversations coefficients of ego-centrism more or less analogous to those we have observed, M. Katz's children, talking among themselves or with their parents, behave quite differently. (pp. xxiii–xxiv)

Another explanation, favored by McCarthy (1933, 1954), is that the problem resided in the ambiguity of the classification system employed by Piaget. For whatever reason, there were notably few confirmations of Piaget's assertion that young children were predominantly egocentric in their speech. The controversy extended into the 1970s (see, e.g., Garvey & Hogan, 1973; E. Mueller, 1972), along with replications of the earlier disconfirmation of Piaget's report.

The issue was significant for the area because it had implications for the understanding of virtually all psychological aspects of development, whether cognitive, linguistic, social, or moral. Beyond the issue of whether egocentric speech was 6% or 40% or 60%, there was agreement that this form of communication tended to decrease as a function of the child's age. Why? Piaget's answer, which seemed compatible with the earlier formulations of Baldwin and Freud, was that egocentric communication directly reflected young children's "personalized" mode of thinking, and that as children became more objective in their views of themselves and of reality, the transition to socialized speech occurred. Egocentric speech became dysfunctional and was discarded. A counterproposal by the Russian psychologist L. S. Vygotsky (1939) constituted a serious challenge to the Piagetian interpretation. The key to Vygotsky's proposal is that, at maturity, two speech systems exist: inner speech and socialized speech. For Vygotsky:

> The relation of thought to word is first of all not a thing, but a process; it is a proceeding from thought to word and, conversely, from word to thought . . . every thought moves, grows and develops, each fulfills a function and solves a given problem. This flow of thought occurs as an inner movement through a series of planes. The first step in the analysis of the relationship between thoughts and words is the investigation of the different phases and planes through which the thought passes before it is embodied in words. (p. 33)

Herein lies the need for a developmental investigation of speech functions, for it may provide us with an answer as to how thought and speech are interrelated. This investigation:

> reveals, in the first place, two different planes in speech. There is an inner, meaningful semantic aspect of speech and there is the external, acoustic, phonic aspect. These two aspects although forming a true unity, have their own particular laws of movement. . . . A number of facts in the development of children's speech reveal the existence of independent movement in the phonic and the semantic aspects of speech. (1939, p. 33)

How does Vygotsky interpret the role of egocentric speech and how does his interpretation differ from Piaget's? Although egocentric speech has no apparent function of its own in Piaget's formulation—it merely reflects the child's egocentric thinking and is thereby doomed to disappear with the child's cognitive growth—it assumes great functional importance for Vygotsky. Egocentric speech constitutes, in effect, a developmental way station "a stage which precedes the development of inner speech" (1939, p. 38). It is a form of speech that aids in the young child's thought processes but, rather than waning in childhood and becoming dysfunctional, egocentric speech undergoes an evolution with "inner speech" and thought as its end product. Vygotsky (1939) wrote:

> To consider the dropping of the coefficient of egocentric speech to zero as a symptom of decline of this speech would be like saying that the child stops to count at the moment when he ceases to use his fingers and starts to do the calculations in his mind. In reality, behind the symptoms of dissolution lies a progressive development, . . . the formation of a new speech form. (p. 40)

Vygotsky then took a significant step forward in the analysis of both speech functions and their relation to thought, by conducting some ingenious experiments on the nature of egocentric speech. He went beyond naturalistic observations to manipulate theoretically relevant dimensions. He determined, for instance, that the incidence of egocentric speech decreased sharply when children were placed in the company of others who could not possibly understand them—deaf and dumb children, or children speaking a foreign language. Vygotsky reports that the coefficient of egocentric speech "sank rapidly, reaching zero in the majority of cases and in the rest diminished eight times on the average." While these findings seem "paradoxical" for Piaget's view, they were consistent with the idea that "the true source of egocentric speech is the lack of differentiation of speech for oneself from speech for others; it can function only in connection with social speech" (1939, p. 41).

To summarize the rest of Vygotsky's argument and experimental work would take us beyond the limits of this overview (see McCarthy, 1954). The story did not end in the 1930s; many of the same concerns and proposals were to reappear in the 1960s and 1970s. Unfortunately, the brilliant Vygotsky—who was born the same year as Piaget—died in 1934 at the age of 38. His developmental views were brought forward to contemporary psychology by his colleague and collaborator, A. R. Luria.

The functional analysis of language development, while most intriguing on theoretical grounds, constituted only a portion of the total research effort devoted to language. Researchers focused, in addition, on developmental stages in language expression (e.g., prelinguistic utterances, phonetic development, the growth of vocabulary, changes in syntactic complexity as a function of age) and individual differences in language development and how they arise (through experience, schooling, early exposure, etc). The literature on these matters was such that, by the end of this period, no child development text could be prepared without a significant section given to the report and summary of these findings. The mass of data seemed to outrun the ability of theorists to organize it in terms of meaningful models.

DEVELOPMENTAL PSYCHOBIOLOGY AND ETHOLOGY

The Gesellian emphasis on growth and maturation was part of a broader attempt within developmental psychology and developmental biology to unlock the secrets of ontogeny (see McGraw, 1946). On this count, the understanding of the mechanisms of genetic transfer was significantly advanced by (a) the rediscovery of the work of Mendel, and (b) the revolutionary discoveries of the loci of units of chromosomal transmission. But these events raised a significant question for developmentalists. If all somatic cells have the same genetic code, how does differentiation occur in development and why do cells at maturity have distinctly different functions and properties? Where is the "master plan" for development, and how can particular cells be induced to perform their unique and special services for the organism?

Among the embryologists who addressed these issues, Hans Spemann (1938) provided a provocative suggestion following his discoveries that cellular tissues could be successfully transplanted from one area of pre-

sumptive growth to another. If the transplantation occurs at the appropriate time in development, tissues from the presumptive area of the neural plate of amphibia could be successfully transplanted to areas where limbs would arise. The tissue would then develop in accord with its surroundings, so that the tissue would take on the characteristics of skin or muscle, not of the brain. On the basis of these experiments, Spemann proposed that extranuclear or contextual forces served to "organize" the development of cellular materials in the course of ontogeny. Once organization occurred, during the period that was critical for the development of its form and function, then the effects would be irreversible or highly resistant to change (see Waddington, 1939).

Such demonstrations provided the substantive empirical examples for the formulation of a view on development that has come to be known as "organismic" theory or "system" theory of biological development (von Bertalanffy, 1933). In its initial form, organismic theory was concerned with the question: What directs development? The answer, simply stated, is: the organism. Development is directed by the constraints inherent in the relationship among elements of the living system as they act on themselves and on each other. These elements can be cells, clusters of cells, or entire subsystems, such as those formed by hormonal processes. The kernel idea is that the several features of the organism, including its behavior, depend on the whole reciprocating system of which they form parts. The mutual regulation among components permits, among other things, possible feedback to the original source and self-regulation.

Organismic theory was compatible with the Darwinian perspective of evolution as a dynamic, adaptive process. Development is equally dynamic. It required only a modest conceptual leap to consider behavior as being an essential component of the organismic system, and its development could be understood only in terms of other biological and social features of the system. Hence, the "system" in which the organism developed was not merely under the skin. Organization could be broadened to include feedback from other organisms and from the social network in which development occurred. Two developmental-comparative psychologists, T. C. Schneirla and Zing-Yang Kuo, led the way, in the early 1930s, for the application of the organismic perspective to the problems of behavioral ontogeny.

The problem that Schneirla tackled was how to unravel the complex social structure of army ants, who despite their lack of gray matter, were highly coordinated in virtually all phases of their adaptation. Wilson (1975) considers the species as a prototypic "truly social" one. How is the high level of social organization accomplished? Schneirla (1933) attacked the problem by undertaking a series of comprehensive field investigations in Panama and laboratory studies in his facilities at the American Museum of Natural History. He tested the assumption that colony organization does not arise from some single internal source; rather, the complex social system arises as an outcome of the interdependence of developmental events in the brood, workers, queen, and the contextual environmental constraints.

Schneirla identified the pattern of empirical relationships that provided elegant support for his developmental analysis of social organization. He discovered, for instance, that a primary trigger for migration and foraging raids in the colony was the heightened activity produced by the developing larvae. When the larvae emerged from the quiescent phase of development, their activity stimulated the rest of the colony to action, keying both foraging raids and migration. When the activity of the larval brood diminished as a consequence of growth-related changes, the raids ceased and the nomadic phase ended. The surplus food that then became available in the colony (due to decreased needs of the young) fattened the queen and served to trigger a new ovulatory cycle, thus recreating the conditions for reproduction. Looking backward on this work, Schneirla (1957) concluded: "The cyclic pattern thus is self-rearoused in a feedback fashion, the product of a reciprocal relationship between queen and colony functions, not of a timing mechanism endogenous to the queen."

Z.-Y. Kuo, a Chinese psychologist who completed his doctoral training with E. C. Tolman at Berkeley before returning to work in China, came to similar conclusions at about the same time. Kuo was originally motivated by J. B. Watson's claims about the malleability of behavior, given the control over the conditions of development. He went beyond Watson and collected relevant data. In a series of provocative studies, where he produced unique environments for the young animals to grow up in, Kuo demonstrated that key features of social patterns could be changed, and novel ones created. Cats, for instance, could be made to "love" rats, not kill them, if the kittens were raised together with rodents from infancy onward (Z.-Y. Kuo, 1930, 1967). Beyond behavioral plasticity, Kuo addressed the fundamental problem of behavioral origins, and when and how novel behavior patterns arise in the course of ontogeny.

In his study of the origin of "instinctive" behaviors, such as pecking, vocalization, and movement patterns in birds, Kuo assumed that these characteristics arose in development because of necessary feedback relationships among central nervous system, physiological, and behavioral functions. Pushing the organismic proposal on the self-stimulative role of behavior to its limits, Kuo offered the proposal that the behavior of the embryo itself provided feedback that would help to direct its subsequent development. Preyer (1888–1889) had earlier suggested the possibility of such feedback effects in development, but there were scant data relevant to the proposal.

The story of how Kuo explored these ideas can be found in a series of papers that he published during the 1930s, and a summary appears in his later volume on behavioral development (e.g., Z.-Y. Kuo, 1930, 1939, 1967). He first had to solve the problem of how to keep embryos alive while viewing their development (he invented a way to produce a "window" by removing the external shell but keeping the embryo and the membranes surrounding it intact). Kuo was then able to plot, from the onset of development to hatching, the movement patterns in the egg, including the initial stages of heart activity, breathing, limb movement, and pecking. On the basis of these observations, he concluded that the activity of the organism itself was influential in determining the direction of development, including leg coordination and pecking. The initial report of these observations met initial skepticism (e.g., Carmichael, 1933), and for good reason. Some of Kuo's speculations have not been upheld because he did not give sufficient weight to the effects of spontaneous central nervous system innervation in producing cycles of activity and inactivity (Oppenheim, 1973). But his more general assumption that feedback functions can contribute to embryonic development has in some instances been strikingly confirmed. For example, inhibition of leg movement in the chick embryo has been found to be associated with ossification of the joints and difficulty in posthatching mobility (Drachman & Coulombre, 1962). Moreover, self-produced vocal calls by the embryo facilitate the development of posthatching species-typical preferences (Gottlieb, 1976).

As powerful as were Schneirla's and Kuo's demonstrations of the utility of a developmental approach to behavior, they had little immediate effect on child psychology (although Kuo's work was discussed at length by Carmichael, 1933, in the revised *Handbook of Child Psychology,* and Schneirla was a reviewer for the same volume). Not until the next generation was their essential message heard and understood in both comparative and developmental psychology.

Another psychobiological researcher had greater immediate success and visibility. Leonard Carmichael carried the psychological tradition of William Preyer into the 1930s. His *Handbook* chapters (Carmichael, 1933, 1946) provided a scholarly reminder of the unsolved problems of the relations between biological development and behavioral establishment. Carmichael also brought to the attention of child psychologists the impressive body of literature concerned with the analysis of early biological-behavioral development. The chapter by Myrtle McGraw (1946) provided an excellent critical overview of the basic issues of developmental psychobiology.

In Europe, the study of the "biology of behavior," or ethology, experienced a rebirth in Konrad Lorenz's article, "*Der Kumpan in der Umwelt des Vogels*" (1935; translated and published in English in 1937). In this paper, Lorenz reasserted the contribution of evolutionary forces in the determination of behavior, and reminded biologists and psychologists of the importance of early experience and its possible irreversibility. Building on the foundation laid at the turn of the twentieth century by an American, C. O. Whitman, and a German, O. Heinroth, Lorenz offered a convincing argument for studying instinct and the evolutionary basis of behavior. Taking U.S. behaviorists head on, Lorenz argued that the effects of experiences in the "critical period" could not be accounted for in then-available principles of learning and association. Specifically, he distinguished the phenomenon of imprinting (the establishment of filial preferences and species identification in precocial birds) from "association learning" on four counts. Imprinting (1) occurred only during an early critical period, (2) was irreversible in later development, (3) was supraorganismic in its effects (not limited to the imprinted object but to the species of which the object was a member), and (4) took place prior to the developmental appearance of the response that was "conditioned" (e.g., sexual preferences were influenced, even though they were not present in infancy). Virtually no immediate notice was taken of ethological work by developmental psychologists; the gulf between disciplines, combined with World War II, delayed the introduction of these ideas into the mainstream of psychological and developmental thought.

THEORETICAL TRENDS OF THE MIDDLE PERIOD

What theoretical activity took place over this third of the twentieth century? A great deal, for each of the major developmental models established in the previous period underwent revision, modification, and extension. Behaviorism was liberalized and enlivened by a marriage with psychoanalysis. Psychoanalysis itself was split into three recognizable subdivisions: (1) classical psychoanalysis (Munroe, 1955), (2) postpsychoanalytic theory, and (3) neopsychoanalytic theory. Similarly, the Baldwinian approach to cognitive and social development was partitioned and extended: (a) in the theory of mental development now associated with Jean Piaget; (b) in the symbolic interactionism movement in sociology, anthropology, and psychiatry; and (c) in Vygotsky's expansion of the proposal that "each child is part someone else, even in his own thought of himself."

Although Piaget and Vygotsky have been the most prominent representatives of the Baldwinian developmental tradition in the United States, Henri Wallon (1879–1962) became almost as prominent in Eastern Europe, Africa, South America, and, foremost, in France. But then, and now, he has received virtually no recognition from the English-speaking world. His student, René Zazzo (1984, p. 9) observes: "As a direct descendant of J. M. Baldwin and a precursor of the theoreticians of attachment, Wallon viewed the other person as basic and primary" (see also Wallon, 1984b). In brief, Wallon argued for a more integrative, more interactive, and more social view of the developing organism than did his contemporary and competitor, Jean Piaget (see Birns, 1984, pp. 59–65; Piaget, 1984; Wallon, 1984a).

Nor was behavioral Darwinism overlooked. The foundations for modern ethology had been laid by Whitman in America and Heinroth in Europe, and extended in the 1930s and 1940s by Lorenz and Tinbergen. The "organismic" approach affected theories in biology and psychology. Most immediately related to developmental concerns were the developmental psychobiological theory of Schneirla and Kuo and the cognitive-organismic principles of Stern, Lewin, and Werner. At first blush, it seemed as if Baldwin's vision that "every man have his theory" had been fulfilled.

Except for some intrafamilial squabbles, there were few direct confrontations or face-offs among the major theories—not so much out of mutual respect as because of selective inattention. As A. Baldwin (1967/1980) has observed, developmental theories tended to talk past each other rather than at each other; they had different aims, were concerned with different issues, employed different methods, and were challenged by different findings. In due course, as the interests and concerns of the discipline shifted, each of the general orientations was to experience its day in the sun.

A few comments are in order on three major theoretical systems of the period that have not yet been singled out for attention: social learning theory, psychoanalysis and its derivatives, and Lewinian "field theory."

Social Neobehaviorism

The family of theories called "social learning" descended from a wedding of the general behavioral models of the 1930s and psychoanalytic ideas of personality. During the heyday of general behavioral systems, four models of learning emerged as especially influential: (1) the behavior system of Clark Hull (1943), (2) the contiguity learning model of E. R. Guthrie (1935), (3) the purposive behaviorism of E. C. Tolman (1932), and (4) the operant learning theory of B. F. Skinner (1938, 1953). Despite their differences in language and in basic assumptions about the nature of learning, the models shared the belief that the principles of learning were universal, transcending differences in species, age, and circumstances.

Beyond a faith in the universality of the basic principles of behavior, there was a need to specify the implications of these theories for distinctly human problems, including the acquisition of personality patterns and social dispositions. J. B. Watson led the way early in offering bold speculations about the learning and unlearning of fears and loves. The challenge to the writers of the 1930s was to provide a more systematic, and yet equally convincing, case for the learning of significant human behaviors. To this end, a group of able young scientists at Yale University set about to put the study of personality processes on a solid empirical and behavioral basis (Maher & Maher, 1979). This group attempted to link certain concepts of psychoanalysis with assumptions drawn from the general behavioral theory of Clark Hull. The upshot was a remarkably influential set of concepts that was to dominate theoretical formulations in child psychology for the next several decades.

The first major collaborative effort was directed at the analysis of the controls of aggressive patterns, as

viewed from a psychoanalytic-behavioral perspective. The product of this collaboration, a slim volume entitled *Frustration and Aggression,* appeared on the eve of World War II and gained immediate attention and influence (Dollard, Miller, Doob, Mowrer, & Sears, 1939). Although the basic hypothesis that "aggression is always a consequence of frustration" (p. 27) was soon amended by the authors themselves (see Miller, Sears, Mowrer, Doob, & Dollard, 1941), the idea behind the work was enthusiastically endorsed. The associationistic assumptions of psychoanalysis were neatly melded with the stimulus-drive assumptions of Hullian theory.

The direct application of concepts of learning and imitation to children was soon made by Miller and Dollard (1941) in their book *Social Learning and Imitation.* This was not the first such extension; the Sears study of infant frustration (cited in Dollard et al., 1939), and Mowrer's study of enuresis (1938) had already shown that social learning principles could be readily applied to problems of child development. After World War II, the full impact of the social learning perspective was to be felt by child psychology.

Psychoanalysis

By the 1930s, the enterprise of psychoanalysis had undergone multiple divisions and had exercised a significant impact on the study of behavioral development. The most obvious influence was direct, through the teachings of Sigmund Freud himself and those who remained faithful to the orthodox theory. But equally powerful influences were indirect, mediated through the theories of those who—like J. B. Watson, J. Piaget, and R. R. Sears—had been impressed by particular features of psychoanalytic theory. In between were the so-called post-Freudians (those who extended psychoanalytic theory within the constraints established by Freud himself) and neo-Freudians (those psychoanalysts who revolted by challenging certain inviolable assumptions, such as the emphasis on infantile sexuality and the primacy of early experience). These various themes have been expertly traced in discussions of psychoanalytic theory (e.g., Hall & Lindzey, 1957; Munroe, 1955). For our present purposes, some comments on the relation between psychoanalysis and the study of behavioral development are in order.

By the late 1930s, psychoanalysis appeared to many child psychologists to be the answer to their search for a unifying theory of development. One of the more influential writers on the matter was Freud's daughter, Anna Freud. Her view on the adequacy of the theory for understanding personality development—indeed, all features of development—was unambiguous and uncompromising. In the chapter that she prepared for the first edition of *A Handbook of Child Psychology,* Anna Freud (1931) wrote:

> Psychoanalysis does not permit itself to be ranged with other conceptions: it refuses to be put on an equal basis with them. The universal validity which psychoanalysis postulates for its theories makes impossible its limitation to any special sphere such as the conception of the neurotic child or even the sexual development of the child. Psychoanalysis goes beyond these boundaries, within which it might even have been granted the right of judgment, and encroaches upon domains which, as demonstrated by the table of contents of this book, other specialists consider their own. (p. 561)

Psychoanalysis would settle for nothing less than the whole pie of developmental psychology, and it came close to getting it in one form or another through the rest of the twentieth century.

It seemed inevitable that empirically minded U.S. psychologists would attempt to put some of the key propositions of the theory to experimental test—indeed, the enterprise attracted some of the best young scientists in psychology. What did they find? In summing up the then-available results of the experimental assessments of fixation, regression, projection, and other psychoanalytic mechanisms, Sears (1944) wrote:

> One is driven to the conclusion that experimental psychology has not yet made a major contribution to these problems. . . . It seems doubtful whether the sheer testing of psychoanalytical theory is an appropriate task for experimental psychology. Instead of trying to ride on the tail of a kite that was never meant to carry such a load, experimentalists would probably be wise to get all the hunches, intuitions, and experience possible from psychoanalysis and then, for themselves, start the laborious task of constructing a systematic psychology of personality, but a system based on behavioral rather than experiential data. (p. 329)

All this is to say that the experimental testing of psychoanalytic proposals was not a profitable enterprise. Sears was to follow his own advice, as we shall see, and would pave the way for the modern generations of social learning theory.

Despite the equivocal returns on the scientific analysis of the theory, its influence gained, not faded, during the 1930s and 1940s. Virtually every major theoretical system concerned with human behavior—save those that dealt with purely physiological, motor, or sensory phenomena—was accommodated to psychoanalytic theory. Behaviorism (whether "radical" Watsonianism or conventional Hullian theory) and Piagetian cognitive theory alike were significantly influenced in that era, just as ethology and social learning theory were influenced in the present one. The immediate effects on child-rearing practices were as great, if not greater, than the earlier ones associated with Holt and Watson. With the publication of the first edition of Benjamin Spock's (1946) best-selling manual on infant care, the U.S. public was encouraged to adopt practices not inconsistent with psychoanalytic training. The rapid growth of professional clinical psychology—World War II had demanded specialists in diagnosis and therapy—also underscored the need for a theory of assessment and treatment. The major tools available for the task included projective tests (typically based on psychoanalytic assumptions) and methods of psychotherapy (derived, directly or indirectly, from the psychoanalytic interview). Psychology as a profession and a science became increasingly indebted to psychoanalytic theory and practice.

But psychoanalysts themselves proved to be an intellectually heterogeneous lot, and the theory could hardly be viewed as a static, unchanging view of personality. Among the more prominent heretics were Carl Jung, Alfred Adler, Karen Horney, Eric Fromm, and Harry Stack Sullivan. They shared in common an emphasis on the interpersonal implications of dynamic theory, as these were expressed in the family system and in interpersonal exchanges of later childhood and maturity. With this focus on "object relations," there was a concomitant de-emphasis on the importance of infantile sexuality and the reversibility of very early experiences (see Munroe, 1955). Horney (1937) and Sullivan led the way in the neo-Freudian theory of interpersonal relations. In 1940, in a lengthy article in *Psychiatry,* Sullivan outlined a rapprochement between theories of symbolic interaction that had become associated with sociology and anthropology and a neoanalytic interpersonal theory of psychopathology. Sullivan's position was that the "self-dynamism" arises from "the recurrent interpersonal situations of life." Ideas about the self-dynamism (which is not an entity but a process) are derived from the interpersonal settings of life and depend, in large measure, on the "consensual validation" of the views of "significant others" with whom one interacts. Because of the continuing impact of the social system on one's behavior and one's thought of oneself, the development of personality is a continuing, ongoing process. Sullivan's views had a significant impact on subsequent sociological (Cottrell, 1942, 1969), psychiatric (G. Bateson, Jackson, Hayley, & Weakland, 1956; Jackson, 1968), and psychological models of social interaction.

Field Theory and Ecological Psychology

When Kurt Lewin immigrated to the United States in the early 1930s, he had already established himself as a distinguished child psychologist in Germany. U.S. readers were first introduced to his powerful theory of "behavior and development as a function of the total situation" in two articles that appeared in English in 1931. In his classic theoretical paper, "Conflict between Aristotelian and Galileian Modes of Thought in Psychology" (1931a), Lewin offered an elegant defense for studying individual children in the actual, concrete, total situation of which they are a part. He argued that the dynamics of behavior—the study of the forces that exercise momentary control over the direction and form of actions—cannot be clarified by the use of standard statistical methods. Averages that are obtained by combining the results of large numbers of children in a "standard" environment are bound to obscure the precise dynamic controls of behavior, not clarify them. "An inference from the average to the concrete particular case is . . . impossible. The concepts of the average child and of the average situation are abstractions that have no utility whatever for the investigation of dynamics" (Lewin, 1931b, p. 95). Lewin provided a rationale for the conclusion that had been arrived at intuitively by some of his most insightful predecessors (Preyer, Binet, Freud, and Piaget). The conclusion stood in sharp contrast to that arrived at by Galton and most U.S. psychologists.

Lewin's ideas about method were consistent with his theoretical position on the contextual relativity of psychological experience and action. A key element in Lewin's theorizing was his emphasis on the *psychological* environment as opposed to the physical or objectively determined concrete environment. Lewin observed, "All these things and events are defined for the child partly by their 'appearance' but above all by their 'functional possibilities' (the *Wirkwelt* in v. Uexküll's sense)"

(1931b, p. 100). In endorsing animal behaviorist J. von Uexküll's emphasis on the individual's reconstructed inner space (the *Umwelt* and the *Innenwelt*) as opposed to the objective mechanical forces of the external world (see Loeb, 1912/1964), he captured an idea whose implications have yet to be fully realized. Lewin formulated his psychological field theory in keeping with the gestalt and system theoretic approaches. Although behavior is seen as a function of both the person and the environment, these two major variables "are mutually dependent upon each other. In other words, to understand or to predict behavior, the person and his environment have to be considered as *one* constellation of interdependent factors. We call the totality of these factors the life space *(LSp)* of that individual" (Lewin, 1954, p. 919). Lewin's theory was basically a model of action, to account for the directionality of behavior in terms of the forces present in a given psychological environment. But the effective forces belong neither to the person nor to the field alone; actions can be understood only in the totality of forces as they are merged to determine behavior.

In his work in the United States in the 1930s and 1940s, Lewin extended this theoretical model to diverse social and developmental phenomena, including the analysis of conflict, social influence, level of aspiration, and goal setting, as well as the effects of autocratic and democratic environments. Beyond their influence on specific research programs, Lewin's principles of behavior and development became incorporated into the discipline without being identified with his particular school of thought. For instance, his "field theory" demanded attention to the context in which behavior occurred and, particularly, the individual's personal response to that setting. The "environment" was not merely the physical and social context, but the child's perception of that setting. So one and the same "objective" environment may be perceived differently, according to the needs of the child and the forces that operate on him or her; conversely, seemingly identical responses may reflect the operation of quite different psychological forces. There is a contextual relativity to both stimuli and responses, and neither should be divorced from the social/environmental matrix in which each is embedded.

This overview does not permit an account of Lewin's developmental and social theory (excellent summaries may be found in A. Baldwin, 1967/1980, and Estes, 1954). It should be noted that Lewin and the Lewinians pioneered in the study of conflict resolution (Lewin, 1935), level of aspiration (Lewin, Dembo, Festinger, & Sears, 1944), small group processes (Lewin, Lippitt, & White, 1939), and the effects of interruption and frustration (R. G. Barker, Dembo, & Lewin, 1941). One of Lewin's postdoctoral students, Roger Barker, carried the essential concepts of ecological psychology to the next generation (R. G. Barker, 1963, 1964, 1968). Urie Bronfenbrenner (1979) has been enormously influential in extending the essential ideas (Bronfenbrenner, 1979, 1993, 1995). Furthermore, other students inspired by Lewin virtually sculpted the face of modern social psychology. There was also an immediate and direct connection to developmental psychology. Marian Radke Yarrow, an eminent developmental psychologist, was Lewin's protégé at MIT, where she taught the graduate seminar on Lewinian theory to H. Kelley, J. Thibaut, and M. Deutsch, among others.

What did Lewinian theory not cover? Criticisms of field theory note that relatively little attention is given to the processes of enduring change—namely, those of learning. Although Lewin clearly acknowledges that "somatic" changes in the child can have a significant influence on the psychological environment, field theory gives only modest attention to how such developmental changes may be integrated with modifications in psychological forces. Hence, the model is exceedingly convincing as a descriptive model, but how it may be critically tested, modified, and falsified is less clear. Lewin's emphasis woke psychology from its behavioristic slumbers by pointing out that the context-free objective "stimulus" may be an illusion. The implications for methodology and theory, especially in the study of social development and social psychology, were enormous.

COMMENTS ON THE MIDDLE PERIOD

It seems ironic that the most notable development in child psychology during this period was brought about initially by social and economic forces instead of scientific advances. Child research institutes were founded throughout the United States, and, once established, they became enormously influential in the science and remained so throughout the better part of the twentieth century. Behind the foundations and the governmental-university agencies that provided the actual financial support for the institutes, there was a broad nationwide coalition of concerned teachers and parents who pressed

for more attention, scientific and otherwise, to the needs of children. This was the same social/political "movement" that had been given early form and direction by Hall in the 1880s and 1890s. But the establishment of study centers did not a science make, and investigators were immediately challenged to develop more adequate procedures in virtually every sector of child research. Each area of study—intelligence, honesty, emotionality, language, thinking, perception, growth, predictability—presented its own problems of methodology and analysis, and each had to be solved in its own terms. The upshot was an inevitable fragmentation of developmental study.

What were the empirical advances in the period? To attempt to answer that question would be tantamount to compressing the information contained in the three compendia edited by C. Murchison (1931, 1933) and L. Carmichael (1946). Beyond the demonstration that almost all aspects of child behavior and cognition could be profitably studied by empirical procedures—something that had been promised but not demonstrated in the earlier period—we find substantive findings that perplexed the researchers themselves and seemed to defy integration with earlier concepts of the child. These phenomena included the specificity of honesty, the rapid conditionability of fear in infants, the egocentricism of children, the physical normality (or superiority) of bright children, and the modest predictability of behavior over time and space. Spectacular controversies were ignited by studies of early experience that purported to show that children's basic intellectual adaptations could be influenced by especially beneficial or neglectful early experiences. Perhaps more important for the science than controversy were the less dramatic yet critical advances in describing the "normal" (i.e., species-typical) course of sensorimotor, cognitive, and behavioral development.

Theoretical activity in this period proceeded at two "levels," specific and general. At the first level, the empirical advances—methodological and substantive—produced information that demanded attention and integration. Hartshorne and May (1928) offered their "specificity" proposal on altruism and honesty; C. Bühler (1931), her account of three social "types" in infancy; F. Goodenough (1931), her explanation for the development of anger and quarrels; J. Anderson (1939), his hypothesis on the "overlap" in successive tests of infant competence; and so on. These data-based hypotheses constituted a necessary step between empirical studies of child behavior and the overarching theoretical conceptions that had stimulated the research in the first place.

At the second level, various attempts were made to establish a general integrative theory of development to fill the void left by the collapse of the recapitulation hypothesis. For every general developmental theory that vied for hegemony in the 1920s and 1930s, a straight line may be drawn backward to antecedent models of the 1880s and 1890s. The cognitive-developmental proposals of J. Piaget, L. S. Vygotsky, H. Wallon, and H. Werner were immediately linked to the concepts of J. M. Baldwin; the developmental psychobiology of Z-Y. Kuo, T. C. Schneirla, and L. von Bertalanffy followed the prior conceptual advances in animal behavior and experimental embryology; the maturational model of A. Gesell constituted in several respects an extension of the developmental views of W. Preyer; the scientific basis for Watsonian behaviorism was established by the prior work of Morgan, Loeb, and Jennings, among others; and the several versions of psychoanalysis each retained some central elements of the parent theory.

Despite obvious differences among the above models, they shared a similarity in that they were, in a basic sense, developmental. Differences among them arose on assumptions about how developmental processes might be most adequately described and how behavioral phenomena might be most appropriately conceptualized. These assumptions, in turn, reflected which behavioral or cognitive phenomena were addressed by the theory, and in which species. Although psychoanalysis gained a clear edge in popular recognition and clinical applications, organismic models became quietly influential in the research of psychobiological and cognitive investigators. But none of the models achieved clear dominance, and the science could not claim as its own a unifying theory of behavioral development that might complement or extend the theory of biological evolution. Indeed, advances in identifying the contextual events that determined actions and learning raised questions on whether a general theory of behavioral development was possible.

THE MODERN ERA

Following a general depression in research activity during World War II, work on behavioral development began an upward slope in the postwar period and has only recently shown signs of leveling. A new "golden

age" began for the discipline and it has surpassed those of the two previous eras (1895–1905 and 1925–1935). New techniques and approaches were introduced in rapid succession, stimulated in part by advances in electronic recording, coding, and computer analysis. The effective "life span" of research methods—from new projective procedures to questionnaires on authoritarianism or brief experimental procedures for studying learning—appeared to have been shortened from about 15 to about 10 years. Promising ideas—on test anxiety, social reinforcement satiation, impulsivity, and modeling—entered rapidly, dominated the area briefly, then faded away, often without a decent postmortem or obituary.

In large measure, the quickened pace of research activity and analysis could be attributed to great increases in federal support for empirical research and the opening of new teaching and research positions. A new institute established by the National Institutes of Health (NIH) was devoted to research on child health and human development, and other institutes accepted a developmental orientation to understanding problem behaviors (e.g., National Institute of Mental Health, National Institute of Drug Abuse). In addition, the U.S. Congress funded an unprecedented national program to provide poor and disadvantaged children with a "Head Start" prior to school entry. Two psychologists, Urie Bronfenbrenner and Edward Zigler, were instrumental in initiating the program and directing it through its early years. Other developmental psychologists were involved in the creation of television programs to enhance education and learning (e.g., *Sesame Street*). This period has been one of expansion, invention, and criticism, with new innovations and discoveries in virtually all areas of developmental research and application.

One of the more visible early theoretical trends in this period was the rise, domination, and passing of general learning theories. Until their grip began to fail in the early 1960s, behavioral models of learning were hegemonous in U.S. psychology, and developmental psychology was no exception. To enter the theoretical mainstream, research in the several areas of child study, from language acquisition and cognitive learning to social behavior and child rearing, had to be couched in learning terms. Behaviors did not develop, they were acquired. Despite their austere and parsimonious construction, learning models appeared to be remarkably adaptable for developmental psychologists—but not adaptive enough. By the mid-1960s, the area began to rediscover the dynamic developmental models on which the field had been established. They appeared in quite different forms in studies of language and cognition, in investigations of basic motor and perceptual processes, and in longitudinal studies of social and personality development. The area also rediscovered the basic psychoanalytic assumption that the first relationships were critical for understanding psychopathology and the core features of personality.

Many of the ideas and problems that had been pursued over the first half of the twentieth century came again to the forefront, from the study of growth patterns in motor and sensory development, in cognitive changes in thought and language, and in the effects of interactions on social and personality development.

This section of developmental history overlaps with contemporary events, including those covered in other chapters of this edition of the *Handbook*. The closer one comes to current trends, the more difficult it is to disentangle ephemeral interests from enduring changes. Hence, we leave for a final section of this chapter our perception of about the last 20 years of developmental science (the final decade of the twentieth century and much of the 1st decade of the present century). Here, however, on more secure historical ground is a discussion of some of the shifts that have occurred in developmental science up through the 1980s that helped shape the contemporary trends within the field. The focus is on three domains: (1) social learning theory, (2) attachment theory, and (3) cognitive development.

SOCIAL LEARNING: RISE, DECLINE, AND REINVENTION

Contrary to general impressions, there is no single "social learning theory"; there are several. The plurality came about initially because there was only modest consensus on which principles of learning were universal. Over the past half-century, a number of social learning theories have evolved from the basic frameworks established by Skinner and the neo-Hullian theorists, each with its distinctive emphasis and adherents. It has been a complex and often misunderstood endeavor, and we comment here only on some of the historical highlights.

Rise

Robert R. Sears can be recognized as the person whose influence was pervasive in the introduction of the psy-

choanalytic learning synthesis to the study of children. One of the original members of the Yale group that created neo-Hullian social learning theory (Dollard et al., 1939; Miller et al., 1941), Sears was a pivotal influence for students and colleagues at the Iowa Child Welfare Research Station, Harvard University, and Stanford University. With his colleagues at these institutions, many of whom went on to develop influential revisions of social learning (including E. E. Maccoby, J. Whiting, V. Nowlis, J. Gewirtz, Richard Walters, A. Bandura, and Sears's wife, Pauline Snedden Sears), Sears was instrumental in bringing about major changes in the scope and concerns of developmental psychology.

In the first major publication to come from this group (Sears, Whiting, Nowlis, & Sears, 1953), "aggression" and "dependency" were seen as motives that were learned early in the life history of the child. How were they learned? The answer was not an easy one, at least not for Hullians, because the theory of conditioned drives had not been elaborated by Clark Hull (1951) and had been only vaguely outlined by Freud. Drawing from both of these views, Sears and his colleagues argued that these key social motives were acquired as a universal consequence of the early familial experiences of the child. Moreover, variations in the strength of the drives and in their expression were produced by differences in the quality of the parent-child relationship, as indexed by the rewards, punishments, and frustrations that occurred in the mother-child interaction. This social learning theory was extended to account for the development of gender role-typing (through internalization of parental values and self-reinforcement) and conscience (through nurturance and the withdrawal of love by the mother).

The semistructured interview technique was extensively employed to investigate parental attitudes, beliefs, and child-rearing practices. Large-scale studies were conducted by Sears and his colleagues in Iowa, Massachusetts, and California (Palo Alto). One aim was to replicate key findings at each of the three sites by using a common research technique. Employing lengthy in-depth interviews with parents as a primary research technique, these studies attempted to relate child-rearing practices with assessment of children's social behavior and personality patterns. The assessments of children capitalized on advances that had been made in observational methodology, and revised or developed child-appropriate "projective test" measures. Instead of using inkblots or semistructured pictures, the investigators used dolls and dollhouses to permit the preschool child to reconstruct the nuclear family (Bach, 1946). The interview and observational procedures provided the model for a wide range of cross-cultural and cross-age studies (e.g., Whiting & Whiting, 1975).

One of the great strengths of social learning theory and its practitioners was their openness to data, whether supportive or disconfirmatory. Hence, the original statement underwent revisions, both modest (e.g., Sears, Maccoby, & Levin, 1957; Sears, Rau, & Alpert, 1965) and major (e.g., Bandura & Walters, 1959; Whiting & Whiting, 1975), in attempts to extend it and correct its shortcomings.

Decline

What were the shortcomings? Some were identified by the investigators themselves in three large-scale studies of child rearing conducted in Iowa, Massachusetts, and California. When the results of the 20-year research effort were compiled and analyzed, the outcomes provided only modest support for the theory that had inspired the work. The problem was that there were few reliable correlates between variations in child-rearing practices and the children's social behavior and personality patterns.

Eleanor Maccoby, a key participant in this work, indicated that the problem lay as much in the theory as in the method. Looking backward after 35 years, Maccoby (1994) wrote:

> Few connections were found between parental child-rearing practices (as reported by parents in detailed interviews) and independent assessments of children's personality characteristics—so few, indeed, that virtually nothing was published relating the two sets of data. The major yield of the study was a book on child-rearing practices as seen from the perspective of mothers (Sears et al., 1957). This book was mainly descriptive and included only very limited tests of the theories that led to the study. Sears and colleagues later conducted a study with preschoolers focused specifically on the role of identification with the same-sex parent in producing progress toward social maturity. They used a much expanded range of assessment techniques, including observations of parent-child interaction. The hypothesis that identification with parents was a primary mechanism mediating children's acquisition of a cluster of well-socialized attributes was, once again, not supported. (see especially Sears et al., 1965, table 40, p. 246)

Not all of the outcomes were negative, nor were all unreliable. But the overall pattern of the findings provided

scant support for the ideas that had inspired the work in the first place. What was to blame—the theory or the methods employed to test it? The methods could be criticized, and so could the theory.

In an incisive and courageous evaluation published at the height of the social learning era, Marian Radke Yarrow and her colleagues wrote:

> Childrearing research is a curious combination of loose methodology that is tightly interwoven with provocative hypotheses of developmental processes and relationships. The compelling legend of maternal influences on child behavior that has evolved does not have its roots in solid data, and its precise verification remains in many respects a subject for future research. The findings from the preceding analyses of data make it difficult to continue to be complacent about methodology, and difficult to continue to regard replication as a luxury. The child's day-to-day experiences contribute significantly to his behavior and development and are in many respects the essence of developmental theory. An exact understanding is important to science and society. In attempting to build on this knowledge, each researcher is a methodologist and as such has a responsibility for excellence. (Yarrow, Campbell, & Burton, 1968, p. 152)

Two noteworthy contributions by Sears and his colleagues require mention. In a presidential address to the American Psychological Association, Sears (1951) brought renewed attention to the theoretical concept of social interaction and the bidirectionality of familial relations. Although the research methods employed by the Sears group made it difficult to study interactional phenomena directly, these concepts figured importantly in the conceptions that were offered in each of Sears's major subsequent publications. They provided the impetus for renewed attention to the issues that had been initially raised by James Mark Baldwin, and were then represented in the work of psychiatrist H. S. Sullivan (1940, 1953) and sociologist Leonard Cottrell (1942).

The second contribution was the reintegration of child development research into the mainstream of psychology, a position that it had not held for most of the previous half-century. By linking the study of children to the then-current theoretical systems of psychology, the door was opened for a fresh generation of psychologists to enter the field. The gains were not without cost, however, in that much of the earlier developmental work was set aside or ignored by the new group. Traditional developmental studies, as embodied in the chapters of successive editions of the Carmichael *Manual,* were seen as irrelevant for the basic issues of social learning and social control. Instead of descriptions of developmental change, this generation of developmentalists was concerned with explanations of change in terms of the "new" concepts of social interchange, imitation, dyadic analysis, dependency, aggression, and conscience. Overlooked in the social learning revolution was the fact that each of these concepts had been familiar to the founding generation, and the phenomena to which the concepts refer had been extensively researched in the next generation.

Coming back to the evolution of social learning theories, we find that, in the early 1960s, the movement was split into two major divisions, each of which was in intellectual debt to the parental movement and to the reinforcement concepts of B. F. Skinner (1953). J. Gewirtz, S. Bijou, and D. Baer (Bijou & Baer, 1961; Gewirtz, 1961) followed Skinner's lead in applying the ideas and concepts of operant conditioning to analyses of behavior modification in normal and retarded children. But there were problems in negotiating the theoretical transition from pigeons to children. Just as the concept of "conditioned" or "learned motivation" had presented difficulties for the initial social learning theories, the notion of "conditioned" or "social reinforcement" proved to be an enigmatic concept for the operant revision (see Gewirtz & Baer, 1958; Parton & Ross, 1965).

Reinvention

The resurgence of social learning theory was led by Albert Bandura and Richard Walters (1963), who shifted the substantive and explanatory basis of the model. They argued that the wedding of learning concepts to psychoanalysis tended to shortchange both models. Social learning should exploit learning mechanisms, including cognitive processes that govern imitation and reinforcement. In their work, "modeling" was seen as a primary mechanism for the acquisition of novel actions and, as such, a key to understanding socialization and transgenerational transmission. They had, in effect, reinstituted the construct of "imitation" to the nuclear role that it had played in J. M. Baldwin's formulation.

The next modification in social learning theory came shortly afterward, when Albert Bandura revitalized the theory and established it on a foundation of distinctively human, cognitive processes. The need for further revision arose when it became clear that the short-term

studies of imitation and social learning of children were open to alternative, cognitive interpretations. For instance, examination of the determinants and outcomes of modeling (i.e., imitation) in children indicated that children did not behave in a fashion that was analogous to observation learning in animals. A similar phenomenon was observed in the effects of social reinforcement (i.e., verbal reward) with children. Marked variations in reinforcer effectiveness could be induced simply by instructions or other cognitive manipulations, leading to the interpretation that "social reinforcement" in children may more appropriately be viewed in terms of information transmission processes than primary reinforcement processes (see Paris & Cairns, 1972; Stevenson, 1965). Other "information" interpretations of punishment, dependency, and conscience appeared (e.g., Walters & Parke, 1964). A similar revision was made in the interpretation of imitation and modeling, for parallel reasons (Bandura, 1969). Patterson (1979) extended observational methods in inventive ways; hence, paved the way for precise assessments of social learning hypotheses.

Along with Rotter (1954) and Mischel (1973), Bandura shifted the focus of social learning from preoccupation with psychoanalytic conflicts and anxieties to the positive, productive features of children. With the concepts of self-efficacy and self-regulation, he affirmed the distinctive qualities of human adaptation, and he shifted the focus of the orientation from human problems to human potential. But these are not opposed foci in Bandura's revision of social learning theory. On this score, Grusec (1994) observes:

> Bandura's interest in self-efficacy arose from his studies of the role of participant modeling in the treatment of phobic disorders. A striking feature of the outcomes of these studies was the extent to which individuals' perceptions of their own feeling of effectiveness determined how easily changes in behavior and fear arousal were achieved and maintained. According to self-efficacy theory, people develop domain-specific beliefs about their own abilities and characteristics that guide their behavior by determining what they try to achieve and how much effort they put into their performance in that particular situation or domain. (p. 488)

In a century-long cycle, social cognition-learning reformulations came to embrace not only J. M. Baldwin's concept of imitation but also his concept of the self as a central organizing theme.

Some characteristics of behaviorist models have remained virtually unchanged in the several generations of social learning theories. Social learning researchers have maintained a curious stance toward the concept of development. From Watson onward, learning theories have been developmental in the sense that they have shared the "fundamental point" that humans' activities should be studied historically. Social learning views have been slow to consider processes of age-related shifts in development (Cairns, 1979; Grusec, 1994). The implicit assumption has persisted that the incremental changes in cognition and learning are sufficient to account for the major phenomena of social development, including their establishment, maintenance, and change.

ATTACHMENT: DISCOVERY AND LOSS

With the rediscovery of imitation and modeling, students of social learning found fresh and robust phenomena to analyze, and a new generation of social learning models was born. So it was with mother-infant attachment. The systematic investigation of mother-infant attachment in studies of animal behavior, and subsequently in studies of humans, breathed new life into the psychoanalytic framework. According to an early definition by Ainsworth (1972), attachment refers to "an affectional tie or bond that one individual (person or animal) forms between himself and another specific individual" (p. 100).

The prototypic attachment is that which develops between mothers and infants. That a strong tie develops early in life is certainly no new revelation. However, the systematic study of attachment behavior in animals and humans began only in the post-World War II era. Scott (1962, 1963), and Harlow (1958) opened the door for the systematic study of this early affectional relationship with their now classic studies of the young puppy and infant rhesus monkey. At about the same time, Bowlby (1958) and his former postdoctoral associates (Ainsworth, 1963; Schaffer & Emerson, 1964) offered influential statements on attachment in human infants.

The Phenomena of Attachment

Harry F. Harlow (1958) announced in his American Psychological Association presidential address the results of some dramatic findings on the importance of somatosensory contact in the formation of the bond of the

infant monkey to inanimate "surrogate" mothers. According to the initial interpretation of these findings, tactile stimulation—or "contact comfort"—was a more powerful determinant than hunger in the infant's formation of a social attachment. Subsequent work by Harlow and others led to significant modifications in the initial interpretations—on the necessary and sufficient conditions for the development of mammalian attachments (e.g., Cairns, 1966), and on the stability and plasticity of effects induced by early social experience (e.g., Mason & Kinney, 1974; Suomi & Harlow, 1972). Nonetheless, the image of "motherless monkeys" had a catalytic effect in stimulating studies of mother-infant relations and, more generally, investigations of the development of social interactions.

Given the critical role assigned to early experiences in most developmental theories, it is curious that so little systematic work had been conducted on mother-infant attachment before the modern era. It is especially surprising because the intense relationship established between infants and mothers is perhaps the most easily detected and robust social phenomenon observed across mammals. At about the time when infants begin to locomote independently, they become extremely distressed when removed involuntarily or separated from their mothers (or mother-surrogates). Reunion tends to produce an immediate cessation of distress (e.g., the young quit crying, screaming, or bleating). Infants in this age range also express heightened weariness or fear when confronted with strange persons and strange places—or even familiar persons in strange places. These phenomena can be demonstrated in virtually all mammalian species; human babies show intermediate levels of intensity.

The multiple dimensions of early formed bonds were investigated in experimental and observational work with birds (i.e., imprinting) and mammals (i.e., attachment). By the mid-1960s, a comprehensive picture could be drawn of the conditions for the emergence and maintenance of and for change in attachment relationships (Harlow, 1958; Rosenblatt & Lehrman, 1963; Scott, 1963). The findings permitted four empirical generalizations about the nature of mammalian attachment (Cairns, 1966):

1. At birth and in the immediate postnatal period, there is an elegant synchrony between the actions and physiological states of the mother and of the infant. Moreover, the actions of the infant serve to maintain the mother in a maternal condition and sculpt her physiology so that it supports the contemporaneous needs of the infant. A parallel feedback loop serves similar functions for the infant, and a reciprocal relationship becomes established between the actions and states of the infant and those of the mother (Rosenblatt & Lehrman, 1963). Biological needs and social actions become mutually supportive (Hofer, 1994). In effect, the actions and biological conditions of the infant and mother rapidly become organized around each other.

2. Proximity and mutual mother-infant engagement promote the establishment of a social attachment that persists in the absence of the psychobiological conditions that originally promoted the interaction. In most mammalian species, the bond is intense, and involuntary separation triggers disorganization, distress, and disruption in both the infant and the mother. The distress is so extreme that it can be assessed by a host of behavioral and biological assessments.

3. Intense social attachment can be established under diverse conditions (e.g., the absence of milk, the absence of contact comfort, and, paradoxically, the presence of intense punishment). The influence of these conditions depends, in large measure, on the contexts of reciprocal exchange. Moreover, attachment can develop in older as well as younger animals (maternal attachment is but one of the special conditions). Experimental studies have indicated that social attachment strength increases with interaction, time spent, and exclusivity of relationship.

4. Maturational changes trigger modifications in the nature and the quality of attachment; maturation of the young is synchronized with maternal behavioral and physiological changes that are consistent with the mother's preparation for the next generation of offspring. New attachments are formed typically within minutes and hours rather than weeks and months, possibly to balance the tension between conservation and survival (Cairns & Werboff, 1967; Mason & Kinney, 1974). In this regard, the adaptation had to be rapid in order for the vulnerable infant to live.

Attachment Theory

Studies of infant-mother attachment came in the wake of these systematic investigations, and they stimulated enormous scientific and public interest (Maccoby & Masters, 1970). Psychoanalyst John Bowlby began a series of seminars on these issues at the Tavistock Clinic

in London in the 1950s, and expanded the series in the 1960s (Foss, 1961, 1965; see Bretherton & Waters, 1985). Two key research programs reported in these discussions were: (1) the observations of Schafer and Emerson (1964) on the age of onset of attachment and (2) Ainsworth's (1963) observational report of infant-mother attachment in Uganda. Schafer and Emerson (1964) discovered that human infants begin to exhibit discriminative attachment at about 8 to 9 lunar months after birth, and that these attachments were formed with respect to a wide range of persons who were intimately involved in the infants' caretaking.

John Bowlby first became known for his contributions to object relations theory and, specifically, the significance of early mother-infant bonds (i.e., Bowlby, 1946, 1952). Beginning in the early 1950s, he began informal interdisciplinary seminars that involved, along with others, the eminent ethologist Robert Hinde. One outcome of these discussions was a paper published in the *International Journal of Psychoanalysis* where Bowlby integrated concepts from object relations theory with evolutionary assumptions. He thereby generated a framework of attachment that fused psychoanalysis and ethology (Bowlby, 1958). In an important set of volumes, Bowlby described the implications of his "attachment theory" for understanding maternal-child anxiety, separation, and loss (1969, 1973).

In Bowlby's view of attachment, priority is given to the events that occur during the child's early years in the establishment of a relatively stable attachment system. Mother-infant separation is likely to produce enduring negative consequences. The nature of the attachment that is formed in early development gives rise to an internal representational model formed by the child. Moreover, the processes that give rise to an attachment involve intense mutual regulation and mutual organization between the mother and infant. Bowlby (1952) wrote:

> If growth is to proceed smoothly, the tissues must be exposed to the influence of the appropriate organizer at critical periods. In the same way, if mental development is to proceed smoothly, it would appear to be necessary for the undifferentiated psyche to be exposed during certain critical periods to the influence of the psychic organizer—the mother. (p. 53)

Unlike ethological/animal behavior work, Bowlby's object relations/attachment theory has a distinctive focus on individual differences. In addition, its goal, like object relations theory, is to provide a comprehensive account of psychopathology. Like ethological assumptions, it emphasizes the formative effects of early experiences.

Any discussion of modern "attachment theory" must include Mary D. S. Ainsworth, Bowlby's long-term collaborator. Ainsworth conducted a pair of influential observational studies on mother-infant relations in Uganda (Ainsworth, 1967) and Baltimore (Ainsworth, Blehar, Waters, & Wall, 1978). One of the procedures to emerge from the later study was a controlled observation procedure labeled the "Strange Situation" (Ainsworth et al., 1978).[7] This assessment involved a series of very brief separations (i.e., 1 to 3 minutes), with special attention given to the quality of the reunions. The coding of a reunion provided a classification procedure by which children were diagnosed as securely attached (Type B) or insecurely attached (Types A and C), along with various subtypes (Ainsworth et al., 1978). A primary attraction of attachment theory is its presumption that these types are linked to the quality of later relationships and to psychopathology.

An extended discussion of attachment theory and its strengths and shortcomings is beyond the limits of this chapter and would catapult the account into the contemporary period. For the current state of affairs on this enormously influential theory, the modern developmental version of neopsychoanalysis, see Bretherton and Waters (1985) and Goldberg, Muir, and Kerr (1995).

COGNITIVE REEMERGENCE

This era also saw the reemergence of cognitive-developmental questions as a central focus for thinking and research. Stimulated by a national reexamination of the educational process (e.g., Bruner, 1960), in part because of influential volumes on Piaget (Flavell, 1963; Hunt, 1961) and Vygotsky (Cole, 1978), and in part because of the fading vigor of social learning approaches, the problem of how mental development occurs became a dominant concern for developmental researchers. It is a reemergence—rather than a revolution—because the issues of mind, consciousness, and mental development were central to the discipline at its founding.

Virtually all aspects of the field were touched by the fresh emphasis. Investigations of language development,

[7] The "Strange Situation" seems to have been modeled after the assessments of attachment employed with nonhuman mammals (see Scott, 1963).

thinking, sensation, and information processing in children flourished as they had in no earlier era. Even hard-core behavioristic models proved to be vulnerable to cognitive modifications, with the new directions on "mediational mechanisms" being provided by T. and H. Kendler (Kendler & Kendler, 1962) and M. Kuenne (1946). Information-processing approaches were challenged to build bridges to cognitive developmental studies and interpretations. Given the thrust of the movement, it seemed inevitable that the barriers between social development and cognitive development should be transcended, and that it should become once again permissible to refer to concepts of others and of self (see Harter, 1983, 1998, Chapter 9, this *Handbook,* Volume 3; Lewis & Brooks-Gunn, 1979). The recent history of this movement and the statement of the rapprochement among experimental-cognitive concepts, social cognition, and cognitive-developmental concepts are covered in other chapters of this *Handbook* (e.g., see, Baltes, Lindenberger, & Staudinger, Chapter 11, this *Handbook,* this volume; Fischer & Bidell, 1998; Kuhn & Franklin, Chapter 22, this *Handbook,* Volume 2; Overton, Chapter 2, this *Handbook,* this volume).

HISTORICAL THEMES AND CONTEMPORARY ADVANCES

Now, more than 100 years after it began, developmental research and theory continue to be diverse, vigorous, contentious, fresh, and in many instances, brilliant. In concluding this chapter, we recall the themes that were identified in the beginning, to both take stock of the last 2 decades of developmental science and to describe the progress made and the pitfalls encountered in more than a century of scientific work (see also Cairns, 2000; Cairns, Cairns, Rodkin, & Xie, 1998).

Knowledge and Consciousness

Understanding the mind and how it develops and functions remains a major concern for developmentalists. Because of advances in technology, investigators who study the relations between brain processes and cognitive activity have achieved spectacular advances in identifying pathways and plasticity over time. And there is now compelling evidence to support Preyer's speculation that "the brain grows through its own activity." Yet, plenty of controversies remain, and certain basic issues continue to be controversial (e.g., is there an area in the brain devoted to language?) despite impressive advances in understanding and methodology. At least some of the matters that remain unresolved have less to do with how the brain is studied than with how our constructs of the mind are formulated and our measures are organized (Morrison & Ornstein, 1996; see Gottlieb et al., Chapter 5; Magnusson & Stattin, Chapter 8; Overton, Chapter 2; Valsiner, Chapter 4, this *Handbook,* this volume).

Thoughts and Actions

The self and its distinctive processes (e.g., self-concepts, self-efficacy, self-regulation) continue to be central for modern researchers. What was attributed to the "will" in the 1890s is attributed to the self and its processes (motives, values, dispositions) in the 1990s. What has changed, however, are methods, measures, and the findings that they yield. The multilevel, multimeasure methodological procedures of the late twentieth century have exposed some myths. One's own self-attributions are not necessarily the same as descriptions of the self by others, and the differences are systematically linked to the domains assessed, the contexts of assessment, and the meaning of the measures. The story of how the discrepancies between the self and others is now being addressed belongs, however, to today, not to the past. The current state of information on these matters is addressed elsewhere in this volume (see Baltes et al., Chapter 11; Brandstädter, Chapter 10; Rathunde & Csikszentmihalyi, Chapter 9, this *Handbook,* this volume).

Ontogeny and Phylogeny

How may development be best defined: in terms of the ontogeny of individuals, the ontogeny of the species, or the ontogeny of both? This was one of the first issues in the systematic development of the science, and it has been one of the last to be reassessed in the present era. But it is now being addressed as a matter of how cross-generational transfer occurs, and how there may be turning points across generations as well as across ontogeny. According to a recent collaborative statement, "Developmental investigation focuses attention to the ontogenies of both embryos and ancestors, and to the process by which pathways may be repeated or redirected across successive generations" (Carolina Consortium on Human Development, 1996, p. 1). Intergenerational investigations may become a primary

methodology of the future as they become feasible and practical (see, e.g., Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Cairns, Cairns, Xie, Leung, & Hearne, 1998; Elder & Shanahan, Chapter 12, this *Handbook,* this volume).

Nature and Nurture

After a century of controversy, the nature-nurture debate was still being contested both in public and in the laboratory (e.g., Herrnstein & Murray, 1994; Lehrman, 1953, 1970). Recall that J. M. Baldwin resolved the matter by observing that "most of man's equipment is due to both causes working together," and Preyer arrived at the same conclusion.

Today, the split conceptions of nature and nurture, and of the reductionist formulations associated with either a nature (e.g., sociobiology or behavior genetics) or a nurture (e.g., Behaviorism or functional analysis approaches) have passed from the main stream of theoretical and scientific interest (e.g., see Gottlieb, et al., Chapter 5; Overton, Chapter 2, this *Handbook,* this volume) and—through the lens of various versions of developmental systems theories (e.g., see Fischer & Bidell, 1998; Lerner, Chapter 1; Magnusson & Stattin, Chapter 8; Thelen & Smith, Chapter 6, this *Handbook,* this volume)—scientific attention has focused on models and methods that now promise to begin to address the question of how "both causes work together" at the level of biology, interactions, and social networks.

When Does Development End?

Virtually all researchers in this discipline are developmentalists—including arch-maturationist Arnold Gesell. The naïve idea of strict preformism and unidirectional causation has been a straw man since the beginning of the science. But there remain radical differences among investigators in *when* they believe experiences to be extremely relevant, and when they consider them to be irrelevant. Early speculations on this issue were handicapped by a paucity of systematic normative and experimental information. In the absence of longitudinal information on the behavioral adaptations of human beings, there was no adequate basis for selecting or rejecting these theoretical assumptions about the timing and functions of early experience. Neurobehavioral, cognitive, and social developmental research in the modern era has begun to clarify the role of time and timing across several domains. This information is reviewed, for example, by Baltes et al. (Chapter 11, this *Handbook,* this volume), Brandstädter (Chapter 10, this *Handbook,* this volume), Elder and Shanahan (Chapter 12, this *Handbook,* this volume), Overton (Chapter 2, this *Handbook,* this volume), and Valsiner (Chapter 4, this *Handbook,* this volume).

Morality and the Perfectibility of Humans

Values and moral development continue to be important for the discipline, although the work has been handicapped by serious methodological challenges. With a few important exceptions, the conceptual framework for understanding the development of personal values was given less attention than in the earlier eras. The importance of this domain has emerged in the past 20 years, as instantiated by interest in moral and spiritual development (see Oser, Scarlett, & Bucher, Chapter 17, this *Handbook,* this volume), positive youth development (see Benson, Scales, Hamilton, & Sesma, Chapter 16, this *Handbook,* this volume), and the use of strength-based models of human development to conceptualize and study the development of diverse children and adolescents (see Spencer, Chapter 15, this *Handbook,* this volume).

Given this burgeoning theoretical and empirical work, it seems likely that this domain will come to the forefront in the next era. Indeed, the current concern with the self and with self-organization in the social context prepares the way for an integrated view of morality, positive human development, and the capacities for healthy functioning present in all people. As Kohlberg insightfully observed, "An individual is fundamentally a potentially moral being, not because of social authority and rules (as Durkheim and Piaget thought) but because his ends, his will, his self is that of a shared social self" (Kohlberg, 1982, pp. 311–312).

Social Applications

Applications continue to present large opportunities and large problems. Sears (1975) concluded that the discipline was created to be relevant. In this regard, White (1996) wrote:

> Child study of some sort has to be part and parcel of any social design for children. Though developmental psychology is not, in the traditional sense, a policy science it has nevertheless a significant role to play in the organization

> and management of systems of governance directed toward children and families. (p. 413)

As research has become increasingly more tied to specific social concerns and social needs, some have feared that the science would be compromised. That has not occurred. To the contrary, carefully evaluated social applications have helped create a more robust, verifiable, and relevant science (Lerner, Chapter 1, this *Handbook,* this volume). Indeed the burgeoning of interest in applied developmental science that has occurred in the past 20 years and, certainly, since the last edition of this *Handbook* (e.g., see Farmer & Farmer, 2001; Fisher & Lerner, 2005; Gest, Mahoney, & Cairns, 1999; Lerner, Jacobs, & Wertlieb, 2003; and the several volumes of the journals, *Applied Developmental Science* and the *Journal of Applied Developmental Psychology*) has derived at least in part from the use of developmental systems theories to discuss the plasticity of human development and thus the potential of applying developmental science to promote positive human development.

One other by-product of social applications should be mentioned. The rapid growth of the discipline has created some unanticipated hazards for developmental study, not the least of which is the intense competition for publication space and research support. In one unfortunate outcome, closely knit research groups have formed tight theoretical and/or empirical coalitions that promote inclusion and practice exclusion. Under these conditions, dominant methodologies and ideas tend to monopolize resources while ignoring or distorting competing concepts and disconfirming evidence. Although these efforts tend to self-correct in the long term, they may create fragmentation and misunderstanding in the short term. In this regard, efforts to achieve effective applications often act as catalysts to bring ideas and findings to common ground and common standards.

TOWARD AN INTERDISCIPLINARY SCIENCE

In June 1994, a Nobel Foundation symposium comprised of noted biologists and psychologists called for an integrated, unified framework for the study of development (Magnusson, 1996). No single source or single investigator can be credited, since it has become an interdisciplinary, international movement. In the history of the discipline, this is a singular event. Over the past 100 plus years, the insights and emphases of developmental investigators in Europe—from Binet and Stern to Lewin and Bühler—have often been on a different frequency than those in North America, and the reverse held as well. When exceptions occurred—early, with Baldwin, Piaget, Vygotsky, and Freud; and later, with Magnusson, Bronfenbrenner, Bandura, Bruner, and Bowlby—the entire discipline was revitalized.

The contemporary press toward better integrated models of development arose from multiple sources. These include social development and social ecology (e.g., Bronfenbrenner, 1995, 2005; Ford & Lerner, 1992), developmental psychobiology and ethology (P. P. G. Bateson, 1991; Garcia Coll, Bearer, & Lerner, 2004; Gottlieb, 1992; Hinde, 1970; Hood, Greenberg, & Tobach, 1995), the dynamic systems approach (Lerner, 2002; Smith & Thelen, 1993; Thelen & Smith, 1994), developmental psychopathology (e.g., Cicchetti & Cohen, 1995; Hay & Angold, 1993), cognitive development (Baltes & Baltes, 1990; van der Veer & Valsiner, 1991), and developmental science (Carolina Consortium on Human Development, 1996; Magnusson, 1996). Due in part to methodological advances in the study of development, basic perceptual and movement patterns gained fresh life and new direction. It appears that studies of social development, emotion, and cognition may be the greatest beneficiaries of the current drive toward a more integrated developmental framework.

Given the advances in theory—advances which were not possible until empirical data became available to sort out the developmental concepts—the field now seems on the threshold of becoming a true interdisciplinary science. The longitudinal studies initiated in the 1960s and 1970s in Stockholm by David Magnusson, in Finland by Lea Pulkinnen, and in England by Michael Rutter and David Farrington provided models for United States researchers across the last decades of the twentieth century. Longitudinal research on children and adolescents has triggered a new revolution in methodology (e.g., see Duncan, Magnuson, & Ludwig, 2004; Laub & Sampson, 2004; McArdle & Nesselroade, 2003; Mishler, 2004; Molenaar, 2004; Nesselroade & Ram, 2004; Skrondal & Rabe-Hesketh, 2004; von Eye, 1990; von Eye & Bergman, 2003; von Eye & Gutiérrez Peña, 2004; Willett, 2004). Important findings have been generated (e.g., Phelps, Furstenberg, & Colby, 2002; C. H. Young, Savola, & Phelps, 1991). This work has helped the field regain the vitality enjoyed in early eras. The multilevel information is now being organized around individuals in the natural contexts of their lives. When wedded to

concerns of origins and plasticity, this information becomes "the essence of developmental theory" (Yarrow et al., 1968).

CHAPTER 4

Developmental Epistemology and Implications for Methodology

JAAN VALSINER

> [T]he basic law of all mental development [is that] what follows always originates from what precedes and nevertheless appears opposed to it as a new creation . . . every stage of [this] development is already contained in the preceding and is, at the same time, a new phenomenon.
>
> (Wundt, 1900/1973, p. 149)

Child psychology is not necessarily developmental psychology, and developmental psychology only partially deals with children. Children can be studied both in terms of as they are (nondevelopmental child psychology) and as they are in the process of becoming (developmental psychology). Similarly, other systems—natural or cultural—can be investigated either as they develop, or as

This chapter benefited from the input from Kurt Fischer, Gilbert Gottlieb, and particularly from the constructive critique of Nancy Budwig, Miguel Gonçalves, and Richard Lerner on an earlier version of the manuscript.

they exist in some state of status quo. The study of children is developmental only if it is done from an axiomatic standpoint that highlights processes of transformation and emergence (Valsiner & Connolly, 2003).

Children are of social interest in any society—and so is the area of child psychology. Over the twentieth century, child psychology developed in different ways in different societies. Not surprisingly, it is the cultural-historical niche that children occupy in a given country at the given time that guides the implementation of child-oriented social action programs (Salvatore & Pagano, 2005; Valsiner, 2003d). In Europe, child psychology was historically built on developmental biology and reflects the issues of both biological growth and psychological development. In North America, it was built on the social utility of child-related knowledge. Child psychology borrowed its focus from the child study (paedology) movement—which was from the beginning an interdisciplinary effort to understand children's ways of being, including development (Hall, 1883). The focus of understanding children was practical rather than theoretical, and the social utility of knowledge about children prevailed over basic science. Concerns about the welfare of children in a given society seem to motivate psychologists to study children. In contrast, basic developmental science was built on empirical knowledge from other species (e.g., ants—T. C. Schneirla; ducks—G. Gottlieb).

My goal in this chapter is to demonstrate how our contemporary efforts to create general developmental science can transcend the historically established blinders of child psychology. Developmental science is built on the comparative perspective (Valsiner, 2001a) in three ways:

1. Contrasting the development (ontogenetic and phylogenetic) of different species,
2. Considering variability within the species (of humans, first of all—but also those of higher primates), and
3. Emphasizing historical transformations of the minds and societies.

Knowledge about child development needs a methodological framework that equally emphasizes the theoretical and empirical sides of investigation. Our research efforts are empirical, yet their goal is general knowledge and not the mere accumulation of data. Science is about universal knowledge—and psychology deals with generalizations about phenomena that are excessively context specific.

This claim that general knowledge can emerge from the study of context-bound, unique phenomena is not a contradiction of terms. It merely indicates a new challenge to the science: How to find the generality in the never-ending flow of particular phenomena?

LOOKING AT CHILDREN: ADULTS' PLAYGROUND

We study children in child psychology, yet the questions we ask and how we attempt to answer those questions remains anchored in our adult psychological concerns. We study infants to prove that certain early psychological functions are precocious—known as "inborn" (see Fischer & Bidell, Chapter 7, this *Handbook,* this volume, on the fallacy of that argument). The contrast of nature *versus* nurture haunts child psychology, forcing researchers into numerous disputes about their role (rather than leave the contrast behind). For example, we may find the at-risk or delinquent behavior of adolescents—smoking, lies, and music videos; often a part of the exploration of their lives (e.g., thrill-seeking: Lightfoot, 1997)—and investigate these "problems." Yet, study of development usually ends in young adulthood. Thus, child development textbooks fit under the heading of "psychology of adolescents" and are written from the sociomoral perspective of the parents of these adolescents (Lightfoot, 1997; Valsiner, 2000c, see chap. 13 for detailed coverage).

There are curious gaps in unstudied areas. The closer in age the children comes to the researcher, the less their development is focused on. We do not include playfulness of 35-year-olds (or 75-year-olds) in our studies of development, even if human beings are gregarious all through their life course. But there had not been much attention to adults as developing persons—until the new areas of "life-span development" (Baltes, Lindenberger, & Staudinger, 1998; C. Bühler, 1934) and "life-course development" (Elder & Shanahan, Chapter 12, this *Handbook,* this volume) emerged. The role of human action in its cultural contexts is relevant from birth to death (see Brandtstädter, Chapter 10, this *Handbook,* this volume).

Child psychology seems to pride itself for being an empirical science, thus implying a contrast with a

nonempirical approach, whether that be ideological, theoretical, or any other concept. Yet, ironically, such claims allow for various nonempirical limitations—*conceptual blinders*—to guide the discipline.

Blinder 1: Monocultural Assumptions

Child psychology's writing about children is based on the narrow perspective of Western cultural histories and sociomoral concerns; it does not represent knowledge of human children in general. The researchers' social position (usually that of an upwardly mobile middle class—who earns its credentials accepting the demands of social institutions) looks at the children of other social classes (usually lower in the power hierarchy rather than higher) as something to be modified by benevolent actions. This applies both in a societal group (e.g., intervention with the children of the disadvantaged) and across societies (e.g., bringing Western assumptions about the right ways of children's development to the villagers in Africa, or immigrant communities in Europe or North America).

Our contemporary cultural psychology has revealed a "cultural myopia" of Occidental child psychology (Chaudhary, 2004; Rogoff, 2003) so that even our contemporary development of cross-cultural and cultural psychologies have not overcome the problem. The differences between societies are usually seen as those between children, although those differences may begin with the assumptions of adults. There exist many cross-cultural comparisons that reveal these limits. In Japan, when the child is troublesome, the typical message of the Japanese mother is "I am one with you"—a symbiotic relationship. These families are considered "unhealthy" from the Western psychological standpoint:

> A hypothetical Turkish clinical psychologist, fresh out of his or her professional training in the United States, who goes to a Turkish village would face a similar dilemma. Observing the human relationships there, he or she would declare the whole village to be enmeshed, with everybody overlapping with everybody else. (Kagitçibasi, 2003, pp. 167–168)

The world is not normatively segregated into persons who are separate from their social contexts. Just the opposite: They are actively enmeshed in those contexts (hence the need for person-context analysis; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume), and some forms of such active involvement are intuitively foreign to monoculturally fixated researchers (e.g., Benigni & Valsiner, 1995, discussion of "amoral familism" as seen by American political science in Italy). Furthermore, researchers who are "migrants" moving between societies may be "enmeshed" in their professional socialization (which has an emphasis on nonenmeshment) in ways similar to that of their research participants' enmeshment in their lay worlds.

Blinder 2: Reducing Complexity to Socially Accepted Norms

Child psychology has encountered a huge variety of developmental forms, yet it has failed to develop adequate general theoretical models to explain that complexity (Fischer & Bidell, Chapter 7, this *Handbook,* this volume). The complexity (and dynamics) of developmental phenomena calls for the use of different versions of contemporary—mostly qualitative—mathematical models to provide us with general models. Instead, most of child psychology continues to thrive on the basis of reduction of complexity to averaged data and considering these averages as established general norms.

Child psychology repeatedly commits the *pars pro toto* error. For example, looking at a "child in the family context" takes one form of family relations—a neolocal dyadic family where parents dominate, which is historically prominent in Europe and North America—and turns it into a generalized norm. As a result, the role of grandparents, side relatives, siblings, servants, and the like does not remain in focus. When the activities of such kin group around the child are unavoidable during observation, the researchers become puzzled by the "enmeshed" nature of the child. Indeed, the enmeshed family is the worldwide norm, and the Occidental differentiated form is the exception. Instead of looking at the consequences of the historical nuclearization of families and the corresponding psychological differentiation of the person out of the normal state of "enmeshment" (i.e., a developmental question), researchers revert to contrasts between the established final forms of the enmeshed *versus* the individual ways of being. The constructed opposites are then ordered with the researcher's own evaluation ending up as a positive anchor point.

An analogy with evolutionary biology might fit here. Consider the possibility that all—or most—knowledge about primates comes from research laboratories, zoos,

or situations where these primates are kept as pets, and excludes direct observations of these primates in their variety of natural habitats. Empirical knowledge would accumulate well and be internally coherent but not necessarily adequate. Charles Darwin undertook his voyage on *The Beagle* precisely to diversify the data set of biological knowledge base in his time. Our contemporary child psychology's look at the data from European or North American specific cultural contexts of the recent decades, as if that were the norm for children's ways of being in their contexts, would be similar to inferring norms for animal species at large from zoo animals in evolutionary biology. Undoubtedly, animals in zoos, like professionals in their middle-class environments, live in real contexts. Yet, these contexts are specific historical particulars rather than species' universal conditions.

Direct studies that address processes of development are rare in contemporary child psychology. Reasons for limited and selective incorporation of developmental ideas in child study continue to be closely linked with the ideological and applied demands of society on developing child psychology (Valsiner, 1988). Children and adolescents in any society are ideologically guided by their elders, as their role has been crucial in economies at every level of economic advancement of societies. Children have been participating in societies on both the sides of producers and consumers (Nieuwenhuys, 2003), buyers and sellers, as well as destroyers and healers. For example, their playful energies are utilized in the selling of newspapers in the streets, or Girl Scout cookies to middle-class homes or studying in schools, or—last but not least—recruiting child soldiers into armies (Hundeide, 2005). The innovating potential of the young is utilized by the social powers to fit their institutional goals—rather than for the sake of the humanity or the rights of the children.

The innovative capacities of the young are not only human privilege. Juvenile primates invent new actions and lead the process of social change (Hirata, Watanabe, & Kawai, 2001; Kawamura, 1959). All these tasks entail the production of novelty; yet, novelty is also something that by its definition is not pre-controllable. Endorsing development involves both innovation and rupture with the past, so it may lead to progress or devastation and bear substantial risks. Such uncertainty fortifies the need for knowledge about the future of children's development, giving child psychologists their role in society. Yet such a role remains set up as similar to that of fortune-tellers—while actual understanding of child development requires the movement from child study to developmental science.

DEVELOPMENTAL SCIENCE IN THE MAKING

Ambivalence about development, as innovation together with a break in what is known (i.e., a loss), repeated itself throughout the history of making child psychology developmental in its nature. Implementation of developmental ideas has been slow and filled with a recurrent erosion of focus (Cairns, 1998, Chapter 3, this *Handbook,* this volume).

By the end of the twentieth and the beginning of the twenty-first century, we witnessed the growth of a new discipline: *developmental science*. This new discipline transcended the boundaries of child psychology and addressed issues of development in general. Its focus was on person-context relations (see Magnusson & Stattin, Chapter 8, this *Handbook,* this volume) and it built on the general perspective of probabilistic epigenesis (Gottlieb, 1999; Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume).

Since the mid-1990s, the new science has become established in a number of ways. There are now journals, *Developmental Science* (since 1998) and *Applied Developmental Science* (since 1997), and a new handbook, *Handbook of Applied Developmental Science* (Lerner, Jacobs, & Wertlieb, 2003). The label developmental science is inherently appealing to our thinking and is relevant in our social discourses in which issues of development are progressive for institutional uses.

Developmental science is a label meant to hold together the intellectual rebirth of a general perspective that is oriented toward the study of developmental processes. Developmental science, as stated in the mid-1990s:

> refers to a fresh synthesis that has been generated to guide research in the social, psychological, and biobehavioral disciplines. It describes a general orientation for linking concepts and findings of hitherto disparate areas of developmental inquiry, and it emphasizes the dynamic interplay of processes across time frames, levels of analysis, and contexts. Time and timing are central to this perspective. The time frames employed are relative to the lifetime of the phenomena to be understood. Units of focus can be as short as milliseconds, seconds, and minutes, or as long as years, decades, and millennia. In this perspective, the phenomena of individual functioning are viewed at multiple levels—from the subsystems of genetics, neurobiology,

> and hormones to those of families, social networks, communities, and cultures. (Carolina Consortium on Human Development, 1996, p. 1)

As stated, the general developmental orientation is charted on a wide scale, within which the development of human children in their social contexts is but one of the areas of inquiry. The impact of the development from the Carolina Consortium was prominent in the fifth edition of this *Handbook,* and continues to be so in this edition (e.g., Bronfenbrenner & Morris, Chapter 14; Cairns, Chapter 3; Elder & Shanahan, Chapter 12; Gottlieb, Wahlsten, & Lickliter, Chapter 5; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume).

Conceptual difficulties in making sense of development are inevitable in the growth of a science that faces a most difficult phenomenon—a constantly changing object of study. The difficulty in the study of development lies in its complexity, dynamic change, and the lack of a common terminology (Valsiner, 2005b; van Geert, 1986, 1988, 1998, 2003). The major theoretical question is how to conceptualize this complexity and make productive use of psychologists' mainly empirical interests for creating a general understanding of development.

Child psychologists have been working on a multitude of empirical topics with limited concepts of development. In some cases this need not matter—nondevelopmental approaches to the study of children as they are (and not as they are about to become) do not require the adoption of any developmental theoretical framework. The discrepancy between the theoretical and empirical domains in child psychology is scientifically deleterious in those cases where the "developmental perspective" is being claimed in the theoretical realm—but the empirical research methods are not set up to study development. This leads to the dissociation of specific and general knowledge (Shanahan, Valsiner, & Gottlieb, 1996). General knowledge easily vanishes behind the myriad of topic- and context-specific empirical findings, thus the discipline faces a metaphorical loss of the forest behind the trees. Yet it is the universal, basic knowledge that is the result of empirical explorations in science—not mere "accumulation of the data."

BASICS OF SCIENCE: CONSISTENCY OF CONCEPTS, PHENOMENA, AND METHODS

Because psychology—developmental as well as nondevelopmental—is a basic science, its conceptual apparatus needs to be systematically organized and sufficiently generalized. If compared to chemistry, psychology is somewhere beyond the dominance of alchemy but still without the deductive rigor of the Mendeleev's periodicity table (Brush, 1996). While basic science has emphasized its abstract and formal nature of knowledge, without losing touch with critical empirical questions, psychology has become an empirical science with a major loss of abstract generalized knowledge. The socially embedded nature of the history of psychology can explain the nonmonotonic growth of the discipline.

Intellectual Interdependency of Social Sciences: Episodic Growth Spurts

Social sciences develop by intense "burst periods" in different countries (Valsiner, 2003c). In the history of different countries, there have been demonstrably productive rapid growth periods of knowledge and invention of new understanding: the United States in the 1890s and early 1900s, as well as after World War II; Russia and Germany in the 1920s, and so on (Valsiner & van der Veer, 2000).

Social Interdependency of Psychology

Psychology has always existed under the influence of the societies in which it has been embedded (Dolby, 1977). Throughout the twentieth century, new forms of science-society relations have guided psychology away from general theory construction (Benetka, 2002; Danziger, 1990, 1997). Contemporary child psychology tries to act as if general theory building is of no consequence for science—a standpoint that may be considered damaging to the health of any science (Crick, 1988). It is the constant movement between empirical and theoretical knowledge construction that guarantees generalizability in any science (Morgan, 1894). The thinking scientist creates new understanding while operating within the constraints of one's discipline (Knorr Cetina,1999).

It is not surprising that developmental science has been episodically linked with child psychology in its history, and that now, in the beginning of the twenty-first century, we can look at the whole world again, trying to discover within which rapidly changing society one could see developmental science getting a fresh start.

The society within which psychology exists has general worldviews and myths about itself, and the researchers demonstrate their loyalty to the given society

by implicitly accepting these assumptions. For example, the myth of the absolute goodness of Marxism as the basis for all of psychology was the guiding force in Russia during and after the 1920s (Valsiner, 1988). Aside from much ideological refuse produced, this focus also gave the world remarkably fresh ideas (such as Vygotsky's, Basov's, and Bakhtin's). Also, the concerns of high culture in the continental European traditions of the nineteenth century led to the formulations of ideas in *Ganzheitspsychologie* (Diriwächter, 2003) and Gestalt psychology (Ash, 1998). In another example, psychologists' acceptance of the value of pragmatism in the "progressive era" in the United States led to behaviorist orthodoxy (Watson, 1913).

The concentration of most of psychology in the United States in the post-World War II era might have preserved or modified some of these ideas (Valsiner, 2005a), but that was no guarantee for their development. Some aspects of the societal self-mythology led to conceptual and methodological "blinders" that might not have hindered psychology at large, but served to limit developmental science. Thus, a historian of social science remarks:

> Why, in America, was history conflated with nature? The determining factor, I believe, was the national ideology of American exceptionalism. We are inclined to think of American exceptionalism as a kind of national myth, one that began in the exalted language of the Puritan "city upon a hill" and today often degenerates into chants of "America is number one." Indeed the mythic idea of America was born in Europe, when inhabitants of what became the "old" world turned their imaginations on the "new" one. This mythic America has been given many different concrete forms: think of Martin Luther King's American Dream; or the immigrant dream of success; or the American mission to make the world safe for democracy. The background to all these versions of our national mythology, however, is a belief that America occupies an exceptional place in history. (Ross, 1993, p. 103)

Any society is exceptional in its historical uniqueness, but some were more conducive to the growth of basic ideas than others. In addition to the United States, the social-ideological adoption of Marxist dialectics in Russia in the early Soviet period was also based on a belief of exceptionalism (e.g., being chosen to build communism in a backward country). But this developmentally open philosophical stance saturated the social world—from common life to science—and created a favorable ground for cultivating developmental science.

As another example of such ideological favor, the middle-class child from the very specific cultural-historical conditions of the United States is treated as the norm, and all other children (of lower socioeconomic status as defined in the United States, or from other countries) become seen as either negatively (lagging behind) or anxiously (competitively getting ahead—Indian, Japanese, and Chinese schoolchildren in basic sciences) valued deviations. There is a short step from beliefs of exceptionalism to practices of colonialism—the quintessential Western *modus operandi* of the past 200 years. Children other than those from Euri-American middle-class background are discursively treated in ways similar to "the developing world" with all the implications that treatment involves (see Escobar, 1995).

The International Nature of Contemporary Psychology

By the beginning of the twenty-first century, contemporary developmental science became evenly distributed around the world; hence, the dependence on any single society became less relevant in this time of ideas. Now, it is the economic factors of academia that determine the nature and location of research laboratories, university departments, available academic jobs for developmental scientists, and their access to phenomena. But no single society has a monopoly on basic ideas, and their translation into empirical research practices bring new knowledge, which—if adequate—may allow for application.

At present, one of the sacred cows of psychology's socially constructed belief in objectivity is increasingly under challenge: quantification in psychology, which may be more of an analogue of accounting practices than a scientific tool.

Pathways to Objectivity

Quantification has been treated as a given in granting objectivity to psychology. Cohorts of psychology students have been trained to think that quantification is the *via regia* to science and that statistical inference is the scientific method. Quantification in psychology has become a social norm—and a professional imperative—much to the detriment of the focus on phenomena (Cairns, 1986).

Together with such social transformation comes the narrowing of the questions asking "what is knowledge" and "what is methodology." Psychology has now become an intellectual "hostage" to the "empire of chance" (Gigerenzer, 1993). Beginning from the need to study

different children, and empirically chart the ranges of existing phenomena, research practices have become dominated by canonical procedures of inductive inference, coded into a socially constructed hybrid version of statistics as "the scientific method" (Gigerenzer et al., 1989). The axioms on which statistical methods are based allow limited use in psychology (Michell, 1999).

Quantification in Context

Quantification in the process of data derivation is a sensitive operation by the researcher that cannot be accepted axiomatically but needs to be proven adequate in each case. Quantification is essentially transformation of the first level of derived data (as reflected in nominal scale, shared by both qualitative and quantitative perspectives) into a sequence of possibly more constrained levels of data quality (ordinal → interval → ratio scale—see Laird, 2005). Some complex phenomena can be irreversibly lost in the process of quantification by being turned into data that fail to represent these aspects of the phenomena that are crucial for the researcher's theoretical claims.

In any science, the decision to quantify the data—or avoid quantification—depends on the research question. Voices against excessive and automatic quantification have been quite loud all through the history of psychology. Among others, James Mark Baldwin—by the end of his life—was explicit about the reasons why quantification is a problem for developmental psychology. He proclaimed:

> The . . . quantitative method, brought over into psychology from the exact sciences, physics and chemistry, must be discarded; for its ideal consisted in reducing the more complex to the more simple, the whole into its parts, the later-evolved to the earlier-existent, thus denying or *eliminating just the factor which constituted or revealed what was truly genetic.* Newer modes of manifestation cannot be stated in atomic terms *without doing violence to the more synthetic modes* which observation reveals. (Baldwin, 1930, p. 7, emphases added)

In a retrospect from the twenty-first century, Baldwin's revolutionary call for de-quantification of psychology's methodology was precisely right. As mathematicians who look at what psychologist do often point out, the reduction of all mathematics to merely statistical methods is a serious self-limiting act of possible creativity. Furthermore, as Rudolph (2006) points out—the reality of psychological phenomena is probably not captured by real numbers. Thus, Baldwin's claim to eliminate unreflective quantification is not a crusade against mathematical rigor in psychology; in fact, it would open the door for innovations. The science of mathematics is in no way limited to statistics—which, after all, is merely a narrow area within applied mathematics. Formal models that developmental psychology may find fitting belong in the qualitative branches of mathematics (Valsiner, 1997, chap. 3). For developmental science, new inferential logics are needed—ones that work on the basis of qualitative data (Fischer & Bidell, Chapter 7, this *Handbook,* this volume). Such logics are both rigorous in their formal sides and remain adequate to the phenomena.

Statistics as a Form of Inductive Logic

The status of statistics as *one kind* of inductive logic of inference is not deniable, but it overtakes *the whole* of the scientific method when overgeneralized and constitutes a sociohistorical construction of psychology as science. Psychology's objectivity of knowledge is often equated with the use of large numbers of subjects (large *N*), "random sampling," use of "standardized methods," differences between averages (and the statistical significances of those differences), and the use of currently *en vogue* brand-name data analytic packages. Even if such characterization of received research practices is somewhat of a caricature, it refers to a large problem in psychology's methodology. Methods are increasingly segregated from theories, alienated from the phenomena they are applied to, and compared one to another as if they were opposites This can be observed in preferential value ascriptions to either quantitative or qualitative methods, or the belief in the power of standardized methods—independent of the contexts of their uses. Standardization primarily takes the form of institutional attribution of value to the method—and bypasses the issue of how the method produces data out of the original phenomena. Methods have become separate items in an eclectic toolbox of psychology from which they can be taken and applied, rather than tools that are used to craft new knowledge while carefully preserving the phenomena under study.

Data: Collected or Derived?

An alternative view on methodology considers it as a dynamic cycle in the construction of general knowledge. It entails mutually linked components of assumptions about the world at large (axioms), specific constructed

theories of the given target area, understanding of pertinent phenomena, and ways of constructing specific methods to transform some aspects of the phenomena into purposefully derived data. *Data are always constructed*—or better—*derived from phenomena,* on the basis of the investigator's reasoning (Kindermann & Valsiner, 1989; Valsiner, 2000b). The data are not collected just on the basis of the richness of phenomena but in accordance with the researcher's construction of axiomatic and theoretically relevant kinds of data.

Hypotheses Testing: Theory-Driven versus Pseudo-Empirical

The reliance on abduction in knowledge construction provides a new look at the practice of hypotheses testing in psychology. Empirical proof of a hypothesis is productive when it leads to a new idea rather than confirmation of an existing concept—which would border on pseudoempiricism:

> [P]sychological research tends to be pseudoempirical, that is, it tends to involve empirical studies of relationships which follow logically from the meanings of the concepts involved. An example would be studying whether all bachelors are really male and unmarried. (Smedslund, 1995, p. 196)

Child psychology may be vulnerable to the empirical demonstration efforts of researchers' underlying understandings of the issues because children are nonneutral objects of investigation. Furthermore, societies create expectations for normal child development, and much of the researchers' efforts are dedicated to proving that persons at the fringes of such norms are of some (special) kind (e.g., the ones at risk for some negative outcome). Pseudoempiricism can be countered by the careful elucidation of theoretical assumptions and their linkages with research questions that provide the investigator new knowledge that cannot be derived from the meanings of the terms in use.

In contrast, deductively generated (i.e., theories-based) hypotheses would highlight the role of empirical investigation for science. When a hypothesis is set within any of the following four reference frames, the empirical efforts acquire vertically consistent meaning.

Organizing Knowledge Construction: Frames of Reference

We preset our research efforts within the framework of wide general perspectives—frames of reference (Valsiner, 2000c, chap. 5). *Frames of reference* are general conceptual positioning devices within the minds of researchers who set up their research questions and construct methods to unify different levels of the methodology cycle. The same phenomenon can be studied using the different perspectives specified by the multiple reference frames. Frames of reference narrow down the focus of empirical research efforts, like the magnification levels in a microscope; while some details become observable better in selecting a particular frame, others vanish from the view.

The reference frames are necessary and needed "blinders" or theoretical general orientation tools that make focusing on our desired object possible, while eliminating distractions. Although four frames can be discerned in psychology, two of these are relevant to developmental science.

The Intra-Individual (Intra-Systemic) Reference Frame

The intra-individual frame of reference treats all issues of an individual system's (e.g., person's or society's) organization as if it is fully determined by relationships within the system. Consider an intrinsic organization of human (self-reported) personality structure such as Freud's construction of generic personality structure as involving the ideas of *id, ego,* and *superego.* These three components are located within each person, and their particular set of relationships gives rise to the immense variety of psychological phenomena of personality-in-contexts. For example, the intra-individual frame of reference separates the person from the environment, or vice versa. A study of the environment as such—not taking into account the environment's relations with the persons who inhabit it—could be equally expressed within the intra-individual frame.

The Inter-Individual (Inter-Systemic) Reference Frame

This frame involves comparison of features that are projected into the systems on the basis of external features of the projected characteristics that differ between the systems. In contrast with the intra-systemic frame, the focus here is removed from the projection itself (which is taken for granted) to the differences in the "expressions" of the projected characteristics from one system to another.

This reference frame is most widely used in psychology. It involves comparisons of individuals (e.g., "Mary

does better than Susie on test X"), or samples of subjects (e.g., males and females). It is assumed the parties compared have some characteristics inherent in themselves, *but in a different quantity* than in the others. So, comparing males and females on the characteristic of "aggressiveness" presumes that the *quality* of that characteristic is the same for men and women, but that its *quantity* may differ in some systematic way between the two genders.

The inter-individual frame of reference is widely popular in psychology—a discipline with idealized quantitative tactics of data construction—which makes comparisons between "more" and "less" "having X" cases an appealing and easy empirical research goal. Yet, such popularity is increasingly viewed as an obstacle for science (Essex & Smythe, 1999; Smyth, 2001) because it obscures a number of relevant aspects of the phenomena: their systemic organization, their stability and dynamics, and finally, their development. The use of the inter-individual reference frame guarantees that access to processes of development is denied by the very actions of the researcher.

The result of the use of this reference frame is demonstrated by the difference between the compared subjects and usually fortified by statistical safeguards to grant solidity to the finding (i.e., its replicability in the overwhelming majority of similar samples, randomly drawn). It is in the use of the inter-individual reference frame that statistical methods are adequately usable because the assumptions of this frame and those of statistics fit in a vertically consistent way (see Figure 4.1).

The inter-individual frame of reference relies on human propensity for evaluative competitive comparisons. Not only is the finding "Johnny *does better* than Jimmy in math" a statement about differences between the two children but it also simultaneously reflects the claimer's evaluative preference. Why is it assumed that having a higher score on a math test is "better" than having a lower score? This belief is encoded into our collective cultural-meaning system of seeing educational achievement as valuable.

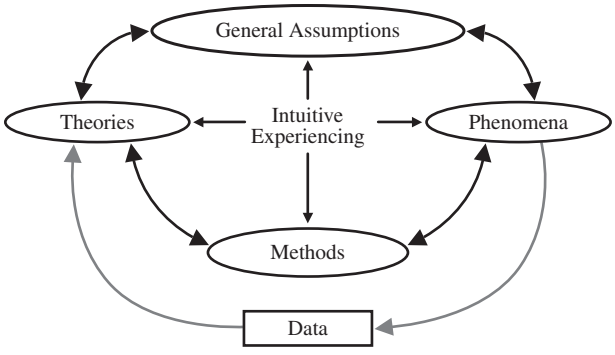

Figure 4.1 The basic structure of methodology as a cycle. *Source:* From "Changing Methodologies: A Co-Constructivist Study of Goal Orientations in Social Interactions," by A. U. Branco and J. Valsiner, 1997, *Psychology and Developing Societies, 9*(1), pp. 35–64.

The Individual-Ecological Reference Frame

The individual-ecological frame of reference considers a system (e.g., person, social group, community) that is the focus of attention of the investigator as that system acts on its environment and as the results of such action participate in the transformation of the system. This reference frame involves mutual consideration of the person and the environment and focuses on their relationship. It allows a glimpse into the goal-oriented actions of the person who acts on the environment with some future-oriented purpose (e.g., solving a problem). The action results in feedback from the changed environment on the person. That feedback participates in the change of the person into a new state.

Human development through problem-solving activities, over the whole life span, is a realistic phenomenon that can be studied through the use of individual-ecological frame. Each problem for our actions is given by some problem situation in a here-and-now setting. We set up a goal (desired solution) and try to act toward reaching that goal. The process of trying will lead to modification of ourselves; we transform due to the exchange relation with the problem situation. The goal-oriented, problem-solving effort is the context for development of the problem solver. It is not necessary to compare the problem solver with others of the kind (this was the focus of the inter-systemic reference frame), but the process of unfolding of solutions and construction of novel ones is the focus area of the individual-ecological frame.

The Individual-Socioecological Reference Frame

The individual-socioecological reference frame is an extension of the individual-ecological one. It includes *both the focus on system ⟷ environment and the role of others' social regulation of that relationship.* The developing person faces one's environment, acts on it, and transforms oneself. However, the environment is largely pre-prepared by another person (e.g., parents set up "appropriate environments" for children), and the person's

acting within an environment is socially guided in explicit and implicit ways.

The individual-socioecological reference frame thus includes the same features as the individual-ecological frame:

- An active person
- Environment
- Person's acting toward the environment

What distinguishes this frame is:

- The guiding role of somebody else acting to coordinate person environment relationships (be it another person, social institution, or a symbolic object within the environment)
- The transformation of the person as a result of this socially guided action

The researcher who adopts the individual-socioecological reference frame would study the same phenomenon that a user of the individual-ecological frame might study, yet do it differently. In the individual-socioecological frame, the researcher needs to analyze the structure of social suggestions that exist in the encounter between the person and the environment. Some of these suggestions are encoded into the environment itself, others are produced by the other persons who are active in the same environment, regulating the person's conduct in it (see elaborations in Magnusson & Stattin, Chapter 8, this *Handbook,* this volume).

Consensual Habit: Changing the Question

Very often, empirical research practices replace one frame of reference (Valsiner, 2000c, chap. 5) with another. For example, the phenomena of mother-infant mutual bonding is a relevant aspect of human relationships detectable across country, time, and context. In contrast, the abstracted use of infants' (or mothers') attachment type (A, B, C, or other) as *de facto* personality characteristics that predict some future state of the children (or mothers) shows a loss of the basic question of attachment (as a relationship that is a basis for *becoming*) and its replacement by another question (that of prediction of a future *way* of *being* on the basis of general attachment traits—the earlier way of being). What at first was a dynamic phenomenon (the process of mother and infant relating with each other to form a functional affective bond) becomes changed into a question of formal statistical relationships between two features of static being (a person "has" attachment type A, B, or C, and that predicts some "state of affairs" over time).

Translation of the research questions from dynamic and developmental ones into static ontological ones is rampant in psychology. This process happens due to the social constraints from the use of conventionalized methods and data analytic strategies in the research process. Efforts to "predict behavior" lead to the verification of essentialist stability of such behavior and its mental derivates (thoughts, beliefs, values) rather than to the investigation of the processes of behaving, thinking, believing, and valuing. As Wittgenstein pointed out years ago, a conceptual confusion reigns in psychology, resulting in the "problem and method passing one another by" (Wittgenstein, 1958, p. 232).

Methodology as an Epistemic Cycle

The components in the methodology process cycle (see Figure 4.1) are depicted as existing at different levels of generality: The axiomatic views of the world (general assumptions) are more general than theories or intuitive reflections about phenomena, and the latter is more general than the methods that generate data.

In this scheme of scientific epistemology, an emphasis is reserved for the subjectivity of the researcher who intuitively experiences phenomena in connection with his or her axioms and constructs theories from a personal standpoint. Scientists are not feelingless robots but subjective, personally involved human beings who have their subjective preferences and positions from which they look at their research.

All new models representing an object of investigation are created by subjective individuals—usually in their privacy of introspection, but at times through their immersion in the group of like-minded thinkers. Immersion in a group results in intellectual interdependency (see Valsiner & van der Veer, 2000) both among and between scientists, as well as in the societies they inhabit.

The methods and the data are constructed by the researcher on the basis of the specific structure of the process cycle. Methodology here is equal to the cyclical process of general knowledge construction, where different parts of the cycle feed into other parts. It would be appropriate to depict Figure 4.1 not merely as a cycle but also as a helix; there is never a full return to the previously generated knowledge, even if there may be outward resemblance between what is new and what is old.

Such helical development of scientific knowledge allows us to benefit from the history of ideas, a need to make sense of a basic issue (such as development) in the present leads us to look back in the history for times when similar needs were detected. An analysis of the "turns" in the nonlinear development of the helix of knowledge may allow us to avoid creating similar pitfalls in our current science.[1]

Two Kinds of Consistencies

The major role of methodology in any science is in granting consistency between the abstract/theoretical and empirical/concrete facets of the research process, keeping in close touch with the phenomena that are the object of investigation (Branco & Valsiner, 1997; Cairns, 1986; Winegar & Valsiner, 1992). Developmental psychology has been in a severe methodological crisis over recent decades because in most cases its empirical enterprise and assumed theoretical stance have not been consistent with one another (Molenaar, 2004; Molenaar, Huizenga, & Nesselroade, 2003; Smedslund, 1994; Valsiner, 1997, chap. 3). Vertical consistency between assumptions, theories, methods, data, and phenomena is necessary for valid knowledge construction. In its stead, we see many efforts to create horizontal consistency at different levels: between varied methods (standardization of fixed methods, empirical validation of methods based on other methods), between theories (clashes between proponents of theories), and between worldviews (see Figure 4.2; broken arrows denote horizontal and solid arrows show vertical consistency).

It is the vertical consistency that matters for scientific knowledge, although most of the social organization of psychology is dedicated to discussions along the lines of horizontal consistency. So, questions about the "right methods" for the study of X when answered with horizontal consistency lead to answers of either subjective evaluation (quantitative methods are "better"—or "worse"—than qualitative ones) or social censorship ("you'll never get your papers published if you use such methods"). In contrast, the same question answered with vertical consistency requires an analysis of whether the method preserves relevant aspects of the investigator's desired phenomena. For example, intelligence test items, or personality inventory items, separated from their respective "standardized methods," can be productively used to study specific questions of the cognitive processes of children (Piaget, 1922) or the adult self-construction processes (Valsiner, Diriwächter, & Sauck, 2004). The problem-solving tasks of such methods gain access to specific psychological processes; dequantification of existing quantitative methods is a promising area of research.

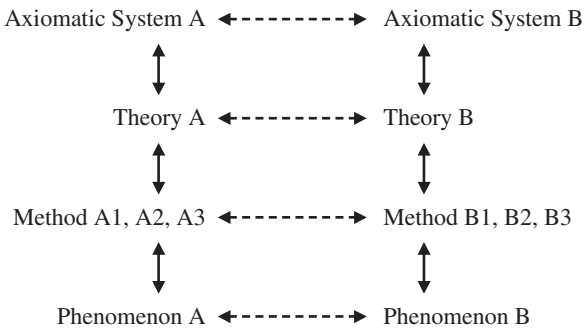

Figure 4.2 Vertical and horizontal consistency in methodology.

Objectivity through Subjectivity

The actual process of knowledge construction entails human subjectivity—for example, that of the scientist in relation to the objective reality. Science operates through the integration of empirical/inductive and theoretical/deductive lines or of "two inductions" in the terms of C. L. Morgan (Morgan, 1894, chap. 5, 2003; Valsiner, 2003a). Morgan's epistemological scheme is worth closer attention (see Figure 4.3).

The scientist (psychologist) is constantly operating on an intramental understanding—the "first induction" or "subjective induction"—of what is being studied, how to study it, and what to expect. Here the role of a philosopher and psychologist converge: Both rely on their powers of thinking to make sense of some phenomenon.

However, the scientist moves, differently from philosophers, away from such intrapsychological reflection to gain knowledge through observing others (through extrospection). The results of such observation lead to the "second induction" or "objective induction." The second induction is the process of relying on the

[1] As an example, consider our contemporary renewed interest in the brain localization of different mental functions, brought to fashion by technological advances (functional magnetic resonance imaging [fMRI]). The research questions about functional localization in the deep structures of the brain, remains similar to the question phrenologists posed—only in respect to the skull. Modern neuroscience reenacts some version of "intracranial phrenology"—thus, actually denying the science the potentially great benefits that new technology affords in principle.

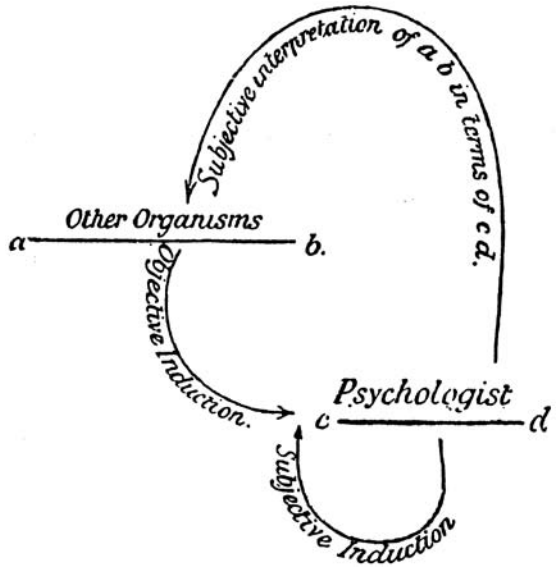

Figure 4.3 C. L. Morgan's scheme of two inductions. *Source:* From *An Introduction to Comparative Psychology,* by C. L. Morgan, 1894, London: Walter Scott.

empirical evidence emphasized in psychology. Here the scientist resembles a writer, composer, or painter—all of whom, in their own ways, rely on the experiences with the outside world to create a new form of understanding.

Knowledge Creation as Abductive Process

Without the first induction, the second induction is unable to make sense of the world; both work together. The crucial question is how the two inductions meet. Morgan's effort was to demonstrate that the unity of both inductions is necessary for scientific inference.

New knowledge emerges from the unity of inductive processes through *abduction.* Abduction is a process of creative synthesis—a qualitative "leap" of our understanding—into a new general state of knowing (Peirce, 1892, 1935). As such, scientific knowledge goes beyond the commonsense knowledge of any society rather than follow it. The conceptual frameworks of developmental science need such creative synthesis.

FOUNDATIONS OF DEVELOPMENTAL THINKING

Developmental science attempts to transcend our Western culturally structured knowledge of children. In that effort, it extends itself toward understanding human development within varied societies (comparative-cultural knowledge base—Valsiner, 2000c, 2001a), across human history (Stearns & Lewis, 1998), across life course (Brandtstädter, Chapter 10; Elder & Shanahan, Chapter 12, this *Handbook,* this volume), and across species (Matsuzawa, 2001). The interdisciplinary nature of developmental science is itself created by generalization of this knowledge.

Special Axiomatic Features of Development

The ability to maintain consistently a developmental viewpoint in child (or adult) psychology is constrained by four fundamental conditions:

1. The irreversible nature of development based on the irreversibility of time (Bergson, 1907/1911; Prigogine, 1973)
2. The complex, yet dynamic and often ill-defined, nature of the developing structure (organism, person, social network, community, etc.) and its equally dynamic and structured environment (Bronfenbrenner, 1979; Bronfenbrenner & Crouter, 1983; Bronfenbrenner & Morris, 1998; Magnusson and Stattin, Chapter 8, this *Handbook,* this volume)
3. The multilevel nature of the developing system and the environment (Gottlieb, 1992, 2003; Lerner, 1991)
4. The focus on variability in person-environment relationships as phenomenon (rather than error), and the analysis of new qualitative forms of development that emerge from these relations (Fischer & Bidell, Chapter 7; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume; Molenaar et al., 2003; Valsiner, 1987, 2004a)

None of these four features of psychological phenomena are obligatory for nondevelopmental areas of psychology. Traditions in nondevelopmental psychology can succeed by ignoring both the irreversibility of time and the structure of the phenomena.

Development as Construction of New Forms

Development can be defined as the constructive transformation of form in irreversible time through the process of organism $\longleftrightarrow$ environment interchange. The emphasis on novelty construction in development is based on the basic assumption of the open-systemic nature of development (Ford & Lerner, 1992; Lerner, 1978, 1984; Valsiner, 1987). All biological, psychological, and social organisms exist and develop only because

of their permanent exchange relations with their environments. Hence, models that explain processes of development are those that either imply their dynamic interchange or take it into account in direct ways. Developmental phenomena are self-organizing systems rather than ontological objects (Allen, 1981; Jantsch, 1980).

Developmental and Nondevelopmental Perspectives

In the most general terms, nondevelopmental and developmental perspectives are opposites that deal with the same phenomena. They can be contrasted, but not eclectically mixed (Branco & Valsiner, 1997; Valsiner, 2000c). The nondevelopmental perspective is based on the axiom of identity:

$$X = [\text{is}] = X$$

Questions of development are ruled out from that axiomatic basis. In contrast, the developmental perspective is based on the *axiom of becoming,* which takes two forms:

$$X \rightarrow [\text{becomes}] \rightarrow Y$$
$$X \rightarrow [\text{remains}] \rightarrow X$$

The axiom $X \rightarrow [\text{remains}] \rightarrow X$ is not the same as the identity axiom of nondevelopmental perspectives—$X = [\text{is}] = X$. *Being* is conceptualized as an ontological entity, while *remaining,* as a process of maintaining an emerged state of the system, is implied. Both becoming and remaining are processes that guarantee both relative stability and change in development. In the case of remaining, the system maintained in its general form depends on constant innovation of the form by new parts. Biological organisms maintain themselves by both new cell production and old cell death, while the form (the structure of the organism) in general remains the same.

Multilevel Nature of Developmental Processes

Developmental science investigates transformation of structures at different levels of generality: phylogeny, cultural history, ontogenesis, and microgenesis. Each of these levels of processes are characterized by its own functional time unit; for instance, a period of 1 million years in phylogeny may be a reasonable time frame, while in cultural history 500 years may suffice. Ontogeny is limited to the maximum length of the organism's lifetime, while microgenesis may be limited to developmental transformations that occur in milli- or microseconds.

The hierarchical systems view of developmental processes is elaborated in the theory of probabilistic epigenesis (Gottlieb, 1997, 1999, 2003; Gottlieb et al., Chapter 5, this *Handbook,* this volume). In addition to the fourfold separation of the levels of organization (genetic activity, neural activity, behavior, and environment), the phenomena of human psychology require further differentiation beyond the behavioral level, through the inclusion of higher mental functions in the scheme (see Figure 4.4).

Figure 4.4 reminds us about the systemic hierarchical organization of all living systems. The issue at stake for science is not whether there are levels (a "yes" verdict is axiomatically given here), or their ontological structure (e.g., the nature of thought or affect). How many levels are posited depends on the theoretical intentions of the researcher. The levels are conceptual organizing devices that keep the researcher from assuming the unstructured field of "variables" of various kinds. Development entails the coordination of structures of functioning processes. In such hierarchical systems the notion of causality takes on a new meaning—the whole system of multilevel processes becomes the "general cause" for development. In it, the higher order levels of organization execute control over lower levels (cf. the issue of "downward causation"; Moreno & Umerez, 2000). At the same time, these "causal effects" are never linear mechanical "causal arrows," but entail negotiation between the levels of organization. Such causal processes are in effect processes of buffering between the levels.

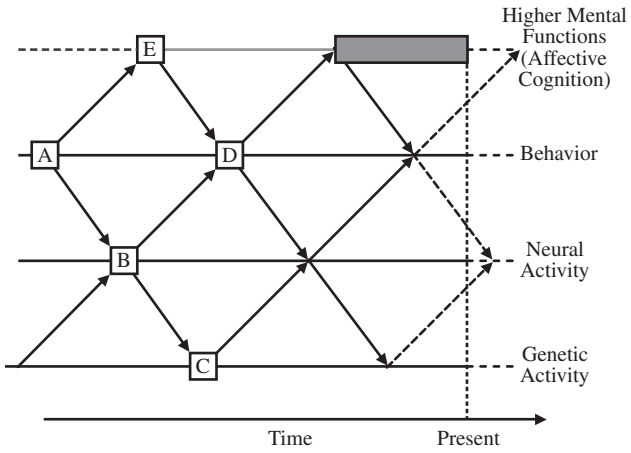

Figure 4.4 An organizational scheme of parallel processes involved in development.

However, independent of how many and which levels of organization are described by authors, the crucial feature of development of organisms remains the existence of qualitatively different levels of organization.

Dynamic Order in Hierarchical Complexity

One issue of developmental science includes how the relations between *adjacent* levels are organized.[2] Let us begin from recognizing development as a systemic, multilevel process:

> Individual human development involves *incremental and transformational processes* that, through a *flow of* interactions among current characteristics of the person and his or her current contexts, produces *a succession of* relatively enduring changes that *elaborate or increase* the diversity of the person's structural and functional characteristics and the patterns of their environmental interactions *while maintaining* coherent organization and structural-functional unity of the person as a whole. (Ford & Lerner, 1992, p. 49, emphases added)

If the previous framework is consistently put to practice in child psychology, it leads to basic reorganization of the methodology of psychology. Each of the emphasized facets of this definition indicates a need to reconceptualize child psychology's socially conventional ways of deriving the data from phenomena (Kindermann & Valsiner, 1989).

First, the *flow* of interactions between person and context leads to the necessity of utilizing time-preserving analytic units in the empirical research. Such units would be characterized by time-based description of *transformation* of the phenomenon under study in a specifiable direction. Ford and Lerner (1992, pp. 140–142) formulate *behavior episode schemata* as an example of time-based units of analysis. In repeated everyday life contexts, persons construct generalized schemata that would guide their actions in similar-looking settings, depending on their goals.

Second, the focus on *sequential transformation* calls for developing new techniques for both qualitative and quantitative analyses of complex developing systems (e.g., the use of a web metaphor—Fischer & Bidell, Chapter 7, this *Handbook,* this volume; use of a "catastrophe theory" in looking at marriage, Gottmann, Murray, Swanson, Tyson, & Swanson, 2002; use of systemic cycles in family, Stratton, 2003). A conclusive step here would be the unification of qualitative and quantitative sides of developmental transformation—something from the realm of chemical reactions (Prigogine, 1973) carried over to developmental science.

Third, the explanation of *maintenance of coherently functioning whole,* the structure that sets the stage for further development under some (but not other) circumstances, requires a basic reformulation of causality in open systems.

Psychology mixes the levels of functional organization of systems, and child psychology in its sociomoral vulnerabilities has contributed greatly to such confusion. Interestingly, it is the most biologically astute—bordering on developmental science—part of psychology, "evolutionary psychology," that has been at the forefront for creating such confusions (Crawford & Krebs, 1998; Lickliter & Honeycutt, 2003a, 2003b). Arguments within evolutionary frameworks leap over the biological, psychological, and social phenomena organizational levels, as if the world were one primordial soup in which all organisms are trying to cheat the others by gaining the upper hand for the control of resources (Strout, 2006). The environments of species are sufficiently different, even if they "share" the same habitat, that human higher psychological functions (of morality, values, and meanings) cannot be explained through evolutionary psychology unless these models honor the hierarchical—yet mutually inclusive—separation of levels of organization.[3]

DEVELOPMENTAL SYSTEMS ANALYSIS: RETHINKING MORGAN'S CANON

The emphasis on the irreversible, constructive, and hierarchically redundant nature of development necessitates clear methodological ground rules through which explanation of development is possible. The "principle of parsimony" ("Morgan's Canon") has served as the

[2] This point is relevant in the wake of abuses of the human genome discoveries—it has become tempting to link the genetic level of organization with complex psychological phenomena (e.g., claims of discovery of "the gene" for intelligence or schizophrenia).

[3] Imanishi (2002, p. 43) provides a nice comparison with grasshoppers: "Where we see a steppe, the grasshopper may see a forest." This continues the classic von Uexküll (1957) demonstration of varied perceptual inputs of different species.

constraint that has guided a number of generations of researchers toward creation of nonsystemic, elementarist causal explanations. The canonical form of Morgan's Canon is usually presented as:

> In no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the outcome of the exercise of one which stands lower in the psychological scale. (Morgan, 1894, p. 53)

Leaving aside the selectivity of psychologists' construction of the "principle of parsimony" by borrowing this quote out of the context of the rest of Morgan's texture of thought (see Morgan, 2003; Valsiner, 2003a), it can be emphasized that this principle, as stated, effectively blocks the construction of systemic-causal explanations of development (Lerner, 1995). It forces the investigator to overlook the emergence of new regulatory mechanisms that operate *between* adjacent (i.e., both "lower" and "next higher") levels of the "psychological scale."

Developmentally, the emergence of a new regulatory mechanism (e.g., a higher-level semiotic mediating device, in the intra- or interpsychological spheres) may be initially "fragile" and ill formed. Development entails such transitional forms between levels: The higher levels are constantly in formation, yet before they are formed they cannot be clearly detected (see Figure 4.4). Hence, the canonical interpretation of Morgan's Canon makes it impossible to explain development; while development entails the emergence of hierarchically complex regulatory mechanisms (i.e., differentiation), research efforts guided by Morgan's Canon "blind" psychology's methodology to such emerging mechanisms.

This contrast may be used as an example of high-level semiotic constraining of the activities of scientists who are interested in human development. The blind spot in developmental psychology's activities is generated through a highly abstract constraint that has operated across the history of the discipline and over a varied range of specific research topics. However, it is not constructive merely to demonstrate developmental psychology's self-constraints. Existing constraints need to be adjusted to the nature of developmental phenomena.

The following reformulation could adjust the principle of parsimony to the systemic-structural conditions of development:

> If we assume development to be a multilevel probabilistically epigenetic process, in no case may we interpret an observable (i.e., emerged) outcome as being caused by a unitary lower level process (within the hierarchical network of processes), but always as a result of causal systemic processes that operate between levels. Attribution of causality to a singular-level ("higher" or "lower") causal system is possible *only and only if* we have ruled out any possible regulatory impacts from adjacent levels, especially by a process at the next higher level in the hierarchy.

This reformulation sets up a sequence of investigative activities in ways that at first require examination of the lack of between-levels ties. If such inquiry rules out such ties, then construction of causal explanations (of a systemic kind) within the given level is possible. *If* that examination *fails to rule out possible ties between levels,* then the construction of explanatory frameworks needs to retain the hierarchical (between-levels) nature of the phenomena under study, at least to the next immediate level of hierarchy.

As an example, consider Figure 4.4. The modified "canon" requires that to consider explanations for transformation A $\rightarrow$ D at the behavioral level only; it has to be proven first that neither the higher level (E) nor the lower level (B) phenomena are involved within the causal system. Inferences of causality that bypass the involved intermediary levels in linear causal terms (e.g., A causes C; see Figure 4.4) are inadmissible. Yet, *through* the system A $\rightarrow$ B $\rightarrow$ C, the actual role of A in transforming C may exist. Biological and psychological systems operate by systemic causality models in which catalytic processes are of special relevance.

Systemic Causality in the Biological and Psychological Worlds

Psychologists are used to thinking of the analysis of variance, in which the attribution of causes goes to "main effects" and "interactions," without much further thought about what the nature of such inductively derived "causes" is. This may, for some time, suffice in nondevelopmental psychology, but it fails in its developmental counterpart. The study of development cannot productively make use of linear models of causality (X causes Y or X causes Y given Z; see Valsiner, 1987, 2000c) and is in need of assuming systemic ones (e.g., system A-B-C leads to Y or system A-B-C given catalytic conditions P-Q leads to Y). These systemic versions of causality entail researchers' focus on cyclical systemic processes that lead to "caused outcomes" mostly as by-products of the self-regenerating (main-

taining) activity of the causal system. In this respect, causality in development can be taken to be reciprocal or mutual (Ford & Lerner, 1992, pp. 56–58; Lewin, 1943; Weiss, 1969, 1978). Such cyclical models are normal assumptions in biology (e.g., the "Krebs cycle," Krebs, 1964) but are rare in psychology.

Psychological Synthesis

Causal systems in biological and social sciences are systemic and catalytic. The system doing the causing has to maintain itself in the course of existing. A general scheme of that process is presented in Figure 4.5 (Minch, 1998, p. 47).

The process of synthesizing two separate substrates (*A, B*) into a new compound (*AB*) is made possible through a catalyst (*C*) which temporarily binds to the input substrates: first to *A* (arriving at intermediate compound *C-A*), then to *B* (arriving at intermediate compound *C-A-B*—binding *A* and *B* into one whole). The catalyst then releases the newly synthesized compound *A-B* and re-creates itself (*C*). Without the binding role of the catalyst, the synthesis need not be possible (direct, unmediated synthesis $A + B \rightarrow A\text{-}B$ cannot proceed). The making of a new compound—a new whole—is set up.

This generic example of catalytic process illustrates the difference between organismic and classic formal causality models in scientists' thinking. The same picture depicted in Figure 4.5 would be easily explained away by a statement, "*C* causes the emergence of *A-B*" (e.g., "poverty causes children's violence," or, if researchers avoid direct causal language, use "poverty predicts children's violence"). As we see from Figure 4.5, such general statements are insufficient, even if in some abstract sense true (indeed, the cycle of transformation of *C* into *C* through *C-A* and *C-A-B* can be said to "cause" *A-B*). Surely, such abstracted statements can operate as mentally economical shorthand in scientists' interactions by implying the whole set of known processes in the system; one does not need to repeat them verbatim.

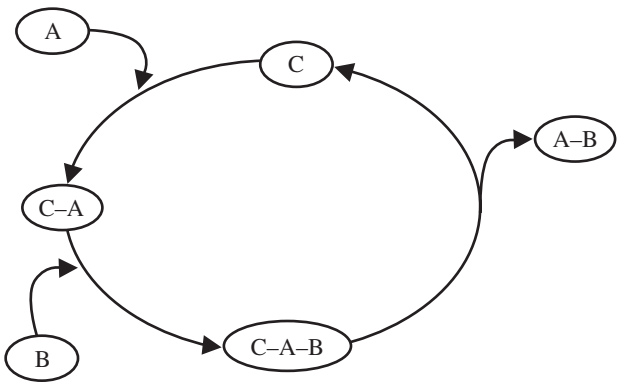

Figure 4.5 An example of a systemic causal model. C is a catalyst that makes it possible to synthesize A and B, while reproducing itself in a cycle.

Autopoietic Systems and Generation of Novelty

Figure 4.5 tells us a story of a system maintaining itself, while generating a composite (*A-B*). Developmental science needs to go beyond maintenance of synthesis to explain the synthesis of the novel and unexpected. Developmental systems need to be viewed not only as reverberating in their established regenerative cycles but also as autopoietic in their nature (Maturana, 1980).

Under certain conditions, the causal systems innovate themselves by constructing a new part to be incorporated into themselves or by reorganizing the processes that unite the parts within the system. This possibility creates a specific condition for the study of development, as it renders it impossible to infer from the outcomes of some developmental process anything about the causal system that produces the outcome. If a new outcome A-B-*D* (in terms of Figure 4.5) can be detected, it is not possible to infer that the previously proven causal system (A + B mediated by C) has produced it. There is a possibility that the causal system has modified itself (see also Figure 4.6). The structure of

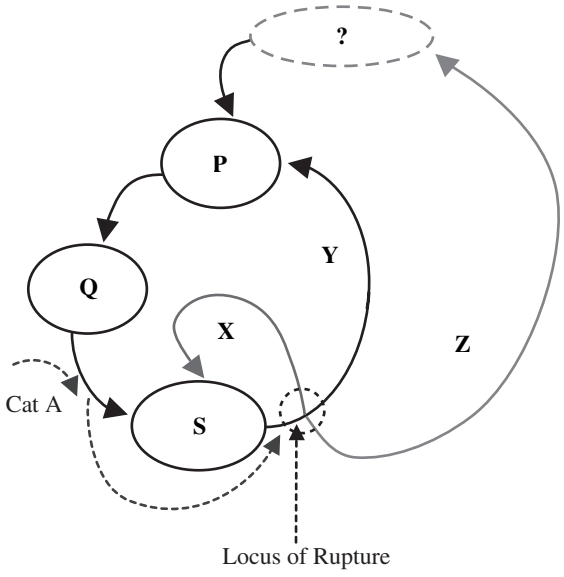

Figure 4.6 The intransitive hierarchy and its innovating rupture.

the "causal cycle" may have been altered, given the detection of the outcome such as a new by-product.

At first, it is necessary to prove that this new outcome could not emerge from the functioning of the previous system. The very same outcome in development can be reached (or maintained) via different causal systems (i.e., the *equifinality principle* that is characteristic of all open systems), and different outcomes can be generated by the same causal system. This theoretical aspect of development has been noted as a complicating issue for empirical research practices (Baltes & Nesselroade, 1973) and has particular repercussions for human development (Bornstein, 1995; Kojima, 1995). The equifinality principle leads to new methods of sampling (e.g., historically structured sampling).

Dynamic Hierarchies in Developmental Processes

Hierarchies are used by different thinkers who construct models of child development that are ill defined and ideologically flavored concepts. The ideological connotation seems to be a transfer from societal models (e.g., of citizens' equality, in terms of political freedoms) in a Western democratic society. Given these connotations, the use of hierarchy concepts in differentiation models is often tentative, as there is the understanding that the usual view of hierarchy—that of a "top-down" strict control process—may be limiting (see Ford & Lerner, 1992, p. 114).

However, hierarchies can be of different kinds and stability. Hence, the use of differentiation models need not signify a reduction of the flexibility of the developmental process to some strict scheme. Any hierarchic organization can be viewed as a temporary construction (which vanishes as soon as its control function is no longer necessary). Nor are hierarchies necessarily strict in their logic.

Transitive and Intransitive Relations

Any hierarchical relationship can be of two possible general kinds: *linear hierarchy,* which is based on the logical relation of *transitivity* (i.e., if A $\longleftrightarrow\!\!\!\!\!\rightarrow$ B and B $\longleftrightarrow\!\!\!\!\!\rightarrow$ C then A $\longleftrightarrow\!\!\!\!\!\rightarrow$ C, where $\longleftrightarrow\!\!\!\!\!\rightarrow$ indicates a dominance relation in an otherwise mutual relationship); or *cyclical hierarchy,* which is based on intransitive relations (see Figure 4.5; e.g., A $\longleftrightarrow\!\!\!\!\!\rightarrow$ B and B $\longleftrightarrow\!\!\!\!\!\rightarrow$ C and C $\longleftrightarrow\!\!\!\!\!\rightarrow$ A). For example, if a dominance hierarchy is presumed, it is assumed to remain stable and fixed. This is a clearly nondevelopmental view; it may be a formal model for nonliving objects but not for organisms. Interestingly, the fixed intransitive hierarchy also guarantees the stability of the system.

Figure 4.6 illustrates the functioning of an intransitive hierarchy and locates the place for potential developmental transition. Usually, when "hierarchy" as a term is used in psychology, it is the first level of hierarchy—based on transitivity—that is being considered. For example, most of the interpretations of Werner's hierarchical integration concept (except his own—see the following) have assumed the linear (transitive) fixation of the emerging differentiation.

In contrast, a case of intransitive hierarchy could be the case for flexible hierarchical control processes between the levels of integrated structure. It is the second kind of hierarchy, based on intransitivities, that dominate the regulatory processes in the biological and psychological worlds. Most of the biological regulatory processes are of a cyclical structure. In both hierarchies, plasticity is embedded in the possibility that change in any relationships can proliferate change in the whole structure (e.g., Lerner, 1984). Yet, the intransitive hierarchies are themselves not yet open to development; in fact, such hierarchy preserves the status quo through fluctuation of the context-dependent kind (see Figure 4.6).

We reach here a major epistemological generalization about what the theories of *causality* or *relationships* mean in psychological and biological systems. Instead of the usual acceptance of *linear direct* causality models (A causes B; see Valsiner, 2000c, p. 74), an appropriate model of causality is a *systemic catalyzed* approach (system A-B-C results in X if catalytic condition Z is present). Such understanding has productively been put into place in biochemistry (Krebs, 1964). From that viewpoint, mere discovery of statistical "relationships" between variable X and variable Y in a correlational analysis reveals little about the actual functioning of the system in which X and Y are systemically linked. Correlational data do not explain—they need explanation themselves!

The move to the use of systemic catalyzed causality models replaces our focus of analysis from the structure of the system as it is (once the structure is described) to that of under what conditions that system might be modified. This focus is nothing new in science: In 1927, Kurt Lewin emphasized the conditional-genetic nature of unitary complex phenomena (*konditional-genetische*

Zusammenhänge—p. 403) where, through the study of varied conditions of functioning (*Bedingungsstruktur*) of the system, its potentials for transformation into a new state—as well as conditions of its breakdown—could be revealed. Vygotsky's use of the same epistemological mind-set led him to elaborate the "method of double stimulation" as the methodological tool for developmental psychology (see Figure 4.9; also Valsiner, 2000c, pp. 78–81).

Intransitive Hierarchies in Real Life

We are not merely building abstract theoretical models here. The intransitive hierarchy may be a tool for thought that allows us to understand seemingly paradoxical unities of seemingly opposite phenomena in psychological phenomena.

As an example, consider a frequent question on the minds of sociologists and psychologists concerning dominance relations between genders. Much of the passion of ordinary human beings has been devoted to movements for liberation—for example, equality for women in many worlds. Seemingly paradoxical findings come out of efforts to look into these women's worlds (Villenas & Moreno, 2001). What is implied in these movements is the idea of intransitive hierarchy (see Figure 4.6) and its desired reversal (male dominance over females becomes equality, which means women's dominance over men, given the centrality of women in reproduction of the species, Rogers, 1975). Furthermore, anthropologists going to do their work in non-Western societies may find the gender relations far more complex than the simple label of "dominant over . . ." can cover. Meigs (1990) found in Hua males in New Guinea Highlands three parallel gender ideologies: one, male-chauvinistic; the second, subdominant and envious of female reproductive power; and the third, egalitarian. Movement between these three ideologies may be an example of a cyclical intransitive hierarchy where males may be dominant over females who are dominant over males, and so on.

Notice that such context-specific prioritizing of parts of a cyclical whole creates a system of high variation that is dynamically stable. Change is rampant in this system; yet, development is not. The question then stands: In what hierarchical order could development emerge? Clearly the transitive hierarchy is out of the question because of its fixity, but so is the regular intransitive hierarchy (see Figure 4.6 where trajectory X prevails). It is easy to see how blocking of the cycle (trajectory Y) turns the intransitive hierarchy into a transitive one. It is only the case where a rupture of the cycle—a new transformation of the system—opens up the creation of a new part of it (trajectory Z).

Evidence for such self-organized emergence of novelty is present in the genetic regulation of viruses. The genome of *Coccolithovirus,* for example, includes its own regulatory machinery for changing the basic structure of the genome under specific catalytic conditions of the environment (Wilson et al., 2005). This is an empirical illustration of the catalyzed rupture of the previous intransitivity cycle—albeit at the level of genome regulation. In the psychological realm, similar ruptures in the existing intransitivity cycles operate at the level of emergence of new sign hierarchies (Valsiner, 2001b; Zittoun, 2005).

Variability Is the Phenomenon and Not an "Error"

Variability, both within a system over time and between systems, is crucial for any understanding of development (Molenaar, 2004); hence, the trajectories described at the data level form families of similar trajectories. To arrive at such family descriptions, the individual case—individual trajectory of development—is the crucial feature of the data. Generalizations in this perspective are made from single cases to the generic functioning of the personality system (Lamiell, 2003). The empirical task of the researcher is first to analyze the systemic functioning of the single systemic case, and once the single case is explained, then to aggregate knowledge of the ways in which the system works, across persons into a generic model (Molenaar et al., 2003; Thorngate, 1986, 1992).

Contemporary psychology is used to the discourse about "individual differences," which at first glance seems to be about variability. Yet, this is not the case; talk about "individual differences" is about the description of quantitative deviations from some anchor point (the average, or any other criterion) and its usual utilization is for the purpose of not recognizing variability that exists within phenomena (Valsiner, 1986). Technically, having evidence about individual differences makes it possible to make statements about "relationships between variables," which as qualities are not considered to differ. A correlation coefficient found to represent a relationship between X and Y reifies the assumed lack of variability of X or Y and emphasizes their qualitative homogeneity. In contrast, a view of the scatter plot of

the data from which the correlation coefficient is derived retains the evidence for variability.

The talk about "individual differences" is imprecise, as in reality there are two "individual differences": (1) those within the system over time (intra-individual differences) and (2) those between systems at the same time (inter-individual differences). Furthermore, it has been proven that the two differences are not isomorphic (Molenaar et al., 2003). This leads to a need for a radical innovation of empirical research strategies. Reliance on the averages or prototypes and modeling developmental phenomena with the assumptions of the "general linear model" need to be abandoned as misfitting with the realities of systemic phenomena in psychology, especially of developmental phenomena.

The Intra-Systemic Variability

Developmental science separates this variability—fluctuations of the system <> environment relations over time—from the study of samples. Intra-systemic variability is observable only by repeated observations of the system and can be investigated either quantitatively (Nesselroade & Molenaar, 2003) or qualitatively (Mey, 2005). It is characterized by the parameters of the study of individual lives (C. Bühler, 1934): The description of the life course in relation to the environmental conditions (e.g., Chernoff, 2003; Mernissi, 1994; Shostak, 1981). Each life course is unique in its details, and that uniqueness is knowable by comparing its subsequent forms with the previous ones. Yet, behind such maximum uniqueness of the person over time can be universal life course features, invariants that can be discovered by abstracting and generalizing from such individual courses. The study of intra-systemic variability can include both unique "local description" and the finding of universal principles from comparisons of the life courses.

The Inter-Systemic Variability

As Molenaar et al. (2003) have demonstrated, the variability encountered between systems (in a sample drawn from some larger unit called "population") is not, and cannot in principle be, isomorphic with the intra-systemic one. This finding renders the study of groups of people—samples—irrelevant for creating scientific knowledge about general principles that are applicable at the individual level. A generic model that emerges from an analysis of samples is not applicable to individuals in the sample (except for the boundary case—which is practically impossible—of complete homogeneity of the sample).

In what ways can inter-individual variability be productive material for developmental science? It can provide a basic background: The whole set of available examples (i.e., inter-individual variability or the sample of individual cases) is the basis for *selection of specific cases* on which a proposed model is tested intra-systemically. If the hypothesized generic model of the single case (e.g., drawn from the middle range of the sample distribution) is demonstrated to function in the cases who are "outlayers" in the distribution, the researcher is on his or her way toward basic knowledge (Valsiner, 2003b). This strategy is well known in linguistics, where adequacy of a theoretical proposition is tested on singular examples from language, testing for extreme cases that may refute the proposition. Finding of such single counter-cases forces the theoretical system to reconstruct, or at times may lead to the abandonment of, the system.

Sampling Reconsidered: Historically Structured Sampling

The refocusing of developmental methodology from samples to the systemic study of individual cases and generalization from these sets up sampling in a novel light (Sato, Yasuda, & Kido, 2004). Developmental systems are characterized not by their states of being but their processes of becoming. Their individually unique trajectories may converge temporarily at some time point (*equifinality point*), only to diverge later.

Under the traditions of sampling—selecting individual cases creates a sample to represent a "population"—the focus has usually been on random sampling. It is assumed that randomness of sampling guarantees the best version of representation. In contemporary social sciences, we find a new tradition of experience-based sampling (Csikszentmihalyi & Larson, 1987; Kubey & Csikszentmihalyi, 1981). This emphasis grew out of taking specific pointed samples of everyday life experiences and accumulating those over time. The result, however, is not qualitatively different from the sampling persons, only here we have a "population of experiences" of a person, over time (i.e., such sampling verifies the intra-individual variability).

If we are interested in constructively combining the inter-individual and intra-individual forms of variability for the sake of arriving at generalizations within idiographic science, the idea of sampling acquires new

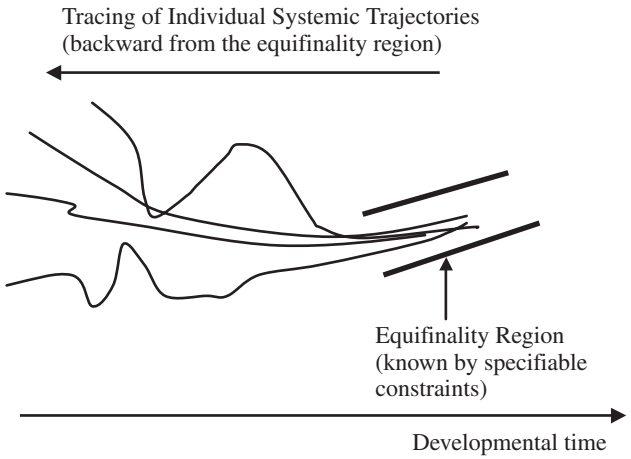

Figure 4.7 Sampling of developmental trajectories based on the equifinality point (region)—HSS or Historically Structured Sampling. *Source:* From "Whom to Study in Cultural Psychology: From Random to Historically Structured Sampling," by J. Valsiner and T. Sato, in *Pursuit of Meaning: Theoretical and Methodological Advances Cultural and Cross-Cultural Psychology,* J. Straub, C. Kölbl, D. Weidemann, and B. Zielke (Eds.), 2006, Bielefeld, Germany: Transcript.

meaning. We can speak of equifinality point sampling, or, more generally, about historically structured sampling (HSS; Valsiner, & Sato, 2006). Because the research question in developmental science is not to characterize intrinsic general properties of the systems, but rather to understand their functioning in the process of their relating with their environments, it is the question of what is general in the variety of trajectories converging to the same temporary equifinality point. Furthermore, developmental phenomena are historical in their nature; particular systems converge at the equifinality region under different circumstances. The HSS considers precisely that variety of circumstances; beginning from the specified equifinality region, it traces individuals backward in their history to varied antecedents (see Figure 4.7).

CENTRALITY OF FUNCTIONAL STRUCTURING

The terms *form* (or structure) and *function,* as well as *construction,* and *transformation,* are of key relevance for models of development. Usually, we see these two pairs of concepts as if they were opposites: Structure is viewed as static (and function as dynamic) and transformation merely changes in pre-given ways (rather than by construction of novelty). Yet, the organisms that develop unite the two sides: They are structurally organized (which makes it possible to support different functions), and they transform themselves through construction of novel structure (Guerra, 2003; Slunecko, 2002).

Each term has been disputed frequently by those with opposing axioms. Thus, the basic "battle" between European Gestalt (and *Ganzheit*) psychology, on the one hand (Ash, 1998; Diriwächter, 2003, 2004), and American associationism, on the other, has framed much of the history of developmental psychology (Cairns, 1998). This battle never ended—nor could it—because the difference between axiomatics (structure versus structure as reducible to elements) is in itself a matter of assumptions, not of truth. Likewise, organisms constructing their own development—that is, active creation of novelty—is of an axiomatic nature.

This very general idea of development of structures is well rooted in the history of developmental biology and psychology. Its roots are obviously in the *Naturphilosophie* of the eighteenth and nineteenth centuries and can be traced to Johann Wolfgang Goethe's ideas about biology. By the end of the nineteenth century, the focus on development was a widely recognized central topic in psychology, so its conceptualization was not foreign to well-known thinkers whose role in developmental psychology is usually not emphasized, such as Wilhelm Wundt, Franz Brentano, George H. Mead, Georg Simmel, and others.

The question that arose—then and now (e.g., Rogoff, 2003, pp. 52–62; see also Budwig, Valsiner, & Bamberg, 1998)—was the unit of analysis of complex developmental phenomena. In the beginning of the twentieth century, the question of the different organizational levels of quality was part of general discussion. The phenomenological basis for much of that discussion was the ordinary feature of the lives of philosophers and psychologists of the time—making music, and listening to it (live—the era of CDs was yet to come!):

> The starting point of the theory of Gestalt qualities was the attempt to answer a question: what is melody? The most obvious answer: the sum of the individual tones which make up the melody. But opposed to this is the fact that the same melody may be made up of quite different groups of tones, as happens when the same melody is transposed into different keys. If the melody were nothing other than the sum of the tones. Then we would have to have here different melodies, since different groups of tones are involved. (von Ehrenfels, 1932/1988, p. 121)

Centrality of Transfer and (Synthetic) Units of Analysis

The "whole" issue of development is that of structural transposition: from one context to another, and from one form of a structure to an altered (developed, progressed, or regressed) form. The developmental thinkers of the beginning of the twentieth century attempted to make sense of the whole-part relations in different ways, through abduction (C. S. Peirce), creative synthesis (W. Wundt), or "vertical" transfer of experience from one context to another via generalization. The "whole" was to be studied as a living form, a structure, that cannot be understood without the constant dynamically interacting parts, essential to life, stemming from present as well as past (Krueger, 1915, pp. 166–171).

This holistic look at the unit of analysis led Lev Vygotsky (1927/1982) to formulate the dialectical systemic unit of analysis:

> Psychology, as it desires to study complex wholes . . . needs to change the methods of analysis into elements by the analytic method that reveals the parts of the unit [literally: breaks the whole into linked units—*metod . . . analiza, . . . razchleniayushego na edinitsy*]. It has to find the further undividable, surviving features that are characteristic of the given whole as a unity—*units within which in mutually opposing ways these features are represented* [Russian: *edinitsy, v kotorykh v protivopolozhnom vide predstavleny eti svoistva*].[4] (p. 16, my elaboration of translation)

Such generalization arises through the formal operations the researchers perform on the phenomena to make sense of them. Its root metaphor has been the contrast between water and its components (oxygen and hydrogen).[5] Quite obviously the properties of water are not reducible to those of either hydrogen or oxygen. Yet, water remains universal in its chemical composition independent of whatever biological system (e.g., human body, cellular structure of a plant) or geological formation (e.g., an ocean, or a coffee cup!) in which it exists.

The focus on holistic units of analysis leads to the need of recognition of the existence of different organizational levels within any developing system and the maintenance of these levels in our efforts to explain phenomena through appealing but far-off (in terms of neighborhoods of levels) causal mechanisms. As Kenji Imanishi (2002, p. 22) wittily remarked, "[It] is nonsense to explain why birds fly and fish swim in terms of cells which cannot fly or swim." The explanation can come from an organizational level that synthesizes the work of cells—some form of network of cells in the nervous system, providing the basis for the swimming and flying. Yet, such a network includes cells as parts, not as causes. Causality is in the functioning of the system—the network of cells—not in the individual components of the whole. The reduction of causality for complex phenomena to the elementary components of the phenomena creates confusion, not clarity. This becomes particularly visible when the contemporary fascination with the human genome project leads to claims about locating "the gene" for some complex human phenomena (be it schizophrenia, school performance, or any other "dependent variable") in the vast number of base pairs. Actual evidence of genetic regulation demonstrates that such simple one-to-one connections are biologically impossible—as those traverse the multiple organizational levels of the system. Yet psychologists' (and laypersons') minds continue their search for simple ways to attribute causality—or blame—to rhetorically socially accepted simple "causes." Child psychology seems still far from abandoning the conceptual impasse "the nature *or* nurture" problem.

CONSTRUCTING GENERAL MODELS FOR DEVELOPMENTAL SCIENCE

The selection of models for closer historical and conceptual scrutiny was guided by their axiomatic assumptions. There are two basic parameters for the selection: *reliance on dynamic restructuring* over time (differentiation, de-differentiation, and integration), and *focus on the interchange with nonrandom, structured, and goal-oriented guiding environments.*

[4] It is important to note that the intricate link with the dialectical dynamicity of the units—present in the Russian original—is lost in the English translation, which briefly stated the main point: "Psychology, which aims at a study of complex holistic systems, must replace the method of analysis into elements with the method of analysis into units" (Vygotsky, 1986, p. 5).

[5] This metaphor has been used in scientific discourse since the time of J. S. Mill: "Not a trace of the properties of hydrogen or of oxygen is observable in those of their compound, water" (R. Keith Sawyer, personal communication, February 20, 2002).

It is obvious that these two classes of models utilize the two frames of reference appropriate for developmental analysis: the individual-ecological and the individual-socioecological frames. The first class of models includes those that assume differentiation and equilibration. The second class concentrates on relations with the guiding environments. All of the models are structuralist in their basis (yet allowing for dynamics) and are historically rooted in developmental biology (rather than psychology) as well as in philosophies that have emerged on the basis of biological worldviews.

Differentiation and Equilibration: Dynamics of Structures

Any conceptual model of development that entails the core of a previous state of the developing organism (X) becoming transformed into a reorganized structure (X—Y), and/or becoming transformed from more articulated (plural) systemic forms to a singular one can be considered to belong to "differentiation models." Theoretical discourse that focuses on *something-becoming-something else* is called *genetic* or *co-genetic logic* (Baldwin, 1906; Herbst, 1995). Formalization of such developmental logic has been in its infancy during the twentieth century. Nevertheless, any differentiation model implies some (usually not explicated) form of logic of change in irreversible time.

The image of differentiation—growth of structure over time—is certainly a very easy thought model to assume for any naturalist who looks at the growth processes in nature. The history of differentiation models can be traced back to the view on nature propagated by Goethe, and certainly to the traditions of *Naturphilosophie*. It is from that background that the founder of embryology, Karl Ernst von Baer, fit differentiation with his observations of the ontogeny of organ systems (von Baer, 1828). The integrated nature of differentiated organ systems was a given for a natural scientist, and there is never a need to reiterate that it is only the organized biological system (rather than its components) that lives. The focus on differentiation was slightly more complicated in the development of evolutionary thought (Gottlieb, 1992; Oyama, 1985).

We can elaborate the general nature of the differentiation models further. If the transformation of structure in the direction of greater systemic complexity (i.e., $X \rightarrow \{X—Y\}$ transformation) can be conveniently referred to as progression, then its reversal (i.e., transformation of $\{X—Y\} \rightarrow X$) may refer to regression. Regression is included in the differentiation models. For the sake of completeness, we should speak of *differentiation and de-differentiation* models, following the lead of Kurt Goldstein (1933, p. 437). It is important to reiterate that any process of de-differentiation (often subsumed under the label "regression," which implies a return to a previous state) is a part of an *ongoing* process of development. Any "return" to a previous state is ruled out by the irreversibility of time, which renders every new developmental state to be unique. However, states that can be viewed as *similar* (see Sovran, 1992) to previous ones can be detected when we study human life courses. Development can be conceptualized graphically as a helix that is unfolding in irreversible time. At different parts of the curves of the helix, a new state can resemble a previous state; yet, a new state never repeats a preceding one.

Numerous examples of differentiation models have been used in different areas of child psychology. These models have emerged on the basis of biological (Sewertzoff, 1929; von Baer, 1828) and linguistic (its diachronic focus, à la Saussure—Engler, 1968) research targets. In the studies on child language development, we encounter descriptions of how children's recognition or production of phonemes or words is transformed in ontogeny. Stage models of cognitive development indicate differentiation of cognitive structures (Case, 1985; Fischer, 1980; Fischer, Yan, & Stewart, 2003), and microgenetic analyses of children's mental operations reveal transformation of problem-solving strategies with age (Valsiner & van der Veer, 2000, chap. 7). Despite their wide *de facto* usage, general axiomatic formulations have been rare in developmental psychology.

James Mark Baldwin and the Developmental Logic (Genetic Logic)

Baldwin's work has been seminal in various aspects of developmental psychology (Valsiner & van der Veer, 2000). His role in the elaboration of the differentiation models was equally profound, as it took place in the context of his creation of the ideas of "genetic logic" or "logic for development" (Baldwin, 1906). This logic for development has to take into account the open-endedness of the developmental process: how novel forms may emerge at some junction, given a previously existing structure and its current relation with the environment. The organism is active within its environment

through a process of constant experimentation, trying and trying again (engaging in "persistent imitation"), which leads to the differentiation of the environment and intrapsychological world.

Heterogeneity of Experiences

Baldwin clearly understood the theoretical dangers of viewing the organism's environment in terms of its static features. The world of the developing person is variable. That variability takes realistic forms, which entail social interaction:

> [T]he child begins to learn in addition the fact that persons are in a measure individual in their treatment of him, and hence that individuality has elements of uncertainty or *irregularity* about it. This growing sense is very clear to one who watches an infant in its 2nd half-year. Sometimes the mother gives a biscuit, but sometimes she does not. Sometimes the father smiles and tosses the child; sometimes he does not. And the child looks for signs of these varying moods and methods of treatment. Its new pains of disappointment arise directly on the basis of that former sense of regular personal presence upon which its expectancy went forth. (Baldwin, 1894, p. 277)

From such heterogeneity of the person's social environment follows the need for selective treatment of that heterogeneity by the person. The previously established "schema" (see Baldwin, 1908, p. 184) allows the person to become selective as to the variety of actual environmental inputs. According to Baldwin (1898), the person:

> becomes a law unto himself, exercises his private judgment, fights his own battles for truth, shows the virtue of independence and the vice of obstinacy. But he has learned to do it by the selective control of his social environment, *and in this judgment he has just a sense of this social outcome.* (pp. 19–20)

It is obvious that the social nature of a person is expressed in his personal individuality. That individuality becomes differentiated from its social roots and acquires relative autonomy. Mere slavish mirroring of the social world is rendered impossible by the heterogeneity of the autonomy, which triggers the need for "systematic determination" of new knowledge by way of *internalized* selection mechanisms that operate within mental processes: cognitive schemata (Baldwin, 1898, p. 10). Such schemata—not as *re*presentations of the world but as anticipatory *preorganizers* of the person's future encounters with the world—continued in the work of Frederick Bartlett (Rosa, 1993), Jean Piaget (Chapman, 1988, 1992), and Lev Vygotsky (van der Veer & Valsiner, 1991). Thus, the relevance of presently emerging differentiated structures of thought or action was to provide a basis for future encounters with ever-unpredictable environments.

Pierre Janet and the Hierarchy of Psychological Functions

Perhaps the most central figure for the development of psychological thought in the first decades of the twentieth century was the shy French psychiatrist Pierre Janet (Valsiner & van der Veer, 2000, chap. 3). He was the originator of the analysis of subconscious processes. Janet's work was the basis for various activity theories that have proliferated in this century (Boesch, 1983, 1991; Leont'ev, 1981).

Janet's main focus was on the demonstration of differentiation of thinking and acting phenomena in the structure of personality and demonstration of their mutual integration (Janet, 1889, 1926, 1928). In the process of differentiation, some parts of the functional system establish their role as regulators over the others. Different clinical cases provide evidence for hierarchical control of the normal functioning of the mind by way of pathological excesses that can be obtained by simple alteration of the control system. On the one extreme, one can find the complete blocking of concrete action by way of thought processes (Janet, 1921). On the other extreme, it is possible to find thought processes that automatically are triggered by perceptual experiences and lead to uncritical and unchecked execution of actions (Janet, 1925, p. 210).

The Concept of Tension

The ways in which persons handle the differentiation and integration of their personality systems are certainly highly variable. The concept of *psychological tension* is present at all levels of Janet's thought-action hierarchy (Sjövall, 1967, pp. 52–56). At the higher level of that hierarchy, the phenomena of personal *will* can be observed as the highest control mechanisms. Thus, will is not a mystical entity outside of the regular action-control hierarchy in opposition to it; rather, it is the highest level of the hierarchical system, which emerges through development.

The process of differentiation is characterized by tension between parts of the previously differentiated

structure. This tension leads to focusing of the psychological work on them, so that:

> The patients who are ill-satisfied with their action watch themselves and by dint of observations, through anxiety about themselves, they fall into a sort of perpetual autoanalysis. They become psychologists; which is in its way a disease of the mind. (Janet, 1921, p. 152)

The crucial feature of handling such tensions is the *personal synthesis* of past experiences in the present through the use of language (Meyerson, 1947). Similar emphases on processes of fusion versus differentiation can be found in the work of Henri Wallon (1942, 1945).

Heinz Werner's Differentiation Model

Heinz Werner was, together with Jean Piaget and Lev Vygotsky, one of the three key developmental scientists of the twentieth century. Analyses of his work have been well represented in this *Handbook* in the past (Langer, 1970; Valsiner, 1998a) and have been given recent attention, which unearthed a number of unknown intellectual interdependencies between the scientist and his social setting (Valsiner, 2005a).

The Orthogenetic Principle

For English-language psychology, the general version of Werner's view is a quote from his presentation at the first Minnesota Symposium on Child Development. It is usually presented as:

> Developmental psychology postulates one regulative principle of development; it is an orthogenetic principle which states that wherever development occurs it proceeds from a state of relative globality and lack of differentiation to a state of increasing differentiation, articulation, and hierarchical integration. (Werner, 1957, p. 126)

The origin of differentiation goes back to Goethe (cf. Werner, 1926, p. 32). To understand Werner's intentions, it is his elaboration of the idea that needs to be considered. It is important to emphasize Werner's focus on the emergence of the polarity (differentiation) of the "subject" and its "object":

> [I]ncreasing subject-object differentiation involves the corollary that the organism becomes increasingly less dominated by the immediate concrete situation; the person is less stimulus-bound and less impelled by his own alternative states. A consequence of this freedom is the clearer understanding of goals, the possibility of employing substitutive means and alternative ends. There is hence a greater capacity for delay and planned action. The person is better able to exercise choice and willfully rearrange a situation. In short, he can manipulate the environment rather than passively respond to the environment. This freedom from the domination of the immediate situation also permits a more accurate assessment of others. (Werner, 1957, p. 127)

The orthogenetic law was not meant to be a unilinearity prescribing principle at the level of concrete developmental phenomena. In actuality, Werner recognized the multilinearity of developmental trajectories (Werner, 1957, p. 137). Differentiation included de-differentiation as its complementary part. The process of hierarchical integration involved qualitative reorganization of the "lower" (i.e., previously established) levels of organization, when the higher levels emerged in their specificity:

> [D]evelopment . . . tends toward stabilization. Once a certain stable level of integration is reached, the possibility of further development must depend on whether or not the behavioral patterns have become so automatized that they cannot take part in reorganization. . . . The individual, for instance, builds up sensorimotor schemata . . . these are the goal of early learning at first, but later on become instruments or apparatuses for handling the environment. Since no two situations in which an organism finds itself are alike, the usefulness of these schemata in adaptive behavior will depend on their stability as well as on their variability (which is a case of paradoxical "stable flexibility").
>
> . . . if one assumes that the emergence of higher levels of operations involves hierarchic integration, it follows that lower-level operations will have to be reorganized in terms of their functional nature so that they become subservient to higher functioning. A clear example of this is the change of the functional nature of imagery from a stage where images serve only memory, fantasy, and concrete conceptualization, to a stage where images have been transformed to schematic symbols of abstract concepts and thought. (Werner, 1957, pp. 139–140)

Werner's perspective on subject-object differentiation consistently led to psychological mediating devices emerging as human-made organizers of the mental and affective processes. In this, there existed a clear parallel with Lev Vygotsky's emphasis on semiotic mediating devices (see van der Veer & Valsiner, 1991). In Werner's

terms, these mediating devices emerge in the differentiation process and lead to planful behavior and specifically personal motivation (Werner, 1940, p. 191).

Werner's inclusion of motivation among the emerging set of mediating devices serves as an example of theoretical alleys in psychology that have been suggested and forgotten. Persons as constructors of their own motivation—via construction of cultural meanings—allow new forms of self-regulation to emerge in ontogeny and innovation of cultural meaning systems (as well as differentiation of language forms, e.g., metaphoric devices) in human history.

Werner was explicit about the *directiveness* of developmental processes (see Werner, 1957, p. 126 footnote), although most of his contemporary (and subsequent) developmental psychology has been wary of introducing teleological ideas into its core. Werner's thinking entailed a clear distinction between "primitive" (lower) and "civilized" (higher) forms of thinking (e.g., see Werner & Kaplan, 1956). This distinction was common in cognitive psychology of the 1920s and 1930s and was not a prey to ideologies for its value inclusiveness. Lev Vygotsky's thought explicitly accepted that notion, as did that of significant other contributors to our knowledge of development (e.g., Goldstein, 1971).

Microgenetic Investigations

Werner's own empirical credo was that of the experimental study of unfolding psychological phenomena in time. His *microgenetic* experimental focus was developed in parallel with Friedrich Sander's methodology of *Aktualgenese* (for an analysis, see Valsiner and van der Veer, 2000, chap. 7). If Werner, in the 1950s, had remained consistent with his method and the principle, all hypotheses generated at that intellectual junction would have needed to have been developmental (posit that one or another course of differentiation or de-differentiation be observable under specifically set experimental conditions). The hypotheses should have been about the actual *process of unfolding of structure* in development rather than about the *outcomes* of such development. Previously, Werner himself had argued against the elimination of the processes from consideration (Werner, 1937). However, by the 1950s, Werner's research program had changed: The range of empirical studies conducted under his supervision was rarely oriented to the processes under investigation, and he began using the outcomes-oriented statistical inferential techniques of the time (Lane, Magovcevic, & Solomon, 2005).

George Herbert Mead: Coordination of the Self and the Other

Analysis of Mead's work recently put it into the perspective of his own intellectual environment (Cook, 1993; Joas, 1985; Valsiner & van der Veer, 2000). For example, to overcome the separation of the person and society, as well as the intellectual fusion of these in pragmatist talk, Mead suggested a double-feedback loop model of differentiation of *both* the person (different "me's" as well as the "generalized other"; Dodds, Lawrence, & Valsiner, 1997) and the social world. The person acting within an environment changes it, and feedback and outcomes from this process lead to the intrapsychological reconstruction of the self. The reconstruction, in turn, further feeds actions on the environment resulting in a change, and so on. The process of differentiation of the subject and object maintains the dynamic relation between them, yet the process is constantly undergoing change:

> [R]esponse to the social conduct of the self may be in the rôle of another—we present his arguments in imagination and do it with his intonations and gestures and even perhaps with his facial expression. In this way we play the rôles of all our group; indeed, it is only so far as we do this that they become part of our social environment—to be aware of another self as a self implies that we have played his rôle or that of another with whose type we identify him for purposes of intercourse. The inner response to our reaction to others is therefore as varied as is our social environment. (Mead, 1913, p. 377)

The inner and outer worlds of acting persons thus become differentiated in coordination, and transformation in one leads to transformation in the other (see Figure 4.8).

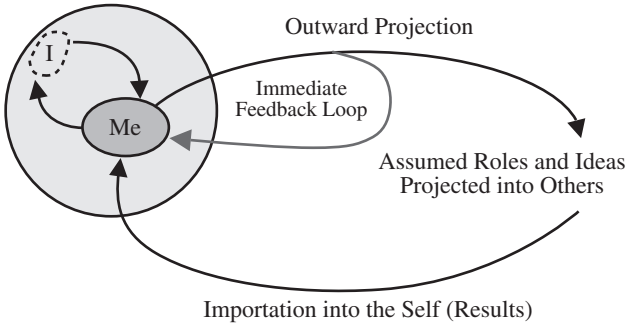

Figure 4.8 A schematic depiction of the core of development as understood by G. H. Mead.

The self is open-ended for novelty construction in three ways:

1. The *internal feed-forward cycle* (ME → I → ME). This is the internal loop that drives the accessible part of the self (ME) to changes in its state and to acting in new ways toward the environment.
2. The *immediate feedback cycle*. This operates "on line" when a person acts toward the environment, even before any response from the environment is obtained, the person analyzes what is being created as an output (e.g., I write these lines, before you tell me how stupid they are, I myself understand that they are).
3. The *pragmatic feedback cycle*—importing of the results of one's actions toward the environment into the self.

The integration locus of all three loops is the intrapsychological self-unit termed *ME* that links the internal and external dynamic flows of constant dynamic input. Some of it comes from results of actions, other, anticipation, or the "internal infinity" (the I) of the person.

Lev Vygotsky and Dialectical Synthesis

The core of Vygotsky's work was the demonstration of the presence of construction of novelty in the process of living-through experiences (Van der Veer & Valsiner, 1991, 1994, chap. 9; Vygotsky, 1971). Development from his viewpoint entailed differentiation of psychological functions (from "lower" to "higher" levels, distinguished by the semiotic mediation of volitional processes).

Vygotsky was aware of the need to rethink existing methods of psychology to allow for the study of the differentiation process. Hence, his "method of double stimulation" entails the analysis of the process by which the subject constructs further differentiation of the stimulus field, given the goal orientation of a task (Valsiner, 2000c). The main reason for constructing such methodology was the need to discover the moment at which a person arrives at a dialectical synthesis, both within the line of actions (similar to Karl Bühler's study of thinking processes, Valsiner, 1998b; followed by Köhler's insight-based problem solving by apes) and between the lines of action and semiotic reflection. In the latter case, the current problem-solving situation can be restructured in terms of its meaning, which guides the person's relations with that situation. Human capacity to move from acting to speaking to contemplating to generalization of the meaning to general states of the *psyche* (e.g., the states of "depression" or "happiness") constitutes a process of psychological differentiation in which higher mental functions become integrated into the structure of all functions in a control role.

The Method of Double Stimulation

The method of double stimulation (MeDoSt) entails a number of radical ideas in reconstructing developmental psychology's experimental method (see Figure 4.9). First, it is explicitly structuralist, as the subject is viewed as encountering the *whole field* of the experimental setting (and not merely the elements of it that are purposefully varied—"independent variables"). Second, the subject is considered as the active agent who reconstructs that field by introducing into it the goal subfields ("stimulus-objects," in Vygotsky's terminology) and means to reach those goals ("stimulus-means"). This functional differentiation of the structured stimulus field into "goals" and "means"—leaving the rest of the field to constitute the background—is *guided* by the experimenter, but cannot be *determined* by him or her. The experimenter gives the subject a task embedded within the field, but the subject can refuse to perform that task and turn it into another one. The *psychological experiment is only partially controllable* by the experimenter.

Double stimulation entails two distinctions: "stimulus-object" (the task and its goals) and "stimulus-means" (means to the end of reaching the goal). This is the basic agent/subject-object differentiation that is necessary for any problem-solving setting to emerge (Simon, 1999). This component is shared between *Homo sapiens* and other primates or even species further away from humans on the evolutionary ladder (see Sarris, 1931, on dog's

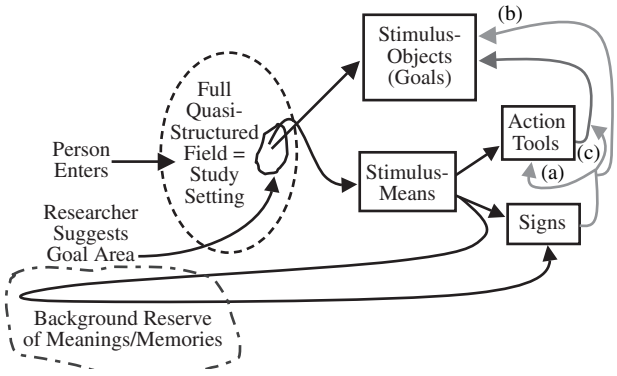

Figure 4.9 Components of Vygotsky's method of double stimulation.

mental capacities). Vygotsky borrowed the focus on means/ends distinction from Köhler's observations of chimpanzees.

There is a secondary differentiation of "double stimuli" between the two means that can be used to organize the subject's conduct in the experimental field. The *action tools* are created in the situation and constitute a synthesis of new functional uses of previously available objects—without, or with, modifications. There exist different qualitative levels of such synthesis; some do not require the presence of the human mind. Thus, the Japanese monkeys that invented the technique of potato washing (Hirata et al., 2001) merely regrouped their available environmental and bodily resources to invent a completely novel way of solving the problem of access to food. Likewise, Köhler's chimpanzees at Tenerife, as well as many generations of primate problem solvers in laboratories and zoos, or in the wild, creatively combined existing resources in new ways (Matsuzawa et al., 2001). A crucial qualitative breakthrough occurs in phylogeny when existing forms of the action resources are modified by the actor to fit the task and the modification know-how retained in the collective memory of the species. For chimpanzees, the making of action tools shows the difference here.

The MeDoSt requires the investigation of the uses of varied *signs*—semiotic means by the actor. Like action tools, signs can be constructed in the here-and-now setting for specific task demands, or imported to the present setting from a previous setting. It is through these semiotic mediating devices that a link between past and present situations becomes extrapolated to an anticipated future. Human subjects, through the use of language—thinking and speaking—constantly make their own meaning.

The construction and use of semiotic means includes the context of a psychological experiment. The subject (participant-to-be-studied) makes sense of the flow of events that is happening to him or her after agreeing to take part in a study.[6] The signs a human being uses three parallel functions:

1. They allow the person to give meaning to the act of instrument construction or selection (*a* in Figure 4.9).
2. They provide meaning for the act of striving toward reaching the goal (*b*).
3. They maintain the persistence of the effort of using the tools to reach the goal (*c*).

Human intrinsic motivation is semiotically constructed; the meaning of "trying, and trying again" (persistent imitation, Baldwin, 1906) is based on the personal culture (Valsiner, 2000c) and fortified through affectively hyper-generalized semiotic means.

This interpretational activity of the subject is not controllable by the experimenter, and the subjects' emerging meanings of the research situation cannot be eliminated. Human psychological research is necessarily personological and historical in its nature. Generations of psychologists since Ebbinghaus have tried their utmost to eliminate that inter-individual variability of past knowledge carrying over into the study context. They failed. Vygotsky's methodological ingenuity was in his decision to turn that inevitably uncontrollable moment of human interpretation around and make a virtue of something that would usually be considered vice (Toomela, 2003). The meaning-making process in a study was investigated. The equivalent of the "dependent variable" in his method was the microgenetic process by which the subject attempted to reach the goal and the corresponding construction of meanings. The empirical basis of Vygotsky's ideas was that of Gestalt psychological experimentation with primates and of Mikhail Basov's investigations of children's behavior.

The Zone of Proximal Development

The *zone of proximal development* (ZPD) is usually defined as the difference between what a child can accomplish with guidance, relative to individual performance (i.e., the sociocentric definition), or the process in which the child transcends the present level of development in constructive play (Vygotsky, 1966). In both cases, the concept is a hostage to the realities of irreversible time.

Irreversibility of time sets up very specific demands for the developing person. First, the person is always the agent in any ongoing interaction with the environment. Other agents are only episodically involved; that is, no

[6] The labels used to denote people who participate in psychological research are an interesting case of meaning-making on their own. Having originally been called *observers* (in the introspectionist paradigm—people who observed their inner psychological processes) they became *subjects* (e.g., the widely used slang "running the subjects"—a remnant of the time when the white rat took the place of the introspecting person), and in our time they became *research participants,* which denigrates the role of the researchers because they also are participants in the encounter with persons they want to study.

"social other" can live the life of the particular developing child. The experience of the developing child is unique (as was emphasized by Bergson), and although that flow is constituted through social interaction, its psychological nature remains personal and inevitably subjective. The nature of this experience can be called the "time-dependent egocentrism" of development. The idea of the central role of intra-psychological affective and mental processes does not diminish the role of the social others in the course of human development, but merely keeps the focus on the developing child who is the only person knowledgeable about his or her life experiences (Valsiner, 1989).

Second, the personal experiencing process of microgenesis of action within environment determines the *possible* conditions for the construction of the immediate next moment in a personal experience. Out of those possibilities, the actual experiencing dictates the actual next present moment (formerly the nearest future). The crucial role here remains in the synthesizing functions of the person's psychological system, which accomplishes that with, or without, immediate social support (in the form of scaffolding or teaching). Thus, the role of the social other in the learning process is both important and unimportant. It is important because the social others set up the environments that are experienced by the developing person. At the same time, the presence of the social others in each and every encounter of the child with the environment is not necessary (or is it possible); the developing child experiences both individually and socially guided encounters with the world as a singular person. The origin of the ZPD can be found in Henri Bergson's thinking:

> [C]onsciousness is the light that plays around the zone of possible actions or potential activity [French: *activité virtuelle*] which surrounds the action really performed [French: *qui entoure l'action effectivement accomplie*] by the living being. It signifies hesitation or choice. Where many equally possible actions are indicated without there being any real action (as in a deliberation that has not come to an end), consciousness is intense. Where the action performed is the only action possible (as in activity of the somnambulistic or more generally automatic kind), consciousness is reduced to nothing. Representation and knowledge exist none the less in the case if we find a whole series of systematized movements the last of which is already prefigured in the first, and if, besides, consciousness can flash out of them at the shock of an obstacle. From this point of view, *the consciousness of a living being may be defined as an arithmetical difference between potential* [virtuelle] *and real activity. It measures the interval between representation and action.* (Bergson, 1907/1911, pp. 159–160; French original inserts from Bergson, 1907/1945, pp. 154–155)

If we leave aside Bergson's occasional return to mechanistic concepts (i.e., of "arithmetical difference"), the rest of his conceptualization of the constructive nature of consciousness seems very modern. The developing person constantly faces complex choice points in one's life course where new actions (and their semiotic representations) need to be constructed. These constructions are the nearest "neighbors" to the already existing actions. The person constantly moves beyond a previously established state to areas of acting and thinking that had not yet been actualized. This is the essence of the "zone of proximal development" idea later used as a metaphor by Vygotsky.

The Zone of Proximal Development as the Meeting Zone of Present and Future

The ZPD is necessarily a concept where the teacher and learner roles are interdependent and asymmetric: The teacher attempts to "keep" the learner within his or her "zone of operation" generated by the teaching goals, while the learner may attempt to renegotiate the limits of his or her zones. The negotiation of teaching/learning tasks may involve intricate distancing-undistancing movement by both sides (Maciel, Branco, & Valsiner, 2004).

What is (and is not) projected into the ZPD depends on the success (or luck) of the microgenetic intervention and on the process of encounter between the social other and the developing person (our target organism). A teaching experiment is merely a context in which one of the two teleological orientations (i.e., the goal orientation of the teacher) is relatively fixed in its direction, while the other (of the learner) is not (and cannot be) assumed to have similar directionality (Branco & Valsiner, 1992). Rather, the learner has the possibility to diverge from or converge with the goal orientations of the teacher. The learner can likewise assume a neutral or noncooperative stance, undermining the teaching efforts (Poddiakov, 2001, 2005). As a result, it is not possible to "measure" the ZPD on the basis of the mere success or failure of a teaching experiment (i.e., on the basis of outcomes of the teaching efforts). Instead, a direct look at the process of joint construction of a teaching/learning event can give the investigator an insight into the learner's move beyond the present state of development.

Mikhail Basov's Theory of Dynamic Structural Forms

Basov's work, now available to a modern readership (Basov, 1991), originates from Gestalt psychology and its unification with developmental principles (Valsiner, 1988, chap. 5). In contrast to Vygotsky, who remained largely unspecific when the processes of dialectical synthesis were questioned, Basov demonstrated the emergence of novel differentiated structures through the use of three increasingly complex forms (and the "transitional forms" between them) constructed in ontogeny (Basov, 1929, 1931, 1991; see also Valsiner, 1988, chap. 5).

First, the *temporal chain of acts* is a form where actions follow one another without specific connections in time. These are actions triggered by the given situation at the given time. Neither past experience nor expectations for the future are involved in this flow of context-specific behaving. An example of this form may be taken from the erratic sequence of activities of a toddler, who may move from one area to another, involved in a sequence of activities without linkage to one another.

Second, the *associatively determined process* is a structural form of behavior that operates on the basis of associations between the present state and past experiences. This differentiated structure entails continuity in time from past to present (e.g., our contemporary modeling efforts of temporal processes through Markovian analyses, and other forms of time-series analyses, are axiomatically limited to detect this form of differentiation by Basov). However, the differentiation of form here does not include any orientation toward the future; hence, it cannot be viewed as the ultimate result of differentiation.

Third, the *apperceptively determined process* constitutes the unification of the linkages past → present and present → expected future. The expectations for the future—the apperceptive focus—provide the structure of action in any given moment of its focus. This is used to integrate selected associative ties with past experiences into the structure, which then is instrumental in bringing about *a* future.

Basov's perspective in paedology bears certain resemblance to the action perspectives of our day (see Brandtstädter, Chapter 10, this *Handbook,* this volume). He clearly anticipated the need to consider the goals-oriented nature of human action as the maker of the *foci* in the otherwise loosely differentiated field of human *psyche.*

Kurt Lewin's Topological Psychology

Lewin's dynamic view on human action and thinking was a significant contributor to psychological ideas (Zeigarnik, 1981). It was a general methodological orientation that radically transcended the associationist worldview of most of psychology. Thus, he stated:

> Field theory is probably best characterized as a method: namely, a method of analyzing causal relations and of building scientific constructs. This method of analyzing causal relations can be expressed in the form of certain general statements about the conditions of change. (Lewin, 1943, p. 294)

The unity of the fields leads to explanations of change in terms of field structure and forces (Lewin, 1935, 1938, 1939) or gradients (Gurwitsch, 1922; Waddington, 1966, 1970). The effort Lewin undertook was to overcome the "Aristotelian models" in psychology (Lewin, 1931; Valsiner, 1984). Instead of letting an average or most frequently observed case represent the reality of psychological functions (i.e., what Lewin designated as "Aristotelian model" of thought), he attempted to analyze the whole field structure of the active person. The emphasis on the field structure and its transformability was a productive way to accomplish this goal.

Processes in the Field of Life Space

Even as its main focus was to describe the fields of the present state of the psychological functioning of the person (Lewin, 1935, 1936a, 1936b, 1938), the developmental side of his field theory existed in efforts to explain the person's navigation within a field and in microgenesis of the person's "life-space" change. That navigation entails reconstruction of personal meanings (Lewin, 1942). The person's psychological field structure during an entrance into a novel environment is undifferentiated and becomes differentiated through the sequence of the person's actions while exploring the environment (Lewin, 1933, 1943). Empirical work that was guided by Lewin provided classic illustrations of such situation transformation process (e.g., the Zeigarnik effect; Zeigarnik, 1927). Zeigarnik and Lewin demonstrated the formative role of unfinished activity on the memory processes.

Lewin's general ideas on methodology matched these empirical practices. His focus on the experimental method in developmental psychology as targeting the

conditions under which one or another *transformation of the field could be demonstrated* (i.e., conditional-genetic analysis; Lewin, 1927) opened the door to others for direct investigation of differentiation processes (e.g., Boesch, 1991; Bourdieu, 1973, 1985; Bronfenbrenner, 1979; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Valsiner, 1987). The starting point for all systematically developmental analyses is some version of a field theory (Valsiner & Diriwächter, 2005) or the use of dynamic-structural metaphors ("the web"; see Fischer & Bidell, Chapter 7, this *Handbook,* this volume). Any perspective on development that claims to be based on the dynamic relationship of the organism with the environment has built its methodology in terms of fields rather than on points.

DYNAMIC APPROACHES IN DEVELOPMENTAL PSYCHOLOGY

In different areas of present developmental psychology, one can observe continuities with, and elaboration of, different kinds of differentiation models. Thus, Ford and Lerner (1992) demonstrate how the structure of "life course" emerges through differentiation (Ford & Lerner, 1992, pp. 200–204). Their version of the differentiation model entails a focus on *heterarchy* (in opposition to hierarchy), a differentiating structure in which "influences" move both from a "top-down" and a "bottom-up" direction (Ford & Lerner, 1992, p. 114).

Fogel (1993, 1999), being interested in the process of adult-infant communication, uses a differentiation model to investigate the emergence of relationships from the flow of interactive coregulation. The emergence of gestures from the flow of adult-infant interaction has been analyzed in depth by Lyra (Lyra, Pantoja, & Cabral, 1991; Lyra & Rossetti-Ferreira, 1995; Lyra & Winegar, 1997). In addition to articulation and hierarchical integration, development entails the process of *abbreviation* of the differentiating phenomena relative to their preceding states (Lyra, 1999).

The presence of abbreviation—loss of some aspects of the previously differentiated phenomenon—has been noted as important by researchers over many decades (e.g., Dewey, 1895, pp. 26–29). This loss has also been described as "fossilization of behavior" in the words of Lev Vygotsky. The function of such abbreviation in human semiotic construction is to preserve the phenomena of the past as feed-forward markers in the present—"one of the main functions of symbols is to 'abbreviate' reality" (Lyra & Rossetti-Ferreira, 1995). Differentiation of the speech and action lines in ontogeny, and the establishment of relative autonomy between them, allows semiotic mediating devices to take over regulation of development in dynamic, flexible ways. In the domain of social actions, children's construction of social roles in play (Oliveira, 1997; Oliveira & Rossetti-Ferreira, 1996) as well as adolescents' construction of personal secret meanings (Oliveira & Valsiner, 1997), are also examples. All these examples demonstrate how general principles of differentiation guide a developing person toward autonomy of the intrapsychological and interpersonal domains. Georg Simmel's (1906, 1908) ideas of the emergence of secrecy as a cultural phenomenon fits the differentiation notion. In the opposite end of the personal/social separation, the processes of coregulation of interaction give rise to differentiated systems of metacommunication (Branco & Valsiner, 2005; Fogel & Branco, 1997).

Dynamic Systems Theory

Contemporary work using differentiation models received positive impetus from dynamic systems theory (DST), and particularly from the potentials that experimental theoretical psychology (van Geert, 1998, 2003) provides for its formal modeling efforts. In the recent 2 decades, the use of DST has increased in developmental psychology (Lewis, 1995, 2000; 2005; Smith & Thelen, 1993; van Geert, 2003). It has an appeal for psychologists that most other recent formal analysis methods lack.

DST is sensitive to nonlinearity of processes, it builds its models on phenomena of variability, and it allows the researchers to see unity within the diversity (Aslin, 1993). DST introduces a future state of the system—that of attractor state—into its theoretical core. In a discipline where future is largely ignored—as it entails behavior that is not yet present—such theoretical insight is certainly revolutionary. DST has reintroduced to psychology the focus it needs: dynamic processes. These dynamic processes include emergence of novel structures from the relations between previously existing ones, under some circumstances of the system-environment relations (such as far from equilibrium states; Nicolis, 1993). This makes DST into a fitting suitor for the developmental sciences that have suffered from the absence of models that take emergence of novelty into account (Fogel, 1999; Lewis, 2000, 2005; van Geert, 2003).

The two central concepts of the dynamic focus include the *trajectory* (movement through time) and the

attractor. Trajectories represent the outcomes of dynamic processes. These outcomes can be described by their direction: extrapolating from the previously observed part of the trajectory to its continuation or from an expected continuation to the present, which is the basis for the introduction of attractors. For a dynamic system, the "attractor" is the end point of the trajectory. Dynamic processes tend toward a relatively stable state of the system; thus, the idea of an attractor entails *tending toward.* An *attractor* is the region of the state space toward which all nearby trajectories tend (Clark, Truly, & Phillips, 1993, p. 74). Specifying such points or areas of convergence in the future provides the present movement toward this future specifiable state.

Progressing Equilibration

The ideas of differentiation and integration have reemerged consistently in the history of developmental psychology. Nevertheless, these ideas have been used to capture the external picture of development as it unfolds over time. The internal (process) mechanisms of such differentiation are rarely made explicit (Janet's "tension" idea, alongside various efforts to consider "synthesis" in the differentiation process are steps in that direction). This has led some leading developmental scientists to admit a state of stagnation in our science, particularly when the issues of application are of importance:

> [M]ost of the research falls well short of identifying the crucial mediators of the causal processes or the effective elements of prevention or treatment. We know a lot about risk and protective indicators, but much less about risk and protective causal processes. (Rutter, 2003, p. 376)

It is in the equilibration models where the issue of organization of the making of new differentiated states comes to the focus of attention. Equilibration models expand our thinking about differentiation. Some such models focus on the actual synthesis of the novel form at a higher level of hierarchical integration. These models include systems that entail:

- An initial state of harmonious existence of a system
- Emergence of some disruption in that state, due to perturbations in the organism-environment relations
- Time-dependent (as well as teleological) movement toward the restoration of the initial state of harmony (equilibration) or synthesis at a higher level of hierarchical organization (progressing equilibration, synthesis)

It is the teleological movement that is the major constitutive criterion of the equilibration models because in some version neither does the outcome need to be accepted as restoring the "harmony" nor is the original "harmony" harmonious. Thus, dialectical perspectives that posit transition from one form of "contradiction" to another (new) one (Riegel, 1975, 1976), as well as all disequilibration models, fit under the general label of Dyamic Systems theory. Likewise, equilibration/disequilibration is central for the focus on organization and disorganization within developmental systems theory (Ford & Lerner, 1992, pp. 171–173).

The prehistory of the equilibration models in recent Western theoretical thought goes back to the thinking of Herbert Spencer who viewed the existence of living organisms in terms of a system of movements toward an *average* equilibrium state (1864; paragraphs 170–176). As such, this emphasis was merely a transition of the dominant role attributed to the average in the time-based change processes (Valsiner, 1984, 1986). Mere extension of the average-affirming processes to cover those of development was a way to fit the latter into an organized frame of preservation of the predictability of change processes.

Development through Disequilibriae: Peirce, Bergson, and Piaget

Charles Sanders Peirce formulated what, in our time, could be recognized as a law of development through disequilibration:

> [P]rotoplasm is in an excessively unstable condition; and *it is the characteristic of unstable equilibrium, that near that point excessively minute causes may produce startlingly large effects.* Here, then, the usual departures from regularity will be followed by others that are very great; and the large fortuitous departures from law so produced, will tend still further to break up the laws, supposing that these are of the nature of habits. Now, this breaking up of habit and renewed fortuitous spontaneity will, according to the law of mind, be accompanied by an intensification of feeling. The nerve-protoplasm is, without doubt, in the most unstable condition of any kind of matter; and consequently, there the resulting feeling is the most manifest. (Peirce, 1892, p. 18, emphasis added)

Peirce here undoubtedly antedated the popular fascination with "chaos theory" of our time. He emphasized that it is through the constant process of disequilibration—taking place in irreversible time—that conditions are created for the living organisms to construct new preadaptational forms. The irreversibility of time arrives, slowly and painfully, into the theoretical models of developmental scientists of the twentieth century through the philosophy of Henri Bergson.

Bergson's (1889, 1896/1988, 1907/1911) philosophy is widely known, but not well known in its substance. He borrowed greatly from the traditions of "organic evolution" thought of the 1890s, which were the focus of discourse thanks to the efforts of Henry Osborn, James Mark Baldwin, and C. Lloyd Morgan. Bergson's emphasis on the contrast between living and nonliving objects related closely with the natural-scientific debates of the 1890s. The idea of duration is the basis for his claim of a drastic difference between the living systems and the isolated ones (i.e., physical objects), as living systems are always in the *process of becoming.* Bergson's criticism of the science of his time was directed at the unwarranted transfer of analytic ideas from the study of the inanimate world to that of natural systems. In natural systems, the past (through selective memory) enters into the construction of novelty in the present. The process of becoming is that of creative adaptation that goes beyond the immediate needs of the environment.

Constructive Orientation to the Dynamic World: Anticipatory Preadaptation

Bergson's developmental thought was based on the concept of *adaptation.* That concept, popular as it was (and is), can carry different meanings. First, it has been seen as a direct reaction to the conditions that are causing change—either "positive" (by way of giving rise to new variations) or "negative" (elimination of emerged variations that do not fit the environmental demands). Bergson (1907/1911) disagreed with both of these meanings (on the basis of their mechanistic elaboration, p. 63) and called for seeing adaptation in the process of the emergence of novel mechanisms in ways *coordinated with* context demands (but not "molded" or "shaped" by them). Thus, in psychological development, the psychological functions develop new organizational forms that make it possible for them to encounter new conditions in the future (as opposed to the idea of "fitting in" with the environmental demands of the present). The adaptations are organic (systemic) growths, oriented toward a set of future possibilities (which, as those do not exist in present, cannot be precisely defined). Nevertheless, these new forms canalize the further encounters of the organism and the environment (e.g., Bergson's discussion of canalizing involved in vision, pp. 105–108; and in the role of concepts in canalizing conscious processes, pp. 305–308). In creative adaptation, the organizational forms that emerge in adaptation go beyond a "fit-with" the present state of the survival conditions and set the basis for facing the challenges of the possible future demands. Bergson's kind of adaptation is a prime example of the relevance of the "goodness of misfit" in the process of development (Valsiner & Cairns, 1992).

Jean Piaget's constructivist perspective on personal and social knowledge creation emerged at the intersection of his psychodynamic orientation and psychometric work tasks (Amann-Gainotti, 1992; Amann-Gainotti & Ducret, 1992; Chapman, 1988; see also an autobiographic retrospect in Piaget, 1952). In his work, Piaget looked at genetic epistemology from his dynamic structuralist perspective, being ambiguous about the stance of this perspective in terms of evolutionary thought (Hooker, 1994). Piaget's structuralism was a continuation of the Gestalt psychological thought, yet it posed as a third alternative to both elementaristic empiricism and holistic philosophizing (Piaget, 1970a, 1971a, chap. 1). Thus, by *genetic epistemology,* Piaget had in mind "study of the way in which the subject constructs and organizes his knowledge during his historical development (ontogenetic and sociogenetic)" (Piaget, 1965, p. 31). The study of the construction of the structure of knowledge allows for the understanding of that very structure that is being constructed.

A structure contains "certain unifying elements and connections, but these elements cannot be singled out or defined independently of the connections involved" (Piaget, 1971b, p. 139). As the structures are dynamic, they are involved in functioning in the context of their wider structural ties:

> [F]unction is the action exerted by the functioning of a substructure on that of the total structure, whether the latter be itself a substructure containing the former or the structure of the entire organism. (p. 141)

Piaget's dynamic structuralism was aimed at capturing both the developmental process and the continuous maintenance of existing organizational forms. The latter aspect has led investigators to trace the philosophical influences of Immanuel Kant in his thought (e.g.,

Fabricius, 1983), while the former can be linked with his continuing concern with creativity in evolution very much along Bergsonian lines (Chapman, 1988, 1992; Piaget, 1952).

Piaget's building of his theoretical system on the open-systemic nature of knowledge construction led him to address the issues of possibilities, impossibilities, and necessities (Piaget, 1986; Piaget & Voyat, 1979; Vuyk, 1981). The process of knowledge construction is dynamic; each possibility for structural transformation is an outcome of a previous transformation and makes it possible to move on to the next structural state. The basis for such a dynamic restructuring process is the general property of autoregulation.

Progressing Equilibrium

The main developmental mechanism that emerged in Piaget's mostly empirical research (and quite slowly—over 4 decades—by 1957) is that of equilibration (Moessinger, 1978; Rowell, 1983). Piaget's equilibration concept encompasses *progressing equilibration* (*equilibration majorante*), a process that would not reach an equilibrium state. Hence, Piaget's notion of development is open-ended in its allowance of construction of new structures:

> We can observe a process (hence the term "equilibration") leading from certain states of equilibrium to others, qualitatively different, and passing through multiple "nonbalances" and reequilibrations. Thus the problems to be solved involve various forms of equilibrium, the reasons for nonbalance, and above all the causal mechanisms, or methods, of equilibrations and reequilibrations. It is especially important to stress from the very beginning the fact that, *in certain cases, the reequilibrations merely form returns to previous equilibriums;* however, those that are fundamental for development consist, on the contrary, in the formation of not only of new equilibriums but also in general of better equilibriums. We can, therefore, speak of "increasing equilibrations," and raise the question of self-organization. (Piaget, 1977, pp. 3–4, emphasis added)

Piaget had his own uncertain equilibrium between the mind-sets of classical logic and of the Bergsonian focus on irreversible duration. In classical logic, the thought processes were free of the irreversibility of time, and hence one could introduce concepts such as reversible operations, regression to previous equilibriae, and so forth. In contrast, within the Bergsonian mind-set, phenomena that look like "regressions" are actually de-differentiations of more complex previous structures in ways that are similar to, but not identical with, some previous states. It can be argued (Valsiner, 1987, pp. 52–58) that Piaget's theoretical construction was imbued by that tension all through his career, leading to inconsistencies in his various expressions of equilibration.

Piaget relied heavily on equilibration as a process that contains two "part" processes: assimilation and accommodation. *Assimilation* entails the "integration of external elements into evolving or completed structures" (Piaget, 1970b, p. 706), while *accommodation* is defined by Piaget as "any modification of an assimilatory scheme or structure by the elements it assimilates" (p. 708). Piaget created these part-processes of the progressing equilibration as mutually interdependent parts of the same functional whole:

> [A]ssimilation and accommodation are not two separate functions but the two functional poles, set in opposition to each other, of any adaptation. So it is only by abstraction that one can speak of assimilation alone . . . but it must always be remembered that there can be no assimilation of anything into the organism or its functioning without a corresponding accommodation. (Piaget, 1971b, p. 173).

Ironically, many psychologists' renderings of Piaget's equilibration idea have failed to recognize this mutuality of the two processes. Piaget himself perhaps fed into the tendency to separate assimilation and accommodation from each other, as he reverted back to writing about their relationships in terms of a "balance" or "ratio" (e.g., Piaget, 1970b, p. 708).

Development through "As-If" Structures Unfolding in Time

The irreversibility of time sets up duality of human psychological functions: Our actions and reflections on those actions are between ourselves and our environment (*res media*—Fischer & Bidell, Chapter 7, this *Handbook,* this volume) but also between the present and the impending future in all of its uncertainty. Hence, persons can only act *as-if* they were different from what they are (in the present) as they anticipate what they might be (in the future). They act as if they were another person, but in reality they remain themselves. Still, by acting in the "as-if" mode they create the conditions for their own development.

At the turn of the century, the focus on human *as-if* (als-ob) type actions was systematically analyzed by Hans Vaihinger (Vaihinger, 1920). Vaihinger's philosophy brought into science the inherent duality in the existence. The person simultaneously IS and IS-NOT-YET—in every act of being is a process of potential becoming (Valsiner & van der Veer, 1993). The person is constantly on one's way that entails some form of ambivalence between *Heimweh* and *Fernweh* (Boesch, 1997, pp. 79–128)—our movement is oriented toward exploring the unknown while holding on to the known. Development necessarily entails construction of an "as-if" (or, desired state) image (Smythe, 2005), which is then striven for by the developing person. The basic duality that guides human development is that of constructing a constant contrast between the present state ("as-is") and the desired state ("as-if"). This contrast requires the relevance of constant empathic process between the two states (Josephs, 1998). The developing person has to "feel into" the existing "as-if" state and act to overcome this difference.

"Feeling Into" Others (Einfühlung): Intersubjectivity

Similar issues were raised by Theodor Lipps's "aesthetic theory" of *Einfühlung* or "feeling into" (Lipps, 1903, 1923; Witasek, 1901). When asking how an observer of an object of art can experience feelings similar to that of the author or another observer, it raises a relevant general question about human understanding (Wispé, 1987). On the basis of early childhood empathy, sophisticated versions of aesthetic experiencing can develop in ontogeny that are viewed as complex forms of coordination between the differentiated "as-is"→"as-if" structures as those unfold in time. Vygotsky's focus on "dialectical synthesis" (Vygotsky, 1925/1971) as well as Baldwin's focus on "aesthetic semblance" (Baldwin, 1911, 1915) were examples of theoretical constructions that elaborated that major issue.

In our times, the question of "as-if" type existence is largely subsumed under the label of intersubjectivity. The basis for any construction of *intersubjectivity* is a set of fundamental axioms for the social world:

> [F]irst, the existence of intelligent (endowed with consciousness) fellow-men and, second, the experienceability (in principle similar to mine) by my fellow-men of the objects in the life-world . . . I know that "the same" Object must necessarily show different aspects to each of us. First, because the world in my reach cannot be identical with the world in your reach, and so on; because my here is your there; and because my zone of operation is not the same as yours. And, second, because my biographical situation with its relevance systems, hierarchies of plans, and so on, is not yours and, consequently, the explications of the horizon of objects in my case and yours could take entirely different directions. (Schütz & Luckmann, 1973, p. 59)

Two socially constructed idealizations are involved here: *interchangeability of standpoints* and *congruence of relevance systems* (Schütz & Luckmann, 1973, p. 60). Any teaching/learning situation is at odds with this concept of intersubjectivity: The teacher's standpoint (role) is not interchangeable with that of the student, and the congruence of relevance systems of the teacher with those of the learner need not be taken for granted. Furthermore, we know that intersubjectivity itself has a multilevel structure of organization (Coelho & Figueiredo, 2003; Gillespie, 2003; Kirschner, 2003) and it has a reality component in interobjectivity (Moghaddam, 2003).

Post-Piagetian and Post-Vygotskian Models

It is notable that amid the variety of development models formulated after Piaget, the focus has remained on the description of levels (or stages) rather than on the mechanisms through which the developing child advances from one state or stage to another. Fischer's "skill theory" (Fischer, 1980; Fischer & Bidell, 1998, and Chapter 7, this *Handbook,* this volume; Fischer & Ferrar, 1987, 1992; Fischer et al., 2003) makes an effort to conceptualize the transition through a focus on unevenness of development at any time. On the basis of such unevenness, the progressing equilibration (or dialectical synthesis of novelty) can be easily put into theoretical use in the model. This was attempted by Pascual-Leone (1976), yet without persistence or empirical precision. However, the careful analysis of Robbie Case in the domain of children's cognitive progression provides precision to the transition between stages (Case, 1985, 1991). The issue of plasticity remains a crucial unsolved problem for post-Piagetian models of development because the mechanism of transition from state to state may include both orderly and disorderly forms, difficult to conceptualize in mechanistic terms (see Lerner, 1990; Toomela, 2003). Equilibration models necessarily have to deal with qualitative, directed, and progressive change (see Moshman, 1998) for which there exists relatively few formalized models.

Efforts to use contemporary fascination with "neural network" modeling (Fischer, Bullock, Rotenberg, & Raya, 1993) have led the question of explanatory mechanisms of cognitive development back to the time when it was still connected with neurological sciences (e.g., that of Bekhterev, 1994). Bekhterev's ever-grandiose system of a hierarchy of associative reflexes was the *de facto* model of the contemporary "neural networks" as those proliferate in computer-based models.

CULTURE IN HUMAN DEVELOPMENT

The focus on the "as-if" leads to reliance on semiotic mediation by human beings. By the end of the twentieth century, it became understood in psychology that it is not possible to ignore the major nature of human psychological phenomena—their socially constructed meaningfulness. Psychology is the science of meaningful conduct, and developmental psychology is the science of the emergence and transformations within the forms of such conduct (Valsiner, 2001c).

The emergence of various versions of cultural psychologies in conjunction with issues of developmental psychology (Boesch, 1989, 1991, 2003; Chaudhary, 2004; Cole, 1990, 1995; Eckensberger, 1997, 2003; Obeyesekere, 1990; Shweder, 1991, 1995; Shweder & Sullivan, 1990, 1993; Toomela, 2003; see also for reviews Jahoda, 1993, 1995; Krewer, 1992; Simão, 2005) provides an indication for the tendency in the discipline to break through the traditions of meanings avoidance that have been the core of the crisis in the discipline (K. Bühler, 1927/1978; Vygotsky, 1927/1982). It can be argued that human psychological phenomena exist within the *semiosphere,* a sphere of semiotic signs (Lotman, 1992), being constituted and reconstituted by active persons who are involved in processes of acting and reflecting on actions in parallel.

Focus on Participation

The desire to see persons as becoming involved in social events has fascinated researchers in the social sciences over the decades (Valsiner & van der Veer, 2000). Barbara Rogoff has attempted to make sense of the teaching/learning processes through a focus on participatory observational learning in cultural contexts for activities (Rogoff, 1990, 1992, 1993, 2003; Rogoff & Lave, 1984). Also, Michael Cole has taken further the notion of "zone of proximal development" and situated it in the middle of activity contexts. Cole's emphasis on the unity of teaching and learning processes emerges from his studies of cultural tools (Cole, 1995; Newman, Griffin, & Cole, 1989; Scribner & Cole, 1981). His theoretical construction is based on the "cultural practice theory" (Laboratory of Comparative Human Cognition, 1983).

The problem of relationships between microgenetic and situationally emerging ontogenetic phenomena in human development occupies the central focus of the "cultural practice theory." Cole has been interested in the ways in which context *selection* (Laboratory of Comparative Human Cognition, 1983, pp. 332–333) and *creation* (Newman et al., 1989, p. 12) are socioculturally organized. Cole's consistent interest in the zone of proximal development is congruent with his claim that "a cultural practice theory takes cultural contexts, that is, socially assembled situations, not individual persons or abstract cultural dimensions as the unit of analysis" (Laboratory of Comparative Human Cognition, 1983, p. 334). The main mechanism by which culture and person are related is that of *mutual interweaving*. Cole (1992, p. 26) uses the metaphor of "intermingling of threads from two ropes"—those of biological "modules" and cultural "contexts."

James Wertsch's work derives from the Vygotskian semiotic mediation viewpoint (Wertsch, 1979, 1983, 1995), on the one hand, and the activity theoretic perspective (Leont'ev, 1981), on the other (Wertsch, 1981). In his thinking about the ZPD, Wertsch viewed the dynamic process of situation redefinition as the primary means by which persons involved in a joint activity context guide one another's development. The partners are constantly in some relation of intersubjectivity (sharing similar situation definition), which they transcend by the process of situation redefinition (Wertsch, 1984, pp. 7–13).

By the mid-1980s, Wertsch turned to the integration of his semiotically mediated activity approach with the wider sociolinguistic context (Wertsch, 1985) that has been characterized by the dynamic worldview of Mikhail Bakhtin's literary theory (Bakhtin, 1981). His theoretical stance acquires a new layer: While the activity-framing remains in the background of Wertsch's accounts, the new layer of the theory entails a focus on interpretable utterance. Wertsch takes over Bakhtin's emphasis on dialogicality and makes it work

for his system. The multiplicity of "voices"—appropriated by the person from the sociocultural environment—led to the study of the complexity of these messages (Wertsch, 1990, 1991, 1995). The result is a consistent return to the study of ambivalences embedded in communicative messages. Different voices can be seen in the utterances in ways that "interanimate" or dominate each other during speaking in situated-activity contexts. On the basis of these contexts, macrolevel psychological phenomena, like historical identity, emerge in the process of development (Penuel & Wertsch, 1995).

Dialogical Models of the Self

In the second half of the 1990s, the tradition of looking at complex phenomena of the self in the dialogicality of "voices" gained greater popularity (Hermans, 1995, 2001, 2002, 2003). That perspective has yet to become utilized in developmental science or in the German tradition of cultural psychology (Boesch, 1983, 1989, 1991, 2003) that has focused on the construction of personal meanings (*fantasms*) at the intersection of acting and experiencing collective-cultural myth-stories in society. The parallel processes of striving-for-the-far-off (*Fernweh*) and striving-for-the-feeling-of-home (*Heimweh*) provide many possibilities for developmental science. The systemic activity approach is further advanced by Eckensberger (1995, 1997, 2003).

A recent tradition of looking at the uses of symbolic resources in the coping process with ruptures in the life course is a novel development of great promise (Perret-Clermont, Pontecorvo, Resnick, Zittoun, & Burge, 2004; Simão, 2003; Valsiner, 2001b; Zittoun, 2005; Zittoun, Duveen, Gillespie, Ivinson, & Psaltis, 2003). The field is poised at a major breakthrough—a development of new methodology will allow us to look at meaningful phenomena in the process of their transformation into new states. Such a breakthrough cannot come through accumulation of empirical research into "the literature" and by determining majority trends in that ("democracy of the literature"; Valsiner, 2000a). Instead, consistent science of development can emerge from the inter-disciplinary enrichment between the theoretical cores of all sciences where development as a direction of investigation matters—anthropology, sociology, protein genetics, embryology, and so on. Child psychology can participate in this progress if it adopts abstract thought models that fit the nature of developmental phenomena in the realm of psychology.

CONCLUSIONS: FROM DEVELOPMENTAL MODELS TO NEW METHODOLOGY

This chapter has been about consistency of basic ideas: If development is what we claim to study, the ways of studying it cannot be discordant with that objective. If development is conceptualized as a "process," it must be investigated as such rather than relying on standard nondevelopmental outcome "measures" to govern the empirical part of the knowledge construction effort. If development is conceptualized as involving "person" and "environment" relations, these relations must be studied in their actual functioning rather than static "snapshots" of the relating partners (see Magnusson & Stattin, Chapter 8, this *Handbook,* this volume). If variability is the crucial aspect of all developmental phenomena it makes no sense to get rid of it in our empirical data construction through averaging or prototyping (Fischer & Bidell, Chapter 7, this *Handbook,* this volume; Valsiner, 1984, 1986). Instead, alternative ways of conceptualizing that variability are appropriate (e.g., reaction norms, ranges, constraints, return to topological models).

Our contemporary developmental science has reached a critical junction. We borrow carefully from all the predecessors of developmental ideas—such as Baldwin, Mead, Vygotsky, Piaget—and turn those into new forms of theory and method construction. Method construction is predictably hard, as the social consensus in psychology does not appreciate direct study of development. Furthermore, the development of new empirical procedures is built on the remaking of a number of links in the general "methodology cycle" (see Figure 4.1).

First, the basic idea of causality in making sense of developing systems needs adjustment, and the phenomenological basis of child psychology as part of developmental science needs to take a world-wide and history-wide look at the lives of children, parents, grandparents, and then at social-religious and educational institutions that offer generous-looking help to the former in their coping with poverty and affluence, war and peace, and the private and public sides of living. This amounts to a kind of figure/background reversal; it becomes axiomatically accepted that all developmental phenomena are of quasi-structured fields (or webs, as Fischer and Bidell elaborate in Chapter 7, this *Handbook,* this volume). In the conceptual domain of such phenomena, new formal models will fit, and old—analysis of variance and correlation techniques—will not be

usable because they violate the axiomatic bases of developmental science.

Second, the advancement of person-centered (as opposed to variable-centered) research orientations in developmental science fit with the irreversible life-course nature of phenomena (Magnusson, 1988; Magnusson & Cairns, 1996; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume). These orientations bring back to the center of our attention models of differentiation, equilibration, and unity of person-environment structures in mutual teaching/learning processes. This holistic look is further developed through models of signification fields (Rossetti-Ferreira, Amorim, Soares da Silva, & Carvalho, 2004) that constitutes new methodology for capturing the dynamics of the social context as it guides the development of the person. Understanding of development itself develops through construction of theoretical models, careful analysis of their nature, their fit with the phenomena, and the retaining of models that maintain the relevant facets of the phenomena of development as abstract generalizations. It is time for the study of child psychology to transcend its nature as belonging to the genre of "area studies"—where the area is that of children—and become genuinely productive science of development.

It may be that the time in early twenty-first century is ripe for that. Developmental science is once again saturating child psychology with developmental ideas and research practices, but it has a long way to go. For example, James Mark Baldwin's call for a "genetic logic" in the beginning of the past century is still far from being developed into a full-fledged formal core of the study of development. Yet, science keeps advancing, in its bursts and *status quos,* leaving monoculturally relevant discourses about children far behind and moving toward constructing a general, yet context sensitive, science of development.

CHAPTER 5

The Significance of Biology for Human Development: A Developmental Psychobiological Systems View

GILBERT GOTTLIEB, DOUGLAS WAHLSTEN, and ROBERT LICKLITER

This chapter describes the history and current status of a psychobiological systems view of development, its implications for a developmentally oriented conception of behavior genetics, its application to a research area such as intersensory development, and the broader implications of a developmental psychobiological systems view of human development. A brief evaluation of current thinking in biology, developmental neuroscience, developmental psychobiology, and sociology is included.

Authorship of the chapter's five text sections is as follows: (1) "A Developmental Psychobiological Systems View . . ." (G. G.); (2) "Developmental Behavior Genetics . . ." (D. W.); (3) "Application . . . Intersensory Development" (R. L.); (4) "Broader Implications . . ." (G. G.); and (5) "Summary and Conclusion" (G. G.). The historical trends in the first section, leading to the current developmental systems view, are also reviewed in Gottlieb (1996). G. G.'s research and scholarly pursuits are supported in part by NIMH Grant MH-52429 and NSF Grant BCS-0126475. D. W.'s support comes from NIH Grant 2 RO1 AA012714 and OGP-45825 from the Natural Sciences and Engineering Research Council of Canada. R. L.'s research is supported in part by NIMH Grant MH-48949.

A DEVELOPMENTAL PSYCHOBIOLOGICAL SYSTEMS VIEW: HISTORY AND CURRENT STATUS[1]

The current definition of *epigenesis* holds that individual development is characterized by an increase in novelty and complexity of organization over time—the sequential emergence of new structural and functional properties and competencies—at all levels of analysis as a consequence of horizontal and vertical coactions among its parts, including organism-environment coactions (Gottlieb, 1991). Our present understanding of the various defining features of epigenesis has been laboriously worked out over the past 200 years.

The Triumph of Epigenesis over Preformation

The triumph of epigenesis over the concept of preformation ushered in the era of truly developmental thinking. Namely, that to understand the origin of any phenotype it is necessary to study its development in the individual. This insight has been with us since at least the beginning of the 1800s, when Etienne Geoffroy Saint-Hilaire (1825) advanced his hypothesis that the originating event of evolutionary change was an anomaly of embryonic or fetal development. The origin or initiation of evolutionary change was thus seen as a change in the very early development of an atypical individual. Although not a believer in evolution (in the sense that a species could become so modified as to give rise to a new species), Karl Ernst von Baer (1828) used the description of individual development as a basis for classifying the relationships among species: Those that shared the most developmental features were classified together, while those that shared the fewest features were given a remote classification. Von Baer noticed that vertebrate species are much more alike in their early developmental stages than in their later stages. This was such a ubiquitous observation that von Baer formulated a law to the effect that development in various vertebrate species could be universally characterized as progressing from the homogeneous to the heterogeneous or from the general to the specific. As individuals in each species reached the later stages of their development, they began to differentiate more and more away from each other, so there was less and less resemblance as each species reached adulthood. Figure 5.1 is a reproduction of von Baer's classification of various classes of vertebrate species, based on his developmental observations.

The Birth of Experimental Embryology

Von Baer's emphasis on the importance of developmental description represented a great leap forward in understanding the question of "What?" but it did not come to grips with the problem of "How." He and his predecessors evinced no interest in the mechanisms or means by which each developmental stage is brought about—it simply was not a question for them. It remained for the self-designated experimental embryologists of the late 1800s to ask that developmental question: Wilhelm His, Wilhelm Roux, and Hans Driesch. His (1888) wrote, in reference to von Baer's observations:

> By comparison of [the developmental of] different organisms, and by finding their similarities, we throw light upon their probable genealogical relations, but we give no direct explanation of their growth and formation. A direct explanation can only come from the immediate study of the different phases of individual development. Every stage of development must be looked at as the physiological consequence of some preceding stage, and ultimately as the consequence of the acts of impregnation and segmentation of the egg. (p. 295)

It remained for Roux, in 1888/1974, to plunge a hot needle into one of the two existing cells after the first cleavage in a frog's egg, thereby initiating a truly *experimental* study of embryology.

The arduously reached conclusion—the one we hold today—that individual development is most appropriately viewed as a hierarchically organized system began with Hans Driesch being dumbfounded by the results of his replication of Roux's experiment. While Roux found that killing one cell and allowing the second cleavage cell to survive resulted in a half-embryo in frogs, Driesch (reviewed in 1908/1929) found that disattaching the

[1] This first section heading introduces "A" systems view, not "The" systems view. For a partial illustration of the variety of developmental systems views in the behavioral sciences, interested readers are referred to Ford and Lerner's (1992) description of their version of a systems view of human development and, at even more abstract level, Oyama's (1985) depiction of her ideas about developmental systems and evolution. Figure 5.6 gives the essence of Gottlieb's notion of a developmental psychobiological systems approach as it has been worked out, beginning with the central concepts of bidirectionality and probabilistic epigenesis in 1970.

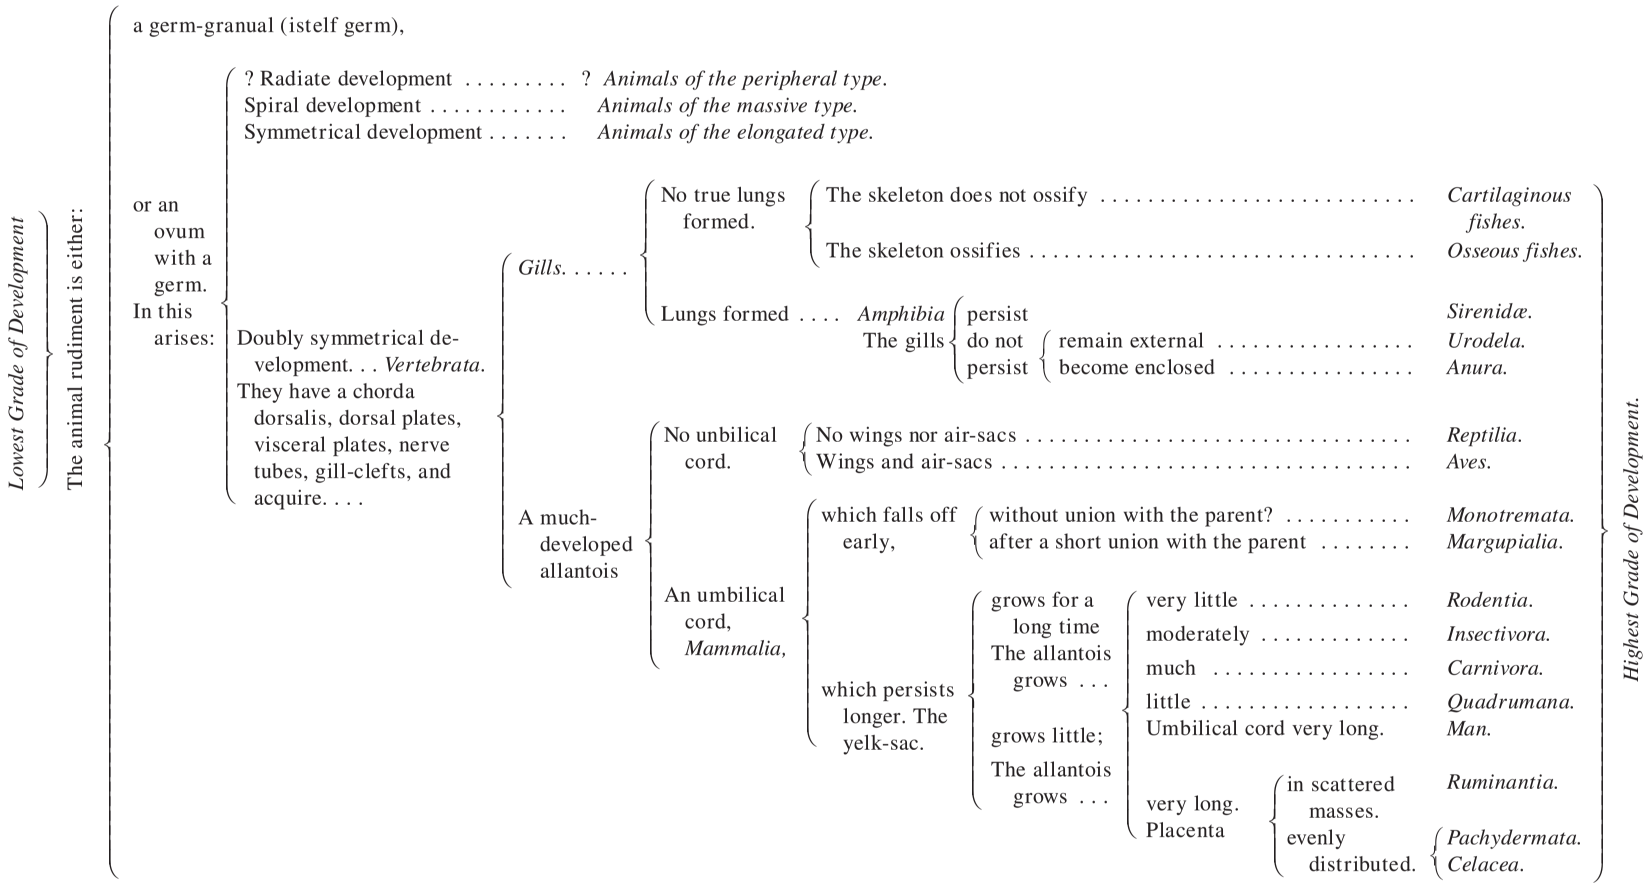

Figure 5.1 Von Baer's scheme of the progress of development. Von Baer's developmental classification of various classes of vertebrate animals (fish, amphibians, reptiles, birds, and mammals [Monotremata through Cetacea]) appears along the right vertical axis. His three other "types" of bodily organization are briefly designated in the upper left portion of the figure. Von Baer's scheme is not evolutionary in the conventional sense of ancestors giving rise to descendants. Rather, he sees an increasing complexity of prenatal structural organization going from the top to the bottom of the figure. For von Baer, the most complex prenatal organizations reflect the highest grade of ontogenetic development. Grades of development proceed from lowest (beginning on the left side of the figure) to highest (right side of the figure), whereas structural organizational complexity goes from the lowest (top) to the highest (bottom) on the right vertical axis. *Source:* From *Über Entwickelungsgeschichte der Thiere: Pt. 1. Beobachtung und Reflexion,* by K. E. von Baer, 1828, Konigsberg, Germany: Borntrager; and *Scientific Memoirs, Selected from the Transactions of Foreign Academies of Science, and from Foreign Journals: Natural History,* by A. Henfry and T. H. Huxley, 1853, London: Taylor & Francis.

first two cells in a sea urchin resulted in two fully formed sea urchins, albeit diminished in size. [When the disarticulation procedure was later used in amphibians, two fully formed embryos resulted as in Driesch's experiment with sea urchins (Mangold & Seidel, 1927).] Driesch came to believe that some nonmaterial vitalistic influence (an "entelechy") was at work in the formation of the embryo, one that will forever elude our best experimental efforts, so, he eventually gave up embryology in favor of the presumably more manageable problems of psychology.

Because Driesch had found that a single cell could lead to the creation of a fully formed individual, he gathered, quite correctly, that each cell must have the same prospective potency, as he called it, and could, in principle, become any part of the body. He thought of these cells as *harmonious-equipotential systems.* For Driesch, the vitalistic features of these harmonious-equipotential systems is their ability to reach the same outcome or endpoint by different routes, a process which he labeled equifinality. Thus, in the usual case, two attached cleavage cells give rise to an embryo; and in the unusual case of two separated cleavage cells, each gives rise to an embryo. To Driesch, these experimental observations provided the most elementary or "easy" proofs of vitalism; for those still laboring in the field of embryology today, they continue to provide a provocative challenge for experimental resolution and discovery.

For the present purposes, it is important to note that, if each cell of the organism is a harmonious-equipotential system, then it follows that the organism itself must be such a system. Driesch's concept of *equifinality*—that developing organisms of the same species can reach the same endpoint via different developmental pathways—has become an axiom of developmental systems theory.[2] In a systems view of developmental psychology, equifinality means that (a) developing organisms that have different early or "initial" conditions can reach the same endpoint, and (b) organisms that share the same initial condition can reach the same endpoint by different routes or pathways (cf. Ford & Lerner, 1992). Both of these outcomes have been empirically demonstrated by the behavioral research of D. B. Miller (Miller, Hicinbothom, & Blaich, 1990) and R. Lickliter (Banker & Lickliter, 1993) in birds, and by Noel (1989) and Carlier, Roubertoux, Kottler, and Degrelle (1989), among others, in mammals. The uniquely important developmental principle of equifinality is rarely explicitly invoked in theoretical views of developmental psychology, so it may seem unfamiliar to many readers. K. W. Fischer's (1980) theory of skill development in infancy and early childhood is one of the rare exceptions in that it explicitly incorporates the notion of equifinality: "[D]ifferent individuals will follow different developmental paths in the same skill domain. . . . The developmental transformation rules predict a large number of different possible paths in any single domain" (p. 513).

Microgenetic studies of human development are most likely to reveal equifinality because, under these conditions, the response of individuals to the same challenges is closely monitored and described for shorter or longer periods (e.g., Kuhn, 1995). In one study, Bellugi, Wang, and Jernigan (1994) monitored the attempted solutions of Williams syndrome and Down syndrome children, aged 10 to 18 years, to the block design subtest on the Wechsler Intelligence Scale for Children-Revised (WISC-R). The children in both groups performed equally poorly, but the attempted solutions by the Down syndrome individuals approximated in a global way the designs they were trying to copy, whereas the Williams group uniquely failed to reproduce the correct global configuration of the blocks. As shown in Figure 5.2, the children in both groups got the same low scores, but they achieved them in very different ways (by different pathways).

Another example involved a study of language development in young hearing and deaf preschool children. Each group devised an arbitrary system of signs to refer to events and objects, but the hearing children achieved the outcome by using the language of their adult caretakers as their model, whereas the deaf preschool children, being born to hearing parents who did not know sign language, developed their own arbitrary set of gestures to communicate meaningfully with peers and adults (Goldin-Meadow, 1997).

As a final example, in lines of mice selectively bred for high and low aggression, individuals in the low line become as aggressive as the high line if they are tested four times from day 28 to 235 of life (Figure 5.3; Cairns, MacCombie, & Hood, 1983). Once again, the developmental pathways to the same endpoint are different.

[2] Egon Brunswik, in his infrequently cited monograph for the *International Encyclopedia of Unified Science,* "The Conceptual Framework of Psychology" (1952), was the first to call attention to equifinality as an important principle of psychological development.

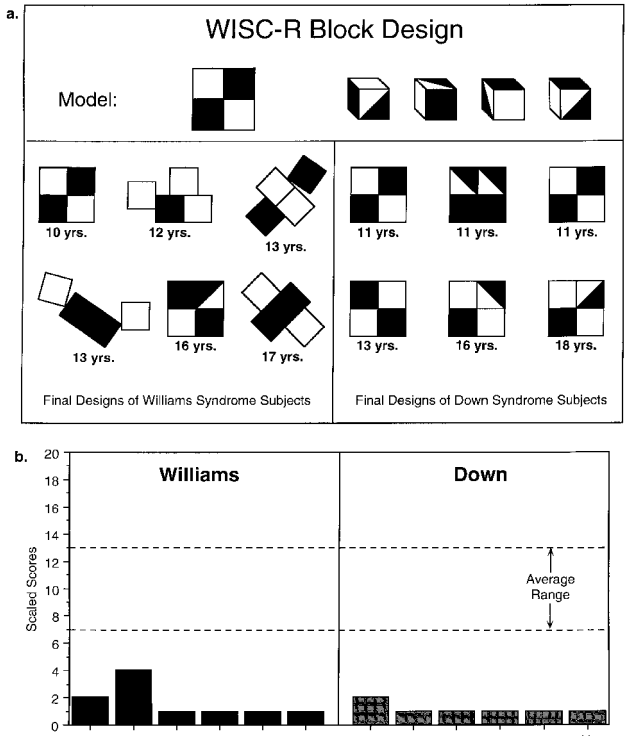

Figure 5.2 Contrasting block design performance in Williams syndrome (WS) and Down syndrome (DS) children. (1) Both WS and DS designs reveal striking differences in their errors. WS subjects uniquely fail to reproduce the correct global configuration of the blocks. (2) The differences in the errors are not reflected in quantitative scores, which are comparably low. *Source:* From "Williams Syndrome: An Unusual Neuropsychological Profile" (pp. 23–56), by U. Bellugi, P. P. Wang, and T. L. Jernigan, in *Atypical Cognitive Deficits in Developmental Disorders: Implications for Brain Functions,* S. H. Broman and J. Grafman (Eds.), 1994, Hillsdale, NJ: Erlbaum. Copyright 1994 by Dr. U. Bellugi, the Salk Institute, La Jolla, California. Reprinted with permission.

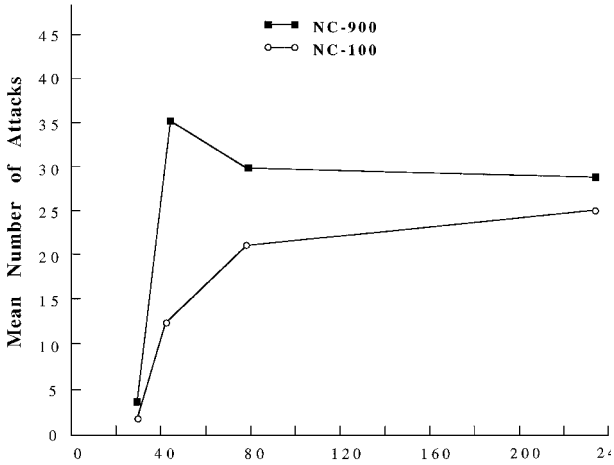

Figure 5.3 Mean number of 5-sec blocks in which subjects of high-aggressive (NC-900) and low-aggressive (NC-100) lines attacked their test partners. (The same subjects were repeatedly tested at days 28, 42, 72, and 235.) *Source:* From "A Developmental-Genetic Analysis of Aggressive Behavior in Mice: I. Behavioral Outcomes," by R. B. Cairns, D. J. MacCombie, and K. E. Hood, 1983, *Journal of Comparative Psychology, 97,* pp. 69–89.

However, in these mouse experiments, equifinality does not mean there is a genetic pathway in the high line and an experiential pathway in the low line—the expression of aggression is genetically and experientially mediated in both lines. The crucial experience in the developmental pathway to high aggression in the high line is rearing in social isolation between days 21 and 45, whereas the crucial experience in the developmental pathway to high aggression in the low line is repeated testing from days 45 to 235. This latter finding raises a highly significant question: Would the usual line difference in aggression at day 45 be erased if the low line were repeatedly tested before day 45 rather than after day 45?

Systems versus Mechanico-Reductive and Vitalistic-Constructive Viewpoints

As our overview of the precursors to our present concept of the systems nature of development moves from the late 1800s to the 1930s, we encounter the insights of the systems or organismic embryologists, Paul Weiss and Ludwig von Bertalanffy, and the physiological geneticist Sewall Wright.

In his wonderfully lucid and historically complete opus on the topic of development, *Modern Theories of Development: An Introduction to Theoretical Biology* (originally published in German), von Bertalanffy (1933/1962) introduced the system theory, as he called it, as a way of avoiding the pitfalls of machine theory, on the one hand, and vitalism, on the other. The error of the "machine theory" of development, as von Bertalanffy saw it, was its attempt to analyze the various aspects of the development process in terms of their individual component parts or mechanisms, conceived of as proceeding independently of one another. Von Bertalanffy believed that the fundamental error of the classical concept of mechanism, which was adopted wholesale from physics, lay in its application of an additive point of view to the interpretation of living organisms. In comparison:

> Vitalism, on the other hand, while being at one with the machine theory in analyzing the vital processes into oc-

currences running along their separate lines, believed these to be coordinated by an immaterial, transcendent entelechy. Neither of these views is justified by the facts. We believe now that the solution of this antithesis in biology is to be sought in an organismic or system theory of the organism which, on the one hand, in opposition to machine theory, sees the essence of the organism in the harmony and co-ordination of the processes among one another, but, on the other hand, does not interpret this coordination as vitalism does, by means of a mystical entelechy, but through the forces immanent in the living system itself. (von Bertalanffy, 1933/1962, pp. 177–178)

Nowadays, we make von Bertalanffy's point by distinguishing between theoretical and methodological reductionism. Theoretical reductionism seeks to explain the behavior of the whole organism by reference to its component parts—a derivative of the older additive, physical concept of mechanism. Methodological reductionism holds that not only is a description of the various hierarchically organized levels of analysis of the whole organism necessary, but a depiction of the bidirectional traffic between levels is crucial to a developmental understanding of the individual.[3] For purposes of recognizing historical precedent, it is appropriate here to present the diagrams of Paul Weiss and Sewall Wright, which exemplify the strictly methodological reductionism of the hierarchically organized systems view of development. (We use what we hope is not an annoying plural form of system because the various levels of organismic functioning constitute, within themselves, systems of analysis: the organism-environment ecological system, the nervous system, the genomic system, and others. Von Bertalanffy himself later, 1950, came to use the plural form in his conception of "General Systems Theory.")

In Paul Weiss's (1959) scheme of the hierarchy of reciprocal influences (Figure 5.4), there are seven levels of analysis. The *gene* (DNA) is the ultimately reduced unit in an ever-expanding analytic pathway that moves from gene to *chromosome*—where genes can influence each other—from cell *nucleus* to cell *cytoplasm,* from cell to *tissue* (organized arrangements of cells that form organ systems such as the nervous system, circulatory system, musculoskeletal system, etc.), all of which make up the *organism* that interacts with the external *environment.* The entire schema represents a hierarchically organized system of increasing size, differentiation, and complexity in which each component affects, and is affected by, all the other components not only at its own level but at lower and higher levels as well. Thus, the arrows of influence in Figure 5.4 not only go upward from

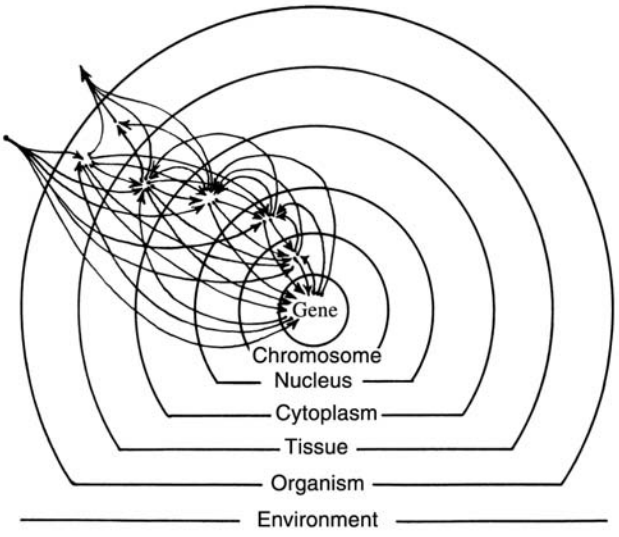

Figure 5.4 Embryologist Paul Weiss's hierarchy of reciprocal influences from the lowest level of organization (gene) to the highest level (external environment). *Source:* From "Cellular Dynamics," by P. Weiss, 1959, *Reviews of Modern Physics, 31,* pp. 11–20. Copyright 1959 by Reviews of Modern Physics. Reprinted with permission.

[3] Systems thinking is catching on in neuroscience. As a tribute to his long and productive career in neuroembryology, the *International Journal of Developmental Neuroscience* publishes an Annual Viktor Hamburger Award Review. In 1993, the award went to Ira B. Black, who published a review on "Environmental Regulation of Brain Trophic Interactions," which detailed the influence of neural activity on multiple trophic (growth) factors during development, further attesting to the feasibility of working out the bidirectional relations depicted in Figure 5.6. Black himself raised that optimistic question at the conclusion of his review: "Are we now in a position to move from environmental stimulus to impulse activity, trophic regulation, mental function and behavior . . . ?" (p. 409). A later Viktor Hamburger Award Review continued that theme with Carla Shatz's (1994) "Role for Spontaneous Neural Activity in the Patterning of Connections between Retina and LGN during Visual Systems Development," which is also in keeping with the first author's broad definition of the term *experience* ("spontaneous or evoked functional activity") in this chapter and earlier (Gottlieb, 1976). Even when an organism's experience arises out of an interaction with the external environment, there is an essential internal (cellular) correlate to that activity, so that is the rationale for including endogenous activity as part of the experiential process. Perhaps, for some readers, it would be more appropriate to drop the term *experience* and use the term *functional activity* at both the neural and behavioral levels of analysis. To the first author's way of thinking, experience and functional activity are synonymous.

the gene, eventually reaching all the way to the external environment through the activities of the whole organism, but the arrows of influence also return from the external environment through the various levels of the organism back to the genes.

While the feed-forward or feed-upward nature of the genes has always been appreciated, the feed-backward or feed-downward influences have usually been thought to stop at the cell membrane. The newer conception is one of a totally interrelated, fully coactional system in which the activity of the genes themselves can be affected through the cytoplasm of the cell by events originating at any other level in the system, including the external environment. For example, external environmental factors such as social interactions, changing day length, and so on, can cause hormones to be secreted (review by Cheng, 1979), and these hormones result in the activation of DNA transcription inside the nucleus of the cell (i.e., "turning genes on"). There are now many empirical examples of external sensory and internal neural events that excite and inhibit gene expression (e.g., Anokhin, Milevsnic, Shamakina, & Rose, 1991; Calamandrei & Keverne, 1994; Mauro, Wood, Krushel, Crossin, & Edelman, 1994; Rustak, Robertson, Wisden, & Hunt, 1990), thereby supporting the *bidirectionality* of influences among the various levels of analysis from gene to environment (to be discussed later).

Weiss was an experimental embryologist, so it was probably merely an oversight that he did not explicitly include a developmental dimension in his figure. Another schematic of a system view, also not explicitly developmental, was put forward by Sewall Wright in 1968. In Wright's schema (Figure 5.5), once again, the traffic between levels is bidirectional and the activity of the

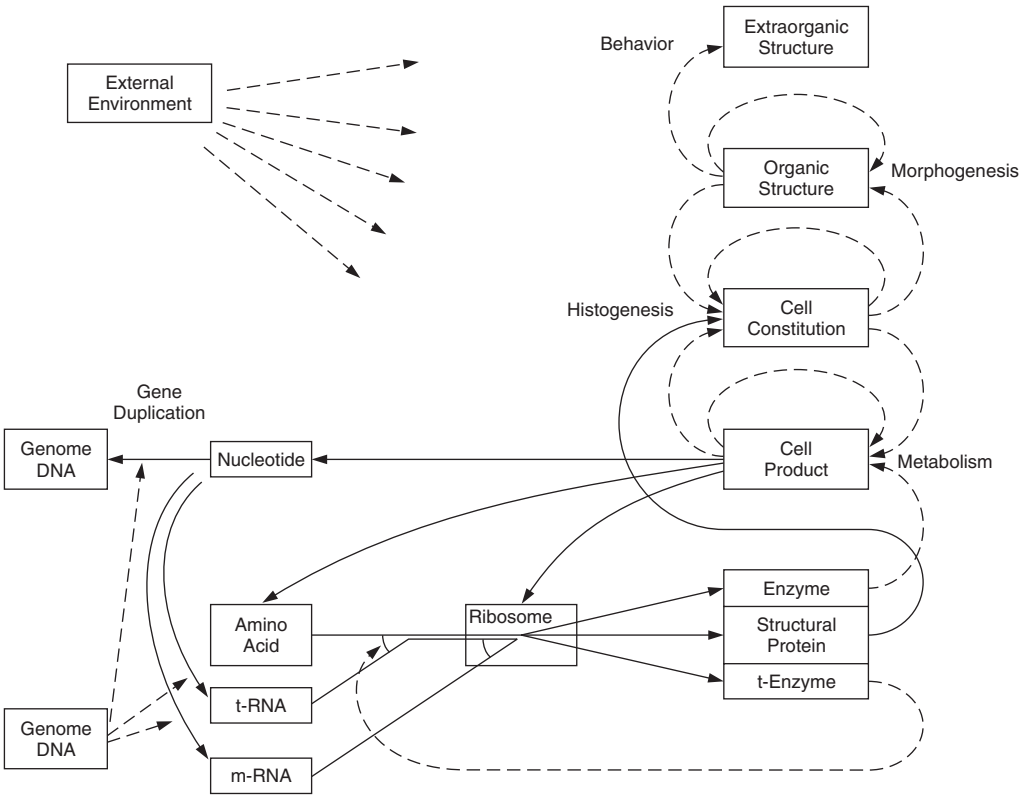

Figure 5.5 The fully coactive or interactional organismic system, as presented by Sewall Wright, a physiologically oriented population geneticist. *Source:* From *Evolution and the Genetics of Populations: Vol. 1. Genetic and Biometric Foundations,* by S. Wright, 1968, Chicago: University of Chicago Press.

genes is placed firmly inside a completely coactional system of influences. It is a small but important step to apply this way of thinking to the process of development (see Figure 5.6).

Influences of Sensory Stimulation on Genetic Activity

Some behavioral scientists, including developmental psychologists, seem to be unaware of the fact that the genes (DNA) themselves are subject to influences from higher levels during the course of development. Therefore, it is useful to stress that contingency as a part of the *normal* process of development. For example, one category of genetic activity called *immediate early gene expression* is specifically responsive to sensory stimulation. A higher number of neurons is found in the brains of animals that have been appropriately stimulated, and a deficiency in the number of cortical neurons in animals that have been deprived of such normal sensory stimulation (e.g., Rosen, McCormack, Villa-Komaroff, & Mower, 1992, and references therein). Not so long ago, neuroscientists of very high repute, including at least one eventual Nobel Prize winner, were writing in a vein that would seem to make sensory-stimulated immediate early gene expression an impossibility rather than an important feature of normal neurobehavioral development. For example, Roger Sperry (1951) wrote, "[T]he bulk of the nervous system must be patterned without the aid of functional adjustment" or "Development in many instances . . . is remarkably independent of function, even in . . . [the] sense . . . [of] . . . function as a general condition necessary to healthy growth" (p. 271). Twenty years later, Sperry (1971) continued to observe: "In general outline at least, one could now see how it could be entirely possible for behavioral nerve circuits of extreme intricacy and precision to be inherited and organized prefunctionally solely by the mechanisms of embryonic growth and differentiation" (p. 32). Sperry was not alone in expressing a genetically predeterministic conception of neural and behavioral epigenesis. Viktor Hamburger, perhaps the foremost student of Nobel laureate Hans Spemann, echoed Sperry's beliefs on several occasions that, to his credit, he later ameliorated:

> The architecture of the nervous system, and the concomitant behavior patterns result from self-generating growth and maturation processes that are determined entirely by inherited, intrinsic factors, to the exclusion of functional adjustment, exercise, or anything else akin to leaning. (Hamburger, 1957, p. 56; reiterated in toto in 1964, p. 21)

With noted authorities on the development of the nervous system making such statements in books and articles apt to be read by biologically oriented psychologists, it is not surprising that a genetically predeterministic view entered into psychology, especially when psychology was trying to recover its balance from accusations of the other error—environmentalism. One of the values of a systems view of development is the explicit utilization of both genetic and experiential influences, not merely a nervous (and often empty) lip service averring that both are surely necessary.

The Developmental Manifold Concept

Development is composed of a system of influences, both intraorganismic and extraorganismic. Even behavior that appears to be innate or instinctive has as its prenatal and postnatal background this system of influences, ranging from genes, the cytoplasm of the cell, protein-protein relations, cell-cell interactions, sensory stimulation, motor activity, and so on. These influences are part of the normal, species-typical internal and external environments, and I (G. Gottlieb) have called them the "developmental manifold" to call attention to the various constituents that give rise to any and all behavioral phenotypes (outcomes of development). In fact, I have followed T. C. Schneirla (1956) in calling all these influences *experiences.* Obvious forms of experience that we label learning are a subset in this much broadened definition. (See the section: Experience Defined as Functional Activity.)

I was led to the developmental manifold concept by my own research investigations into the role of prenatal factors in the development of instinctive behavior in ducklings (Gottlieb, 1971a). In 1965, I had shown that ducklings and chicks hatched in incubators, and thus deprived of maternal contact, could nonetheless identify the maternal assembly call of their own species after hatching. The only vocal-auditory experience they had was exposure to their own and sibling vocalizations prior to entering the test situation. In 1966, I showed that enhancing exposure to sibling vocalizations lowered the latency and increased the duration of their behavioral response to their own species maternal call. However, it was necessary to devise an embryonic devocalization procedure to

truly rule in the critical importance of the embryonic vocalizations in perfecting the perceptual selectivity of the response that was evident after hatching. With the help of John Vandenbergh, I was able to devise an embryonic muting operation that did not otherwise interfere with the health of the embryo and hatchling (Gottlieb & Vandenbergh, 1968). Now, the selectivity of the postnatal response to the species' maternal call could be examined in ducklings that had not experienced their own or sibling vocalizations. And the result showed the devocalized mallard duckling's usual auditory selectivity was not in place: They could not distinguish the mallard maternal call from the chicken maternal call. The control birds that had been allowed to hear their own embryonic vocalizations for 18 to 23 hours before being devocalized did show the usual preference for the mallard maternal call over the chicken maternal call (Gottlieb, 1971a, pp. 141–142). This experiential influence is not attributable to any conventional or obvious form of learning because the embryonic and maternal calls have different primary acoustic features and do not sound at all alike to the human ear.

The outcome of these experiments led to the formulation of the developmental manifold concept:

> The present results indicate that the epigenesis of species-specific auditory perception is a probabilistic phenomenon, the threshold, timing, and ultimate perfection of such perception being regulated jointly by organismic and sensory stimulative factors. In the normal course of development, the manifest changes and improvements in species-specific perception do not represent merely the unfolding of a fixed or predetermined organic substrate independent of normally occurring sensory stimulation. With respect to the evolution of species-specific perception, natural selection would seem to have involved a selection for the entire developmental manifold, including both the organic and normally occurring stimulative features of ontogeny. (Gottlieb, 1971a)

In 1987, West and King took the developmental manifold idea a step further by pointing out that: In addition to our genes, we not only inherit a fairly standard embryonic and fetal stimulative environment but also parents, peers, and the places they inhabit. They coined the term *ontogenetic niche* to signify the species-typical ecological and social legacies that accompany genes. Thus, we not only inherit nature (genes) but also nurture (the usual prenatal and early postnatal environmental conditions that prevail in any given species).

Developmental Causality (Coaction)

Behavioral (or organic or neural) outcomes of development are a consequence of at least two specific components of coaction (e.g., person-person, organism-organism, organism-environment, cell-cell, nucleus-cytoplasm, sensory stimulation-sensory system, activity-motor behavior). The cause of development—what makes development happen—is the relationship of the two components, not the components themselves. Genes in themselves cannot cause development any more than stimulation in itself can cause development. When we speak of coaction as being at the heart of the developmental analysis of causality, what we mean is that we need to specify some relationship between at least two components of the developmental system. The concept used most frequently to designate coactions at the organismic level of functioning is *experience*. Experience is thus a relational term.

Because developing systems are by definition always changing in some way, statements of developmental causality must also include a temporal dimension describing when the experience or organic coactions occurred. For example, one of the earliest findings of experimental embryology had to do with the differences in outcome according to the time during early development when tissue was transplanted. When tissue from the head region of the embryo was transplanted to the embryo's back, if the transplantation occurred early in development, the tissue differentiated according to its new surround (i.e., it differentiated into back tissue), whereas if the transplant occurred later in development, the tissue differentiated according to its previous surround so that, for example, a third eye might appear on the back of the embryo. These transplantation experiments demonstrated not only the importance of time but also the essentially coactional nature of embryonic development.

Significance of Coaction for Individual Development

The early formulation by Weismann (1894) of the role of the hereditary material (what came to be called *genes*) in individual development held that different parts of the genome or genic system caused the differentiation of the different parts of the developing organism, so that there were thought to be genes for eyes, genes for legs, genes for toes, and so forth. Driesch's experiment (1908/1929),

in which he separated the first two cells of a sea urchin's development and obtained a fully formed sea urchin from each of the cells, showed that each cell contained a complete complement of genes. This means that each cell is capable of developing into any part of the body, a competency that was called *equipotentiality* or *pluripotency* in the jargon of the early history of experimental embryology and is called *totipotency* and *multipotentiality* in today's terms (e.g., DiBerardino, 1988). Each cell does not develop into just any part of the body, even though it has the capability of doing so. Each cell develops in accordance with its surround so that cells at the anterior pole of the embryo develop into parts of the head, cells at the posterior pole develop into parts of the tail end of the body, cells in the foremost lateral region of the embryo develop into forelimbs, those in the hindmost lateral region develop into hind limbs, the dorsal area of the embryo develops into the back, and so on.

Although we do not know what actually causes cells to differentiate appropriately according to their surround, we do know that it is the cell's interaction with its surround, including other cells in that same area, that causes the cell to differentiate appropriately. The actual role of genes (DNA) is not to produce an arm, a leg, or fingers, but to produce protein (through the coactions inherent in the formula DNA ↔ RNA ↔ protein). The specific proteins produced by the DNA-RNA-cytoplasm coaction are influenced by coactions above the level of DNA-RNA coaction.

In sum, when certain scientists refer to behavior or any other aspect of organismic structure or function as being "genetically determined," they are not mindful of the fact that genes synthesize protein in the context of a developmental system of higher influences. Thus, for example, as experiments on the early development of the nervous system have demonstrated, the amount of protein synthesis is regulated by neural activity, once again demonstrating the bidirectionality and coaction of influences during individual development (e.g., Born & Rubel, 1988; summaries in Changeux & Konishi, 1987).

The Triumph of Probabilistic Epigenesis over Predetermined Epigenesis

In 1970, Gottlieb described an extant dichotomy in conceptualizing individual development as the predetermined and probabilistic epigenesis of behavior. *Predetermined epigenesis* saw a genetically inspired structural maturation as bringing about function in an essentially unidirectional fashion, whereas *probabilistic epigenesis* envisaged bidirectional influences between structure and function. The range of application of the probabilistic conception did not seem very broad at the time. In 1976, Gottlieb explicitly added the genetic level to the scheme so that the unidirectional predetermined conception was pictured as

$$\text{Genetic activity} \rightarrow \text{Structure} \rightarrow \text{Function}$$

in a nonreciprocal pathway, whereas the probabilistic notion was fully bidirectional:

$$\text{Genetic activity} \leftrightarrow \text{Structure} \leftrightarrow \text{Function.}$$

Now that spontaneous neural activity as well as behavioral and environmental stimulation are accepted as playing roles in normal neural development, and that sensory and hormonal influences can trigger genetic activity, the correctness and broad applicability of the probabilistic notion are undeniable and widely confirmed. In this sense, the probabilistic conception of epigenesis has triumphed over the predetermined view.

Building on the probabilistic notion, Gottlieb (1991, 1992) has more recently presented a simplified scheme of a systems view of psychobiological development that incorporates the major points of von Bertalanffy, Weiss, and Wright on the subject, and adds some detail on the organism-environment level that seems useful for a thoroughgoing behavioral and psychobiological analysis. Any merit this way of thinking about development may have must be traced to the pioneering efforts of psychobiological theoreticians such as Z.-Y. Kuo (summarized in 1976), T. C. Schneirla (1960), and D. S. Lehrman (1970). At present, the probabilistic, bidirectional conception is being used both implicitly and explicitly by a number of more recent psychobiologically oriented theorists (e.g., Cairns, Gariépy, & Hood, 1990; Edelman, 1988; Ford & Lerner, 1992; Griffiths & Gray, 1994; Hinde, 1990; Johnston & Edwards, 2002; Magnusson & Törestad, 1993; Oyama, 1985).

As shown in Figure 5.6, Gottlieb has reduced the levels of analysis to three functional organismic levels (genetic, neural, behavioral) and has subdivided the environmental level into physical, social, and cultural

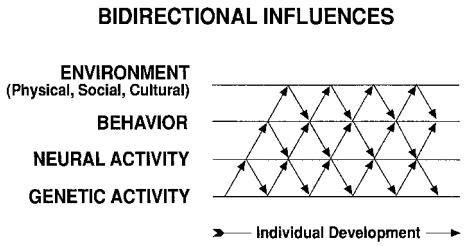

Figure 5.6 A systems view of psychobiological development. *Source:* From *Individual Development and Evolution: The Genesis of Novel Behavior,* by Gilbert Gottlieb, 1992, New York: Oxford University Press. Copyright 2002 by Gilbert Gottlieb.

components.[4] Those who work with nonhuman animal models stress the influence of the physical and social aspects of the environment; those who work with humans prominently include cultural aspects as well. The criticism that one hears most about this admittedly simple-minded scheme is not that it is overly simple but that it is too complex: There are too many influences, running in too many directions. In short, a developmental psychobiological systems approach is alleged to be unmanageable and just not useful for analytic purposes. What we hope to show in the remainder of this chapter is that such a scheme is not only useful but represents individual development at a suitable level of complexity that does justice to the actualities of developmental influences.[5]

Experience Defined as Functional Activity

Before turning to a review of developmental behavior genetics and intersensory influences in an effort to link all four levels of analysis in Figure 5.6, it is necessary to offer a definition of the term *experience* that will allow us to discuss experiential events occurring at each level of analysis, not just at the organism-environment level. Experience is synonymous with function or activity, and is construed very broadly to include the electrical activity of nerve cells and their processes: impulse conduction; neurochemical and hormonal secretion; the use and exercise of muscles and sense organs (whether interoceptive, proprioceptive, or exteroceptive); and, of course, the behavior of the organism itself. Thus, the term *experience,* as used here, is not synonymous with *environment,* but rather stresses functional *activity* at the neural and behavioral levels of analysis. The contribution of such functions to development can take any three forms: (1) *inductive,* channeling development in one direction rather than another; (2) *facilitative* (temporal or quantitative), influencing thresholds or the rate at which structural and physiological maturation, or behavioral development occurs; or (3) *maintenance,* serving to sustain the integrity of already induced neural or behavioral systems. The various courses these three experiential influences can take during development are show in Figure 5.7.

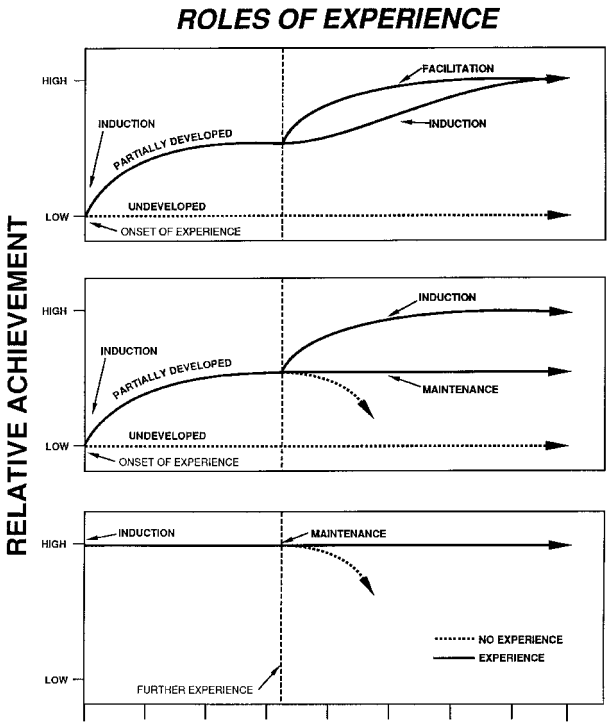

Figure 5.7 The various roles of experience (functional activity) during the course of development at the neural and behavioral levels of analysis. *Source:* From *Individual Development and Evolution: The Genesis of Novel Behavior,* by Gilbert Gottlieb, 1992, New York: Oxford University Press. Copyright 2002 by Gilbert Gottlieb.

[4] Gariépy (1995) has correctly pointed out that psychological functioning as such is not included in the four levels of Gottlieb's systems diagram (Figure 5.6). The reason for that omission is that psychological functioning or mediation (perception, thinking, attitudes, love, hate, etc.) must be inferred from analysis at the overt level of behavior and the environment, as made clear by the notion of methodological behaviorism introduced by E. C. Tolman in 1932. In this sense, all psychologists are methodological (not theoretical) behaviorists (cf. Brunswik, 1952).

[5] At the conclusion of their review of genotype and maternal environment, Roubertoux, Nosten-Bertrand, and Carlier (1990) observe: "The effects constitute a very complex network, which is probably discouraging for those who still hope to establish a simple relation between the different levels of biological organization, and particularly the molecular and the behavioral. The picture is indeed more complicated" (p. 239).

Summary of the Features of a Developmental Psychobiological Systems View

In its finished form, the developmental psychobiological systems approach involves a temporal description of activity at the genetic, neural, behavioral, and environmental levels of analysis, and the bidirectional effects of such activity among the four levels. When the related notions of bidirectionality and probabilistic epigenesis were first put forth (Gottlieb, 1970), they were largely intuitive. They seem now to be established facts in many, if not all, quarters. Given the experimental-embryological heritage of all systems views, two further assumptions or propositions are warranted:

1. Because of the early equipotentiality of cells and the fact that only a small part of the genome is expressed in any individual (Gottlieb, 1992), what is actually realized during the course of individual psychological and behavioral development represents only a fraction of many other possibilities (also see Kuo, 1976, on this point).
2. A developmental systems view entails the notion of equifinality; that is, the possibility of variation in pathways to common developmental endpoints. (A more detailed review of the early history and current status of this systems view can be found in Gottlieb, 1997.)

DEVELOPMENTAL BEHAVIOR GENETICS

In the next two sections of this chapter, this developmental psychobiological systems view is further elaborated with reference to developmental behavior genetics and intersensory influences on neural and psychobiological functioning in the prenatal and postnatal period.

Approaches to the Genetic Analysis of Development

Research on development usually addresses one of two broad questions and employs methods appropriate to each. This has often led to misunderstanding, especially in the realm of developmental behavior genetics, when results from one methodology have been invoked to answer a question that requires a different methodology.

Two Questions about Development

The first question concerns the causes of the average or typical course of development from the fertilized ovum to the elaborated adult. It occupied the earliest embryologists and remains one of the foremost intellectual challenges of modern science. Large differences between species are often examined in this context. Many of the most important advances in understanding average or species-typical development have utilized the experimental method to modify the course of individual development via surgical operations, altered sensory experience, or chemical treatments (Jacobson, 1991; Purves, 1994).

This approach (development of the individual) is exemplified in studies of the origin of the nervous system, using tracer molecules such as horseradish peroxidase (HRP). When injected into one cell of a 16-cell frog embryo, the HRP is then transmitted to all cells that are derived from that one by mitosis, and staining the differentiated embryo for HRP several days later reveals the developmental fate of the one cell (Moody, 1987). Although one cell may give rise to a particular kind of neuron in the central nervous system under normal circumstances, when that specific cell is destroyed in the 16-cell embryo, the fate of an adjacent cell is then altered to produce the required neuron (Jacobson, 1981), and an apparently normal organism emerges from a deliberately abnormal embryo. This kind of experiment reveals the crucial role of interactions between cells for the differentiation of the embryo into a system of organs. It manipulates neither the heredity nor the environment of the embryo; instead, it explores the internal processes of individual development.

The second question (the population approach) asks about the origins of individual differences in phenotypes among adults of the same species. Historically, this has been the focus of psychologists concerned with testing human mental abilities (Francis Galton, Cyril Burt) as well as geneticists interested in crop yields and evolution (Ronald Fisher, Sewall Wright). What sometimes passes for developmental behavior genetic research on human children typically employs correlational methods of statistical analysis and proceeds in virtual isolation from experimental neuroembryology (see critique by Gottlieb, 1995).

In its earliest stages, the science of genetics was nondevelopmental. At the same time, embryology

progressed along a separate course, with little concern for genetics (Allen, 1985; Sarkar, 1999). Mendel believed that his "constant differentiating characters" of garden peas were themselves inherited. His was a mosaic theory of heredity wherein each characteristic of the individual (height, color, or shape) was determined by a separate unit of heredity. This concept was adopted by those who rediscovered Mendel's laws and by Bateson (1913), who termed the units *genes.* From the outset of genetics in the twentieth century, a gene was named for its most salient phenotypic effect (e.g., *white eye* in fruit flies, *diabetes* and *waltzer* in mice), implying that a gene codes for the specific phenotype and the mutant reveals a gene's true function.

Pursuit of answers to the two major questions need not involve minds inhabiting two solitudes. Darwin integrated knowledge of embryology and individual variation in a masterful way to bolster his conclusions about evolution, and more recent theorists have also highlighted the importance of organismic development for natural selection and evolution (Gould, 1977; McKinney & McNamara, 1991; Salthe, 1993). Indeed, developmental systems theory offers unique insights into the relations among embryogenesis, individual differences, and evolution (Gottlieb, 1992; Johnston & Gottlieb, 1990).

Generally speaking, a theory that emphasizes the bidirectional nature of interaction between hierarchical levels of a living system (Figure 5.6) also encourages synergistic relations between allied scientific disciplines. A good example of this disciplinary synergism is evident in the multilevel analysis of gene-environment interaction by Johnston and Edwards (2002), reproduced in Figure 5.8. In contrast, the strongly reductionist approach of quantitative behavior genetics has devoted little attention to the levels between gene and behavior, thereby isolating psychology from comparative embryology, developmental genetics, and neuroscience.

The study of individual differences cannot provide a comprehensive account of organismic development. Many of the genes we possess are effectively the same in almost all members of a population. A gene is a segment of a long DNA (deoxyribonucleic acid) molecule that occurs at a particular place or locus in a chromosome or a mitochondrion (mtDNA). The *gene* is sometimes defined as the stretch of DNA that codes for a specific kind of protein molecule. During development, the DNA is transcribed into an intermediary molecule, messenger ribonucleic acid (mRNA), that is subsequently translated into a protein molecule. The DNA is

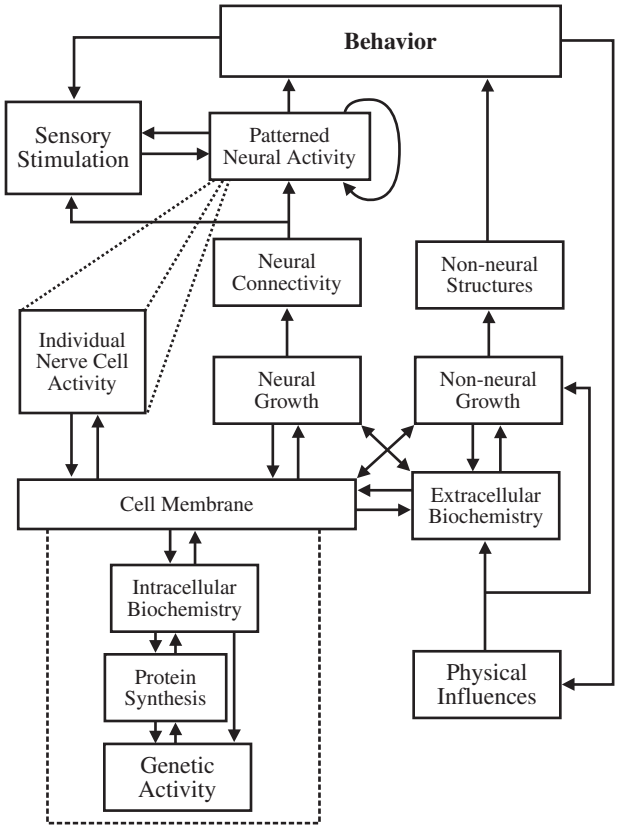

Figure 5.8 Model of behavioral development showing all factors involved in developmental construction of behavior and interactions among them, as proposed by Johnston and Edwards (2002). Nonneural elements encompass hormones (part of extracellular biochemistry), bones, muscles, feathers, and so forth. Sensory stimulation is influenced by behavior as the animal moves in its milieu, both producing and modifying the stimulation, but also by connectivity of the nervous system and the current state of neural activity. The elliptical arrow shows the effect of spontaneous neural activity. All enduring experiential effects on development act by modifying events at the cellular level, but there is no direct connection between genetic activity and behavior. Solid lines represent causal relations, whereas dotted lines indicate one thing is nested within another. *Source:* From "Genes, Interactions, and the Development of Behavior," by T. D. Johnston and L. Edwards, 2002, *Psychological Review, 109,* pp. 26–34. Reprinted with permission of the authors and the American Psychological Association.

a double helix consisting of two long chains of the nucleotide bases adenine (A), cytosine (C), thymine (T), and guanine (G), in a linear sequence that provides a code for the linear sequence of amino acids in a protein. At this molecular level, one might say that the gene *codes* for or *programs* the structure of the protein (Stent, 1981). What the consequences of this protein

may be for a cellular, neural, or behavioral phenotype depend strongly on the other genes possessed by the individual (Greenspan, 2004) and the sequence of environments encountered (Sokolowski & Wahlsten, 2001; Wachs, 1992). A specific gene sometimes occurs in two or more forms (alleles) that differ in one or more nucleotide bases in a population of individuals. If these different alleles code for slightly different amino acid sequences in the protein, and if the less common allele occurs with a frequency of at least 1% in the population, the locus is said to cause protein polymorphism. If not, the locus cannot give rise to noteworthy phenotypic differences among individuals. For many genes that are of critical importance for development, mutations are rapidly eliminated by natural selection, and almost all members of the population have the same allele.

Animal Models and Molecular Genetics

Recent innovations in molecular biology have made it possible to create viable mutations in genes where only one allele was known heretofore (Wynshaw-Boris, Garrett, Chen, & Barlow, 1999), or to insert an entire gene from one species into an early embryo from another species so that it becomes incorporated permanently into the genome to create a transgenic animal (Julien, Tretjakoff, Beaudet, & Peterson, 1987). Targeted mutations have greatly expanded the number of genes where allelic variants are available for research on brain and behavior. For example, in the mouse brain, the small molecule glutamate is a neurotransmitter that excites the postsynaptic neuron, and the receptor on the synaptic membrane that detects and reacts to glutamate is composed of several subunits, each of which can be encoded by a different gene. There are also gene-encoded molecules that interact strongly with glutamate or participate in the transport of glutamate at the synapse. As of 2004, researchers had identified 40 genes that encode either an enzyme, transporter, or receptor subunit involved in glutamate function in the nervous system (www.informatics.jax.org). Mutant alleles are known for 27 of these genes, and all but two cases have been targeted changes. Prior to the recent invention of targeting methods, spontaneous mutations had arisen and been identified in only two of these genes. One was the *Lurcher* mutation detected by Phillips (1960) and later shown to be an allele of a gene named *hotfoot* where several mutants were discovered over the years. Both are alleles of the *Glutamate receptor, ionotropic subunit delta 2* gene (*Grid2*). Also, the *eye blebs* gene was a severe mutation with widespread phenotypic effects discovered in 1969 (Beasley & Crutchfield, 1969), and it proved to be an allele of the *Glutamate receptor interacting protein 1* gene (*Grip1*). Meanwhile, no fewer than 58 alleles in 27 genes have been created by gene targeting, thereby greatly expanding the range of mutations available for research on glutamate function.

The elegant and even fantastic experiments that can be done with nonhuman genes and embryos are of course not available for research on humans. Although a detailed description of the usual sequence of events in early human prenatal development has been compiled, and similarities with other mammalian species are apparent (O'Rahilly & Müller, 1987), our most reliable information about mammalian embryogenesis comes from laboratory animals. Ethical considerations rightfully restrict what can be done to the human neonate in the name of science, and we rely on animals to teach us about many biological processes.

Considering the power of molecular biology to alter the genome, it is important to recognize the substantial degree of common origin or homology of humans and other animals at the molecular level. At least 99% of the genes found in humans also occur in mice (Mouse Genome Sequencing Consortium, 2002). Many genes in the lowly fruit fly also occur in both mice and humans (Adams et al., 2000; Sokolowski, 2001). As a general principle, developmental processes viewed at the molecular level tend to be broadly applicable across a wide range of species, whereas higher-level functions involving behavior or cognition are more apt to be species specific. A psychology of language development in children may find little benefit in attempting to converse with mice and fruit flies, whereas genetic analysis of synapses in the human nervous system can be illuminated by well-controlled studies of insect or worm nervous systems.

Mice are proving especially valuable in the search for animal models of human dysfunction because they are mammals and are readily adapted to a wide range of experimental alterations of their genes (Phillips et al., 2002; Tecott, 2003). While it has been possible to reproduce several single-gene defects of humans in a mouse model, it is also apparent that neurological disorders created in mice to mimic Alzheimer's or Parkinson's disease nevertheless differ in important ways from the human condition (Dodart, Mathis, Bales, & Paul, 2002). What appears to be an identical defect at the molecular level in a single gene often proves to have species-typical

features when that gene is placed in the context of a living organism.

Single Gene and Multiple Factor Research on Individual Differences

Among scientists who are primarily interested in individual differences within a species, two methodologies prevail (Greenspan, 2004). Some strive to detect and then understand the properties of a single gene and then elucidate the network through which that gene works to influence the lives of nerve cells and the behaviors of the organism (Wahlsten, 1999b). Others begin with phenotypic differences between strains of lab animals or relatives in human populations that they believe must differ at a large number of relevant genetic loci, each of which has a rather small influence on the phenotype. The phenotypes analyzed with this research are usually influenced substantially by several aspects of the environment, and the phenotype is then regarded as a complex, multifactorial character rather than a monogenic trait (Phillips et al., 2002). Those studying the influences of many genes of small effect would like to know the specific genes involved, but their methods are frequently incapable of detecting these. Instead, their immediate goal may be to characterize hereditary and environmental effects in broader terms.

Single gene effects are most easily studied when a mutation is available for research. The normal allele is sometimes termed the *wild type* and symbolized as +, so that animals captured in the wild state would typically have homozygous genotype +/+. The mutant allele might cause serious disruption of gene function and be symbolized –. If the mutation is recessive, only the homozygote –/– shows a phenotypic abnormality, whereas the heterozygote +/– appears and acts much as the +/+ animals. Researchers then measure a large number of phenotypes in animals with the +/+, +/–, and –/– genotypes to determine whether effects of the mutation are neatly localized or widespread. In most instances, a mutation having a large effect on certain phenotypes also changes the values of many other phenotypes, a phenomenon known as pleiotropic gene action. Even when we are considering variation in only one gene, the situation can be far from simple. Whether a specific mutation is recessive or dominant can depend on the thing we choose to measure (Moore, 2001) and the stage of development when the observations are made. The consequences of a mutation usually depend on genes present at other loci (epistasis) as well as the environment (Greenspan, 2004; Scriver & Waters, 1999; Sokolowski & Wahlsten, 2001).

In past decades, the list of readily available mutations for research was short. Most of them arose spontaneously in a lab from unknown causes. The supply of spontaneous mutations is now being augmented by chemical mutagenesis; male mice are fed a substance such as ethylnitrosourea that induces mutations at a high frequency more or less randomly across the genome. Large enterprises have been established to screen their offspring for mutations in thousands of mice (Belknap et al., 2001; Moldin, Farmer, Chin, & Battey, 2001; Nadeau & Frankel, 2000). By focusing on a specific phenotypic domain such as activity, anxiety, or memory, researchers hope that many if not all of the genes that are most important for those functions might be identified.

Most mutations with large effects must be painstakingly propagated in sheltered conditions in the laboratory. The spectacular features of their phenotypic effects make them easy to study with small samples of animals, but the widespread effects of seriously debilitating mutations make the experiments difficult to interpret. Scientists working with fruit flies have found some very interesting genetic variations in wild populations that lead to less dramatic and viable alterations in behavior, such as how far the larvae move when feeding (Sokolowski, 2001) or how readily the flies adapt to changes in day length (Greenspan, 2004). Greenspan (1997) has argued that these genes with smaller effects should be less likely to alter a wide range of phenotypes, thereby making it easier to elucidate the network of other genes with which they work closely.

Aspects of the brain and behavior that are influenced by numerous polymorphic genes as well as environmental variation are termed *quantitative* or *complex traits.* Only within the past decade has the identification of specific genes involved in complex traits become a realistic goal (Belknap et al., 2001; Flint, 2003; Phillips et al., 2002). The discovery of thousands of phenotypically neutral marker loci spread widely across the entire genome has been a boon to linkage analysis, and generous funding of research projects involving large samples of animals, especially mice, has provided the necessary statistical power to detect linkage with a gene that may be responsible for only 5% of the phenotypic variance in a trait (Crabbe, 2002). When the data indicate that a gene relevant to a quantitative trait is located somewhere in an interval along a particular chromosome, the region is referred to as a quantitative trait locus (QTL). Usually

the interval is so wide that hundreds or even thousands of genes are to be found there, and the challenge then is to narrow the search and pinpoint which specific gene is the basis for the QTL. This final step has proven to be extremely difficult (Nadeau & Frankel, 2000). Nevertheless, this approach is capable of bridging the gap between single gene and multifactorial approaches.

Classical methods of selective breeding, strain comparisons, and cross-breeding with lab animals as well as twins and adoption in humans can reveal interesting things about the involvement of nonspecific hereditary and environmental variation, but in themselves they cannot reliably point to any specific gene or even define the number of polymorphic genes that influence a behavior.

Three Sources of Individual Differences

Although it is often presumed that all differences between individuals emanate from heredity, environment, or a combination of the two, there are now good reasons to believe that a third source may exist that is neither hereditary nor environmental (Finch & Kirkwood, 2000; Whitelaw & Martin, 2001). Instead, interesting differences may emerge from within the developing organisms but not be transmitted to the next generation (Collins, 1985; Layton, 1976; Lupski, Garcia, Zoghbi, Hoffman, & Fenwick, 1991; Wahlsten, 1989). The influence of a third factor, referred to as the unknown factor *X* by Haldane (1938), is sometimes termed *developmental noise* or *randomness* to convey the idea that it does not show the regularities typical of genetic effects (Lewontin, 1991). The concept may be invoked in situations where genetically identical individuals are reared in unusually uniform environments but nonetheless differ markedly in phenotypic outcomes (Gärtner, 1990; Spudich & Koshland, 1976). This possibility of a third source of variation is inherent in Schneirla's (1957) concept of "circular relationships of self-stimulation in the organism" (p. 86) whereby the organism is "interactive with itself."

For example, the corpus callosum is absent in BALB/c and strain 129 mice, wherein 20% to 50% of the animals in a genetically uniform strain are clearly defective, but the other littermates are normal (Wahlsten, 1989; Wahlsten, Metten, & Crabbe, 2003). Which mouse will be missing the corpus callosum as an adult is determined prior to birth. The spatial location in the uterus of defective and normal embryos in a litter of mice exhibits a random pattern and is unrelated to a wide range of prenatal environmental variations (Bulman-Fleming & Wahlsten, 1991). Detailed studies of the growth of axons in the embryo cerebral cortex (Ozaki & Wahlsten, 1993) indicate that a distinct threshold for the formation of the corpus callosum occurs because of the relative timing of two processes: (1) growth of axons toward the middle of the brain and (2) formation of a tissue bridge leading to the opposite hemisphere. Small differences in the timing move an individual to one side of the threshold or the other, thereby generating a random distribution (Wahlsten, Bishop, & Ozaki, in press). The extent of random phenotypic variation depends on the organism's heredity as well as its rearing environment (e.g., Wahlsten, 1982), yet this third source of individual variation arises from within the developing organism and is distinct from heredity and environment.

The Nature of Heredity

Developmental behavior genetics seeks to understand the role of heredity in the development of an organism's nervous system and behavior. To address this issue, it is important to state what is meant by heredity. An entity is usually defined by contrast with what it is not. Heredity is not environment. Heredity (H) is inside the organism, whereas environment (E) is outside it. Unlike the third source that is also internal, heredity is transmissible across generations. The formula seems simple enough until one begins to dig more deeply into the data on development.

Heredity at Conception

At conception of a one-cell embryo, a clear distinction between H and E can be perceived. Heredity is everything transmitted from the parents. Every speck of matter in the embryo, the entire organism, is inherited; the chromosomes in the nucleus, the mitochondria, the endoplasmic reticulum, and other organelles in the cytoplasm, and even the cell membrane are integral parts of heredity (Ho, 1984). Environment is then the exterior, those aspects of the surroundings that impinge on the embryo but are not part of it. This definition of H and E provides an unambiguous, exhaustive partition of everything in the vicinity of the new organism. For developmental theory, it is more satisfying than the assertion that heredity consists only of DNA molecules, because this dogma leaves most of the embryo out of the picture or classifies the cytoplasm inside the embryo as part of the environment.

Even this definition of H and E at conception entails difficulties. The entire one-cell embryo is transmitted from the parents but not all of it is in turn transmissible to the next generation, and some of what is obtained from the parents was not possessed by them as heredity. Consider cases where a human embryo has an extra chromosome, such as trisomy 21 (Down syndrome) or the XYY male. These arise *de novo* during germ cell formation; they do not afflict the parent, and they are rarely passed on to the next generation. Thus, there can be a defect of the substance of heredity that is not itself hereditary. Such phenomena reveal the frailty of our attempts to impose rigid definitions on nature.

To demonstrate the importance of some aspect of heredity for development, one must raise organisms with different heredities in the same environment (see Sokolowski & Wahlsten, 2001). Similarly, the role of environment can best be revealed by raising organisms with the same heredity in different environments. It is sometimes argued (e.g., Lorenz, 1981), that depriving a bird of the opportunity to hear the song of a conspecific can prove the song is encoded in the genes if the bird sings well despite the lack of a skilled tutor. Notwithstanding the Nobel prize conferred on Lorenz, his logic was flawed (Johnston, 1988; Lehrman, 1970; Lerner, 1992). The sensory deprivation experiment tests the importance of only one specific feature of the environment that involves learning by observation, and it reveals absolutely nothing about any gene. Likewise, some psychologists argue that monozygotic (one-egg or MZ) twins reared apart can reveal the importance of genes for mental development (Bouchard & McGue, 2003). This logic is also flawed. MZ twins, having the same heredity, provide a good opportunity for evaluating effects of different environments; a difference between two co-twins could not originate in their different heredities, but concordance of the two could reflect identical H, highly similar E, or, most likely, similarity of both factors.

Studying a Difference in Heredity

There is no way to show the importance of heredity as a whole for development in general, but elegant experiments can prove that a specific difference in heredity leads to a distinct difference in development. Perhaps, the clearest demonstration is provided by a genetically pure strain of mice created by over 60 generations of mating brother and sister. At every genetic locus on all chromosomes, each animal is homozygous for the same allele. This extraordinary purity allows the researcher to produce hundreds or even thousands of mice with the same genotype. The purity is ephemeral, however; a rare, spontaneous mutation sometimes transforms one allele into a new version of the gene that does not function very well and may even lead to a gross malformation of the brain or a bizarre behavior. The mutant animal can be compared with normal siblings, and any major difference in phenotype can be attributed to a difference in a single gene. These coisogenic mice are the same at every other genetic locus. Furthermore, they are conceived in the same mother at the same time and nurtured by the same parents in the same laboratory cage.

The *diabetes* mutation (*db*) in mice originally occurred in the strain named C57BL/6Ks. It is recessive; an animal exhibits the diabetic and obesity phenotype only if it inherits two copies of the mutation, one from each parent, and has genotype *db/db.* The design of this experiment then consists of groups that differ only at the *db* locus on chromosome 4, and the 25 g difference in their body weights and elevated serum levels of glucose and insulin seem to be attributable to the difference at just one genetic locus. The logic of the experiment is clear enough: The *db/db* genotype must cause the diabetes and obesity because the genetically different siblings were conceived and reared in the same environment. Nevertheless, the phenotypic difference is environment dependent. If the *db/db* mice are "pair fed" by feeding them the same amount of food that their +/+ siblings ate on the previous day, the genetically mutant mice no longer become obese or show symptoms of clinical diabetes (Lee & Bressler, 1981). The *db* gene does not code for diabetes. Instead, the *db/db* genotype yields mice that are more sensitive to their dietary environment than their normal siblings.

The *obese* mutation (*ob*) on chromosome 6 also causes obesity and diabetes when mice are reared with free access to food in the lab, but restricting the diet of *ob/ob* mice does not prevent the symptoms of diabetes. Researchers discovered that the normal allele of the *ob* gene codes for a previously unknown protein named leptin that is synthesized in white fat cells and then circulates to the brain via the blood (Zhang et al., 1994). Administering leptin to *ob/ob* mice prevents their obesity and diabetes, but leptin has no beneficial effect on *db/db* mice. Through a series of sophisticated experiments (see Wahlsten, 1999b), it was established that the normal form of the *db* gene codes for the structure of the receptor molecule that detects leptin in the hypothalamus. The gene was renamed the leptin receptor (*Lepr*) gene, and the mutation is now expressed as an allele of that gene ($Lepr^{db}$). Likewise, we now refer to the *ob* mu-

tation as an allele of the leptin gene (Lep^{ob}). In this case, knowing how the two genes interact with each other physiologically helps to understand the specific environmental factor that is most important for the phenotypic expression of the mutant genotype. The functioning of the two genetic factors could only be comprehended by learning about their interactions with each other and the environment.

There is no human equivalent to coisogenic mice. When different alleles of a specific gene can be detected from their protein product or from the DNA itself, it is possible to compare two groups of individuals who definitely differ at a single locus, but they will not be identical at other genetic loci or in their upbringing. This heterogeneity creates a danger that the allelic difference in one gene will be correlated with some other genetic or even an environmental difference that is the effective cause of a difference in behavior. Apparently, this happened when alcoholism was found to be associated with a particular allele of the dopamine type 2 receptor (DRD2) gene. The frequency of the allele also differs greatly between ethnic groups that differ as well in the rate of alcoholism, creating a spurious correlation. When ethnically homogeneous groups were studied (Kidd et al., 1996) or diversity within a family was assessed (Wong, Buckle, & Van Tol, 2000), the association of alcoholism with the DRD2 alleles vanished.

An Operational Definition of Heredity

Defining heredity at conception appears to be reasonably straightforward, but, as development progresses, the distinction between H and E becomes less apparent (Rose, 1998). This can be appreciated by examining some of the standard methods used to manipulate and preserve variations in heredity in animals. An inbred strain is created by breeding within a family for dozens of generations. Two inbred strains maintained in the same laboratory environment differ mainly because of their ancestries, the specific parents that served as founders of the strains almost 100 years ago (Russell, 1985). Likewise, selective breeding entails mating of a male and female that both score high or both score low on some test. After only a few generations of selective mating and rearing in the same laboratory, the high and low lines usually diverge substantially, thereby revealing that at least part of the original phenotypic variation in the foundation population may reflect hereditary differences.

Consider an easily measured phenotype, the size or weight of the adult brain. Inbred strains differ considerably, ranging from 410 mg for DBA/2J to 520 mg for BALB/cJ (Wahlsten, 1983). Brain size is an outcome of development; it is not encoded in the DNA and it is strongly influenced by nutrition. If the DBA/2J and BALB/cJ strains differ in brain size by about 100 mg, it may seem reasonable to attribute this phenotypic difference to their different heredities if they are reared in the same environment. What is meant by heredity in this context?

The term *heredity* is used in two ways in the scientific literature. One invokes the dogma that all heredity consists of genes or DNA molecules, which requires that any phenotypic difference between strains be deemed genetic. The other invokes an operational definition; if the strain difference reflects a difference in heredity, then heredity in the particular experiment includes *everything that actually differs between the strains*—everything except the laboratory environment they share in common. This latter approach is very much a developmental one because it takes into account all of the factors that could reasonably influence the development of the brain.

Non-Mendelian Heredity

The DNA molecules in the chromosomes (both the autosomes and sex chromosomes), as well as those in the mitochondria of the cytoplasm, are important components of heredity. The autosomes in the cell nucleus are transmitted via the laws of Mendelian inheritance, whereas the genes resident in the mitochondria are transmitted solely via the female. Neurological disorders from defective mitochondrial DNA, such as Leber's optic neuritis in humans, can affect both the male and female offspring but cannot be transmitted via the male (e.g., Wallace et al., 1988). The different mtDNAs carried by certain strains of mice can influence several kinds of behavior (Roubertoux et al., 2003). Another kind of inheritance from parent to offspring involves DNA or RNA of viral origin. Mouse leukemia virus is passed to the embryo via the ovum, and mouse mammary tumor virus is bequeathed to the neonate postnatally through the milk (Grun, 1976). Many strain-specific cancers in mice are transmitted "vertically" from parent to offspring rather than "horizontally" between nonrelatives. These non-Mendelian hereditary factors also interact with the host genome; they more readily infect, proliferate, and transmit to offspring in some strains than in others. Unless special experiments are done, the strain-specific viruses endure for many generations and appear as an integral part of heredity. For example, the C3H/HeJ strain of mice has carried the mouse mammary tumor virus since its inception in 1920, but in

2001 the staff at the Jackson Laboratory eliminated the virus from this strain by fostering newborn mice to lactating females free from the virus (http://jaxmice.jax.org/info/bulletin/bulletin07.html).

The embryo of a certain inbred mouse strain develops in a uterine environment of that strain, and this can contribute to apparently hereditary differences between strains. After birth, the neonate drinks the milk and lives in a nest provided by a female of the same strain. All its social interactions from an early age are with mice of the same strain. Although these features are undoubtedly environmental, they differ substantially between inbred strains and can cause strain differences in the brain or behavior. Viewing the maternal environment as a part of heredity may seem like an unfortunate confusing of two distinct concepts. Nevertheless comparisons of inbred strains and selectively bred lines that we ordinarily regard as demonstrating effects of heredity do entail differences in maternal environment. Either the maternal milieu is part of heredity in these simple experiments, or strain comparisons cannot by themselves prove the importance of a difference in heredity, let alone a genetic influence. It may be argued that ultimately the maternal environment itself depends on strain-specific genetic activity. Undoubtedly, the mother's uterine environment depends in many ways on her genotype as well as her own environment, and her environment in turn has depended on the grandmother's genotype and maternal environment. From the standpoint of individual development, however, the mother's influences on embryonic development via the genes passed to the new organism and via the uterine environment are quite distinct. The genetic part of heredity exists in the embryo's interior; the maternal environment impinges on its exterior. Because of the confounding of the embryo's genotype, its cytoplasm, and its prenatal environment, most of the commonly employed research designs with standard strains or lines of laboratory animals cannot prove that a strain difference in phenotype arises solely from a difference in genes located in the nucleus of the zygote.

Dissecting Heredity

Whether a particular component of heredity is important for a specific phenotypic difference between strains can only be ascertained with experimentation. Reciprocal hybrid crosses, F_2 hybrid crosses, and backcrosses can demonstrate the contributions of autosomes, sex chromosomes, mtDNA, cytoplasmic organelles, and maternal environment (Roubertoux et al., 2003; Sokolowski & Wahlsten, 2001). Using these methods, it has been shown that F_2 hybrid mice develop faster than inbred mice partly because they benefit from a superior hybrid maternal environment (Wahlsten & Wainwright, 1977), and that BALB/c mice have large brains partly because of the BALB/c maternal environment (Wahlsten, 1983). The importance of the prenatal maternal environment can be assessed by grafting the ovaries of either of two inbred strains into an F_1 hybrid female, then fostering to a surrogate mother at birth (Carlier, Nosten-Bertrand, & Michard-Vanhée, 1992). Carlier, Roubertoux, and Pastoret (1991) combined the reciprocal crossing and ovarian grafting methods and found that the reciprocal hybrid crosses developed differently in inbred and F_1 hybrid maternal environments. Thus, there can be interactions between different components of heredity, and it is generally not meaningful to state that a certain percentage of a strain difference is simply attributable to each component of heredity, such that the percentages add to 100%.

Separating the Effects of Heredity and Environment

From its inception, developmental psychology has been keenly interested in the role(s) of heredity (H) and environment (E). Numerous methods have been devised to separate their effects both experimentally and statistically. At the same time, many theorists regard these two entities as fundamentally inseparable. The naturalist John Muir (1911/1967) expressed the holistic doctrine admirably when he taught: "Whenever we try to pick out a thing by itself, we find it hitched to everything in the universe." Developmental systems theory also emphasizes relationships between things, and it attributes the properties of a living system to the dynamic interactions among its parts and between different levels (Figure 5.8; Ford & Lerner, 1992; Gottlieb, 1992; Johnston & Edwards, 2002; Oyama, 1985).

Separating heredity and environment may appear to be a rather easy task from the standpoint of a reductionist theory because the parts of a system are held to possess inherent and intransigent properties that can be added up to characterize the whole organism (the whole equals the sum of its parts). For developmental systems theory, however, the boundaries drawn for convenience at one moment are expected to become somewhat fuzzy and transient as development proceeds (Moore, 2001; Rose, 1998). Given a competent embryo in an adequate

environment, the organism will differentiate, assimilate its environment, and grow. The question of whether H or E is more important for its development is nonsensical because both are absolutely essential. An embryo without an environment is inconceivable.

Heritability and Additivity

The logic of the simple two-group experiment with coisogenic mice is inscrutable. Because all else seems to be equated, must not the precise numerical magnitude of the difference between group mean scores be attributed solely to the genetic difference? In reality, this inference will be valid only in one situation: when the effects of H and E are strictly additive. If the value of the phenotype is indeed the arithmetic *sum* of components attributable to H and E, then the difference between the group mean phenotypes equals the difference between the group values of H, irrespective of the value of E, as the logic of the experiment implies. If the two factors are not additive and are multiplicative instead (a form of H × E interaction), the group difference in mean phenotypes depends on the difference in H values as well as the specific value of E (see Figure 5.9). Thus, although the magnitude of the difference in heredities is certainly of critical importance under either situation, when H and E are not additive the observed group difference depends just as much on the one environment chosen for the study as it does on the two genotypes, and the observed group difference is then specific to the environment common to all subjects in the study.

A simple two-group experiment cannot reveal whether H and E are additive or not. Some kind of factorial design is required to test for the existence of interaction or interdependence of H and E (Sokolowski & Wahlsten, 2001). The crucial point is that nonadditivity of H and E will have major consequences for the numerical results of the two-group experiment, even though the interaction effect cannot be perceived in the data when only one factor is manipulated. The elegant study of coisogenic mice reared in the same laboratory environment is an excellent method for demonstrating the importance of a difference in heredity, but, in principle, it cannot truly separate the effects of heredity and environment quantitatively if they are not separable developmentally.

The same considerations apply to any study of environment with a single inbred strain; the results may illustrate a genotype-specific reaction to environment, but there is no guarantee at all that its shape will be the same for other strains. When there is heredity-environment

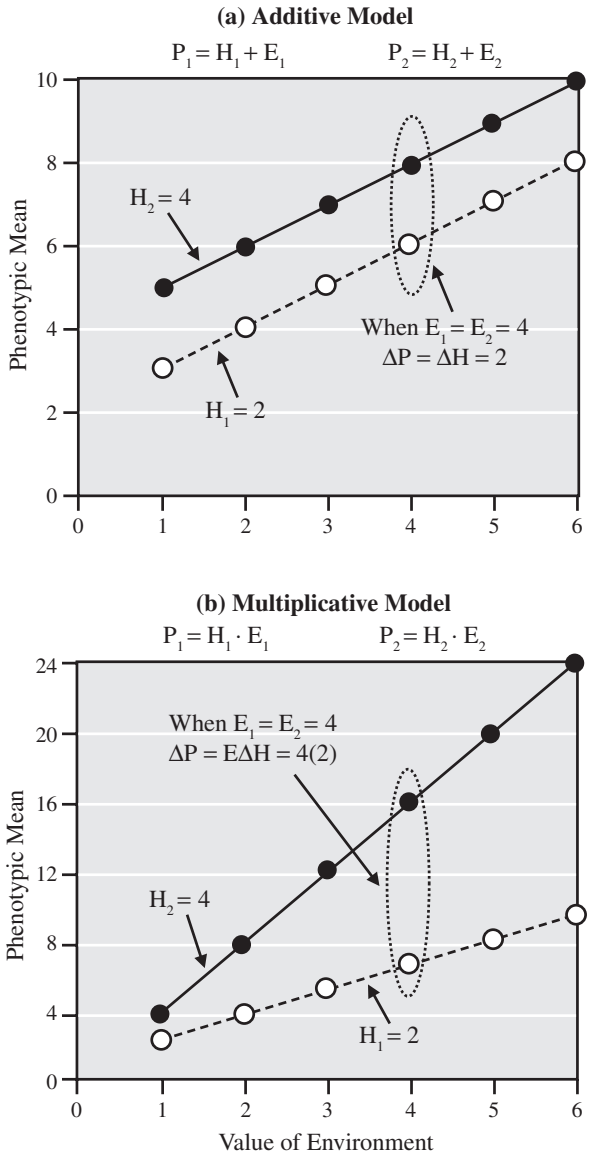

Figure 5.9 Two models of the quantitative relation between hereditary (H) and environmental (E) factors that jointly determine the magnitude of the phenotype (P). Independent groups of animals from strains 1 and 2 are reared in six environments having values spaced equally apart. (A) In the additive model, the difference between strain means is 2 units in every environment. (B) In the multiplicative model, the difference between strain means depends strongly on both H and E values, such that under environmental conditions where E = 4 units, the strain difference is 8 units. If an experiment involves two strains reared in only one environment, the data may appear to indicate that the strain difference is a result purely of the genetic difference. Nevertheless, in the presence of gene-environment interaction, the size of the difference depends on both H and E.

interaction, the degree of apparent heritability of some characteristic depends on the specific rearing environment, and the environmental plasticity depends on the organism's heredity, whether or not the experimental design is capable of revealing this (Wahlsten, 1979).

Numerous factorial experiments involving genetically different strains reared under different conditions have been done with fruit flies, rats, and mice. After a thorough review of the available literature on mice, Erlenmeyer-Kimling (1972) concluded that "gene-environment interactions are numerous and treatment effects are frequently reversed in direction for different genotypes" (p. 201). Since then, many other dramatic demonstrations of nonadditivity have been published. Consider the results of an experiment by Hood and Cairns (1989) with two strains of mice that had previously been bred selectively for either high or low frequency of fighting when reared in isolation. They then reared the strains either in isolation or in social groups

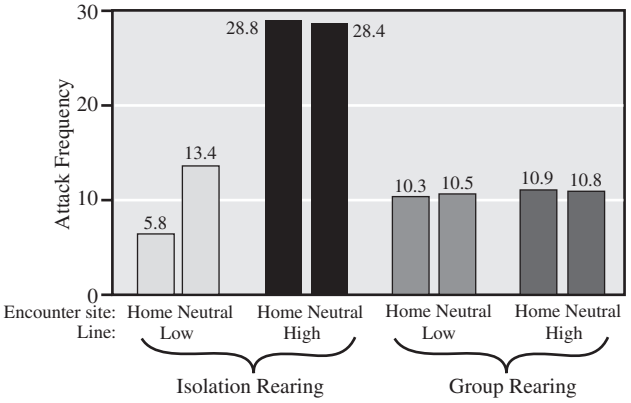

Figure 5.10 Mean attack frequency against an intruder mouse by males of two selectively bred lines of mice reared after weaning either in isolation or in social groups. The encounter took place in either the test male's home cage or a neutral location. Encounter site had no appreciable effect on test results. During the original selective breeding experiment, males were reared in isolation prior to testing, and again in this experiment there was a very large line difference when mice were reared in isolation. When males were reared in social groups with other males of the same line, however, the attack frequency of high line males was greatly reduced, and a difference between selectively bred lines was no longer apparent. The heredities of the mice had not been changed by rearing conditions, but the hereditary difference between lines was no longer manifest in behavior under social housing conditions. *Source:* From "A Developmental-Genetic Analysis of Aggressive Behavior in Mice: Pt. 4. Genotype-Environment Interaction," by K. E. Hood and R. B. Cairns, 1989, *Aggressive Behavior, 15,* pp. 361–380.

(see Figure 5.10). The strain difference was very large with isolated mice, which typically were much feistier, but disappeared when the animals were reared socially in groups. Thus, there is no *general* sense in which one can say that one of the strains is more aggressive than the other.

When there is H x E interaction, the strain-specific norms of reaction will differ. However, it does not follow that the norm of reaction is itself genetically encoded. The most we can claim is that a *difference* in the two norms of reaction results from a *difference* in heredity when the strains are reared in the same environment until the time in life when the experiment with different environments begins.

The norm of reaction, which is characteristic of an entire organism carrying thousands of genes through a multifaceted environment, can itself be modified by the environment and is not determined exclusively by the genotype. For example, when the ovaries of an inbred BALB donor mouse are grafted into either a BALB or an F_1 hybrid female and then the host female is mated with a BALB male, embryos and later neonates that are all genetically BALB can be observed in two maternal environments (Bulman-Fleming & Wahlsten, 1988). Adult brain size depends on litter size prior to weaning; mice from larger litters have smaller average brain size. Litter size is an environmental factor because inbred mice from smaller and larger litters are the same genetically, but the slope of this norm of reaction is steeper in the inbred than in the hybrid maternal environment (Figure 5.11).

The typical heritability analysis that is so familiar in quantitative behavior genetic studies of human traits attempts to assess the percentage of phenotypic variance in a population that is attributable to genetic variance. This analysis assumes that there are many genes with small effects, scattered widely across the chromosomes, and that they combine additively with each other (no gene-gene interaction) and with the environment (no H x E interaction) to determine the phenotype of an individual. However, these assumptions are not consistent with current knowledge from molecular and developmental biology (Greenspan, 2004; Sokolowski & Wahlsten, 2001; Wahlsten, 1994). Furthermore, the presence of real H × E interaction can markedly alter the estimation of parameters in a statistical model that assumes the absence of interaction (e.g., Tiret, Abel, & Rakotovao, 1993; Wahlsten, 1990), while effects of the prenatal maternal environment can substantially effect the apparent degree of "heritability" in a twin study (Devlin, Daniels, &

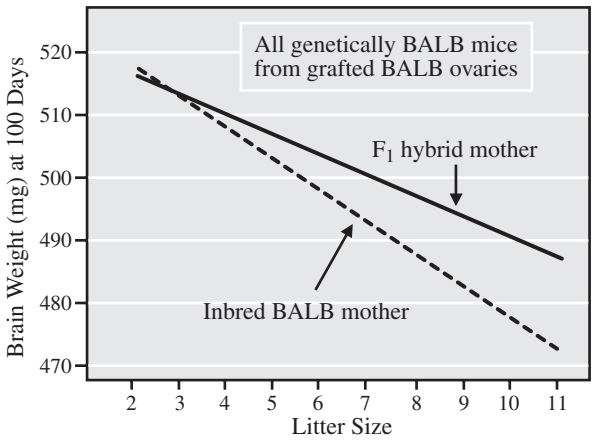

Figure 5.11 Brain weight in 100-day-old mice from the highly inbred BALB strain. All were derived from BALB ovaries grafted into a host female who was later mated with a BALB male. The host female was either a genetic BALB or a hybrid between BALB and the C57BL/6J strain. Hybrid mice are markedly superior to inbred mice in their reproduction and nurturing of offspring. For both kinds of mothers, mice from smaller litters had substantially larger adult brain size. The slope of the linear norm of reaction that expresses the environmental effect on brain growth was itself dependent on the maternal environment. Inbred mothers were relatively less capable of nurturing larger litters. *Source:* From "Effects of a Hybrid Maternal Environment on Brain Growth and Corpus Callosum Defects of Inbred BALB/c Mice: A Study Using Ovarian Grafting," by B. Bulman-Fleming and D. Wahlsten, 1988, *Experimental Neurology, 99,* pp. 636–646.

Roeder, 1997). It is even possible to devise a plausible model lacking any genetic variation at all that shows high "heritability" with conventional quantitative genetic analysis (Guo, 1999).

Documenting the Norm of Reaction

With an inbred strain, dozens of animals having the same genotype can be randomly assigned to several different rearing conditions. The C57BL/6J strain is not usually obese, but rearing them on a diet high enough in fat can cause obesity and physiological diabetes, as indicated by greatly elevated blood glucose and insulin (Surwit, Kuhn, Cochrane, McCubbin, & Feinglos, 1988). Although insulin levels are strongly modified by diet in C57BL/6J mice, other strains are far less sensitive to dietary fat. C57BL/6J mice are usually not vulnerable to seizures induced by a loud noise, but when they are exposed to a priming noise at one of 15 different ages, it is found that exposure on any day from 14 to 20 days of age leads to severe sound-induced seizures at 28 days of age (Henry & Bowman, 1970), whereas DBA/2J mice tend to seize without priming (an example of equifinality). The degree of paw preference in the C57BL/6J mouse strain can be substantially altered when they must reach for food in an asymmetrical environment, whereas mice of the CDS/Lay strain tend to work with the preferred paw and resist the pressure to switch (Biddle & Eales, 1999).

When many different environmental conditions are examined, an extensive profile or norm of reaction can be documented (see Gottlieb, 1995; Platt & Sanislow, 1988; Sarkar, 1999). The norm of reaction expresses phenotype as a function of environment for a specific genotype, and a complete norm of reaction for one genotype would involve variation along many relevant dimensions of environment. When the profiles of reaction to different environments differ among individuals having different genotypes, this demonstrates gene-environment interaction. If the norms of reaction are virtually the same for two genotypes, alternatively, genes and environment could nevertheless interact intimately in a physiological sense, even though the data set would not show gene-environment interaction in the statistical sense.

Replicated genotypes are essential for documenting a genotype-specific norm of reaction. An elaborate environmental experiment of this kind is not feasible with most organisms that have not been highly inbred, but a norm of reaction can sometimes be defined as an average across genetically different individuals, provided random assignment to condition is employed. For example, wild alligator eggs taken from the same clutch and incubated in a laboratory at six different temperatures revealed that above 32 degrees C all become male, and below 32 degrees C all become female (Ferguson & Joanen, 1982). Temperature dependent sex determination is widespread in reptiles, and different species have different critical temperatures for switching to the male or female pathway (Bull, 1983; van der Weele, 1995).

Random assignment of human volunteers to different treatment conditions could potentially reveal an averaged norm of reaction, because random assignment insures that group differences are not correlated with genetic differences (Blair & Wahlsten, 2002). That is, good research on mild environmental effects can be done without genetic homogeneity among the subjects. In this case, however, the variability within treatment conditions will reflect both genetic and environmental differences among individuals. The profile of group

average scores may be thought of as an average of numerous individual norms of reactions, whereas the within-group variance reflects departures of individual norms of reaction from the group average (Figure 5.12). This interactionist perspective on designed experiments conflicts with the usual analysis of variance (ANOVA) model used to evaluate the results statistically. We expect that individuals in the same treatment group will differ in their response to the experimental treatment, partly because of their genetic differences, whereas the ANOVA model posits that all individuals in a group are affected equally by a treatment and individual differences within a group arise from things that are independent of treatment.

Separating Heredity and Environment in Humans

The basic ideas of the norm of reaction and heredity-environment interaction apply to any species: protozoa, insects, vertebrates, and even plants. Human beings have no special properties that render heredity and environment additive. Nonetheless, it is often claimed by quantitative behavior geneticists that twin and adoption studies can separate the effects of H and E. The assertion that the adoption method can effectively separate H and E presumes that the prenatal environment is of no account for individual differences or that the uterine environment of all women is virtually the same. This is not at all realistic (Boklage, 1985; Lerner, 1995, p. 152). The state of the mother's health and nutrition during pregnancy has a major impact on the brain development of the fetus, and every mode of sensory experience except vision is active in the fetus during the last trimester of human pregnancy (e.g., Busnel, Granier-Deferre, & Lecanuet, 1992; DeCasper & Spence, 1986; Gottlieb, 1971b). Precisely how significant each of these effects may be in the context of an adoption study cannot be determined when rigorous control of conditions is lacking. Prior to being separated from its biological parent(s), the fetus and then the child lives in an environment provided by its genetic benefactors. Consequently, the adoption method cannot conclusively separate the effects of H and E.

In some situations, adoption provides an excellent means to study differences in the postadoption environment. For example, Schiff, Duyme, Dumaret, and Tomkiewicz (1982) compared school performance and IQ test scores of French siblings who had the same poverty-stricken mother; one or two children were adopted into a high socioeconomic status (SES) home, while another child remained with the mother. The mean IQ of the adoptees was elevated by 16 points. The two groups had

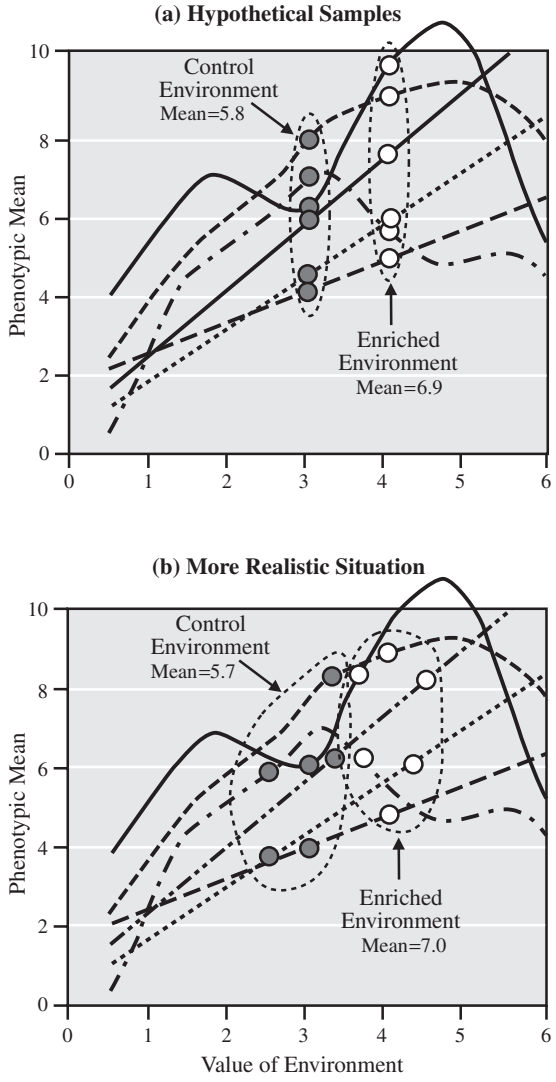

Figure 5.12 Test scores for six individuals under two environmental treatment conditions when the shape of the norm of reaction relating test score to environment is different for each genetically unique person. (1) If each person in a group is indeed exposed to exactly the same amount of environment, it is evident that environmental enrichment will have different magnitudes of effect on different individuals. Some might even do worse than under the control condition. Group means would then be averages of points on several different norms of reaction. (2) It is more likely that people in a particular treatment condition would not experience exactly the same value of environment, although values under the enriched condition would generally be higher. Nevertheless, group mean test scores would differ under the two conditions.

substantially different postadoption environments but were matched for many factors acting prior to adoption. Capron and Duyme (1989) employed the same approach to conduct a 2×2 factorial study of pre- and postadoption SES in relation to later IQ. Contrary to the opinion that

their study effectively separated H and E (McGue, 1989), the authors explicitly recognized that preadoption H and E were confounded.

Outstanding control of heredity can be achieved in humans with genetically identical monozygotic (MZ) twins, but separation of the effects of H and E is not possible because MZ twins share a common prenatal and early postnatal environment. When MZ twins are reared in different homes, there may be an opportunity to assess the plasticity of behavior, provided the environments are sufficiently dissimilar to make the test reasonably powerful. Unfortunately, for research, the environments of "separated" MZ twins are often quite similar because they are reared in branches of the same family, in the same neighborhood, or in similar SES homes in the same culture (Farber, 1981; Taylor, 1980). Comparison of MZ twins reared apart clearly points to the importance of nongenetic factors when the twins are substantially different; but when they show a close phenotypic resemblance, it is usually not possible to know why. A high correlation of test scores of MZ twins reared apart provides support for the hypothesis of a strong genetic influence on behavior but cannot prove it true.

Comparing MZ versus dizygotic (two-egg, or DZ) twins reared in the same home involves a similar confounding of H and E. The heredities of MZ twins are surely more similar than those of DZ twins, and so are their environments. Consequently, the elevated phenotypic correlations of MZ twins very likely reflect their common experiences to some unknown extent (Hoffman, 1991). Precisely what fraction of an observed correlation is attributable to nongenetic similarity cannot be determined unless psychologists provide a good measure of the environments that are specifically pertinent to the development of the behavior being studied (Wachs, 1992).

Thus, the adoption and twin methods provide useful and well-controlled situations for studying environmental effects on development, even though they cannot cleave precisely the effects of heredity and environment. Adoption and twin studies can provide evidence suggestive of genetic effects on behavior, but the only conclusive way to prove a genetic effect on human behavior is through linkage analysis, whereby behavioral variation in a family is highly correlated with alleles at a marker locus occurring at a specific location in the DNA of a chromosome. Numerous genes with a major impact on human mental development have been mapped to specific chromosomal loci, and these are typically quite rare in the population because their effects are often devastating. Those hypothetical loci with more subtle effects in the normal range of human behavioral variation remain elusive, despite much searching by intrepid gene hunters.

The Scope of Gene-Environment Interactions

Heritability analysis is constructed on a foundation of additive models that presume genetic and environmental effects are biologically separate and statistically independent. Yet, molecular genetic research has established beyond doubt that the actions of numerous genes are regulated by environmental conditions (Gottlieb, 1998). Well-controlled experiments with various species of plants and animals have shown many times over that sensitivity to environmental change is genotype dependent (norm of reaction) and that the consequences of allelic variation at one genetic locus can be understood only in relation to genes at other loci (epistasis or gene-gene interaction). As Nijhout (2003, p. 418) trenchantly observed: "everything we know about the mechanisms by which genes affect traits suggests that a simple additivity hypothesis must be wrong." Genes affect other things and are themselves affected as parts of a multidimensional, nonlinear biological system.

In the search for single genes that are important in medical and psychiatric disorders, the interactionist perspective is proving to be fruitful and has gained widespread credibility. In an editorial in *Science,* Brenner (2003) looked forward to a future when "those who have a genetic background that makes them especially liable to one of the diseases of our civilization will have to learn how to take extra care." It is now recognized that the search for major genes involved in complex disorders is especially difficult because "multiple genes and their interaction with each other and with the environment are involved" (Edenberg et al., 2004). A recent study of depression placed the hypothesis of gene-environment interaction in the forefront of their study and discovered that people carrying the short allele in the promoter region of the serotonin transporter gene (5-HTTPR) were more likely to develop depression when they experienced several stressful life events, whereas those with the long allele were less likely to become depressed even when under considerable stress (Caspi et al., 2002). The idea of interaction can even be found in the popular press, for example, a report relating a higher risk of later schizophrenia in fetuses exposed to maternal flu during gestation speculated this would occur only "in a small number of genetically susceptible fetuses" (Tanner, 2004).

Nevertheless, additive models continue to be the stock-in-trade in the quantitative genetic analysis of human behavior and cognition. The principal rationale for this countercurrent is that, while probably real, gene-environment interactions are so small statistically that they can safely be ignored. It has been claimed that tests of H × E interaction pertinent to human psychological characteristics have been tried but consistently failed to find any such effects (Detterman, 1990; Plomin, 1986). In reviewing twin studies on alcoholism that sought to assess interaction, Heath and Nelson (2002) observed that "few studies have been able to document the importance of such effects." Scarr (1992) argued that interactions are commonly observed in research with lab animals because strong environmental treatments are employed that are outside the normal range of variation, whereas interactions over a more moderate range of environments are generally too small to be of concern to the theoretician.

There are three issues involved in these pleas. First, because there are no sources of humans with identical genotypes that can be assigned to different environments, the presence or absence of H × E interaction in studies of human mental abilities is effectively unverifiable. Second, the usual two-way analysis of variance methodology that is used to test for interaction is markedly insensitive to several kinds of real interaction that would be of interest to psychologists, and the sample sizes required to search for interaction effects with adequate power are usually far greater than those commonly employed in research (Wahlsten, 1991, 1999a). Third, there is the question of the reality of interactions when environmental variations are modest and entirely normal.

In experiments combining two or more factors, the hypothesis of interaction is tested against the null hypothesis of an additive relationship. Statistical power of the test is the probability that the additive null will be rejected when there really is an interactive, nonadditive relationship. It has been shown that, for many kinds of interaction that might reasonably be expected in research on behavior, the power to detect an interaction is far lower than the power to detect the main effects of heredity in an analysis of variance (Wahlsten, 1990). The power of a statistical test depends strongly on the number of individuals observed in the study; more subjects yield greater power. It seems that researchers often employ too few subjects to make a test of interaction effects credible, and claims of no visible interaction are often based on wholly inadequate data.

The extent of the problem can be seen with a simple study where two strains of animals are reared in two environments. Suppose that the true group means are as in Figure 5.13. Both heredity and environment have important effects, but the effect of the environmental treatment on strain B is twice as large as the effect on strain A. Doubling a treatment effect is noteworthy and we would like to be able to detect this magnitude of interaction effect. If we set the probability of a Type I error (false positive) at 0.05 and want power to be 90%, the method of Wahlsten (1991, 1999a) reveals that the experimenter would be well advised to employ seven individuals per group if the only serious concern is the presence of main effects but would require 44 per group to be able to detect the interaction effect with the same degree of power. For this specific example, six times more subjects would be needed to detect a substantial interaction. Calculations of this kind should inspire us to ask when colleagues say they have searched for gene-environment interactions but could find none: What kind of interaction were you seeking and what was the power of the test? Did you use enough subjects to make the test credible?

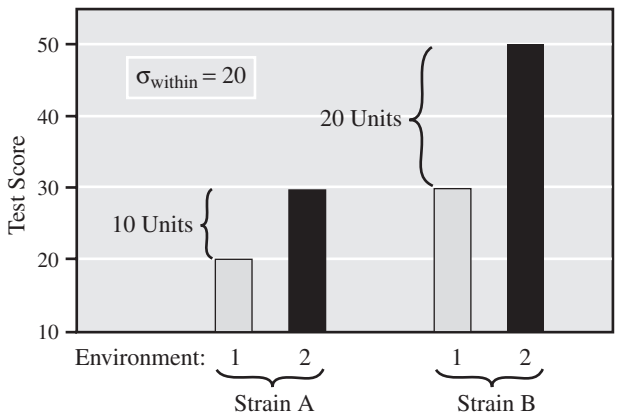

Figure 5.13 Example of heredity-environment interaction where two strains are reared in two environments. The environmental effect is 10 units for strain A but twice as large for strain B, such that the strains differ by 10 units in environment 1 but 20 units in environment 2. Relative to the standard deviation within a group (20 units), the environmental effect size is 0.5 for strain A and 1.0 for strain B. This is a substantial interaction that ought to be detectable in an experiment, and sample size should be chosen to confer adequate power on the test of the interaction effect. As explained in the text, the sample size needed to detect the interaction is about six times larger than the number of animals needed merely to detect the main effect of strain or environment at the same level of statistical power.

The question of interaction effects when environments are confined to the normal range has only been addressed recently in animal research. It is quite true that most studies in neural and behavioral genetics apply strong environmental treatments to substantially different genetic strains to maximize the likelihood of seeing real effects. Recent concerns about the replicability of experiments across laboratories have inspired systematic evaluations of the importance of everyday, ubiquitous variations in how we raise and test our animals in different labs. In these studies, serious efforts were made to minimize environmental differences. Crabbe, Wahlsten, and Dudek (1999) even implemented simultaneous shipping, breeding, and testing of animals in three labs. Nevertheless, strain differences on tests of open field activity and cocaine activation but not ethanol preference were significantly related to the lab where the experiment was conducted (see Wahlsten, Metten, Phillips, et al., 2003). One ineradicable difference among animal testing labs is the technician who administers the test, surely a mild environmental treatment but potentially important nonetheless. In an analysis of data on pain reactions in various strains of mice over a period of 8 years, Chesler, Wilson, Lariviere, Rodriguez-Zas, and Mogil (2002) found that the largest effect on pain sensitivity, larger than even the genetic effects, was indeed the technician giving the test!

Interactions do occur when environments differ only moderately but are unlikely to be detected statistically unless adequate samples are studied. Just as in the cosmos where dim objects require powerful telescopes to be perceived from Earth, statistically small effects in factorial designs demand larger samples to ensure they are visible above the level of unexplained, seemingly random variation within treatment groups.

The Hardware-Software Distinction

Additivity of effects of genes and environment presumes that the two things act separately in the process of development. A theory, often implicit but sometimes explicit, of how this might occur asserts that genes code for brain structure (the hardware) whereas experience stores information (software) in this inflexible matrix of prewired connections. The electronic computer thus serves as a convenient metaphor for the G + E formulation.

The hard-soft distinction originates in early theories of genetics and mental ability. Bateson (1913) held that Mendelian unit-characters or genes are the "fundamental elements, and consequences of environmental interferences are subordinate to them," and he claimed that nongenetic variability among individuals is "due to interference which is external." Spearman and Burt in psychology explicitly connected heredity with brain structure. Spearman (1904) asserted the existence of *natural innate faculties* and argued that "all such individual circumstances as after birth materially modify the investigated function are irrelevant and must be adequately eliminated" mathematically. Cyril Burt (1909) maintained of intelligence that "we may eventually seek the psycho-physical basis, underlying this capacity, in a particular characteristic of general neural constitution; the accentuation of such a neural characteristic would then produce the type of mind known as intelligent, while its biological inheritance would form the condition of the transmissibility of the mental trait" (p. 169). More recently, the ethologist Konrad Lorenz (1965) held that genes provide a "genetic blueprint" for the structure of the brain. The quantitative behavior geneticist Wilson (1983) wrote that "the brain is the ultimate structure underwriting human behavioral development" and its "precise wiring is coded in the DNA" (p. 10). The behavior geneticists Scarr and McCartney (1983) claimed that: "Maturational sequence is controlled primarily by the genetic program for development. In development, new adaptations or structures cannot arise out of experience per se" (p. 424).

The theory of a genetically hard-wired brain was proposed before the basis for neural connections and transmission was understood and prior to the emergence of modern neuroscience. The existence of neural plasticity in early ontogeny has been widely accepted for some time (Harris, 1981), but only in the past 2 decades has the notion of rigid adult brain structure been subjected to rigorous experimental tests. It is now well established that the synaptic connections in the cerebral cortex are substantially dependent on and altered by sensory and motor experience (Black & Greenough, 1998; Purves, 1994). According to Greenough, Black, Klintsova, Bates, and Weiler (1999), there is a multifaceted "brain adaptation" to experience even in mature individuals. New synapses can be added in mere hours while older, less active ones are eliminated (Kasai, Matsuzaki, Noguchi, Yasumatsu, & Nakahara, 2003). Synaptic turnover and changes in synaptic spine density are thought to be crucial for learning and memory (Rampon & Tsien, 2000). Gene expression arrays reveal that numerous genes related to "formation of new synapses and

reorganization or strengthening of existing synapses" are induced by even a few hours of enriched experience in mice (Rampon et al., 2000). Not just the synapses but even entire neurons are generated or eliminated in the brain as a function of early experience (Bredy, Grant, Champagne, & Meaney, 2003) and in the adult brain (Greenough, Cohen, & Juraska, 1999; Jessberger & Kempermann, 2003; Kempermann & Gage, 1999).

A rigid distinction between hardware and software may be essential for electronic computers, but this distinction does not fit with what is known about brain development and function. Experience alters brain structure. Genes do not code for brain structure or any other physical structure, but the actions of genes in response to events in their surroundings are crucial for the emergence of structures. At the same time, brain is not formless putty on which experience imposes structure arbitrarily. How a new experience alters the brain depends on the organism's heredity and the succession of prior experiences. Once the theorist concedes that genes and environment do not have separate actions in development, a credible theory of biologically additive effects is difficult to conjure.

Implications of the New Molecular Biology

Powerful new molecular techniques for the study of development have inspired some to proclaim that a scientific revolution is happening. Developmental psychology emerged and matured as a scientific discipline long before the era of molecular genetics. It is therefore important to assess whether modern molecular genetics challenges key developmental concepts and demands their revision. Our conclusion is that molecular biology confirms rather than negates ideas such as bidirectional causation and gene-environment interaction. Indeed, molecular investigations have now revealed in great detail the inner workings of interactions that previously were evident only at the level of the neural or behavioral phenotype.

The molecular revolution in biology has brought several major technologies to the experimenter's workbench:

- The sequence of nucleotide bases in the DNA of any organism can now be decoded readily, and the complete genome sequence has been ascertained for several species.
- The simultaneous expression of thousands of genes in mRNA can now be detected in small pieces of tissue from individuals of different ages under different environmental conditions.
- Knowing the DNA structure of any gene, special molecular probes can be used to disable it.
- Thousands of small and phenotypically neutral DNA polymorphisms have been identified that greatly facilitate the discovery of genetic variants that may be important for behavioral variation.

Taken together, these methods have revealed a staggering degree of complexity in living things. While many phenomena of limited scope have been beautifully illuminated with new techniques, the larger portrait of life remains unclear.

The Gene Tally

Intensive, expensive, and largely automated procedures have been devised to determine the DNA sequence of several organisms, including humans and mice that are central to concerns of developmental psychologists. Once the entire DNA sequence was determined, a vast cornucopia of new genes spilled onto the analyst's desktop in one surge. One profound complication to emerge from this work concerns the nature of the gene itself. Not too many years ago, it was widely assumed that knowledge of the DNA sequence would uncover all genes and the structure of each gene would specify the protein for which it codes, thereby telling us a great deal about its function. Now, we realize that the mRNA transcript from a gene can be spliced together and translated into more than one protein (Keller, 2000; Rose, 1998). It is also apparent that many other genes are intimately involved in regulatory processes but do not code for proteins as such. Furthermore, the vast majority (98%) of human and mouse DNA consists of noncoding DNA (introns) that does not specify protein at all; its function remains a mystery. These and other puzzling facts have generated uncertainty about precisely how many genes are embedded in the entire DNA sequence of a species. The initial estimate in February of 2001 for protein encoding genes in humans was 31,778, but this was scaled back to 22,808 by September of 2002. The 2001 tally indicated that more than half of the genes were entirely new to science at the time. In 2003, the best estimate was set at 24,500, but researchers "admitted they were nowhere near establishing a final count" (Pennisi, 2003) and cautioned that several thousand of these might be pseudogenes that look like a gene at the DNA level but

are silent and never become expressed in protein. Furthermore, an alternative and sophisticated approach to gene counting suggested the total could be as high as 45,000. In October of 2004, the International Human Genome Consortium (2004) reported progress on assembling the DNA sequence and conservatively set the likely number of protin-encoding genes at between 20,000 and 25,000. The history of assembling the human genome and the latest estimates are available at the Ensembl Human web site (http://www.ensembl.org/Homo_sapiens/index.html).

When the genome sequence of the laboratory mouse was completed (Mouse Genome Sequencing Consortium, 2002), there were 22,011 stretches of DNA that looked like a gene, but researchers cautioned that some genes "are missing, fragmented or otherwise incorrectly described, and some predicted genes are pseudogenes or are otherwise spurious." What was abundantly clear was the great similarity of the human and mouse genome resulting from homology or descent from a common ancestor. Fully 99% of mouse genes also exist in humans, and in many long regions of a chromosome, amounting to about 90% of the total genome, the linear order of genes seen in mouse is identical to the order evident in humans.

Mouse-human homology at the gene level provides strong support for the use of lab mice as experimental models of many human genetic disorders, but caution is warranted. The Mouse Genome Sequencing Consortium (2002) identified 687 mouse genes that were highly similar to human genes where mutant forms are known to be important for medical diseases. The surprise was in the fine details of the sequence for each gene. The specific form (allele) of a gene causing disease is usually rare in the human population because it reduces reproductive fitness, while the normal allele predominates. For several human genes where the sequence of the disease-producing allele has been determined, the normal allele in the mouse is the same as the mutant form in humans, yet the mice are healthy. These include familial Parkinson's disease, cystic fibrosis, Becker muscular dystrophy, and Crohn's disease. This finding demonstrates the importance of the developmental context of a gene. One species' genetic disaster may be another species' sustenance.

The vast number of genes is itself exceeded several fold by the rich diversity of proteins, which number in excess of 1 million kinds in humans (Anni & Israel, 2002). A gene in mammals typically consists of several exons whose DNA codes for the sequence of amino acids in a protein, and the exons are separated by long stretches of DNA called introns that do not code for amino acids. After the RNA is transcribed from the gene, the intronic portions are removed in the cell and the RNA from the exons is spliced together before being translated into a protein. This splicing can be done in several ways, however. In some cases, all the exons are represented in the sequence, but it often happens that one or more exons are not included in the final mRNA. By making use of various combinations of exons, the cell can generate more than a dozen functionally different proteins from just one gene.

In addition, each protein has the capacity to interact with other proteins. Many kinds of protein have been shown to interact significantly with five or more other proteins in *Drosophila,* resulting in a huge and intricate network of interactions (Giot et al., 2003). Although genes contain DNA that is relatively stable across generations, the proteins derived from genes do the major work of a cell or a system of cells, and development can be understood only by knowing how proteins function. Thus, comprehensive knowledge of genes should be regarded only as a preliminary step toward understanding the molecular biology of living things.

Gene Expression Arrays

Knowing the sequence of a gene, it is possible to synthesize a short, complementary sequence of DNA (cDNA) that will bind specifically to the mRNA that is produced from that one gene in a piece of tissue. A small dot of that cDNA can be deposited on a glass slide, and one slide can be made with several thousand dots, each of which can detect the quantitative level of expression of just one among the thousands of genes. The sample of highly expressed genes will include those known for decades as well as heretofore unknown genes. Thus, gene expression can be examined free from any preconceived notion of what a particular gene does (Lee et al., 2002).

Despite the exquisite sensitivity and specificity of this technique, the vast numbers of genes that are assessed simultaneously can, given our current crude understanding, yield only a picture with broad strokes. For example, data were combined for 553 microarray experiments on the nematode worm *C. elegans* to study the expression of more than 11,000 genes under several conditions and at different ages to identify clusters of genes that had similar expression profiles (Kim et al., 2001). Researchers termed the 44 visible clusters *mountains* on the gene expression landscape because

they could be seen as high points in a three dimensional plot. Mountain number 6 contained 909 genes whose mRNA levels were correlated with each other at a median Pearson $r = .21$, and many were especially active in neural tissue.

The genome-wide assessment of expression has provided overwhelming evidence that environmental conditions alter the activity of very large numbers of genes. For example, the circadian light-dark cycle entrains a 24-hour expression pattern for about 10% of all genes expressed in a particular tissue in mice, amounting to 1,000 or more genes, but the set of genes that fluctuate most widely with time of day depends on the specific tissue (Storch et al., 2002). It is also apparent that some genes are regulated to a greater degree than others in response to environmental change (Lee et al., 2002).

Given the large numbers of genes (more than 10,000) being assessed in one experiment with arrays, the risks of detecting false positive relationships are substantial and criteria for claiming a real change in expression tend to be somewhat arbitrary. Other difficulties in interpreting these experiments exist (Nisenbaum, 2002), and it is prudent to exercise caution at this early stage of the investigations. By far the biggest problem with gene arrays is that, at present, the results using different systems from different manufacturers show little overlap, so data from different studies are difficult, if not impossible, to compare (Marshall, 2004). The magnitude of the problem is suggested by the fact that, in 2003 alone, there were approximately 3,000 published microarray studies (Marshall, 2004).

Targeted Mutations

When the DNA sequence of a gene is well documented, this knowledge can be used to construct a molecular probe that will insert a fragment of foreign DNA at a targeted location in the specific gene of interest to the investigator. This is a transgenic method because it transfers DNA from one species to another. When the insertion event is transmissible to progeny, the new mutation is an allele at the genetic locus. Targeted mutations have been created in hundreds of genes in mice to generate allelic diversity at loci where previously only the normal, "wild type" allele had been known (Müller, 1999; www.informatics.jax.org). In many instances the allele is termed a *null mutation* or *knockout* because it completely abolishes the capacity to synthesize protein that normally depends on that gene. The mouse has special importance in this realm because targeted mutations generally cannot be done in humans for ethical reasons and the mouse is very similar genetically to humans.

A method with many steps usually poses difficulties of interpretation and requires elaborate controls for extraneous variables. A knockout effect cannot be conclusively attributed to a specific gene without the use of additional breeding experiments to prove that another, nearby gene was not involved (Gerlai, 1996). Although these experiments are not overly complicated (Crusio, 2004; Wolfer, Crusio, & Lipp, 2002), they do take time and are sometimes neglected in the rush to publish exciting findings.

One of the great surprises from knockout research is that the animal may be viable and even relatively healthy despite the total loss of function of what was believed to be an essential gene. For example, a knockout of the *dopamine-ß-hydroxylase* gene in mice creates an animal that is completely unable to synthesize norepinephrine, a key neurotransmitter and neurohormone that is featured prominently in neuroscience texts. If these mice are helped to survive the difficult period from the late fetus until weaning, many of them are able to survive as adults and negotiate mazes with only minor deficits (Thomas & Palmiter, 1997). Frustrated researchers have in some cases made a heroic but futile search for a dramatically altered phenotype after knocking out a gene. These results do not show that the gene is functionally irrelevant. Instead, they indicate a considerable degree of flexibility in the developmental system, whereby other mechanisms can compensate for the loss of one of the parts.

Knockout research in mice has generally focused on one or a few genes of specific interest to the investigator, but the method has the potential to yield information on all genes in the genome. Researchers have created mutations in almost every gene of the single-celled yeast organism *Saccharomyces cerevisiae* (Giaever et al., 2002). Others were able to insert DNA fragments into more than 21,000 of the 29,454 genes of the plant *Arabidopsis thaliana* (Alonso et al., 2003). The technology exists to perform a similar feat with mice, but the prospect of breeding and maintaining more than 20,000 mutants to assess behavioral function is not appealing.

Molecular Markers

To detect the presence of a mutant gene that may be important for individual differences in a population, one can show that variations in some phenotype tend to be transmitted from parent to offspring in close association with

DNA markers that themselves do not alter the phenotype (Crabbe, 2002). The closer the marker is to some unknown gene on the same chromosome, the more likely the two will be transmitted together because they are genetically "linked." Prior to the era of molecular genetics, linkage analysis was often inconclusive or insensitive because there were so few markers available for research. The situation changed dramatically with the discovery of thousands of polymorphic loci spread widely across the chromosomes where there happened to be long and senseless repetitions of the nucleotide bases adenine and thymine (AT repeats). These markers are generally located in the noncoding DNA and therefore have no effect on phenotypes, and they undergo mutations at unusually high rates, such that differences often occur between even closely related individuals. Even more common are loci where there is a difference at a single nucleotide in the population. Technology now exists to detect these single nucleotide polymorphisms (SNPs or "snips") with relative ease, and the specific DNA sequences for thousands of SNPs are known in humans and mice. The most recent update of the dbSNP database (build 122 at http://www.ncbi.nlm.nih.gov/SNP) indicates that a whopping 235,026 SNPs are now well documented for humans and 544,636 for mice. These variants have made it much easier to detect a gene with major effects on development and localize it to a short segment of a chromosome.

A recent study by Edenberg et al. (2004) illustrates the power of the new molecular tools. The team assessed alcoholism and electroencephalogram (EEG) brain waves in families with several alcoholics as well as nonalcoholics. Earlier evidence had indicated the involvement of a receptor for the inhibitory neurotransmitter molecule GABA (gamma-amino butyric acid), but there were four GABA receptors in a cluster on chromosome 4. The existence of several dozen SNPs in this region of chromosome 4 was indicated by the public databases of human genes, especially the dbSNP site, and the researchers found that variation in clinical diagnosis and EEG was strongly associated with SNP genotype in the GABRA2 gene but not the other three nearby genes. Finally, they sequenced the DNA in the GABRA2 gene in 48 individuals and found that the nucleotide polymorphisms did not alter the amino acids in the GABA receptor molecule. Instead, they concluded that the polymorphism pertinent to alcoholism is located in a region of the gene that is important for the regulation of gene action.

It is now believed that many genetic variants involved in complex human disorders do not alter the structure of the protein encoded by a gene but instead influence the binding of regulatory molecules to regions of the gene that turn transcription on and off during development. This possibility should be regarded as hypothesis until the specific regulatory mechanism is identified for any particular gene, but it is a credible hypothesis. For many other genes cited in the psychiatric literature, the data demonstrate only that a marker locus is correlated with phenotypic diversity and that the marker is close to some gene of importance in nervous system and behavioral function. In many cases, the actual gene responsible for phenotypic variation is not known. It is quite possible that a marker locus is located in an intron of one gene but the exons of that gene do not produce individual differences, while that gene is close to another gene on the same chromosome that happens to be the source of the phenotypic variation. To interpret this research literature properly, one must read the fine print carefully and have a substantial knowledge of molecular genetics.

The allure of the new biotechnologies is great, and their achievements are impressive indeed. What they have not done, however, is provide ready answers to questions posed by developmental psychology at the level of nervous system and behavior. On the contrary, the behavioral development of transgenic and knockout mice has rarely been examined (Branchi & Ricceri, 2002). Reductionism expects that phenomena at the more macroscopic levels of reality can be explained best by reference to events at the molecular level; consequently, a reductionist language has evolved among many molecular biologists that relegate environmental factors to subordinate clauses, consistent with Bateson's (1913) view of the primacy of the gene. To a developmentalist, the abundant new information about molecular gene activity has not dispensed with the need to understand principles at the level of the behaving organism. Instead, it has opened a portal into a world of stunning molecular complexity.

APPLICATION OF A DEVELOPMENTAL PSYCHOBIOLOGICAL SYSTEMS VIEW: THE CASE OF INTERSENSORY DEVELOPMENT

As the two previous sections of this chapter have made clear, there is a growing appreciation of the value of grounding the study of human development in a system

of multiple influences, rather than continuing to utilize simpleminded explanatory dichotomies such as genes or environment, instinct or learning, maturation or experience, and structure or function. It seems to us that an emphasis on the various ontogenetic processes involved in the emergence of phenotypic outcomes effectively eliminates these explanatorily empty dichotomies. In their place, a developmental psychobiological systems approach provides a more comprehensive view of development—a view that attempts to integrate genetic, neural, behavioral, social, and cultural levels of analysis (see Figure 5.6). This integrative effort is in keeping with the vision of the pioneering developmentalist Z.-Y. Kuo (1967), who wrote 4 decades ago: *"The study of behavior is a synthetic science.* It includes comparative anatomy, comparative embryology, comparative physiology, experimental morphology, and qualitative and quantitative analysis of the dynamic relationship between the organism and the external physical and social environment" (p. 25).

Kuo's interdisciplinary, multilevel vision for the developmental analysis of behavior is gradually being incorporated into developmental science (Lickliter, 2000b). This is seen in the increasing shift away from simple cause-and-effect models of development that rely on predeterminism, linearity, or reductionism, and the move toward more dynamic, hierarchical, systems-oriented approaches to development. This developmental systems approach has become increasingly evident in several subareas within developmental psychology in recent years including the study of motor development (Thelen, Schöener, Scheier, & Smith, 2001; Thelen & Ulrich, 1991), cognitive development (Bjorklund, 1995; Richardson, 1998), language development (Dent, 1990; Zukow-Goldring, 1997), personality and emotional development (Lerner, 1988; Lewis & Granic, 2000), and social development (Cairns et al., 1990; Fogel, 1993) to cite but a few examples.

The conceptual and methodological shift to a more systems-oriented approach is also increasingly evident in the study of perceptual development (Gottlieb, 1991, 1997), and, especially, the study of early intersensory capabilities. Our environment is inherently multimodal, with objects and events typically experienced through several sensory systems simultaneously. How the individual sensory modalities relate to one another and how their functions are integrated in the brain has been of growing concern to a variety of investigators working in developmental psychology (Bahrick & Lickliter, 2002; Lewkowicz & Lickliter, 1994; Rose & Ruff, 1987), developmental biology (Edelman, 1987, 1992), cognitive science (Bertelson & de Gelder, 2004; Smith & Katz, 1996), and the neurosciences (Calvert, Spence, & Stein, 2004; Stein & Meredith, 1993). Recent empirical and conceptual advances in these related fields have served to guide a growing number of investigators away from simple, single-cause explanations and toward an increasing appreciation of the multiple influences, at various levels of analysis, that contribute to the emergence of intersensory integration.

What follows here is not intended as a comprehensive review of these burgeoning areas of research; rather, it is a brief examination of traditional and emerging conceptual and operational frameworks associated with this area of investigation. The principal goal is to explore how the application of a biologically plausible developmental systems perspective can provide students of perceptual development with a framework that both acknowledges the complex and dynamic nature of development and attempts to integrate developmental data from genetics, neuroscience, and psychology into a coherent and complementary account of how young organisms come to integrate distinct sensory inputs in a coordinated way that allows for a unitary perception of objects and events. Intersensory integration is a fundamental characteristic of normal perception, and to successfully answer the question of "how" it is achieved over the course of development requires an interdisciplinary, multilevel, comparative approach to developmental analysis, as advocated by Kuo (1967) and, more recently, by Gottlieb (1991, 1996, 1997).

Traditional Approaches to Intersensory Development

During the past several decades, there has been substantial research on the intermodal capabilities of human infants (Aslin & Smith, 1988; Bahrick, Lickliter, & Flom, 2004; Lewkowicz, 2000; Lewkowicz & Lickliter, 1994; Meltzoff, 1990; Rose & Ruff, 1987). In a general sense, this research has been largely descriptive in nature and has been directed at establishing the timing of the emergence of various perceptual competencies over the course of the 1st year following birth. This work has successfully documented that young infants display a large and diverse repertoire of intersensory abilities, including the ability to match faces and voices on the basis of voice-lip synchrony (Dodd, 1979), speech sounds

(Kuhl & Meltzoff, 1984), affective expressions (Walker-Andrews, 1997), and gender of the speaker (Walker-Andrews, Bahrick, Raglioni, & Diaz, 1991). Infants have also been shown to be sensitive to a number of temporal parameters unifying auditory and visual stimulation, including synchrony (Bahrick, 1987, Lewkowicz, 2000; Spelke, 1981), rate (Lewkowicz, 1985; Spelke, 1979), rhythm (Bahrick & Lickliter, 2000; Mendelson & Ferland, 1982), and duration (Lewkowicz, 1986). Related work has also demonstrated impressive haptic-visual connections present over the course of the 1st year, including tactile discrimination and cross-modal transfer abilities within the first months of postnatal life (Bushnell, 1982; Clifton, Rochat, Robin, & Berthier, 1994; Rochat & Senders, 1991; Rose, 1994; Streri & Molina, 1994).

Despite these varied and impressive demonstrations of infants' intersensory capabilities, there has been surprisingly limited concern in this body of work for the various possible contributions of prior prenatal and postnatal experience (see Figure 5.7), or with the specific processes and mechanisms whereby intersensory functioning is achieved and modified during early development. This state of affairs is no doubt due in large part to the inherent experimental limitations of working with human infants. Experiential manipulations of human fetuses and neonates are necessarily limited in scope and duration, and traditional experimental techniques such as sensory deprivation or sensory augmentation are prohibited. Experimental limitations aside, we believe the general lack of focus on the processes and mechanisms associated with human intersensory development is also the result of the types of questions that have typically been pursued in this area of research.

Perhaps the most prominent question guiding research in the area of infant intersensory development over the past 30 years is a question concerned with direction: Does intersensory development proceed (a) from initially separate senses to coordinated multimodal experience or (b) from an initial unity of the senses to differentiated modalities? The pursuit of answers to this question has resulted in two prevailing (and opposing) theoretical views, known respectively as the "integration view" and the "differentiation view" of intersensory development (see Bahrick & Pickens, 1994; E. J. Gibson & Pick, 2000, for brief reviews).

In a general sense, the integration view holds that the different sensory modalities function as separate sensory systems during the initial stages of postnatal development and become integrated and coordinated during development through the infant's activity and resulting repeated experience with concurrent information provided by the different modalities (Birch & Lefford, 1963, 1967; Friedes, 1974; Piaget, 1952). For example, Piaget argued that as infants manipulate objects in their environment, they have multiple opportunities to experience the tactile, auditory, visual, and gustatory properties of these objects. It is hypothesized that, through these repeated experiences, infants gradually come to successfully associate their various multimodal sensations. In contrast, the differentiation view of intersensory development holds that the different senses form a primitive unity early in development, and, as the infant develops, information arising from the different sensory modalities is differentiated (Bahrick, 2000; E. J. Gibson, 1969; J. J. Gibson, 1966; Marks, 1978). Thus, E. J. Gibson (1969) has argued that infants possess some intersensory capabilities at birth and are innately able to perceive properties of objects or events that are amodal or invariant across sense modalities (e.g., intensity, duration, rhythm, shape). From this perspective, infants are thought to differentiate finer and more complex multimodal relations through their experience over the course of development. Detection of intermodal invariants is central to this view, and the differentiation and extraction of progressively finer levels of invariant structure is considered to be the main developmental task of the infant (Bahrick, 2000).

Assumptions Underlying Traditional Approaches

The enduring debate between the integration and differentiation views has certainly provided a heuristic for directing much of the empirical work concerned with early intersensory functioning in human infants over the past several decades. Both perspectives have, however, relied on several common underlying assumptions that are now questionable in light of our increasing knowledge within neuroembryology and developmental psychobiology. In particular, several of the usually implicit assumptions common to both integration and differentiation theories fail to adequately recognize the complex and dynamic processes of organization and reorganization occurring within (Freeman, 1991; Kellman & Arterberry, 1998) and between (Honeycutt & Lickliter, 2003; Radell & Gottlieb, 1992; Symons & Tees, 1990) sensory systems over the course of both prenatal and postnatal development. This has tended to result in an

overly simplistic and essentially nondevelopmental characterization of the sensory modalities and their emerging sensitivities on the part of both the integration and the differentiation views. For example, an implicit assumption of both viewpoints has been that the sensory systems start out on an essentially equal basis (R. L. Tees & Buhrmann, 1989). This assumption is in contrast to what is known about the neuroembryological development of the sensory systems. The various sensory modalities of birds and mammals (including humans) do not become functional at the same time in development (Alberts, 1984; Bradley & Mistretta, 1975; Gottlieb, 1971b); as a result, the various sensory modalities have different developmental histories during the prenatal and postnatal periods. These experiential differences can significantly affect the ability of a particular modality to process a given type of sensory input at a given point in early development (Gottlieb, 1971b; Lickliter, 1993; Turkewitz & Kenny, 1982).

As a case in point, in humans (and many precocial birds and mammals), the auditory modality becomes functional at some time during the late stages of the prenatal period, whereas the visual modality has its functional onset at birth. A number of recent studies utilizing avian and mammalian embryos and infants have demonstrated that the sequential heterochronic emergence of function in the various sensory systems can have an important influence in determining the nature and modification of intersensory relationships during early development (Foreman & Altaha, 1991; Foushee & Lickliter, 2002; Gottlieb, Tomlinson, & Radell, 1989; Kenny & Turkewitz, 1986; Lickliter, 1990; Symons & Tees, 1990). For example, the auditory modality has been shown to have functional priority over the later developing visual system during the early stages of the postnatal period in several precocial animal infants (Gottlieb & Simner, 1969; Johnston & Gottlieb, 1981; Shillito, 1975). This early sensory dominance hierarchy is due in part to the fact that, at the time of birth, these two sensory systems have had different amounts of prenatal experience (Lickliter, 1994). Neither the integration view nor the differentiation view has typically considered the possible influences of such timing or asynchronicity issues in their accounts of intersensory capacity (but see Mellon, Kraemer, & Spear, 1991; Spear, Kraemer, Molina, & Smoller, 1988). The result has been a general lack of appreciation of the role of functional constraints or limitations in the realization of early patterns of perceptual organization (but see Lickliter, 2000a; Turkewitz & Kenny, 1982; Turkewitz & Mellon, 1989). Because of the sequential onset of function among the various sensory modalities, each sensory system has a unique developmental history by the time of birth. Alterations of typical patterns of sensory stimulation may have significant effects on perceptual organization and responsiveness.

The integration and differentiation views have also tended to ignore or downplay the fact that the sensory modalities are somewhat specialized for the processing of different kinds of perceptual information. For instance, the auditory modality is known to be relatively more effective at processing temporal rather than spatial changes; in contrast, the visual modality is relatively more effective at processing spatial rather than temporal changes (Kubovy, 1988; Welch & Warren, 1986). The different senses are not simply equivalent ways of perceiving objects or events; they can differ in both the precision and rapidity of their responsiveness to different perceptual information (Bushnell & Boudreau, 1993; Soto-Faraco, Spence, Lloyd, & Kingstone, 2004). Differential salience rankings inherent in specific kinds of perceptual information can result in some object or event properties (e.g., temperature, texture, size, weight, temporal frequency, spatial motion) being apprehended more quickly or appropriately in one sensory modality than in others. These salience rankings of various stimulus properties are not likely to be the same in any two modalities (Bushnell, 1994), nor are they likely to change within or across modalities in uniform or equivalent ways over the course of development. For example, Lewkowicz (1988) has shown that, in human infants, the relative dominance of concurrent auditory and visual inputs can be reversed. Thus, the common assumption that responses to amodal properties can be assessed or discussed without reference to the particular properties included, and their relative salience within and across modalities, is overly simplistic. The infant's ability to integrate or differentiate information across the various sensory modalities is likely influenced by the relative salience ranking of different sensory inputs (Bushnell, Shaw, & Strauss, 1985; see also Spear & Molina, 1987).

How such salience factors and their influences are realized and how they change over early development remain poorly understood and have rarely been considered by either integration or differentiation views. This has contributed to an enduring underappreciation of the task-specific and context-sensitive nature of developing intersensory capabilities in much of the work derived from these opposing views.

Perhaps most important, integration and differentiation theories of intersensory development have generally assumed that intersensory functioning is a unitary phenomenon that can be characterized by a single developmental pathway. However, as noted by Ryan as long ago as 1940, and as echoed more recently by Turkewitz and his colleagues (Botuck & Turkewitz, 1990; Turkewitz & Mellon, 1989), there are a number of different types or categories of intersensory functioning, including intersensory inhibition and facilitation, association of multimodal characteristics (multimodal coordination), and abstraction of common information (intersensory equivalence). There is no reason to necessarily assume that these different instances of intersensory functioning share common developmental mechanisms or pathways. Indeed, each distinct type of intersensory functioning may have its own developmental trajectory and be influenced by different neural, physiological, psychological, and social mechanisms. In this light, Turkewitz and Mellon (1989) argue:

> It is therefore possible for intersensory equivalence to be both present and absent at birth, for the senses to be simultaneously unified and separate, and for development to proceed by both differentiation and integration. That is, development may be characterized not by the presence or absence of intersensory functioning at various stages, but by the prevalence or conspicuousness of different types of intersensory functioning at different stages of development. (p. 289)

The insight that intersensory perception is not a unitary process (Lewkowicz, 2002; Turkewitz, 1994; Walker-Andrews, 1994) is not yet widely appreciated, despite growing evidence to indicate that diverse intraorganismic and extraorganismic factors can interact probabilistically to determine whether information to the different sensory modalities will or will not be integrated. Besides the factors briefly reviewed above (i.e., the changing functional properties of the sensory systems, the differential salience hierarchies of the various modalities, and the processes of differentiation and integration), nonspecific stimulus characteristics such as the relative intensity or amount of stimulation presented to the various modalities (Lewkowicz & Turkewitz, 1980; Lickliter & Lewkowicz, 1995; Radell & Gottlieb, 1992), and specific organismic characteristics such as the state of arousal of the infant (Gardner & Karmel, 1984; Gottlieb, 1993; Reynolds & Lickliter, 2004) have been shown to contribute to the infant's emerging capacity for specific intersensory functions.

Thus, individual intersensory functioning is multidetermined, with diverse internal and external variables interacting, often in a nonlinear fashion. As pointed out by Thelen and Smith (1994), moving and perceiving provides infants with varied, multimodal "takes" on how the world looks, feels, sounds, tastes, and smells. These experiences of hearing and seeing and touching and moving are all time-locked and are known to change together as the infant's activity, state, and actions change. What is needed to more fully unpack and assess these varied factors and their interactions is a developmental systems view that approaches the study of intersensory development at a suitable level of complexity that does justice to these varied influences and provides a biologically plausible, yet conceptually nonreductionistic, account of the development of intersensory functioning. Steps are being made in this direction.

Developmental Psychobiological Systems Approach to Intersensory Development

Recently, there has been increasing appreciation of the need to move beyond descriptive studies and toward the experimental examination of the various sensory and nonsensory factors that contribute to the emergence of infants' intersensory functioning (Bahrick & Lickliter, 2002; Lewkowicz, 2002; Lewkowicz & Lickliter, 1994; see Turkewitz, 1994 for an alternative view). As suggested earlier, this shift in focus from "what" and "when" questions to "how" questions is requiring investigators to reconsider and even revamp several of the traditional conceptual and methodological approaches that have been employed in the study of early perceptual organization. The larger goal of this reorientation is to understand and explain individual functioning and its organization without denying the complexity of the phenomena to be understood.

In our view, such a change in focus will best be served by adopting research strategies that are explicitly interdisciplinary in nature and that place strong emphasis on comparative developmental studies (Lickliter & Bahrick, 2000). In other words, an empirical concern with the complexity of the processes and mechanisms underlying intersensory development will profit from information obtained from a variety of analytical levels and drawn from a variety of animal species. Given that the development of any specific behavioral capacity is the product of dynamic, bidirectional interaction among multiple, hierarchically organized levels (see Figure 5.6), we believe that the utilization of interdisciplinary,

comparative, and convergent research strategies is essential to discovering and defining the various conditions, experiences, and events (both internal and external to the organism) necessary and sufficient to understand normal perceptual development.

As discussed earlier, Gottlieb (1991, 1992) has distinguished three functional organismic levels (genetic, neural, and behavioral) and three environmental levels (physical, social, and cultural) of analysis central to a developmental psychobiological systems approach (Figure 5.6). The complex network of interdependent bidirectional relationships among gene action, neuroanatomy and physiology, behavior, and social influences clearly poses a challenge for those who still hope to identify simple unidirectional linkages between levels of organization. This complexity also poses a challenge for researchers committed to unraveling the intricate web of nested influences involved in early development, but for different reasons. Such a complex network requires the discovery of dynamic, bidirectional relationships rather than single antecedent-consequent linkages. Despite this challenge, some initial progress is being made in this regard. Although the genetic and cultural levels of Gottlieb's psychobiological systems framework remain relatively unexplored in the study of early intersensory capabilities, several researchers have taken first steps toward attempting to integrate neural and behavioral levels of analysis (e.g., Knudsen & Brainard, 1991; Knudsen & Knudsen, 1989; Stein & Meredith, 1990; Stein, Meredith, Huneycutt, & McDade, 1989; R. L. Tees, 1994) and the physical and social levels of analysis (Columbus & Lickliter, 1998; Gottlieb, 1993; Lickliter & Gottlieb, 1985, 1988; McBride & Lickliter, 1993). These initial efforts at multilevel analysis are all comparative studies and have employed a variety of avian and mammalian subjects.

Operationally, these varied experiments have manipulated the sensory experiences of developing animals and produced systematic changes in neural and/or behavioral responsiveness to multimodal information. For example, Knudsen (1983) raised developing barn owls with one ear plugged, changing the relative timing and intensity of inputs to the two ears and altering the relative weights of the binaural cues used to construct the bird's auditory receptive fields (e.g., auditory map) in the optic tectum, the brain region involved in the localization of sensory events. Despite the fact that these ear-occluded birds had to learn to function on the basis of abnormal binaural cues, they nonetheless developed an auditory map in surprisingly good register with their visual map (Knudsen, 1983). However, when the ear plug was removed after the owls became adults, the input from the previously deprived ear was far stronger than it was when the auditory map was first formed, resulting in misaligned auditory and visual spatiotopic maps. Correction of this misalignment induced by the onset of normal auditory experience was found to be dependent on the availability and use of visual spatial cues. If no visual information was provided (i.e., the owl was reared in the dark), no corrective reorganization was observed (Knudsen, 1985).

King, Hutchings, Moore, and Blackmore (1988) found similar activity-dependent neural and developmental processes in young ferrets. These mammals had either one ear occluded or one eye deviated during early development. In both cases, a shift in the animal's auditory receptive fields was found to be a result of the experimental sensory modification. This functional shift or compensation ensured the successful alignment of the ferret's auditory and visual inputs, despite ongoing experimental modification of either auditory or visual input. Such findings also illustrate how one sensory system's receptive fields or map (the visual) can exert critical developmental influences on the induction and maintenance of another modality's (the auditory) spatiotopic neural map. Presumably, under normally occurring conditions, map alignment reflects ongoing experience with auditory and visual stimuli that are concurrently produced by the same object or event and are thus linked in time and space (Stein & Meredith, 1993). The similarity of the results obtained with owls and ferrets demonstrate how altered sensory experience can drive neural change and how neural change can, in turn, drive behavioral change. These two processes work in a reciprocal, interdependent fashion, again illustrating the bidirectional theme promoted throughout this chapter.

Working at the physical and social levels of analysis, several related studies utilizing precocial birds have demonstrated that social interaction with conspecifics can facilitate the often rapid perceptual reorganization required during early development (see Lickliter, Dyer, & McBride, 1993, for a review). In addition to providing nurturance and protection to the developing organism, the social environment provides an array of perceptual experience, including thermal, tactile, olfactory, auditory, and visual stimulation. Conspecifics can thus be viewed as experiential resources to the developing individual and have been found to play a significant role in the development of species-typical perceptual organization. For example, Lickliter and Gottlieb (1985) found

that young ducklings require physically interactive social experience with siblings to exhibit a species-specific visual preference for a familiar maternal hen over an unfamiliar hen of another species. Young birds that were able to see siblings but were denied physical contact with those siblings in the period following hatching failed to show species-typical visual preferences (McBride & Lickliter, 1993).

The importance of tactile contact with siblings for the development of ducklings' normal auditory learning ability was also demonstrated by Gottlieb (1993), who found that physical interaction with siblings induces such a high degree of malleability in young ducklings that they are able to learn to prefer nonconspecific maternal calls, an ability not present in ducklings who could see and hear but not physically interact with siblings. Lickliter and Lewkowicz (1995) also showed the importance of prenatal tactile and vestibular stimulation from broodmates for the successful emergence of species-typical auditory and visual responsiveness in bobwhite quail chicks. Taken together, these studies of precocial birds (a) provide varied examples of the often nonobvious and multilevel influences contributing to the emergence of normal perceptual organization, (b) remind investigators of the need to be open-minded when attempting to identify the experiences that influence a given perceptual capability, and (c) underscore the often critical role of social processes to psychobiological development. This insight is often overlooked, in that the contribution of the social experiences of human infants has been disregarded in most laboratory studies of intersensory integration.

System Characteristics of Intersensory Development: Structured Organisms and Structured Environments

A synthesis of the findings of various comparative studies from the neural, behavioral, and social levels of analysis suggests several interrelated defining characteristics of intersensory development. Intersensory development is:

- *Multidimensional:* No level, component, or subsystem (including those internal to the infant) necessarily has causal priority in the developmental system.
- *Nonlinear:* The intricacy of developmental causal networks is not always obvious or straightforward; to be identified, the networks require repeated probes at more than one level of analysis.
- *Activity dependent:* Intersensory abilities emerge from the infant's ongoing activities and encounters with the world.
- *Context sensitive:* Emerging intersensory capacities can be strongly influenced or modified by specific features of the infant's immediate surroundings.
- *Task specific:* Local variability can facilitate or interfere with the infant's intersensory performance.

Several of these related characteristics of intersensory development have begun to be acknowledged in work with human infants (in particular, with respect to context-sensitive and task-specific properties; see Bahrick et al., 2004; Lewkowicz, 2002; Streri & Molina, 1994). Few investigators, however, have attempted to combine the cross-disciplinary connections and comparative perspectives that would highlight the social, multidimensional, and nonlinear nature of intersensory development. It is unfortunate that insights from a comparative approach to intersensory functioning continue to be largely ignored in much of contemporary developmental psychology. Nonhuman animal findings can provide potentially useful and productive guidelines for directing the "how" questions about human development (Gottlieb & Lickliter, 2004). For example, experiential modification studies employing sensory deprivation or sensory augmentation, either prenatally or postnatally, have recently yielded important information regarding the experiential conditions necessary for the normal development of intersensory organization in both altricial and precocial neonates (Banker & Lickliter, 1993; Foreman & Altaha, 1991; Gottlieb, 1971b; Gottlieb et al., 1989; Kenny & Turkewitz, 1986; R. C. Tees & Symons, 1987). However, these findings have rarely been utilized in directing investigations of human functioning (but see Bahrick & Lickliter, 2002; Eilers et al., 1993; Lewkowicz, 1988; Wilmington, Gray, & Jahrsdoerfer, 1994).

The continued resistance to incorporating results from the comparative approach into mainstream developmental psychology, and the resulting underappreciation of the principles of multidimensionality and nonlinearity, perpetuate a reductionistic view of the underlying causes of behavior. Many students of human development continue to take for granted that behavior is somehow based on or determined by more "fundamental" or "primary" processes that occur at the genetic and/or neurophysiological level. This linear, unidirectional, bottom-up view of the "biological bases" of behavior—and the privileged status it typically credits to

genetic and neurophysiological components of human functioning—is conceptually flawed, despite its widespread use. Specifically, this bottom-up view of development overlooks the fact that genetic or neural factors are always part-and-parcel of the individual organism's entire developmental system (Gottlieb & Halpern, 2002; Johnston & Gottlieb, 1990; Lickliter & Berry, 1990; Oyama, 1985). No single element or level in the system necessarily has causal primacy or privilege, and the functional significance of genes, neural structures, or any other influence on phenotypic development can be understood only in relation to the developmental system of which they are a part (see Figure 5.6). At each level of the developmental system, the effect of any level of influence is dependent on the rest of the system, making all factors potentially interdependent and mutually constraining (Gottlieb, 1991). Although this relational emphasis makes for complexity, such complexity is not hopeless and can be experimentally unraveled at all four levels of analysis depicted in Figure 5.6 (see review by Gottlieb, 1996).

The important idea that control for any developmental outcome resides in the structure and nature of the relationships within and between internal and external variables (rather than in any individual factor) is not yet widely appreciated in developmental psychology. Nonetheless, we believe this insight from the developmental psychobiological systems approach has important implications for the study of behavioral development. In particular, the notions of diffuse control and reciprocal interaction highlight the need for an explicit empirical concern with the dynamic relationship between the developing organism and its structured environment. From this perspective, it is no longer plausible to attempt to reduce this complex, dynamic relationship to strictly or solely genetic or neural levels of analysis. The minimum unit for developmental analysis must be the developmental system, comprised of both the organism and the set of physical, biological, and social factors with which it interacts over the course of development.

Recognition of the need for an empirical concern with the relationship between the organism and its environment has been evident in the work of several prominent students of perception over the past 50 years (e.g., Brunswik, 1952, 1956; J. J. Gibson, 1966, 1979). These authors argued that to construct psychological theories at an adequate level of complexity, it would be necessary to study representative samples of both subjects and their situations. The relation between the organism and its environment, rather than the nature of the organism itself, was viewed as the appropriate object of study for psychology. For example, J. J. Gibson (1966, 1979) advocated an ecological approach to the study of perception in which the researcher would be explicitly concerned with the structure of the environment, how the organism moves about in it, and what sorts of perceptual information the environment provides to the perceiving organism. From this approach, perception depends on the kinds of experiences that come from having a body with various sensory and motor capacities that are themselves embedded in a more encompassing physical, biological, psychological, and social context (Thelen et al., 2001; Varela, Thompson, & Rosch, 1991). Developmentalists are thus faced with the challenge of determining both how the environment of the fetus or infant contributes to and constrains the perceptual information available to the young organism and how these contributions and constraints are themselves specified by the changing sensorimotor structure and capacities of the developing organism (see Adolph, Eppler, & Gibson, 1993; Lickliter, 1995; Ronca, Lamkin, & Alberts, 1993). For example, Bertenthal and Campos (1990) found that infants' perceptual responsiveness to objects and surfaces can change significantly following some experience with crawling. As new actions become available to the maturing infant, new opportunities for exploring the environment also emerge. This bidirectional approach stresses the fundamental connectedness of the organism to its surroundings and recognizes that empirical investigation beyond the boundaries of the organism is essential to a full understanding of the organism and its behavior.

Ironically, this approach is sometimes viewed as being "environmentalist" in orientation and thus in opposition to a "biological" approach to the study of human development. This dichotomous view derives from an implicit developmental dualism, still common in some quarters of developmental psychology, that attempts to delineate between the relative causal power of internal versus external factors thought to be associated with any given behavioral trait or ability. This dualism and its excessive reductionism are explicitly rejected by the developmental psychobiological systems view advocated in this chapter. We believe that a hard-line distinction between genetic and environmental causation, between internal and external sources of

control, between nature and nurture, is no longer tenable in developmental science. As a case in point, the multilevel, nonlinear, and activity-dependent processes revealed in comparative work on intersensory development are not adequately captured by the traditional dichotomy of internal versus external causation that is still common in much of developmental psychology. What is needed is an approach to intersensory development in which factors within and outside the organism are studied in explicitly relational terms (Gottlieb & Halpern, 2002).

The need for this relational approach is perhaps best illustrated by the notion of "effective" stimulation, an idea originally put forth by the comparative psychologist T. C. Schneirla (1959, 1965). In brief, the idea of effective stimulation holds that the effectiveness of a particular stimulus depends not only on its specific quantitative (physical) value, but also on the properties of the organism's receptors, the organism's general state of arousal, the organism's experiential history, and its developmental condition. In support of Schneirla's insight, there is now a substantial body of evidence showing that an infant's responsiveness to external sensory stimulation is not determined simply by the physical nature of the sensory input provided; rather, the same stimulus can have markedly different effects on the neonate, depending on the amount of concurrent stimulation to which the infant is exposed and on the infant's current level of arousal (see Gardner, Lewkowicz, Karmel, & Rose, 1986; Lewkowicz & Turkewitz, 1981; Lickliter & Lewkowicz, 1995; Radell & Gottlieb, 1992, for examples from both animal and human infants). Quantitative variations in stimulation in one modality can produce systematic changes in responsiveness in another modality, and it is possible to modify the attentional "value" of a given stimulus by altering either the infant's internal state or the amount of external sensory stimulation provided.

This principle of reciprocal determination underscores the insight that early intersensory relationships are affected by the stage, state, and experiential history of the organism, the nature and history of sensory stimulation provided or denied, and the larger physical, social, and temporal context in which development occurs. In other words, context and specific stimulus features both become dominant behavioral determinants, and a depiction of the bidirectional traffic between levels is crucial to a developmental understanding of individual functioning.

BROADER IMPLICATIONS OF A DEVELOPMENTAL PSYCHOBIOLOGICAL SYSTEMS VIEW

In this chapter, we have applied the systems view of psychobiological development only to developmental behavior genetics and to intersensory integration in the infant; therefore, we wish to close our account by calling attention to the wider applicability of the systems concept to human development.

Although there is considerable evidence for vertical as well as horizontal bidirectionality of influences among the four levels of analysis depicted in Figure 5.6 (environment, behavior, neural activity, genetic expression), the top-down flow has not yet been widely understood and appreciated in developmental psychology. Waddington's (1957, p. 36, Figure 5.5) unidirectional understanding of genetic canalization has been the predominant approach for many years and is still promoted in some quarters of developmental psychology (Fishbein, 1976; Kovach & Wilson, 1988; Lumsden & Wilson, 1980; Parker & Gibson, 1979; Scarr, 1993; Scarr-Salapatek, 1976; Sperry, 1951, 1971).

Because the influence of environmental factors on genetic expression is presently being pursued in a number of neuroscience and neurogenetic laboratories, there is now considerable evidence to document that genetic activity is responsive to the developing organism's external environment (Gottlieb, 1992, 1996). In an early example, Ho (1984) induced a second set of wings on fruit flies by exposing them to ether during a certain period of embryonic development; the ether altered the cytoplasm of the cells and thus the protein produced by the DNA-RNA-cytoplasm coactional relationship. This particular influence has the potential for a nontraditional evolutionary pathway in that it continues to operate transgenerationally, as do the effects of many drugs and other substances (Campbell & Perkins, 1988). Because there are now so many empirical demonstrations of external sensory and internal neural events that both excite and inhibit gene expression, the phenomenon has been labeled "immediate early gene expression" (e.g., Anokhin et al., 1991; Calamandrei & Keverne, 1994; Mack & Mack, 1992; Rustak et al., 1990).

In contrast to the (usually) unidirectional bottom-up flow still prominent in developmental psychology, at the behavior-environment level of analysis, bidirectionality was prominently recognized as early as J. M. Baldwin's (1906) "circular reaction," Vygotsky's (van der Veer &

Valsiner, 1991) emphasis on persons' coactions with their cultural worlds, and William Stern's (1938) personology or person-*Umwelt* relatedness, among many other more recent examples (Fischer, Bullock, Rotenberg, & Raya, 1993; Ford & Lerner, 1992).

In a recent comparison of the recognition of bidirectional influences in theoretical accounts of biology, psychology, and sociology, although psychological theory recognizes vertical bidirectionality at the environment-behavior level and micro to macro unidirectional flow at the gene to neural level, sociological theory predominantly sees unidirectional vertical influences at the environment-behavior level and a consequent lack of persons affecting their social and cultural worlds (Shanahan, Valsiner, & Gottlieb, 1997). Indeed, Shanahan et al. concluded that, although examples of bidirectionality can be found across disciplines, unidirectional thinking is still quite common. Only recently have biologists found the macro to micro flow empirically justified, and this top-down influence has not yet taken hold in biology and psychology as a whole (for an exception in developmental psychopathology, see Cicchetti & Tucker, 1994). Sociologists, on the other hand, have not yet widely embraced the micro to macro flow of influences at the behavior-environment level.

Probabilistic Epigenesis

The probable nature of epigenetic development is rooted in the reciprocal coactions that take place in complex systems, as shown in Figures 5.6 and 5.8.

Since the overthrow of biological preformation in favor of epigenesis in the nineteenth century, it has been recognized that development takes place sequentially and is therefore an emergent phenomenon. And since the advent of experimental embryology in the late nineteenth century, it is an accepted fact that cellular and organismic development occurs as a consequence of coactions at all levels from the genes to the developing organism itself. With the gradual realization that influences in developmental systems are fully bidirectional and that genes do not, in and of themselves, produce finished (i.e., mature) traits, the predetermined concept of epigenesis has receded from all but a few viewpoints in biology and psychology (cf. Scarr, 1993). Epigenesis is now defined as increased complexity of organization: the emergence of new structural and functional properties and competencies as a consequence of horizontal and vertical coactions among the system's parts, including organism-environment coactions (Gottlieb, 1991). As noted in the first part of this chapter on a developmental psychobiological systems view, the emergent nature of development is represented well in the concept of equifinality.

As concluded by Shanahan et al. (1997), probabilistic epigenesis is in accord with Baldwin's (1906) understanding of developmental phenomena. The stochastic nature of developmental phenomena ultimately derives from the range of responses at any given level. Thus, responses to tension can vary within levels; and given that responses to stress occur in highly related sets of behavior (i.e., they are organized), there will be variability in the overall patterns between levels. London's (1949) argument for the "behavioral spectrum" exemplifies the concern for a range of responses. From this perspective, developmental phenomena cannot be represented so as to imply subsequent derivations, though they can suggest classes of outcomes. This notion is captured well by Fischer; in his theory of cognition, he adopts the principles of adaptive resonance theory to explain the generation of multiple cognitive forms in ontogeny (Fischer et al., 1993).

Thus, the hallmarks of probabilistic epigenesis—bidirectionality and indeterminacy—are being ever more widely used in developmental psychology, even if they are not yet majority opinions among psychological theorists who are not steeped in our own history of conceptualizing behavior-environment relations, or who have yet to grasp the recent empirical breakthroughs in our understanding of biological development.

SUMMARY AND CONCLUSION

Developmental thinking began in the early 1800s, coincident with the triumph of epigenesis over the concept of preformation. Though practiced only at the descriptive level in this early period, it led to the insight that to understand the origin of any phenotype, it is necessary to study its development in the individual. Late in the 1800s, developmental description was superceded by an experimental approach in embryology—one explicitly addressed to a theoretical understanding and explanation of developmental outcomes. A field or systems view was born when the results of Hans Driesch's experiments made it necessary to conceptualize embryonic cells as harmonious-equipotential systems. Steer-

ing a careful path between mechanical-reductive and vitalistic-constructive viewpoints, in the 1930s, Ludwig von Bertalanffy formalized an organismic systems view for experimental embryology, which was later worked out in more formal detail by the embryologist Paul Weiss and the physiologically oriented population geneticist, Sewall Wright.[6] At present, a systems view of psychobiological development has begun to take hold in developmental psychology, developmental neurobiology, and behavioral genetics. Thus, although there are dissenters, a psychobiological systems view seems workable and useful in understanding human as well as nonhuman animal psychological development.

A systems view of psychobiological development is a useful framework to guide experiment and theory. It is quite rewarding to those who work with nonhuman animals to note that Ford and Lerner (1992) explicitly advocate the utility of a systems concept for developmental psychologists who work with human beings. As noted earlier, similar points of view have been put forward by psychobiologically oriented developmentalists such as Cairns et al. (1990), Edelman (1988), Griffiths and Gray (1994), Hinde (1990), Johnston and Edwards (2002), Magnusson and Törestad (1993), and Oyama (1985), and this represents a realization of the pioneering theoretical efforts of Z.-Y. Kuo, T. C. Schneirla, and D. S. Lehrman. Because a developmental systems view dates back as far as Hans Driesch's theorizing about his embryological experiments in the 1890s, one cannot call it a "paradigm shift," but certainly it is something relatively new in the field of developmental psychology.

CHAPTER 6

Dynamic Systems Theories

ESTHER THELEN and LINDA B. SMITH

Dynamic systems is a recent theoretical approach to the study of development. In its contemporary formulation, the theory grows directly from advances in understanding complex and nonlinear systems in physics and mathematics, but it also follows a long and rich tradition of systems thinking in biology and psychology. The term *dynamic systems,* in its most generic form, means systems of elements that change over time. The more technical use, *dynamical systems,* refers to a class of mathematical equations that describe time-based systems with particular properties.

DYNAMIC SYSTEMS THEORIES

In this chapter, we present a theory of development based on very general and content-independent principles that describe the behavior of complex physical and biological systems. The application of dynamic systems to development process is relatively new, emerging in the past 20 years. However, in many ways it is a modern continuation of a long tradition; accordingly, this chapter begins with a brief historical review of two strands that form the intellectual heritage for dynamic systems theories: theories (and empirical studies) of developmental process and general systems theories. We present a tutorial of dynamic systems principles and show how they may be used to yield a deeper understanding of the processes of change. We show how these ideas can be used to help us understand developmental process as: (a) a conceptual guide, (b) a program for research, and (c) a basis for formal theory. Finally, we consider the relation between dynamical systems approaches to development and other theories of development.

Throughout the presentation, both in the historical heritage of studying developmental process and in dynamics systems theory itself, two themes will recur:

1. Development can only be understood as the multiple, mutual, and continuous interaction of all the levels of the developing system, from the molecular to the cultural.
2. Development can only be understood as nested processes that unfold over many timescales from milliseconds to years.

The value of dynamic systems is that it provides theoretical principles for conceptualizing, operationalizing, and formalizing these complex interrelations of time, substance, and process. It is a metatheory in the sense that it may be (and has been) applied to different species,

ages, domains, and grains of analysis. But it is also a specific theory of how humans gain knowledge from their everyday actions (e.g., Thelen & Smith, 1994).

Intellectual Heritage: Developmental Process

> [T]he induction of novel behavioral forms may be the single most important unresolved problem for all the developmental sciences. (Wolff, 1987, p. 240)

What do we mean when we say that an organism "develops"? Usually, we say that it gets bigger, but always we mean that it gets more complex. Indeed, the defining property of development is the creation of new forms. A single cell and then a mass of identical cells are starting points for legs, livers, brains, and hands. The 3-month-old infant who stops tracking a moving object when it goes out of sight becomes an 8-year-old child who can read a map and understand symbolically represented locations, and, later, an 18-year-old student who can understand and even create formal theories of space and geometry. Each of these transitions involves the emergency of new patterns of behavior from precursors that themselves do not contain those patterns. Where does this novelty come from? How can developing systems create something from nothing?

Understanding the origins of this increasing complexity is at the heart of developmental science. Traditionally, developmentalists have looked for the sources of new forms either in the organism or in the environment. In the organism, complex structures and functions emerge because the complexity exists in the organism in the form of a neural or genetic code. Development consists of waiting until these stored instructions tell the organism what to do. Alternatively, the organism gains new form by absorbing the structure and patterning of its physical or social environment through interactions with that environment. In the more commonly accepted version, the two processes both contribute: Organisms become complex through a combination of nature and nurture. For instance, the guiding assumption of developmental behavior genetics is that the sources of complexity can be partitioned into those that are inherent, inherited, and absorbed from the environment. But whether development is viewed as driven by innate structures, environmental input, or a combination of the two, the fundamental premise in the traditional view is that "information can preexist the processes that give rise to it" (Oyama, 1985, p. 13).

But if the instructions to develop are in the genes, who turns on the genes? If the complexity exists in the environment, who decides what the organism should absorb and retain? The only way to answer these questions is to invoke yet another causal agent who evaluates the information, whether genetic or environmental, and makes decisions. Some clever homunculus must be orchestrating a developmental score while knowing how it must all turn out in the end. This is a logically indefensible position; it says that novelty really does not develop, it is there all along. Postulating an interaction of genes and environment does not remove this logical impasse. It merely assigns the preexisting plans to two sources instead of one.

In this chapter, we follow a different tradition. We agree with Wolff (1987) that the question of novel forms is the great unanswered question. And we also concur that the traditional solutions—nature, nurture, or interaction of both—are sufficient. The tradition we follow, that of *systems theories of biological organization,* explains the formation of new forms by processes of *self-organization.* By self-organization we mean that *pattern and order emerge from the interactions of the components of a complex system without explicit instructions,* either in the organism itself or from the environment. Self-organization—processes that by their own activities change themselves—is a fundamental property of living things. Form is constructed during developmental process (Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume; Oyama, 1985).

Dynamic systems offers general principles for formalizing ideas of biological self-organization in ways that are extraordinarily useful for understanding developmental process and for conducting experimental research. In this chapter, we apply these principles most specifically to perceptual, motor, and cognitive development in infants and early childhood (e.g., Jones & Smith, 1993; Thelen, 1989; Thelen & Smith, 1994; Thelen & Ulrich, 1991). But the theme of the developing organism as a holistic, self-organizing system has appeared many times before in biology and psychology. Before we describe and apply dynamic principles, we situate our systems theory in the wider perspective of systems thinking in development. Toward this goal, our review is selective and thematic, rather than exhaustive. Readers are referred to excellent reviews by Ford and Lerner (1992), Gottlieb (1992), Gottlieb et al. (Chapter 5, this *Handbook,* this volume), Oyama (1985), and Sameroff (1983).

Lessons from Embryology: Form from a Formless Egg

A baby's first step or first word is a dramatic example of new behavioral form. But no example of developmental novelty is as compelling as the emergency of an embryo from the initial state of a seemingly homogeneous and formless single cell, the fertilized egg. And no other aspect of development seems so completely "genetic" in the strict unfolding of species-typical structure.

For well over a century, biologists have studied this transformation of a single sphere into an intricate, three-dimensional organism with beautifully formed organs and well-differentiated tissue types. During the past few decades, however, researchers have made significant advances toward understanding the "impenetrable black box" (Marx, 1984a, p. 425) of this developmental process.

What is now abundantly clear is that embryonic development is an intricate dance between events in the nucleus—the turning off and on of particular gene products—and what one writer has deemed "mundane" biophysical principles in the cell body and surface (Marx, 1984b, p. 1406). Consider how animals get their basic body plans—the specific parts and organs that emerge in orderly time and space dimensions in the first days and weeks of life. Formation of the body pattern occurs when the fertilized egg has divided to about 10,000 cells. By this time, although the cells look like an undifferentiated heap, they are already marked in positions that predict distinct body locations. They have become a founder group of cells.

It is now well established that what appeared to be a homogenous founder cell or group of cells actually contains various and subtle gradients of substances, which form a very general "prepattern" of the structure that will emerge (Wolpert, 1971). These gradients and patterns, in turn, often arise from the "mundane" effects of gravity, the mechanical effects of molecular structure in the cell and at its surface (the pushing and pulling of particular molecules and crystals), or the regulated amplification of small local fluctuations in physiology or metabolism (Cooke, 1988; Gierer, 1981). Even more remarkable, is that once some initial prepattern is formed, the regulating genes in the nucleus are themselves switched on and off by these changing physical and mechanical events outside of the nucleus. Thus, once the initial generalized body fates are determined, the course of more refined tissue and organ differentiation is equally bidirectional between nuclear processes and other cellular events.

During embryogenesis, cells divide, change character, move, and organize themselves into larger collectives of tissues, organs, and organ systems. The process is highly dynamic; that is, the cell and tissue movements themselves are sources of order and complexity. As groups of cells arising from different local gradients move and come into contact, their new positions further change their character, a process known as *induction.* What is especially relevant to our account here is that no single cell itself gives the signal that this region will become a neural tube or limb bud. Rather, it is the group of cells, acting as a collective and within a particular position in the larger collective that determines their ultimate fate. No one cell is critical, but the history and spatial and temporal dimensions of the collective are. Development is constructed through process:

> The pathways of induction and determination involve a historical series of milieu-dependent gene expressions that are coupled to those mechanical and mechanochemical events that actually govern the achievement of form and pattern. At any one time, there is interplay between the place, scale, and size of bordering collectives, and various inductive molecular signals not only maintain the pattern so far established but also transform it into a new pattern. (Edelman, 1988, p. 26)

This picture is much different from one that casts the genes as the puppeteer, pulling the right strings at the right time to control the ensuing events in the cells. In a dynamic view, we consider the marionette and the puppeteer as affecting each other equally. Or, more accurately, we do away with the puppeteer and the marionette altogether: *What is important is the relationships among the strings as they pull and then become slack.*

Embryologists have been among the pioneers in using dynamic systems both formally and metaphorically to model developmental processes. Most notable was the preeminent developmental biologist C. H. Waddington. Waddington's primary interest was the genetic influence on tissue differentiation in the embryo, the emergence of sharply distinctive tissue types—bones, muscles, lungs, and so on—from a single cell. Although a geneticist, he was also a thoroughgoing systems theorist. Waddington (1954) couched developmental process in explicitly dynamic terms: "We can still consider development in terms of the solutions of a system of simulta-

neous differential equations" (p. 238). Especially in his later writings, Waddington described embryonic change in the language of attractors, bifurcations, open systems, stability, catastrophes, and chaos (Waddington, 1977). Figure 6.1 is one of his depictions, in three dimensions, of the multidimensional space subdivided into a number of regions, such that trajectories starting anywhere in one region converge to one certain end point, while those starting in other regions converge elsewhere (Waddington, 1957, p. 28). The figure shows how the gradients established in the egg, through time-dependent processes, become stable, differentiated tissue types. Waddington was especially intrigued by the self-stabilizing nature of development, depicted on his now classic "epigenetic landscape" shown in Figure 6.2. The landscape represents a developing system, where time runs toward the reader, and where the depth of the valleys is an indication of stability (the ball, once in a valley, is hard to dislodge). From an initial undifferentiated

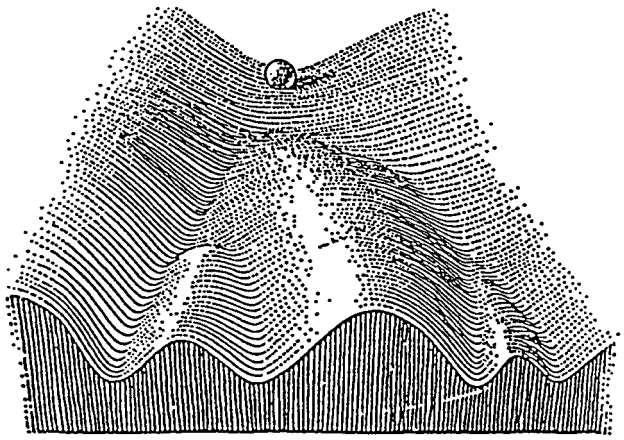

Figure 6.2 Waddington's classic epigenetic landscape. The path of the ball is the developmental history of part of the egg, showing the increasing stability of the developing tissue types. *Source:* From *The Strategy of the Genes: A Discussion of Some Aspects of Theoretical Biology* (p. 29), by C. H. Waddington, 1957, London: Allen & Unwin. Copyright 1957 by Allen & Unwin. Reprinted with permission of Mrs. M. J. Waddington.

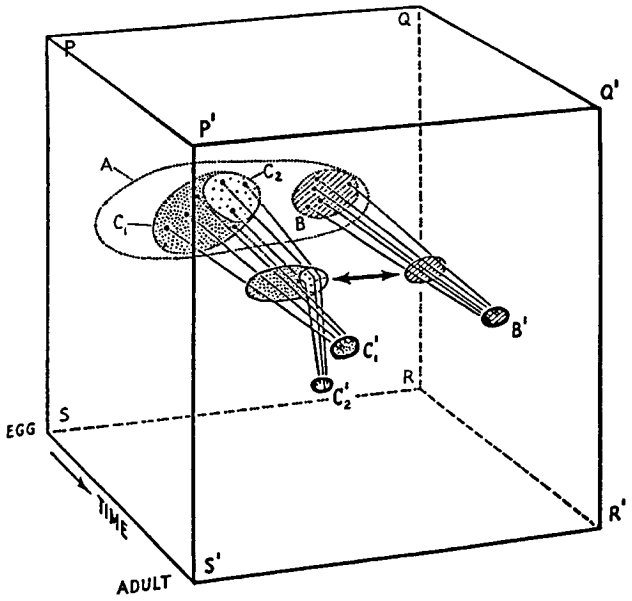

Figure 6.1 Waddington's phase-space diagram of development. Time runs along the z-axis, from plane PQRS at the time of fertilization to P′Q′R′S′ which is adulthood. The other two dimensions represent the composition of the system. The diagram shows how the egg, which has continuous composition gradients becomes differentiated into specific tissues. Some areas in the state space act as attractors, pulling in nearby trajectories. *Source:* From *The Strategy of the Genes: A Discussion of Some Aspects of Theoretical Biology* (p. 28), by C. H. Waddington, 1957, London: Allen & Unwin. Copyright 1957 by Allen & Unwin. Reprinted with permission of Mrs. M. J. Waddington.

state (the ball could be anywhere on the landscape), development creates hillocks and valleys of increasing complexity. As development proceeds, the tissue types become separated by higher hills, signifying the irreversible nature of development. However, the pathways down the landscape also show buffering; that is, development proceeds in globally similar ways despite somewhat different initial conditions, and despite minor perturbations or fluctuations along the way. In his last book, published posthumously in 1977, Waddington called the epigenetic landscape an "attractor landscape" (p. 105). He asked, "How do we find out the shape of the landscape?" He suggested: "So what we should try to do is to alter it, slightly, in as many ways as possible and observe its reactions. We will find that the system resists some types of changes more than others, or restores itself more quickly after changes in some directions than in others" (Waddington, 1977, p. 113). Similarly, in our version of a dynamic systems account, probing the system's stability is also a critical step.

Since Waddington, theorists and mathematicians have offered numerous dynamic models of morphogenesis, the emergency of form (see, e.g., Gierer, 1981; Goodwin & Cohen, 1969; Meakin, 1986; Tapaswi & Saha, 1986; Thom, 1983; Yates & Pate, 1989, among others). The common features of these models are initial conditions consisting of very shallow gradients, differential mechanical factors such as pressures or adhesions

in the cells, or both. The gradient or force fields are represented by one of several classes of differential equations, which express change as a function of time. Some sets of equations involve lateral inhibition, which allows a small local activation to become enhanced and form the node of a pattern. When the equations are solved for variety of parameters, complex spatial patterns are generated, which may consist of cycles, multiple peaks and valleys, and even fractals (complex scale-independent patterns). Combining two or more gradients with different rates of change and coupling their interactions can lead to highly complex patterns, including stripes, columns, and so on: "[V]ery complex real patterns may arise on the basis of elementary field-forming mechanisms and their combinations" (Gierer, 1981, p. 15).

One of the most delightful and fanciful of these models of pattern formation is that of the mathematician J. D. Murray, who provides an elegant model of the ontogeny of mammalian coat patterns: "How the leopard got its spots" (Murray, 1988, 1993). Think about your last visit to the zoo and the remarkable range of coat markings you saw: The complex spots and stripes of zebras, leopards, and giraffes; the simpler stripes of skunks and badgers; and the softly shaded patterns of some ungulates. Murray shows how a *single* mechanism, modeled by a simple nonlinear equation of the developmental process, can account for all the variations in coat markings. The equation is of the reaction-diffusion type, where an initial gradient of some chemical (the morphogen) can take on particular rates of reaction combined with varying rates of diffusion in a close surface. The interactions between the chemical reaction and its rate of diffusion are highly nonlinear, meaning that sometimes the reaction proceeds in a stable manner, but, at other values, the reaction is unstable and no pigment is formed. This nonlinearity leads to either a smooth or a patch-like pattern of reaction products on the surface. Critical factors include the reaction rates; when the process is started, presumably under genetic control; and then, only the geometry and scale of the initial gradient is believed to be some substance that activates melanin (pigment) production in melanocyte cells in the skin surface during early embryogenesis.

The power of Murray's simple model is illustrated in Figure 6.3, which shows the results of the simulations of the equation with set parameters, changing only the scale of surface of the body over which the chemical

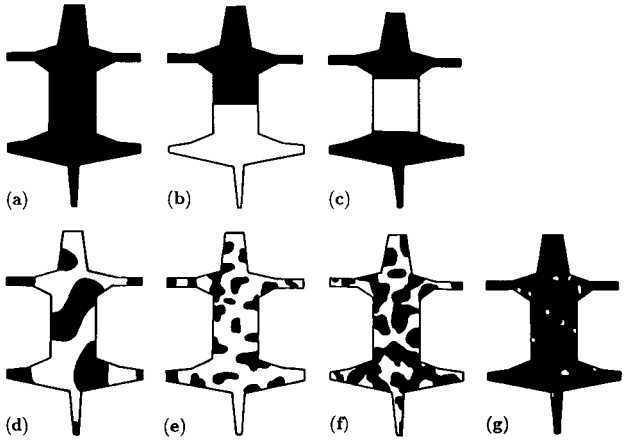

Figure 6.3 The effect of body surface scale on the patterns formed by a reaction diffusion mechanisms for mammalian coat coloration. A single mechanism can account for diverse coat patterns, depending on the parameter values in the equations. *Source:* From *Mathematical biology* (2nd ed., p. 445), by J. D. Murray, 1993, Berlin, Germany: Springer-Verlag. Copyright 1993 by Springer-Verlag. Reprinted with permission.

dynamics occur. As the body is scaled up over 50,000 times (presumably, from a mouse to an elephant), a regular series of patterns emerges: The solid color of very small animals, then the simple bifurcations and the more elaborate spottings, and, again, the nearly uniform coat of large animals. (Indeed, very small and very large mammals are more likely to have solid coats.) In real animals, small random variations in the initial gradient would lead to the noticeable individual variations in coat pattern. The important fact is that the *dynamics* of the reactions create the pattern.

Embryologists and theoreticians of morphogenesis show how, during development, extraordinarily complex structural patterns can arise from very simple initial conditions in dynamic systems. The patterns that result are not specifically coded in the genes. Although all leopards are spotted and all raccoons have striped tails, there is no dedicated gene for spots on the leopard or striped tails for raccoons. Structural complexity is constructed during development because living systems with particular chemical and metabolic constraints spontaneously organize themselves into patterns. In such systems, the issue of "what causes what to happen" is particularly thorny. When all parts of the system cooperate, when a group of cells only takes on a particular fate in the context of its position among other cells, it is simply not feasible to ask whether this structure or this behavior is "caused" by genes or by

environment. Through experimentation and modeling, the efforts of embryologists are directed toward a deep and detailed understanding of process.

The implications of embryology for theories of psychological development are profound. Often we find ourselves searching for the "cause" of development, or the essential structure that makes some behavior—language, walking, number concepts—what it is. Thus, much developmental research has been directed toward discovering invariants—the programs, stages, structures, representations, devices, schemas, or modules—that underlie performance at different ages. A good part of this search is directed toward which invariants are "innate" (present at birth), which are "genetic" (hard-wired into the system by natural selection), and which, by analogy to genes, "determine" developmental outcome (e.g., Gelman & Gallistel, 1978; Spelke, Breinlinger, Macomber, & Jacobson, 1992). But embryology teaches us that the genes do not—in and of themselves—determine developmental outcome. Genes are essential elements in a dynamic cascade of processes. Understanding the development means understanding that cascade.

The Mountain Stream Metaphor

The larger lesson from embryology for psychology is this: the stable regularities we see in developed organisms—the phenomena we seek as psychologists to explain—might not have specific causes that can be demarcated and isolated but rather may be understood only as a dynamic cascade of many processes operating over time. This idea challenges the usual notions of science that we understand by analysis, by isolating *things*—ingredients and components—until we arrive at the essential *stuff.* Explanations in terms of complex and cascading processes as opposed to explanations in terms of a list of parts is difficult even for scientists (see Chi, Slotta, & de Leeuw, 1994). Accordingly, we offer a metaphor that may seem at first far afield, but we hope that thinking about it explains process as the cause of structure.

The metaphor is of a fast-moving mountain steam. At some places, the water flows smoothly in small ripples. Nearby may be a small whirlpool or a large turbulent eddy. Still other places may show waves or spray. These patterns persist hour after hour and even day after day, but after a storm or a long dry spell, new patterns may appear. Where do they come from? Why do they persist and why do they change?

No one would assign any geological plan or grand hydraulic design to the patterns in a mountain stream. Rather, the regularities patently emerge from multiple factors: The rate of flow of the water downstream, the configuration of the stream bed, the current weather conditions that determine evaporation rate and rainfall, and the important quality of water molecules under particular constraints to self-organize into different patterns of flow. But what we see in the here-and-now is just part of the picture. The particular patterns evident are also produced by unseen constraints, acting over many different scales of time. The geological history of the mountains determined the incline of the stream bed and the erosion of the rocks. The long-range climate of the region led to particular vegetation on the mountain and the consequent patterns of water absorption and runoff. The climate during the past year or two affected the snow on the mountain and the rate of melting. The configuration of the mountain just upstream influenced the flow rate downstream. And so on. Moreover, we can see the relative importance of these constraints in maintaining a stable pattern. If a small rock falls into a pool, nothing may change. As falling rocks get larger and larger, at some point, the stream may split into two, or create a new, faster channel. What endures and what changes?

Process accounts assume that behavior patterns and mental activity can be understood in the same terms as the eddies and ripples of a mountain stream. They exist in the here-and-now, and they may be very stable or easily changed. Behavior is the product of multiple, contributing influences, each of which itself has a history. But just as we cannot really disentangle the geologic history of the mountain from the current configuration of the stream bed, we also cannot draw a line between the real-time behavior and the lifetime processes that contribute to it. Likewise, there is no separation of the patterns themselves from some abstraction of those patterns.

The mountain stream metaphor depicts behavioral development as an *epigenetic process;* that is, truly constructed by its own history and system-wide activity. This is a venerable idea with a long history in developmental theorizing.

Epigenesis in Developmental Psychobiology

No one understood a systems approach more deeply than a group of developmental psychobiologists working largely in the 1940s, 1950s, and 1960s, especially T. C.

Schneirla, Daniel Lehrman, and Zing-Yang Kuo, whose tradition is carried on today most eloquently by Gilbert Gottlieb (Gottlieb et al., Chapter 5, this *Handbook,* this volume). These biologists used the word *epigenesist* to describe the process of behavioral ontogeny (see Kitchener, 1978, for discussion of the various meanings of the term *epigenesist*). Their vision is best understood as a contrast with the prevailing scientific thought about behavior and its change, and, in particular, the recurrent issue of nature versus nurture.

In those decades, North American psychology was dominated by learning theorists. As is well known, the goal of these experimental psychologists was to elucidate the general laws of behavior as animals are shaped by experience. Behaviorists used a variety of experimental animals such as rats and pigeons, but they believed that the principle of training and reinforcement applied to all species, including humans. Development, according to behaviorist theories, consists of the animal's reinforcement history. The radical environmentalism of behaviorists is captured in a statement from a critical essay by Lehrman (1971):

> Also basic to what I here call the "behaviorist orientation" is the idea that scientific explanations of, and statements of scientific insights into, behavior *consist* of statements about how the experimenter gains control over the behavior, or about how the actions of the subject can be predicted by the actions of the experimenter. (p. 462)

Although learning continues to be an important aspect of developmental accounts, especially in explaining the socialization of children (Bandura, 1977), learning theories have lost favor as general developmental theories. In part, this is due to their inability to explain species differences and to provide satisfactory accounts of cognitive and language development. Equally troubling is that learning alone does not tell us how novelty arises.

In the 1950s and 1960s, a view of behavior became popular that strongly opposed pure learning theories. *Ethological theories* came from the European school associated with Konrad Lorenz and his students. Lorenz's work was seminal in reorienting psychologists to the role of species-typical behavior and animals' adaptations to their environments. And although ethologists such as Lorenz considered learning to be important, learning always was placed alongside behavior deemed innate or instinctive. According to Lorenz (1965), that distinction between innate and learned was of primary importance in understanding behavior and its development. Indeed, Lorenz believed that behavior could be broken up into elements that were wholly innate and elements that were learned, although the focus of ethologists' studies was most often on the innate parts. The form of a behavior—for example, particular courtship calls or displays, or, in humans, facial expressions—was believed to be "hardwired" and not acquired. Lorenz called this class of movements "fixed action patterns" because they were believed to emerge without specific experience. The object and orientation of these displays may be learned during ontogeny. Geese, for instance, instinctively follow objects on which they become imprinted, but they learned to follow Lorenz instead, if he substituted himself for the mother goose at the appropriate time.

The epigeneticists, in contrast to both learning theorists and ethologists, campaigned to eliminate altogether the question of learned versus acquired. They were especially critical of what they considered the vague and ill-defined meaning of such terms as *innate* or *instinctive.* Lehrman's statement in 1953 is as eloquent and relevant today as then:

> The "instinct" is obviously not present in the zygote. Just as obviously, it is present in the behavior of the animal after the appropriate age. The problem for the investigator is: How did this behavior come about? The use of explanatory categories such as "innate" and "genetically fixed" obscures the necessity of investigating developmental *processes* to gain insight into actual mechanisms of behavior and their interrelations. The problem of development is the problem of the development of new *structures* and activity *patterns* from the resolution of the interaction of existing ones in the organism and its internal environment, and between the organism and its outer environment. (p. 338)

In his book, *The Dynamics of Behavior Development: An Epigenetic View,* Kuo (1967) presented a particularly clear statement of developmental process from a systems view. Kuo emphasized that behavior is complex and variable and takes place in a continually changing internal and external environment. The behavior we observe is an integral part of the total response of the animal to the environment, but there are differentiations—or patterned gradients—of response among different parts of the body. He wrote:

> Ontogenesis of behavior is a process of modification, transformation, or reorganization of the existing patterns of behavior gradients in response to the impact of new en-

> vironmental stimulation; and in consequence a new spatial and/or serial pattern of behavior gradients is formed, permanently or temporarily ("learning") which oftentimes adds to the inventory of the existing patterns of behavior gradients previously accumulated during the animal's developmental history. (Kuo, 1970, p. 189)

During the life span, new patterns are selected from among the range of potential patterns:

> Thus, in every stage of ontogenesis, every response is determined not only by the stimuli or stimulating objects, but also by the total environmental context, the status of anatomical structures and their functional capacities, the physiological (biochemical and biophysical) condition, and the developmental history up to that stage. (Kuo, 1970, p. 189)

In his call for an integrated developmental science, Kuo (1970) exhorted scientists to study "every event that takes place under and outside the skin" as part of the behavioral gradient, and not to look just at global measures of organism or environment: "[W]e must take quantitative measures of stimulative effects of every sensory modality, and make qualitative analyses of the interactions of the component parts of the environmental context or complex" (p. 190). Kuo's extraordinary vision, fashioned from his work as both an embryologist and a comparative psychologist, did not have a direct influence on the mainstream of child psychology, which became enraptured with Piaget (1952) at that time, and later with Bowlby (1969) and attachment theory. Nonetheless, a broad systems view has continued with a group of comparative developmental psychobiologists who have conducted exquisite and detailed studies of the intricate interrelated mechanisms of offspring, parents, and environment in early life. These include Gilbert Gottlieb, Jay Rosenblatt, Lester Aronson, Ethel Tobach, Howard Moltz, William Hall, Jeffrey Alberts, Patrick Bateson, Meredith West, and others. Gerald Turkewitz has been a pioneer in continuing the Schneirla-Kuo tradition in human infancy studies.

One hallmark of this comparative work is minute and detailed understanding of the experiential context of the developing organism, including factors that are not necessarily the apparent and obvious precursors to a particular behavior, but may indeed be critical contributors. "Experience may contribute to ontogeny in subtle ways," Schneirla wrote (1957, p. 90), and also in ways that are nonspecific. Small effects of temperature, light, and gravity, at critical times, for instance, can cascade into large developmental differences. Nonobvious and nonspecific factors are important considerations in a dynamic systems view as well.

A beautiful example of developmental analysis in the systems tradition of Schneirla and Kuo is the work of Meredith West and Andrew King on the ontogeny of bird song. West and King's studies on song learning in the cowbird, a brood parasite, have uncovered subtleties and variations in the developmental process that raise questions about a more simplistic earlier view: Song learning was either directed by an innate template or learned by imitation of other singing males. First, they found an overwhelming effect of context on both the learning and the performing of songs—for example, males' being housed with females during rearing affected their song content. Even though females do not sing, they exert social influence on males that are strong enough to override any specific sensory template (King & West, 1988). The mechanism appears to be females' selective responses (by brief wing-flicking movements) during the time when males are learning song. The female cowbird helps shape the male song by her response. Furthermore, experience with cowbird females is essential for appropriate male mating behavior. When male cowbirds were raised with canaries, they sang to and pursued canaries rather than females of their own species. But this preference was not a rigid imprinting, as the old ethologists would have maintained. When these canary-housed cowbird males were housed with cowbird females in their second season, they reversed their preference.

From this and other evidence, West and King conclude that song development is highly multiply determined and dynamic in the sense of being continually constructed in time and space. An animal's species-typical environment of rearing and its own actions in that environment are as "inevitable [a] source of influence as are an animal's genes" (West & King, 1996). And because these dynamic processes are so interactive and nonlinear, fundamental properties disappear when they are disrupted. For example, experimental perturbations to the expected rearing conditions, such as placing animals in isolation or injecting them with hormones, may have both dramatic and subtle cascading effects. Such manipulations often illuminate the interactions in the system, but they must be interpreted with great care. These insights raise cautions about interpretations of experiments with infants and children because the interaction between the experimental manipulation and the

normal, everyday experiences of the subjects are often unknown. A dynamic systems approach suggests that these contextual factors and their time functions are the critical aspects of performance and development.

Recent research by Goldstein and West (1999; Goldstein, King, & West, 2003) strongly illustrates this point. This work concentrates on the development from the sounds children make *prior to language* to those that may be considered *speech* sounds. Prelinguistic vocal development or "babbling," long thought to be driven exclusively by articulator maturation (e.g., Kent, 1981), takes on new significance when studied from a dynamic systems perspective. When caregivers and infants are studied together as they interact in real time, vocal development shows multicausality and interdependency of timescales. Mothers react in consistent ways to the babbling of even unfamiliar infants, and as babbling becomes more speech-like it more strongly influences mothers' responding (Goldstein & West, 1999). Infants are sensitive to the reactions of caregivers and to their sounds, changing the amount and acoustic form of their babbling in response to changes in the form and timing of their caregivers' behavior (Goldstein et al., 2003).

In the Goldstein et al. (2003) study, mothers of 8- to 10-month-old infants wore wireless headphones, allowing them to receive instructions from an experimenter. When mothers responded (by smiling, moving closer, and touching) contingent to their infants' vocalizations, the infants' babbling incorporated increased voicing and faster consonant-vowel transitions, which are developmentally more advanced forms of production. In contrast, the infants of yoked control mothers, who received the same amount of social stimulation but without contingency, did not change their babbling. Infants must therefore recognize that their sounds produce a change in the environment in order for their sounds to change.

By manipulating caregiver-infant interactions in real time, multiple causes and timescales of vocal development become evident. The mechanisms that create vocal development are not restricted to the infant, but rather the system of caregiver and infant. Patterns of vocalizations are created by the interaction of multiple forces, including the articulatory apparatus, visual and auditory perceptual systems, and learning mechanisms. These components regulate and are regulated by caregiver availability and responsiveness. Vocal development is not an infant ability, but an emergent property of caregiver-infant interaction in that the vocal learning process is created by social interactions. Because developmental advances in babbling change the ways that caregivers react to their infants (Goldstein & West, 1999), setting the stage for new learning to occur, moment-to-moment social interactions are probably linked to the months-long stages (Oller, 2000) that reliably describe the first year of vocal development. From a dynamic systems view, maternal behavior and infant sensory capacities interact to generate the development of more advanced infant behavior. Thus, the patterns of interaction between caregivers and infants are a source of developmental change.

Contextual and Ecological Theorists

The tradition of the embryologists and the epigeneticists emphasized self-organization from multiple processes both in the organism and between the organism and its environment. The focus is on relationships among components as the origins of change, rather than a set of instructions. Such a view naturally turns our attention to the physical and social settings in which infants and children are raised, and it requires as detailed an understanding of the context as of the organism situated in that context. Existing developmental theories can be placed on a continuum as to whether they are more concerned with what is in the child's head or with the specific and changing details of the environment. Piagetian, cognitivist, and information-processing accounts of development, for instance, pay little attention to the particular nature of the physical and social worlds of children. The goal of these approaches is to understand general qualities of mind and how they develop. Because the processes are assumed to be universal adaptations to the world by human brains, it is immaterial, for instance, whether a child learns transitive inference from playing with sticks on the ground, or in a structured school, or by observing groups of people talking and acting. The focus is on the individual as the basic unit of analysis, in the sense that individuals all have common structures and processes above and beyond their differing experiences.

For theorists at the other end of the continuum, a person's experiences in context and culture are not just supportive of development, but are the very stuff of development itself. At this end of the continuum, we group developmentalists who are working in the tradi-

tion of James Mark Baldwin, John Dewey, and Kurt Lewin; more recently, A. R. Luria and L. S. Vygotsky; and who are labeled as *ecological, contextual,* or *cross-cultural* theorists. In addition, some versions of *life-span* perspectives (e.g., Baltes, 1987) also have strong epigenetic and systems assumptions. All these views are well represented in this *Handbook,* this volume, in the chapters by Overton (Chapter 2); Valsiner (Chapter 4); Gottlieb et al. (Chapter 5); Rathunde and Czikszentmihalyi (Chapter 9); Bradtstder (Chapter 10); Shweder et al. (Chapter 13); Elder, Bronfenbrenner, and Morris (Chapter 12); and Baltes, Lindenberger, and Staudinger (Chapter 11). Although there are many versions of contextualism (see reviews by Dixon & Lerner, 1988; Ford & Lerner, 1992), they share certain assumptions about development, and these assumptions overlap with many features of a dynamic systems approach. First and foremost is the quest to eliminate the duality between individual and environment, just as the epigeneticists endeavored to erase the boundaries between structure and function.

All developmental theorists would acknowledge that humans and other living beings can be described over many levels of organization from the molecular and cellular, through the complex level of neural activity and behavior, and extending to nested relationships with the social and physical environments (e.g., Bronfenbrenner, 1979). And all developmental theories also view these levels as interacting with one another. The deep difference between contextualism and more individual-centered approaches is that the levels are conceptualized as *more* than just interacting; instead, they are seen as integrally fused together. Behavior and its development are melded as ever-changing sets of *relationships* and the history of those relationships over time. Thus, as mentioned earlier, we must discard our notions of simple linear causality: That event A or structure X *caused* behavior B to appear. Rather, causality is multiply determined over levels and continually changing over time.

Systems ideas have radical implications for the study of mind. For example, the idea that knowledge is emergent and that human behavior is socially constructed in task and history is beautifully illustrated in Hutchins' (1995) recent study of navigation. Navigation in modern navies is achieved via a complex system of interactions among a large number of people and measuring devices. These interactions are shaped and maintained by the culture of military practice and language, but also by the geography of large ships, the measuring devices, the psychology of individuals, and the encountered tasks. No one element alone does the navigation. Hutchins' analysis, based on both participant observation and computer simulation, shows how all these elements matter—how the smartness of navigation teams emerges, depends on, and is constrained by the physical components, traditional roles, and culture. Navigation teams *are* smart. Their activity is event-driven and goal-directed. The navigation team must keep pace with the movement of the ship and must maintain progress. When things go wrong, there is no option to quit and start over; the right decision must be made at the moment. Hutchins' work shows how these decisions are distributed over the interactions of individuals—none of whom knows all there is to know about the problem. Nor is the optimal system one in which the problem has been logically divided up into mutually exclusive parts and assigned to individuals in a perfect division of labor. Rather, navigation teams are characterized by partially redundant and sometimes rapidly changing patterns of interactions and information flow. The intelligence sits in the patterns of interactions in the whole and has properties quite unlike those of the individuals who comprise that whole.

At the end of his book, Hutchins (1995) reflects on the meaning of culture and socially distributed cognition for cognitive science:

> The early researchers in cognitive science placed a bet that the modularity of human cognition would be such that culture, context, and history could be safely ignored at the outset and then integrated in later. The bet did not pay off. These things are fundamental aspects of human cognition and cannot be comfortably integrated into a perspective that privileges abstract properties of isolated individual minds. (p. 354)

General Systems Theories

We have described theoretical approaches to development at different levels of organization, from embryological to societal. These approaches are based on common assumptions about systems' complexity and the multiple interrelated causes of change. However, the characteristics of developing organisms emphasized in these views—self-organization, nonlinearity, openness, stability, and change—are not confined to biological systems. They are also found in complex physical systems such as chemical reactions, global weather changes, mountain streams, clouds, dripping faucets—

wherever many components form a coherent pattern and change over time. The principles of dynamic systems formulated by physicists and mathematicians to describe the behavior of such complex physical systems may also be the best way to study and understand developing organisms.

Kurt Lewin and Dynamic Force Fields. One of the earliest explicitly dynamic formulations of development was Kurt Lewin's (1936, 1946) topological *field theory* of personality development. Lewin was unabashedly antireductionist. How, he asked, can psychology present all the richness of human behavior as the novelist, but "with scientific instead of poetic means" (Lewin, 1946, p. 792)? Referencing Einstein's theoretical physics, Lewin (1946) proposed:

> The method should be analytical in that the different factors which influence behavior have to be specifically distinguished. In science, these data have also to be represented in their particular setting within the specific situation. A totality of coexisting facts which are conceived of as mutually interdependent is called a *field.* (p. 792)

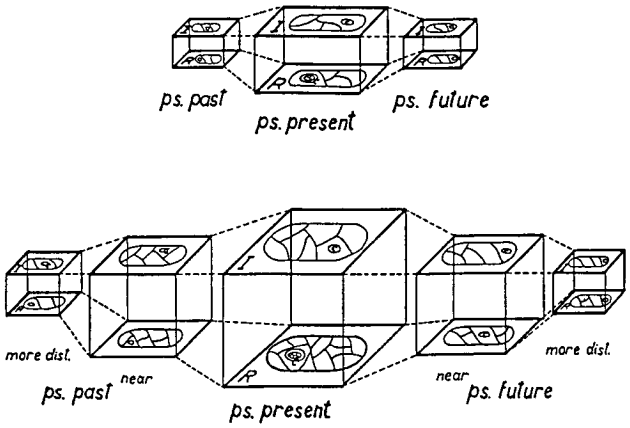

Figure 6.4 Lewin's psychological space (ps.) landscapes, depicted as layered systems of force fields with R = "reality" and I = "Irreality," and showing the connection between the motivational forces in the past, present, and future. The top panel depicts a life space of a young child; the bottom, that of an older child. *Source:* From "Behavior and Development as a Function of the Total Situation" (p. 798), by K. Lewin, in *Manual of Child Psychology,* L. Carmichael (Ed.), 1946, New York: Wiley. Copyright 1946 by John Wiley & Son. Reprinted with permission.

According to Lewin, a given physical setting has meaning only as a function of the state of the individual in that setting. Conversely, individual traits do not exist outside of the setting in which they are displayed. Lewin called these fields of interactions *life spaces*—fields of forces with varying strengths. People move dynamically through this force field, depending on their location in the space, their needs, and previous history. Forces may compete, conflict, overlap, or sum, depending on the person's disposition and the environment. Learning—and development—consist of finding a pathway or discovering a new niche in the life space. And as children carve new pathways, they actually create yet new parts of the space to explore, a process of self-organization.

Lewin depicted this developmental dynamic as shown in Figure 6.4. Life spaces at different points in development are represented by layered force fields, with different zones for varying degrees of "attraction" to those fields. The parameters of the life space have several dimensions: Size of the space, degree of specificity, separation between reality and "irreality" or fantasy, and the influence of psychological processes across time. The life space of a younger child is more limited and less differentiated, and it is influenced more by the immediate past and projects more into the immediate future than the more expansive space of the older child. Waddington's 1977 illustration of a phase-space diagram of development, shown in Figure 6.1, is remarkably similar to Lewin's in identifying preferred region and depicting development as a progressive drift through this space.

Systems Theory as Metaphor. Kurt Lewin's dynamic concepts were rich, but vague and difficult to operationalize. His ideas were poorly matched to either the mechanistic flavor of North American experimental psychology during the 1950s and 1960s, or to the mentalistic assumptions of Piagetian developmental psychology, and his impact on child psychology was little felt during those decades. Systems thinking about development underwent a small renaissance in the late 1970s and early 1980s, however, and these versions were much more explicitly tied to the new sciences of complexity in physics, math, and biology. Two authors, Ludwig von Bertalanffy, a biologist, and Ilya Prigogine, a chemist, were especially influential in this renewal.

Ludwig von Bertalanffy (1968) has usually been credited with originating "General Systems Theory." Since the 1930s, he has heralded an antireductionist

view of biological systems (von Bertalanffy, 1933). The dominant trend in all the sciences, from chemistry to psychology, was to isolate smaller and smaller elements of the system, but von Bertalanffy felt that understanding would come, not from these separate parts, but from the relationships among them. So, while animals are made of tissues and cells, and cells are built from complex molecules, knowing the structure of the molecules even in the greatest detail cannot inform us about the behavior of the animal. Something happens when complex and heterogeneous parts come together to form a whole that is more than the parts. The system properties need a new level of description—one that cannot be derived from the behavior of the components alone. These systems principles, in turn, are so universal that they apply to widely diverse beings and entities:

> We can ask for principles applying to systems in general, irrespective of whether they are of physical, biological, or sociological nature. If we pose this question and conveniently define the concept of system, we find that models, principles, and laws exist which apply to generalized systems irrespective of their particular kind, elements, and "forces" involved. (von Bertalanffy, 1968, p. 33)

von Bertalanffy provided dynamic equations to illustrate these principles: Wholeness or self-organization, openness, equifinality (self-stabilization), and hierarchical organization. In his discussion of systems applications to psychology, von Bertalanffy was especially critical of "homeostasis" models of mental functioning, especially the Freudian assumption that organisms are always seeking to reduce tensions and seek a state of equilibrium. Rather, organisms are also *active;* as an open system, they live in a kind of disequilibrium (what we will call dynamic stability) and actively seek stimulation. This disequilibrium allows change and flexibility; the idea that too much stability is inimical to change recurs in many developmental accounts (e.g., Piaget, Werner) and is an assumption we also find essential for understanding development.

The Nobel chemist Ilya Prigogine was the second principal contributor to systems theory and an eloquent popularizer as well (see, e.g., Prigogine, 1978; Prigogine & Stengers, 1984). Prigogine was primarily interested in the physics of systems that were far from thermodynamic equilibrium. Recall that, in Newtonian thermodynamics, all systems run to disorder. The energy of the universe dissipates over time. The universe increases in *entropy,* and, as Prigogine puts it, the "arrow of time" runs in only one direction—toward disorganization. But many systems, and all biological systems, live in thermodynamic nonequilibrium. They are thermodynamically open: They take in energy from their environment and increase their order—the arrow of time is at least temporarily reversed. Development is a premier example of a progressive *increase* in complexity and organization. Such systems take on special properties, including the ability to self-organize into patterns and nonlinearity or sensitivity to initial conditions. Again, it is critical that such systems are inherently "noisy," for order arises from such fluctuations. In equilibrium systems, the noise is damped out and the system as a whole remains in equilibrium. In nonequilibrium systems, in contrast, fluctuations can become amplified and overtake the organization of the whole system, shifting it to a new order of organization.

A number of developmentalists immediately recognized the relevance of these explicit systems principles for age-old, yet still critical, issues in developmental psychology. Sandor Brent (1978), for instance, saw in Prigogine's formulations of self-organization potential solutions for the questions of the origins of complexity and shifts from one developmental stage to more advanced levels. Moreover, Brent believed that ideas of nonlinearity could explain the seemingly "autocatalytic" aspects of development, where one small transformation acts as the catalyst for subsequent, accelerating changes.

Brent's discussion is strictly theoretical. Arnold Sameroff (1983) tied the new systems ideas more concretely to developmental phenomena. Sameroff has long been interested in developmental outcomes of children at risk, particularly in the failure of linear models to predict pathology from antecedent conditions. In an important and influential paper, Sameroff and Chandler (1975) documented the persistently puzzling finding that some children with very serious risk factors around birth, including anorexia, prematurity, delivery complications, and poor social environments, suffered no or little long-term consequences, while others sustained serious effects. Simple cause-and-effect or medical models of disease must be supplanted with a thoroughgoing organismic model, according to Sameroff, where "Emphasis on a wholistic, actively functioning entity that constructs itself out of transactions with the environment is derived from the properties of biological development" (1983, pp. 253–254).

Adoption of such a systems model, with its assumptions of wholeness, self-stabilization, self-organization, and hierarchical organization, has implications for every aspect of developmental psychology, according to Sameroff. For instance, theories of socialization must become thoroughly contextual, because the notion of open systems means that the individual is always in transaction with the environment. Biological vulnerability or risk, in this case, does not exist in a vacuum, but within the rich network of a more or less supportive family and community culture. Outcome is a joint product of the child and the cultural agenda of the society, and the total system has self-organizing and self-stabilizing characteristics.

Likewise, the issue of *change* motivates the *developmental system theory* of Ford and Lenrer (1992). In reasoning that closely parallels our own, Ford and Lerner begin with a view of humans as "multilevel, contextual organizations of structures and functions" (p. 47) who exhibit varying kinds of stability and variability and who can change both in and between levels. Individual development, according to these theorists:

> *involves incremental and transformational processes that, through a flow of interactions among current characteristics of the personal and his or her current contexts, produces a succession of relatively enduring changes that elaborate or increase the diversity of the person's structural and functional characteristics and the patterns of their environmental interactions while maintaining coherent organization and structural-functional unity of the person as a whole.* (p. 49, italics in original)

The definition, they maintain, implies a lifelong possibility of change, multiple (although not infinite) and nonlinear developmental pathways, discontinuities, and the emergence of new forms. Furthermore, the definition specifies that development is never a function of person or context alone, but indeed results as a function of their dynamic interaction. Figure 6.5 is Ford and Lerner's model of developmental change as a series of probabilistic states, where control systems interact in the person and the environment. States are thus the current configuration of the system, based both on current status and on the system's immediate and long-term history. We will repeat these themes throughout the remainder of this chapter.

Ford and Lerner's treatise is ambitious in scope; it ties biological and social development into a single developmental systems theory. Their intellectual debt is directly to the "organismic" and contextual school of developmental theory, and less so to physical and mathe-

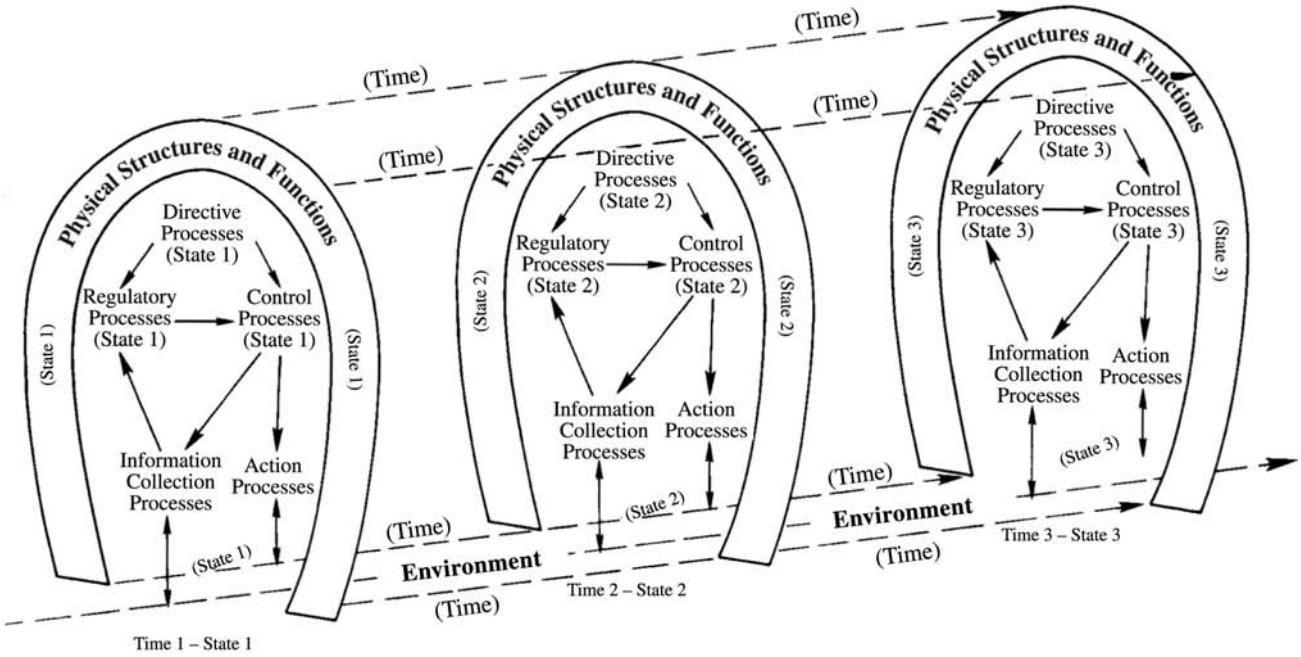

Figure 6.5 Ford and Lerner's model of developmental change as a series of probabilistic states.

matical dynamical systems. Likewise, they are not primarily concerned with operational verification of a systems approach, nor do they connect directly with the experimental and observational studies of individual child development.

This overview of the historical heritage shows systems approaches to have enduring appeal to developmentalists. This makes sense. As developmentalists, we are continually faced with the richness and complexity of the organisms we study and the elaborate causal web between active individuals and their continually changing environments. The recent contribution of the dynamic systems theories to this tradition is that such theories allows us to express, in words and in mathematical formalisms, complexity, wholeness, emergence of new forms, and self-organization. They provide a way to express the profound insight that pattern can arise without design: Developing organisms do not know ahead of time where they will end up. Form is a product of process.

An Introduction to Dynamics Systems Thinking

Despite a long tradition of systems thinking in development, from embryology to the study of culture and society, these formulations have remained more of an abstraction than a coherent guide to investigation or a means for synthesis of existing data. Developmentalists may acknowledge that systems matter, but it has been difficult to design and carry out empirical research based on a core of systems principles. In the remainder of this chapter, we summarize a set of dynamic principles applicable to human development and then show how research can be inspired, conducted, and interpreted from a dynamic perspective. We base our summary of dynamic systems heavily on the brand of dynamics set forth by Haken (1977) called *synergetics.* Note that other formal systems of dynamics have been applied to development, such as van Geert's "logistic growth model," van der Maas and Molenaar's "catastrophe theory" that we will discuss subsequently. Still other examples can be found in Smith and Thelen (1993).

Nature is inhabited by patterns in time. The seasons change in ordered measure, clouds assemble and disperse, trees grow to certain shape and size, snowflakes form and melt, minute plants and animals pass through elaborate life cycles that are invisible to us, and social groups come together and disband. Science has revealed many of nature's secrets, but the processes by which these complex systems form patterns—an organized relationship among the parts—remain largely a mystery. In the past decade or so, however, physicists, mathematicians, chemists, biologists, and social and behavioral scientists have become increasingly interested in such complexity, or in how systems with many, often diverse, parts cooperate to produce ordered patterns. The scientific promise is that a common set of principles and mathematical formalisms may describe patterns that evolve over time, irrespective of their material substrates.

Order from Complexity

The key feature of such dynamic systems is that they are composed of very many individual, often heterogeneous parts: molecules, cells, individuals, or species, for example. The parts are theoretically free to combine in nearly infinite ways. The *degrees of freedom* of the system are thus very large. Yet, when these parts come together, they cohere to form patterns that live in time and space. Not all possible combinations are seen; the original degrees of freedom are compressed. But the patterns formed are not simple or static. The elaborate shapes or forms that emerge can undergo changes in time and space, including multiple stable patterns, discontinuities, rapid shifts of form, and seemingly random, but actually deterministic changes. The hallmark of such systems is that this sequence of *complexity to simplicity to complexity* emerges without prespecification; the patterns organize themselves. Our mountain stream shows shape and form and dynamic changes over time, but there is no program in the water molecules or in the stream bed or in the changes of climate over geological time that encodes the ripples and eddies.

Developing humans are likewise composed of a huge number of dissimilar parts and processes at different levels of organization, from the molecular components of the cells, to the diversity of tissue types and organ systems, to the functional defined subsystems used in respiration, digestion, movement, cognition, and so on. But behavior is supremely *coherent* and supremely *complex,* again showing complexity from simplicity from complexity. The self-organization of mountain streams is manifest; we argue here that the patterns seen in developing humans are also a product of the relations among multiple parts.

Both mountain streams and developing humans create order from dissimilar parts because they fall into a class called *open systems,* or systems that are *far from*

thermodynamic equilibrium. A system is at thermodynamic equilibrium when the energy and momentum of the system are uniformly distributed and there is no flow from one region to another. For instance, when we add alcohol to water or dissolve salt in water, the molecules or ions mix or react completely. Unless we heat the system or add an electric current, the system is stable. Nothing new can emerge; the system is *closed.* Systems such as moving stream beds or biological systems evolve and change because they are continually infused with or transfer energy, as the potential energy of water at the top of the mountain is converted to the kinetic energy of the moving water. Biological systems are maintained because plants and animals absorb or ingest energy, and this energy is used to maintain their organizational complexity. Although the second law of thermodynamics holds that systems should run down to equilibrium, this is only globally true. Locally, some systems draw on energy and increase their order.

Open systems, where many components are free to relate to each other in nonlinear ways, are capable of remarkable properties. When sufficient energy is pumped into these systems, new ordered structures may spontaneously appear that were not formerly apparent. What started out as an aggregation of molecules or individual parts with no particular or privileged relations may suddenly produce patterns in space and regularities in time. The system may behave in highly complex, although ordered ways, shifting from one pattern to another, clocking time, resisting perturbations, and generating elaborate structures. These emergent organizations are totally different from the elements that constitute the system, and the patterns cannot be predicted solely from the characteristics of the individual elements. The behavior of open systems gives truth to the old adage, "The whole is more than the sum of the parts."

The condensation of the degrees of freedom of a complex system and the emergence of ordered pattern allows the system to be described with fewer variables than the number needed to describe the behavior of the original components. We call these macroscopic variables the *collective variables* (also called *order parameters*). Consider human walking, a multidetermined behavior. At the microscopic level of all the individual components—muscles, tendons, neural pathways, metabolic processes, and so on—the system behaves in a highly complex way. But when these parts cooperate, we can define a collective variable that describes this cooperation at a much simpler level—for instance, the alternating cycles of swing and stance of the feet. This cyclic alternation is a collective variable, but it is not the only one. We might also look at patterns of muscle firing or forces generated at the joints. The choice of a collective variable is a critical step in characterizing a dynamic system, but it is not always easy to accomplish, and it may depend considerably on the level of analysis to be undertaken.

Attractors and Dynamic Stability

A critical property of self-organizing, open systems is that, although an enormous range of patterns is theoretically possible, the system actually displays only one or a very limited subset of them, indexed by the behavior of the collective variable. The system "settles into" or "prefers" only a few modes of behavior. In dynamic terminology, this behavioral mode is an *attractor* state, because the system—under certain conditions—has an affinity for that state. Again in dynamic terms, the system prefers a certain location in its *state,* or *phase space,* and when displaced from that place, it tends to return there.

The state space of a dynamic system is an abstract construct of a space of any number of dimensions whose coordinates define the possible states of the collective variable. For example, the behavior of a simple mechanical system such as a pendulum can be described completely in a two-dimensional state space where the coordinates are position and velocity as seen in Figure 6.6. As the pendulum swings back and forth, its motion can be plotted on this plane. The motion of

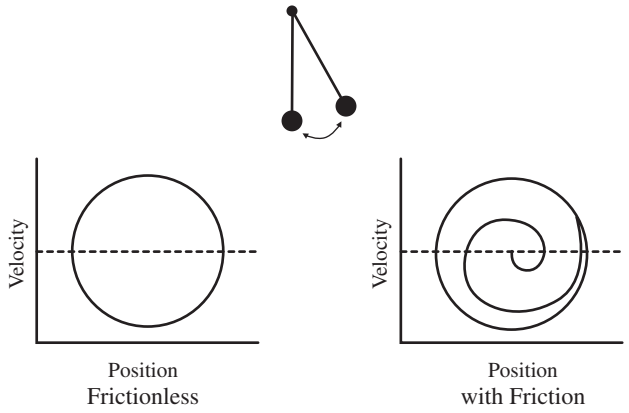

Figure 6.6 A simple pendulum as a dynamic system. Without friction, the pendulum will exhibit a *limit cycle attractor.* With friction, the pendulum will settle into a single, *point attractor.*

an ideal, frictionless pendulum prescribes an orbit or path through the state space that tracks its regular changes of position and velocity. If we add friction to the pendulum, it will eventually come to rest, and its orbit will look like a spiral.

The circular orbit of the frictionless pendulum and the resting point of the pendulum with friction are the attractors of this system. When friction is present, the attractor is a *point attractor* because all the trajectories in the space converge on that resting point, regardless of the system's starting point or initial conditions. Although the pendulum has only one fixed point, biological systems commonly have more than one point attractor; the system may reach one of the several possible equilibrium points, depending on the initial conditions. All the initial conditions leading to a particular fixed point attractor are called *basins of attraction.*

In the pendulum example, without friction, the attractor is of the *limit cycle* or *periodic* type; it will continually repeat its oscillations. When the pendulum is slightly perturbed, it returns, in time, to its periodic behavior. Once the pendulum is given its squirt of energy, these time and space patterns capture all other possible trajectories in the state space, and they represent stable collective variables for the pendulum system. In biological organisms, periodic behavior is often the collective result of the *coordination of* components each with its own preferred pattern (Kugler & Turvey, 1987; Schōner & Kelso, 1988). Consider human locomotion. The cyclic alternation of the legs during normal walking reflects the coupling of two legs 180 degrees out of phase. Such coordination dynamics can be represented on a phase space consisting of all the possible phase relationships between the two legs. In dynamic terms, there is a strong attractor at 180 degrees out-of-phase. Given ordinary conditions, people prefer to locomote by using their legs in alternation, however, there are also periodic attractors at 0 degrees (jumping) or 90 degrees (galloping), but they are far less stable under normal circumstances, and thus are rarely seen (at least in adults!).

Finally, a special type of attractor, the *chaotic* attractor, has received much attention in popular accounts of nonlinear dynamics. *Chaos* has a particular technical meaning in dynamics. Chaos describes systems whose behaviors look random at close glance but, when plotted over a long time on a state space, are not random and display extremely complex geometric structures. There is growing evidence that many biological systems are chaotic—for example, heart rate fluctuations (Goldberger & Rigney, 1988), electrical activity in the olfactory bulb (Freeman, 1987), and patterns of movements in human fetuses (Robertson, 1989).

For developmentalists, the most important dimension of a behavioral pattern preference or attractor is its *relative stability.* The concept of dynamic stability is best represented by a *potential landscape.* Imagine a landscape of hills and valleys, with a ball rolling among them depicting the state of the collective variable as shown in Figure 6.7. A ball on the top of a hill (a) has a lot of stored potential energy; with just a very small push, it will roll down the hill. Thus, the state of the system, represented by the ball, is very unstable. Any nudge will dislodge it. A ball in a deep valley (b), in contrast, has very little potential energy and needs a large external boost to change its position. The latter is a very stable attractor; the former is called a *repellor* because the system does not want to sit on the hill. A ball in a shallow well (c) is moderately stable, but will respond to a sufficient boost by moving into the neighboring well (while not dwelling very long on the hillock in between). Over a long enough time, all the balls in the landscape

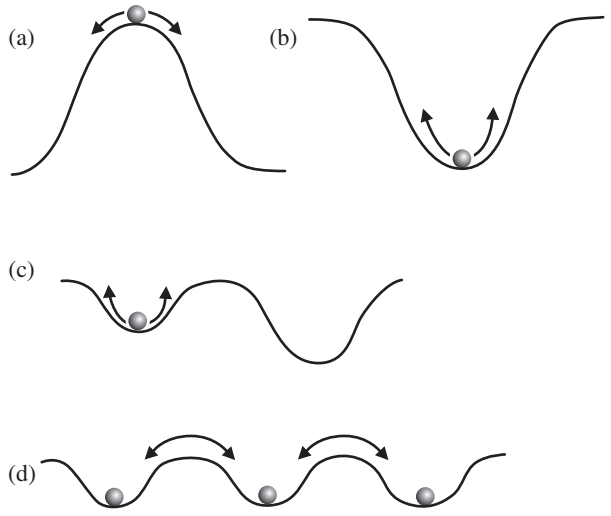

Figure 6.7 Stable and unstable attractors. The stability of the attractor depicted as potential wells. The ball on the top of the hill (a) has a lot of potential energy, and even a very small push will dislodge it; it is a repellor. The ball at the bottom of the step hill (b) requires a large energy boost to send it over the top. If perturbed, it will quickly return to the bottom. It is a stable attractor. The ball in the shallow well (c) is in a less stable situation. Relatively small perturbations will push the ball around, although, given enough time, it will probably end up in the deeper well because of its own stochastic noise. A behavioral system (d) may have multistability.

will end up in the deepest valley, although neighboring valleys may be deep enough that escape from them is very unlikely. Figure 6.7d also shows such a *multistable* attractor, with three point attractors and two repellors between them.

The stability of a system can be measured in several ways. First, stability is indexed by the statistical likelihood that the system will be in a particular state rather than other potential configurations. Second, stability responds to perturbation. If a small perturbation applied to the system drives it away from its stationary state, after some time the system will settle back to its original equilibrium position. As seen in Figure 6.7, when the potential valley is deep and the walls are steep, the ball will return quickly to the bottom. In contrast, the same perturbation applied to a ball in a shallow potential well will take longer to return to equilibrium because the restoring force is less. If the ball is pushed away from a hilltop, however, it will never return. Thus, one indication of system stability is this *local relaxation time* after a small perturbation.

Third, stability is related to the system's response to natural fluctuations within the system. Recall that complex systems exhibiting patterns are composed of many subsystems. Each of these subsystems has noise associated with it, and these intrinsic noises act as stochastic forces on the stability of the collective variable. This is another way of saying that complex systems, even apparently stable ones, are nonetheless dynamic. If the system resides in a steep and deep well, these random forces will have little effect and the ball will not fluctuate very much around the mean attractor pattern. In the shallow well, however, these small forces are more effective and the ball should roll around more. The size of the deviations from the attractor state can be measured, for example, by the variance or standard deviation of the collective variable around the attractor state. The more stable the attractor, the smaller the standard deviation around the attractor.

Soft Assemblies

As Figure 6.7 indicates, calling a pattern an attractor is a statistical statement about where the system prefers to reside, and how resistant it is to internal and external forces. Although some attractor states are so unstable as to almost never be observed, other attractor states are so stable that they look like they are inevitable. Because these behavioral states are so reliably seen under certain circumstances, it is easy to believe that they are generated by hardwired structures or programs within the system. Very stable attractors take very large pushes to move them from their preferred positions, but they are dynamic and changeable nonetheless. This is one way of saying that the system is "softly assembled" (Kugler & Turvey, 1987) rather than hardwired or programmed. The components can assemble in many ways, although only one or several of them are stable enough to be seen. We argue here that, in action and cognition, and in development, many configurations that act like programs, stages, or structures are stable attractors whose stability limits may indeed be shifted under appropriate circumstances. That is to say, many mental constructs and movement configurations—object permanence and walking, for example—are attractors of such strength and stability that only the most severe perturbations can disrupt them. They look as though they are wired in. Other abilities—transitive inference, visual illusions, and many sport skills, for example—have attractors whose stability is easily upset by contextual manipulations or lack of practice, or by not paying attention.

A good developmental example of a softly assembled system is the infant locomotor pattern of creeping on hands and knees. This pattern has traditionally been described as a "stage" in the ontogeny of human locomotion: Nearly all human infants crawl before they walk. It is tempting to think of crawling as a necessary precursor to upright locomotion; indeed, some physical therapists believe infants must go through this stage for successful sensorimotor integration. In dynamic terms, however, we can see creeping as a temporary attractor, a pattern that the system prefers, given the current status of the infant's neuromuscular system and the infant's desire to get something attractive across the room. When babies do not have the strength or balance to walk upright, creeping is a self-assembled solution to independent mobility—a statistical probability, but not an inevitable solution. In fact, some infants use anomalous patterns such as crawling on their bellies or scooting on their bottoms, and some infants never crawl at all. The typical crawling pattern then is a preferred attractor, but not a hardwired stage.

Soft assembly is the core assumption of a dynamic view of development. It banishes forever the vocabulary of programs, structures, modules, and schemas and supplants these constructs with concepts of complexity, stability, and change. Stability defines the collective states of the system, assessed by its resistance to change. Fluctuations around stable states are the inevitable accompa-

niment of complex systems. These fluctuations—the evidence that a system is dynamically active—are the source of new forms in behavior and development.

How Systems Change: Fluctuations and Transitions

We have defined behavioral patterns as variously stable, softly assembled attractor states. How do patterns change, as they do in development or in learning? Here we invoke the notion of nonlinearity, a hallmark of dynamic systems. A pattern in a dynamic system is coherent because of the cooperation of the components. This coherence is maintained despite the internal fluctuations of the system and despite small external pushes on it. Thus, because walking is a very stable attractor for human locomotion, we can walk across the room in high-heeled shoes, on varied surfaces, and even while we are talking or chewing gum. But as the system parameters or the external boundary conditions change, there comes a point where the old pattern is no longer coherent and stable, and the system finds a qualitatively new pattern. For example, we can walk up hills of various inclines, but when the steepness of the hill reaches some critical value, we must shift our locomotion to some type of quadrupedal gait—climbing on all fours. This is an example of a *nonlinear phase shift* or *phase transition,* highly characteristic of nonequilibrium systems.

In the case of our locomotor patterns, the parameter change was simply the steepness of the hill to climb. Gradual changes in this parameter engendered gradual changes in our walking until a small change in the slope causes a large change in our pattern. In dynamic terminology, the slope changes acted as a *control parameter* on our gait style. The control parameter does not really "control" the system in traditional terms. Rather, it is a parameter to which the collective behavior of the system is sensitive and that thus moves the system through collective states. In biological systems, any number of organismic variables or relevant boundary conditions can be relatively nonspecific, and often may be changes in temperature, light, speed of movement, and so on.

For example, Thelen and Fisher (1982) discovered that body weight and composition may act as a control parameter for the well-known "disappearance" of the newborn stepping response. Newborn infants commonly make stepping movements when they are held upright, but after a few months, the response can no longer be elicited. Although the traditional explanation has been inhibition of the reflex by higher brain centers, Thelen and Fisher noticed that movements similar to steps did not disappear when infants were supine instead of upright. This made a central nervous system explanation unlikely. Rather, they noticed that infants gained weight, and especially body fat, at a rapid rate during the period when stepping was suppressed. They reasoned that as their legs got heavier without a concomitant increase in muscle mass, the infants had increasing difficulty lifting their legs in the biomechanically demanding upright posture. Body fat deposition is a growth change that is not specific to leg movements, yet it affected the system such that a qualitative shift in behavior resulted.

Change may thus be engendered by components of the system that are nonobvious, but, in other cases, the control parameter may be specific to the system in question. For example, practice or experience with a specific skill may be the critical factor. For instance, 8- to 10-month-old infants do not reach around a transparent barrier to retrieve a toy (Diamond, 1990b). Normally, infants have little experience with transparent barriers. However, when Titzer, Thelen, and Smith (2003) gave infants transparent boxes for several months, the babies learned to shift their usual response of reaching in the direct line of sight in favor of reaching into the opening of the box. In this case, infants' learning the perceptual properties of transparent boxes through exploration was the control parameter engendering the new form of knowledge.

As we discussed earlier, not all changes in a system are phase shifts. At some values of a control parameter, the system may respond in a linear and continuous manner. Nonlinearity is a threshold effect; a small change in the control parameter at a critical value results in a qualitative shift. Control parameters (whether they are nonspecific, organic, or environmental parameters) or specific experiences lead to phase shifts by threatening the stability of the current attractor. Recall that all complex systems carry in them inherent fluctuations. When the system is coherent and patterns are stable, these fluctuations are damped down. However, at critical values of the control parameter, the system loses its coherence, and the noise perturbs the collective variable. At some point, this noise overcomes the stability of cooperative pattern, and the system may show no pattern or increased variability. However, sometimes as the control parameter passes the critical value, the system may settle into a new and different coordinative mode.

The most elegant demonstration of behavioral phase transitions comes from the work of Kelso and his

colleagues in a long series of studies and models of human bimanual coordination (see the extensive discussion in Kelso, 1995). The basic experiment is as follows: Participants are asked to move their index fingers either in-phase (both fingers flexed and extended together) or antiphase (one finger flexed while the other is extended). They are then told to increase the pace of the cyclic movements. Participants who begin in the antiphase condition usually switch to in-phase just by speeding up with no change in patterns. Thus, both patterns are stable at low frequencies, but only the in-phase is stable at higher frequencies. In dynamic terms, the collective variable of *relative phase* is sensitive to the control parameter, frequency.

Using this simple experiment, Kelso and his colleagues showed definitively that the phase shift from anti- to in-phase movements was accompanied by a loss of system stability. The standard deviations around a mean relative phase remained small until just before each participant's transition, when the deviations increased dramatically. Then, as the participant settled into the in-phase pattern after the shift, deviations were again small. Likewise, when Scholz, Kelso, and Schōner (1987) perturbed the movements with a small tug during the various frequencies, they observed that recovery to the desired frequency was more difficult as participants approach the anti- to in-phase transition. Disintegration of the system coherence was reflected in diminishing strength of the antiphase attractor to pull in the trajectories from various regions of the state space.

Development from a Dynamic Systems Perspective

In this section, we give an overview of dynamical systems using Waddington's epigenetic landscape as a means of illustrating the main concepts. We then use the developmental problem of learning to reach as an example of how these themes can be used to guide experiments and research. Finally, we turn to the development of the object concept, and, in particular, use the A-not-B error to show how these ideas may be incorporated into formal theories of behavior and development.

A Dynamic Epigenetic Landscape

We have thus far described self-organizing systems as patterns of behavior "softly assembled" from multiple, heterogeneous components exhibiting various degrees of stability and change. According to a dynamic systems view, development can be envisioned as a series of patterns evolving and dissolving over time, and, at any point in time, possessing particular degrees of stability. Expanding on the potential landscape representation we introduced earlier, we can depict these changes, in an abstract way, in Figure 6.8 our depiction closely parallels Waddington's famous epigenetic landscape (Figure 6.2) in both its early (1957) and later (1977) incarnations.

The first dimension in Figure 6.8 is time (Muchisky, Gershkoff-Stowe, Cole, & Thelen, 1996). The landscape progresses irreversibly from past to present, from background to foreground. The second dimension—the surface—is that of the collective variable, or a measure of the cooperative state of the system. Each of the lines forming the landscape represents a particular moment in time. These lines depict the range of possibilities of the system at that point in time. The configuration of each line is a result of the history of the system up to that point, plus the factors acting to parameterize the system at the time—such as the social and physical context, the

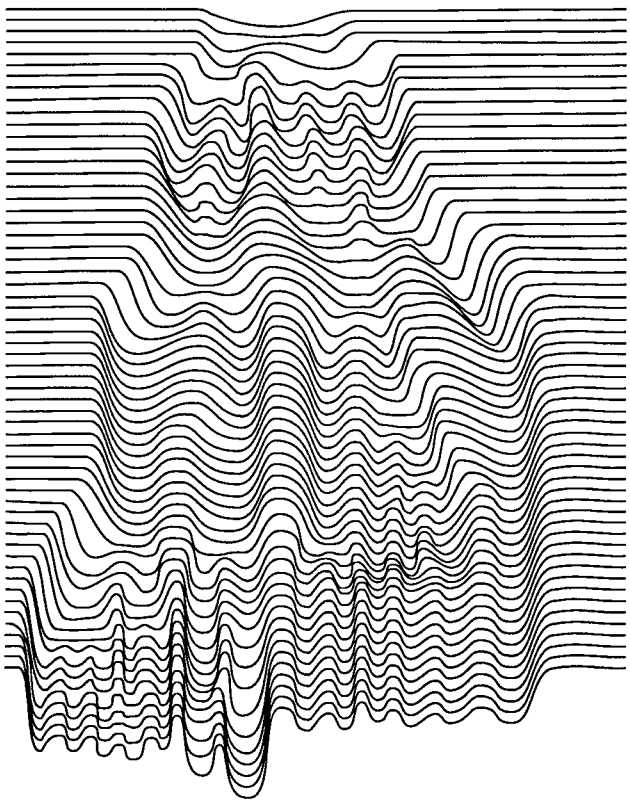

Figure 6.8 An adaptation of Waddington's epigenetic landscape (Figure 6.2). This version depicts behavioral development as a series of evolving and dissolving attractors of different stability.

motivational and attentional state of the child, and so on. The third dimension of the landscape is related to the depth of the variations of the collective variable lines, the various dips and valleys. The depth represents the stability of the system at that point in time, and in that particular combination of constraining factors, and thus captures the probabilistic rather than rigidly fixed nature of behavioral and cognitive states.

Nested Timescales

The landscape represents one critical property of developing dynamic systems: The nesting of changes on multiple timescales. The contexts and conditions that determine the stability of a system at any point in time (t) constitute the initial conditions for the state of the system at the next instant of time ($t + 1$). Likewise, the properties of the system at ($t + 1$) determine its state at ($t + 2$), and so on. The system is thus *reiterative;* each state is dependent on the previous state.

Most important, this reiterative process occurs at all timescales. Thus, a landscape of evolving and dissolving stabilities just as easily depicts the dynamics of a real-time process, such as reaching for an object, producing a sentence, or solving an addition problem as it represents changes in those abilities over minutes, hours, days, weeks, or months. In dynamic terms, the timescales may be *fractal* (Grebogi, Ott, & Yorke, 1987) or have a self-similarity at many levels of observation. For example, coastlines are typically fractal—the geometry of the coastline depends entirely on the scale by which it is measured. Represented on a scale of kilometers, the coast may be described as a simple curve, but that simplicity disappears when the measuring scale is meters or centimeters. Nonetheless, the simple curve *is* the collection of small coves and irregularities apparent to the person walking on the beach as well as to the small sand crab inhabiting a different geometric scale. Likewise, we argue, while perceiving, acting, and thinking occur in their own times of seconds and fractions of seconds, these accumulated actions constitute the larger coastline of developmental change (Samuelson & Smith, 2000).

In a dynamic view, each behavioral act occurs *over time,* showing a course of activation, peak, and decay, and with various levels of stability associated with each point in time, but every act changes the overall system and builds a history of acts over time. Thus, repeating the same behavior in seconds or minutes can lead to habituation or to learning, as the activity of one instant becomes the starting point for the activity of the next. We can thus envision a small-scale landscape evolving in the domain of *real time* as in Figure 6.9. In our illustration, consider behavioral act A with a sharp rise time of activation and a very slow decay. With repetition, the threshold for activating A is diminished because the activity has been primed by previous activations. The behavior becomes more stable, more easily elicited, and less able to be disrupted—the person has learned something. An equally plausible account is that activating A might raise the threshold for a repetition of the same act, as happens in adaptation, habituation, or boredom.

Because the history of acting in real time counts, the real-time dynamics of actions may display this important property of *hysteresis* (e.g., Hock, Kelso, & Schōner, 1993), when the same conditions lead to different behavioral outcomes, depending on the immediate previous history of the system. Behavioral acts therefore carry with them not only the dynamics of their immediate performance, but a *momentum* (e.g., Freyd, 1983) so that the system is always impacted by every act of perceiving, moving, and thinking, albeit to various degrees. Just as minute-by-minute activities carry with them a history and build momentum, so also do these accumulated histories constitute the stuff of learning and development change. Each line in our landscape depicting the probability of the system's states contains its own fractal timescale. Thinking and acting are functions of the history of thinking and acting at the same time that development is also of that history. Habituation, memory, learning, adaptation, and development form one seamless web built on process over time—activities in the real world.

Such a view of nested timescales radically changes our views of what is "represented" in the brain. Typically, in

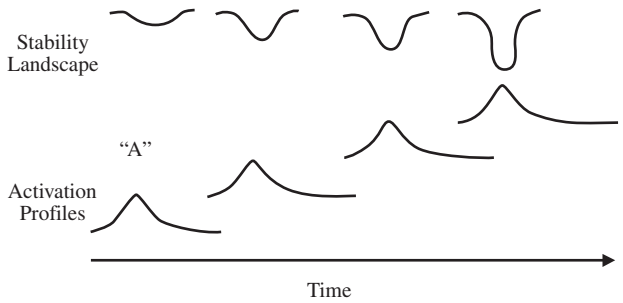

Figure 6.9 Effect of repeating behavior over time. Each activation may act to prime or to lower the threshold for the next repetition. A lowered threshold may make behavior more stable, acting as a local attractor.

studies of cognitive development, researchers present infants and children with tasks designed to assess what the children really know. Thus, experiments that show infants possible versus impossible physical events purport to reveal whether infants know that objects are solid, cannot occupy the same space as another object, obey the laws of gravity and momentum, and so on (e.g., Baillargeon, Spelke, & Wasserman, 1985; see also Cohen & Oakes, 1993). Or, on the basis of their performance with a series of colored rods, children are assumed to "have" the ability to make transitive inferences—to infer a third relation from two others. ("If the blue rod is longer than the green rod and the green rod is longer than the yellow rod, is the blue rod longer than the yellow rod?") If children fail on these tests, they do not have the knowledge of physical properties of objects or the ability to think about two things at the same time.

The core assumption here is that knowledge or abilities are stored "things" that are timeless and exist outside their here-and-now performance. An experimental task is good only as it reflects a "true" reading of the underlying mental structure. This common viewpoint has run into serious difficulties, however, both empirically and theoretically. First, literally thousands of studies have demonstrated that children's knowledge or their ability to use certain procedures is extremely fluid and highly dependent on the entire context of the experimental situation, including the place of the experiment, the instructions and clues, their motivation and attention, and very subtle variations in the task (Thelen & Smith, 1994). For example, based on the colored rod task, Piaget concluded that preschoolers could not make transitive inferences. However, when Bryant and Trabasso (1971) drilled preschoolers in the premise information until they learned and remembered that "the blue rod is longer than the green one," the preschoolers *could* make these inferences. Similarly, the failure of 6-month-old infants to search for hidden objects led Piaget to believe that infants cannot mentally represent objects when they are out of sight (Piaget, 1954). Yet, at the same age, infants act surprised when they *watch* objects disappear from expected locations.

To explain these strange results—how children can know things in one situation, but not another—developmentalists have proposed that the child has the "real" competence all along, but the failure lies in some performance ability. In the case of transitive inference, Bryant and Trabasso (1971) reasoned that the failure was not in lacking the mental structure, but in remembering the premises. When they trained memory, the competence was revealed. Likewise, 6-month-old infants do know that objects persist, but they are deficient in searching—actually reaching out, removing a cover, and retrieving the object. Changing the task to remove the search component revealed the essential knowledge of object permanence. Very young children may thus possess considerable cognitive competence, but the competence is hidden because of immature memory, motor skills, language, or attention.

This distinction between competence and performance has been a major force in developmental thinking for the past 20 years (Gelman, 1969). In domain after domain, researchers have followed this train of logic: Define the *essence* of some knowledge structure, do a thorough task analysis, strip away the supporting process and performance variables, and see whether children possess the "essential" knowledge. By these procedures, researchers have unmasked cognitive competences at earlier and earlier ages, certainly beyond those proposed by Piaget and his followers. In addition, the competence/performance distinction seems to help explain Piagetian *decalage:* Why the same child may perform at one cognitive level in one task and at another level in tasks believed to tap into a similar structure. Again, the difficulty lies in the ability of the task to actually reveal the hidden structure.

Why does a dynamic account render the competence/performance distinction as theoretically insufficient? Because behavior is always assembled *in time.* There is no logical way of deconstructing what is the "essential," timeless, and permanent core and what is only performance and of the moment. Because mental activity has developed in time from fundamentals in perception and action and is always tied in real time to an internal and external context, there is no logical way to draw a line between these continuous processes. The essence of knowledge is not different from the memory, attention, strategies, and motivation that constitute knowing. In addition, seeking a core competence often reduces to an exercise in task analysis. Does watching objects disappear constitute the true measure of object permanence? How many clues are allowed in the experiment, or how many familiarization trials are sufficient to peel away the superfluous performance impedances? Does not being able to retrieve a hidden object mean that the child really "knows," or is knowing separate in this case from knowing in order to act? One danger of such accounts is that, in the quagmire of definitions and task

analysis, developmental process itself is lost. How does it happen that this child behaves as he or she does at this moment in this context? What in the child's history, or in the history of children in general, leads to these patterns in time?

Layered Levels of Analysis. Taking time seriously also means integrating over multiple timescales and levels of analysis. Neural excitation, for example, happens in milliseconds. Reaction times are of the order of hundreds of milliseconds. People learn skills after hours, days, and months of practice. Developmental change occurs over weeks, months, years. Traditionally, psychologists have considered action, learning, and development as distinct processes. But for the organism time is unified and coherent, as are the different levels in the system. Every step an infant takes, for example, is both a product and a producer of change—at the level of neurons, eyeballs and muscles, motivations, and ideas about space and surfaces. A complete theory of walking requires integrating mechanisms of change at all these levels. The study of development, then is necessarily concerned with how change at different times and at different levels of analysis interact.

An illustration of this is presented in the work of Neville and her colleagues (see Neville & Bavelier, 2002 for review) on the neural and behavioral development of deaf individuals. Growing up deaf leads to different outcomes in *visual processing* which are readily apparent in event-related potentials (ERPs) in response to peripheral visual events. She found that such ERPs from visual areas were 2 to 3 times larger for hearing than for deaf individuals. Neville explains these differences in terms of the competitive processes that operate in development between visual and auditory cortical regions. But think about what this means in terms of the dynamics of change. The moment-to-moment experiences of individual deaf children—internal neural activity on the order of milliseconds—is different for a visual system developing without audition than for one developing with audition. The accrued effects of these millisecond differences in neural activity *over the long term* create changes in neural connectivity that then determine the different patterns of neural activity evident in the ERPs of hearing and deaf adults. Events on the order of milliseconds, repeated over a longer timescale cause changes in both slower processes of growth (neuronal connectivity) and also faster processes of neural activation (ERPs).

We note here several other research programs that also explicitly seek an understanding of developmental change in nested levels of analyses (Gershkoff-Stowe, 2001, 2002) show how every word that a child utters changes the processes of lexical retrieval, changes that in turn enable the system to produce many different words in rapid succession. Likewise, Adolph, Vereijken, and Shrout (2003) show how every step taken down an incline plane changes the body dynamics and what an infant knows about slopes. Finally, Thomas and Karmiloff-Smith's (2003) recent work on developmental disorders, and particularly William's syndrome, cogently makes the point that understanding development—and intervening effectively—requires understanding how processes of change on multiple timescales interact with each other to create the developmental trajectory. Their general program of research is based on the idea that static models of brain functioning—where functions are mapped to circumscribed brain regions—are inappropriate for the study and understanding of developmental disorders, including genetically based ones such as William's syndrome. Rather, they argue that the brains of atypically developing children are not normal brains with parts intact and parts impaired (as is the case in normal adult brain injury) but brains that have developed differently throughout embryogenesis and postnatal development. Reminiscent of the conclusions from Neville's studies of brain development in the deaf, structure-function mappings in the brain are a product of a developmental cascade involving processes at many timescales. The simulation studies by Thomas and Karmiloff-Smith (2003) provide particularly useful insights into atypical developmental trajectories, which grow out of small differences in the timing and operation of general processes (see also Elman, Bates, Johnson, & Karmiloff-Smith, 1996).

Lewis has extended the idea of nested levels to the study of emotion and personality. He asks: How do we shift from being happy to sad when we are told of an unhappy event? How and why do moods settle in (e.g., depressions, contentment)? Why are some of us more prone to these moods than others? How do these happy and unhappy episodes and these moods create our personalities? How do our personalities create and play out in our emotional episodes, in our mood swings? Understanding emotion requires understanding how processes at different timescales influence each other. In a recent new theory of emotion and personality development,

Lewis (2000) likens the relationship between emotional episodes, moods, and personality to circular causality across different scales of analyses that characterize coastlines. The large-scale or macroscopic properties of a coastline—the bays, the ridges, the peninsulas—set the conditions for the small-scale or microscopic processes—waves, tidal forces, erosion. But these microscopic properties causally contribute to the long-standing macroscopic properties. This is an example of circular causality. Understanding emotion and personality development requires working out the same kind of circularly causal relationships—from the microscopic emotional states through the midscale of moods to the more stable personality. Table 6.1 summarizes Lewis's three scales of emotional development, showing parallels and distinctions across scales and the current understanding of the psychological and neurobiological mechanisms.

These developmental patterns fit the larger idea behind the landscape in Figure 6.8: The changing stability of patterns over many scales of time. Each line on the landscape represents the states of a behavioral pattern expressed as the collective variable; that is, the condensation of the multiple components into a simpler behavioral expression. Knowing the behavior of the collective variable is an essential first step in discovering the processes of change. But a more complete understanding also requires that we know about the behavior of the components that constitute the cooperative ensemble. This is especially important in developmental studies because the contributions and weights of these elements may themselves change over time and in different contexts. For example, leg mass and fat-to-muscle ratio may be potent contributors to behavioral expression of stepping at 2 months, but changes in these anatomical parameters may be far less important in the transition to independent walking at 12 months. At the later age, although infants need sufficient leg mass and strength to support their weight, the ability to maintain balance using vision and proprioception may be the critical component. Likewise, although focused attention may determine success in early stages of learning new skills, as skills become more automatic, the relative contribution of attention is diminished.

Because the components themselves have a developmental history and relationships among them are continually altered, a fuller representation of our dynamic landscape would look like Figure 6.10 That depiction shows three landscapes layered on top of one another, indicating that the components of the dynamic system themselves have a dynamic. The arrows connecting the layers show that the coupling between the components is complex and contingent, and may change over time. This means that the coupling is always multidirectional, and that effects of the subsystems on one another may cascade over time. To continue our infant stepping example, increasing leg muscle strength through activity in the first months of life facilitates standing, crawling, and walking. Independent locomotion induces change in spatial cognition, probably because as infants move around they pay more attention to their spatial landmarks (Acredolo, 1990; Bertenthal & Campos, 1990). But changes in cognition also feed back to locomotor behavior as more skilled infants explore and exploit more and different aspects of their spatial environment, change their motor planning, and are able to make rapid adjustments to unexpected events.

TABLE 6.1 Summary of Lewis's (2000) Proposed Nested Time Scales in Emotional Development

	Emotional Episode	Mood	Personality
Timescale	Seconds to minutes	Hours, days	Years
Description	Rapid convergence of cognitive interpretation with emotional state	Lasting entrainment of interpretative bias	Lasting interpretative-emotional habits
Dynamic system formalism	Attractor	Temporary modification of state space	Permanent structure of interpretative state space
Possible neurobiological mechanism	Cortical coherence mediated by orbitofrontal organization entrained with limbic circuits	Orbitofrontal-corticolimbic entrainment, motor rehearsal, and preafference, sustainded neurohormone	Selection and strengthening of some corticocortical and corticolimbic connections, pruning of others, loss of plasiticity
Higher order form	Intention, goal	Intentional orientation	Sense of self

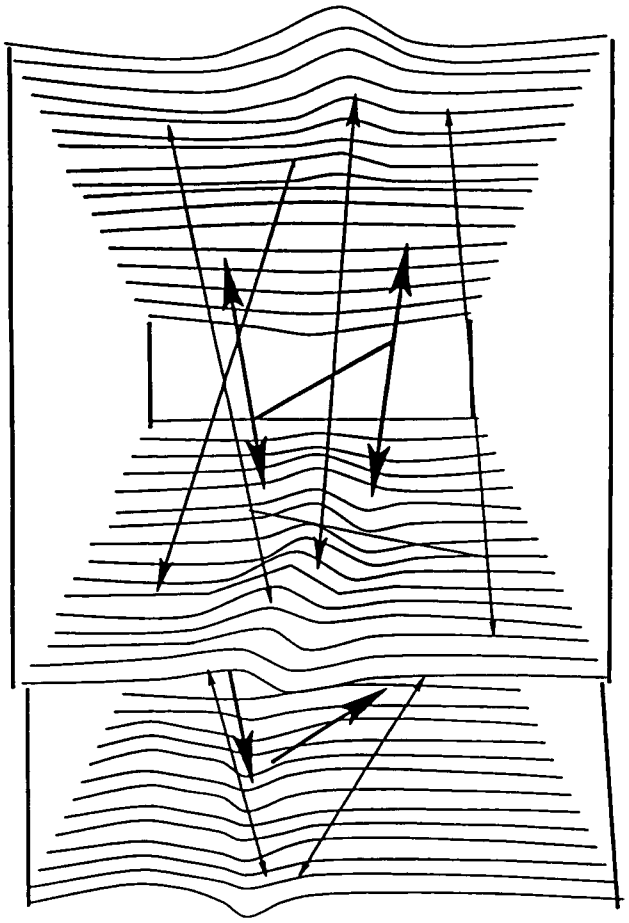

Figure 6.10 The epigenetic landscape as a multilayered system where the components mutually influence each other in changing ways.

Importantly, explanations at every level must be consistent and ultimately reconcilable. This is especially important when considering the neural basis of behavior. Since the time of Myrtle McGraw (1932), there has been a tradition in human developmental studies to seek explanation at the neural level, to look for some observed change in behavior *as caused* by a preceding and determining change in the brain. For example. Goldman-Rakic (1987) and others have suggested that massive reorganization of synaptic connections in the prefrontal cortex are the reason why 8- to 12-month-old infants show improvements in spatial cognition, inhibition of prepotent response tendencies, and even the onset of language. Thatcher and others seek to explain Piagetian stages as a result of stagelike changes in brain activity (Thatcher, 1991, 1992).

A successful search for the mechanisms of change during development may require *integration* of mechanisms at very different levels of organization. For example, by discovering that the deposition of body fat acts as a control parameter in the disappearance of newborn stepping, we have supplied a mechanism of change. A physiologist might ask about the metabolic processes that accelerate the deposition of fat in the postnatal period, and that could also constitute a process-based explanation of change. But the metabolic explanation should not be construed as any more basic and more real than one at any other level. Indeed, because levels and processes are mutually interactive, it is impossible to assign one level as the ultimate causation. Descriptions of change of many components are needed so that multilevel processes and their mutual interactions can be fully integrated.

Multicausality. Developing organisms are complex systems composed of very many individual elements embedded within, and open to, a complex environment. These components continuously interact with each other and in so doing change each other and the system as a whole. This is the idea of *multicausality.* As in many other complex systems in nature, such systems can exhibit coherent behavior: the parts are coordinated without an agent or a program that produces the organized pattern. Rather, the coherence is generated solely in the relationships between the organic components *and the constraints and opportunities of the environment.* This is the idea of an open system, one in which the environment (the task) is a component, equal to all others, in generating coherence. This self-organization means that no single element—internal or external—has causal priority. When such complex systems self-organize, they are characterized by the relative stability or instability of their states. Development can be envisioned as a series of evolving and dissolving patterns of varying dynamic stability, rather than an inevitable march toward maturity. Thus, crawling is a coherent behavior that infants use to locomote when they have sufficient strength and coordination to assume a hands-and-knees posture, an environment to support it and to motivate self-movement, but a system not yet balanced and strong enough to walk upright. Crawling is a stable behavior for several months. But when infants learn to walk, the crawling pattern becomes destabilized by the patterns of standing and walking. There is no program for crawling assembled in the genes or wired in the nervous system. It self-organizes as a solution to a problem in a task context (move across the room), later to be replaced by a more efficient solution.

Heterogeneous Systems and Degeneracy. These ideas about multicausality, self-organization, and openness fit emerging ideas about neural development. The brain is made up of many different parts and processes, but each is in continuous interaction with the other parts and, through the sensory-motor system, with the world (e.g., Churchland & Sejnowski, 1992; Crick, 1994; Damasio, 1994; Edelman, 1987; Huttenlocher, 2002; Kelso, 1995; Koch & Davis, 1994). The brain also has a property that Edelman (1987) calls *degeneracy,* which in neural structure means that any single function can be carried out by more than one configuration of neural signals and that different neural clusters also participate in a number of different functions. Degeneracy creates redundancy such that the system functions even with the loss of one component. For example, Bushnell (1994) states that because we encounter space through sight, sound, movement, touch, and even smell, we can know space even if we lack one modality. Being blind, for example, does not wipe out spatial concepts; instead, as studies of blind children show (e.g., Landau & Gleitman, 1985) comparable spatial concepts can be developed through different clusters of modalities.

Degeneracy also means that different systems can educate each other, without an external teacher. Careful observers of infants have long noted that they spend literally hours watching their own actions (e.g., Bushnell, 1994; Piaget, 1952)—holding their hands in front of their faces, watching as they turn them back and forth, and some months later, intently watching as they squeeze and release a cloth. This second characteristic of multimodality is what Edelman (1987) calls *reentry,* the explicit interrelating of multiple simultaneous representations across modalities. For example, when a person experiences an apple—and immediately characterizes it as such—the experience is visual but it also invokes the smell of the apple, its taste, feel, heft, and a constellation of sensations and movements associated with various actions on the apple. Importantly, these multimodal experiences are time locked and correlated.

Changes in the way the hand feels when it moves the apple are time locked with the changes one sees as the apple is moved. The time-locked correlations create a powerful learning mechanism, as illustrated in Figure 6.11, which shows four related mappings. One map is between the physical properties of the apple and the neuronal activity in the visual system. Another map is between the physical properties of the apple and neuronal activity in the haptic system. The third and fourth

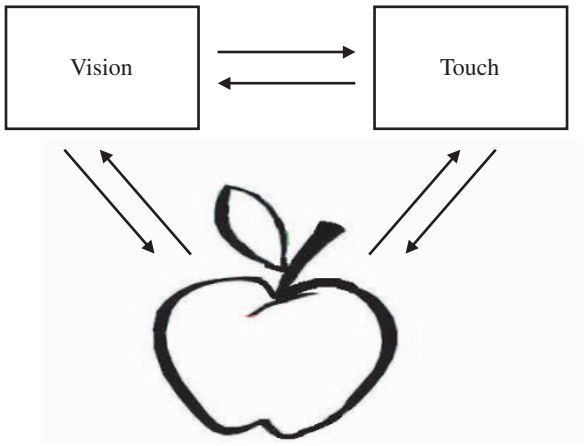

Figure 6.11 Illustration of the time-locked mappings of two sensory systems to the events in the world and to each other. Because visual and haptic systems actively collect information—by moving hands, by moving eyes, the arrows connecting these systems to each other also can serve as teaching signals for each other.

maps are what Edelman calls the *reentrant maps:* Activity in the visual system is mapped to the haptic system, and activity in the haptic system is mapped to the visual system. Thus the two independent mappings of the stimulus—the sight and the feel—provide qualitatively different glosses on the world, and by being correlated in real time, they educate each other. At the same time, the visual system is activated by time-varying changes in shading and texture and collinear movement of points on the apple, the haptic system is activated by time-locked changes in pressures and textures. At every step in real time, the activities in each of these heterogeneous processes are mapped to each other, enabling the system in its own activity to discover higher-order regularities that transcend particular modalities.

Experience-Dependent Plasticity. Neuroscientists have known for nearly half a century that the surface of the cerebral cortex contains maps of the sensory input and movements of various parts of the body arranged in roughly topographic order. The prevailing assumption was that these neatly ordered representations were established in early life by the maturation of the neural anatomy and remained static thereafter. These old truths have been discarded. In the past decade, it has been discovered that, in monkeys, these maps are established and maintained by function, and the adult brain has heretofore unimagined plasticity.

Brain plasticity has now been found not just in the somatosensory cortex, but also in somatic senses in subcortical areas and in the visual, auditory, and motor cortices in monkeys and other mammals (Kaas, 1991, see also Stein & Meredith, 1993). These demonstrations of adult plasticity are very important for understanding development because (a) they demonstrate that brain representations, even those that can be "geographically" located, are dynamic processes, and (b) they provide clues to the very processes by which development may take place.

The now classic experiments were performed by Merzenich and his colleagues on New World monkeys, which have relatively unfissured brains with a clear somatotopic representation of their sensitive hands. A painstaking mapping of the sensation on the finger and hand areas to electrophysiological responses on the cortical surface revealed detailed maps of adjacent areas that were similar, but not identical, in individual monkeys (Jenkins, Merzenich, & Recanzone, 1990). That these areas are plastic, not anatomically rigid, was demonstrated in several ways. First, when the experimenters amputated digits, the maps reorganized so that adjacent areas enlarged to fill in the finger spaces where input was eliminated. Second, when the Merzenich group fused two fingers of adult monkeys together, the monkeys' brains eliminated the boundaries between the digits, and the receptive fields overlapped. When the skin-fusion was surgically corrected, distinctive digit areas returned. Enhanced function of a single finger through training enlarged its cortical representation, which again could be reversed when training ceased. Finally, even when no experimental manipulations were imposed, borders of digit representations changed somewhat over time, presumably reflecting the immediate use history of the finger. These and other experiments revealed, in the words of Merzenich, Allard, and Jenkins (1990) that "*the specific details of cortical 'representations'—of the distributed, selective responses of cortical neurons—are established and are continually remodeled BY OUR EXPERIENCES throughout life*" (p. 195; emphasis and capitals in original).

We end this section with a point to an intriguing new idea: Synesthesia in adults is a remnant of the pervasive interconnectivity and exuberant multimodal nature of the developing brain. *Synesthesia* is defined as the regular involuntary experience of external, durable, and generic perceptions in senses not commonly associated with a certain stimulus (Harrison, 2001). For example, the letter A might be associated with red or the smell of the flowers. Not all possible cross-modal correspondences show up as synesthetic experiences. Instead, they tend to consist of perceiving colored letters or musical notes or colored sounds and tastes. Synesthesia was long considered psychological exotica (see Harrison, 2001) and not systematically investigated—in part because synesthetic experiences are so constrained to a few odd kinds of correspondences, highly individualistic (while some individuals might perceive a high C as orange, others might perceive it as blue), and because very few adults report such cross-modal sensory experiences. However, recent behavioral studies with adults show the psychological reality in phenomena such as pop-out effects in search tasks and recent imaging studies show the neural reality. There are growing suggestions (see Mondloch & Maurer, 2004) that these idiosyncratic synesthetic connections in adults are vestiges of the exuberant interconnectivity in the developmentally immature, an interconnectivity that plays an important role in developmental process, and in the creation of the seemingly separate sensory systems in mature organisms (see also Turkewitz, 1994).

Multimodal Processes in Cognitive Development. One demonstration of the developmental power of heterogenous systems coupled to each other and time locked to the world comes from a study of how babies come to understand transparency. Transparency is a problematic concept; think of birds who harm themselves by trying to fly through windows. Transparency is a problem because correlations between visual cues and the haptic cues that characterize most of our encounters with the world do not work in this case. So babies, like birds, are confused by transparency. In one study, Diamond (1990b) presented infants with toys hidden under boxes such that there was an opening on one side—as illustrated in Figure 6.12. These boxes were either

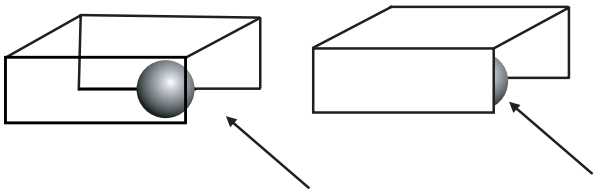

Figure 6.12 A toy (ball) hidden under a transparent box and an opaque box in the Diamond task. The opening is indicated by the arrow.

opaque—hiding the toy—or transparent so that the infants could see the toy under the box. The key result is that 9-month-old infants are better able to retrieve the toy from the opaque than from the transparent container. The problem with the transparent container is that infants attempt to reach for the toy directly, through the transparent surface, rather than searching for and finding the opening.

Infants readily solve this problem, however, if they are given experience with transparent containers. Titzer, Thelen, and Smith (2003) gave 8-month-old babies either a set of opaque or transparent buckets to play with at home. Parents were given no instructions other than to put these containers in the toy box, making them available to the infants during play. The infants were then tested in Diamond's task when they were 9 months old. The babies who had been given opaque containers failed to retrieve objects from transparent ones just as in the original Diamond study. However, infants who played with the transparent containers sought out and rapidly found the openings and retrieved the object from the transparent boxes.

Why? These babies in their play with the containers—in the inter-relation of seeing and touching—had learned to recognize the subtle visual cues that distinguish solid transparent surfaces from no surface whatsoever and had learned that surfaces with the visual properties of transparency are solid. The haptic cues from touching the transparent surfaces educated vision, and vision educated reaching and touch, enabling infants to find the openings in transparent containers. These results show how infants' multimodal experiences in the world create knowledge—about openings, object retrieval, and transparent surfaces.

Experimental studies of human cognition suggest that many concepts and processes may be inherently multimodal in ways that fit well with Edelman's idea of reentrance (e.g., Barsalou, 2005; Glenberg & Kaschak, 2002; Gogate, Walker-Andrews, & Bahrick, 2001; Lickliter, 1994; Richardson, Spivey, Barsalou, & McRae, 2003). One line of evidence for this conclusion is that even in tasks meant to be explicitly unimodal, multiple modalities contribute to performance. For example, *visual* object recognition appears to automatically activate the actions associated with the object. In one study, adults were shown a picture of a water pitcher such as that illustrated in Figure 6.13. The task was simple, to press a button indicating whether the object was a pitcher (yes) or it was not (no). Response time was the dependent measure. This is a purely visual object recognition task. Yet, the participants were much faster at recognizing the object if the button pressed to indicate the yes response was on the same side as the pitcher's handle, as if seeing the handle primed (and readied) the motor response of reaching to that side. Similar results have been reported with a wide variety of objects and in tasks using several different methods. In general, people are faster in visual recognition tasks when the response to be made is compatible with a real action on the object. These results tell us that visual recognition is a piece of, in the same internal language as, action. This is how it must be under the idea of reentrant mappings, where visual recognition is built out of and educated by its time-locked connections with actions on objects.

Figure 6.13 Illustration of the Tucker and Ellis task. On each trial the task is the same, to answer as rapidly as possible the question: "Is this a pitcher." Half the participants answer "yes" by pressing a button on the right and half by pressing a button on the left. Participants are faster when the handle is on the same side as the "yes" response.

Development as Selection. In an earlier section, we proposed very general principles of dynamic systems as a way of conceptualizing developmental change: Patterns assembled for task-specific purposes whose form and stability depended on both the immediate and more distant history of the system. We emphasized that a dynamic view meant that there must be continuity among the components of the system, both internal and external, and among the timescales over which the system lives. Contemporary discoveries of brain organization and function are highly consistent with these dynamic principles; indeed, they provide insights into the precise mechanisms of change.

Properties that point to development as a *selective* process indicate that the brain is a dynamic collective, with self-organizing and dynamic properties; it is designed to extract coherence from multiple, time-locked input; and its organization is maintained by function. In the following account, we rely heavily on Gerald Edelman's (1987) "theory of neuronal group selection" (TNGS) as the neural mechanism instantiating dynamic behavioral development.

Several additional assumptions are critical. First, it is assumed that genetic and epigenetic processes during neural embryology produce the global architecture of the brain (see Edelman, 1987, 1988). In that primary architecture, however, there is enormous variability in both the number of individual neurons and their connectivity. Second, connections between neurons and groups of neurons arise through use. Third, there is an overabundance of neurons and possible connections among them, and thus specificity arises through competition.

Imagine, then a newborn infant whose first experiences in the world include nursing at the breast. Associated with the perceptions of the baby's own movements of lips, jaws, tongue, and throat are the taste of the milk, the sight and smell of the mother's skin, the sound of her voice, and the whole body tactile experience of contact and warmth. Because of the degenerate and reentrant web of connections, these perceptions activate time-correlated groups of neurons meshed together, linking the patterns detected by the originally separate sensory systems. It is also highly likely that these perceptions are associated with neural nets from emotional and motivational centers that signal pleasurable feelings (Damasio, 1994; Edelman, 1987). With each suck and swallow, and repeated nursing episode, overlapping, but not identical, groups of neurons also become activated. Common assemblies become strengthened; less-used pathways become less stable. Because the structure is reentrant, common perceptual elements are extracted from these overlapping inputs that are marked by their correlations in real-world time. This mapping over heterogeneous input is the critical process; new relationships are excited and strengthened because they occur together.

With repetition, such a process of selection by function allows the newborn infant to recognize a constellation of features as a higher-order category: "Time to eat." But it is a dynamic category, invoked now by only partial and incomplete features—the nursing position, for example, or the sight and smell of mother, or the act of sucking itself—and it is continually updated as experience accumulates. When feeding is supplemented by a bottle, for instance, the category "time to eat" may be enlarged to include the perceptual qualities of the bottle and an adjustment in the sucking movements to accommodate changes in the nipple. Higher-order knowledge about feeding, object properties, and the behavior of other humans is thus built by selection through everyday activities—looking, moving, hearing, and touching.

Edelman (1987) clearly follows Piaget (1952) in believing that these early perception-action categories are the cornerstone of development. In particular, the emergence of categories is a specific case of dynamic pattern formation. The task facing newborn infants is to reduce the degrees of freedom at many levels: In the external world—the potentially indeterminate nature of the stimuli—this is done by forming perceptual categories; and in the internal world—the equally indeterminate nature of the multiple joints and muscles—this is done by seeking patterns of motor coordination and control. At the same time, and most important, they must match their internal dynamics to those of the world around them; they must make their perceptual categories and their action categories congruent to function in flexible, adaptive ways. In our dynamic approach, perception, action, and cognition are not disjointed; they are part of a singular process.

Thus, we believe that whether we choose the term *pattern formation,* or *coordination,* or *category acquisition,* we are referring to the same dynamic processes whereby complex heterogeneous elements self-organize to produce coherence in time and space. Dynamic patterns can be fleeting or very stable, but, most important, they are time dependent and seamless. By *time dependent,* we mean that each event in the brain and body has a here-and-now, a history, and an effect on the future. By *seamless,* we mean that these time domains are themselves without interruption. The stuff of development is the dynamics of perception, action, and cognition in real time. What the infant sees, thinks, and does in the present provides the aliment for what the child is in the future, just as what the child did in the past is the substrate for how he or she sees, thinks, and acts right now. Thus, we can envision the neuronal processes postulated by TNGS as a specific form of dynamic pattern formation, with the patterns being the categories of perception and action that form the developmental core of higher mental functions and the patterns of thought that

become increasingly complex and generalized throughout infancy and childhood.

Exploration. How can a learner *who does not know what there is to learn* manage to learn anyway? This is a more difficult question than it might first appear. The issue is whether one needs to prespecify the learning tasks and the learning goals, whether the agent or its designer has to know what needs to be learned to learn. Evidence from human development gets us out of this quandary by showing that babies can discover both the tasks to be learned and the solution to those tasks through exploration, or nongoal-directed action. In babies, spontaneous movement creates both tasks and opportunities for learning. One demonstration concerns the study of reaching (Corbetta & Thelen, 1996). The week-by-week development of four babies was tracked over a 3-month period as they transitioned from not reaching to reaching. Four very different patterns of development were observed. Some babies in the nonreaching period hardly lifted their arms at all, but sat placidly watching the world. Other babies were more high-strung and active, flailing and flapping and always moving. These different babies had to learn to solve very different problems to learn to reach out and grasp an object. The flailer would have to learn to become less active, to lower his hands, to bring them into midline. The placid baby would have to learn to be more active, to raise her hands, to lift them up from their usual positions on her side. Each baby did learn, finding a solution that began with exploration of the movement space.

The course of learning for each baby appeared to be one of arousal, exploration, and the selection of solutions from that exploration space. In basic form, the developmental pattern is this: The presentation of an enticing toy is arousing and elicits all sorts of nonproductive actions, and very different individual actions in different babies. These actions are first, quite literally, all over the place with no clear coherence in form or direction. But by acting, by movements that explore the whole range of the movement space, each baby in his or her own unique fashion, sooner or later makes contact with the toy—banging into or brushing against it or swiping it. These moments of contact select some movements in this space, carving out patterns that are then repeated with increasing frequency. Over weeks, the cycle repeats—arousal by the sight of some toy, action, and occasional contact. Over cycles, increasingly stable, more efficient and more effective forms of reaching emerge. What is remarkable in the developmental patterns of the children is that each found a solution—and eventually converged to highly similar solutions—by following individually different developmental pathways. As they explored different movements—in their uncontrolled actions initiated by the arousing sight of the toy—they each discovered initially different patterns, each had a different developmental task to solve. The lesson for building intelligent agents is clear: A multimodal system that builds reentrant maps from time-locked correlations only needs to be set in motion, to move about broadly, even randomly, to learn and through such exploration to discover both tasks and solutions.

The power of movement as a means for exploration is also illustrated by an experimental procedure known as "infant conjugate reinforcement" (Rovee-Collier & Hayne, 1987). Infants (as young as 3 months) are placed on their backs and their ankles are attached by a ribbon to a mobile which is suspended overhead. Infants, of course, *through their own* actions, discover this link. As the infants kick their feet, at first spontaneously, they activate the mobile. In *a few minutes,* they learn the contingency between their foot kicks and the jiggling of the mobile, which presents interesting sights and sounds. The mobile responds conjugately to the infants' actions: The more infants kick and the more vigorously they move, the more motion and sound they produce in the mobile. In this situation, infants increase their kicking to above the baseline spontaneous levels apparent when babies simply look at a nonmoving mobile. Infants' behavior as they discover their control is one of initial exploration of a wide variety of actions and the selection of the optimal pattern to make the interesting events—the movement of the mobile—occur.

Although this is an experimental task, and not an everyday real-world one, it is a very appropriate model for real-world learning. The mobile provides the infant with many time-locked patterns of correlations. More important, infants themselves discover the relations through their own exploratory movement patterns. The infants themselves are moving contingently with the mobile; the faster and harder they kick, the more vigorously the mobile jiggles and sways. This is for infants a highly engaging task; they smile and laugh and often become angry when the contingency is removed. Thus, the experimental procedure *like the world* provides complex, diverse, and never exactly repeating events yet all *per-*

fectly time locked with infants' own actions. And it is exploration, spontaneous nontask-related movement, that starts the process off. Without spontaneous movement, without exploration, there is nothing to learn from the mobile.

Young mammals—including children—spend a lot of time in behavior with no apparent goal. They move, they jiggle, they run around, they bounce things and throw them, and generally abuse them in ways that seem, to mature minds, to have no good use. However, this behavior, commonly called play, is essential to building inventive forms of intelligence that are open to new solutions.

Embodiment. Nervous system are in bodies—and it is through the body the nervous system is connected to (both affecting and being affected by) the world. There is increasing recognition and research on the ways in which cognition—and development—are deeply and completely the product of our continued interaction with the physical world through our bodies. This attention to the body's role in cognition is seen in the study of language (e.g., Glenberg & Kaschak, 2002; Lakoff & Johnson, 1980), in problem solving and memory (Richardson & Spivey, 2000), in joint attention and intention reading (Yu & Ballard, 2004), and in new approaches to a developmental artificial intelligence (Pfeiffer & Scheier, 1999). A key idea in this literature is that cognition does not just reside in organisms, but resides in their coupled interactions with the world (an idea that is also the heart of Gibsonian approaches to perception; see, Gibson, 1979).

One developmental implication is that the physical world serves as a crucial mechanism in developmental process itself. Not all knowledge needs to be put into the head, dedicated mechanisms, or representations. Some knowledge can be realized in the body, a fact dramatically illustrated by passive walkers. Knowledge of the alternating limb movement of bipedal locomotion—knowledge traditionally attributed to a central pattern generator—appears to reside in the dynamics of two coupled pendulums (McGeer, 1990). Some of our intelligence also appears to be in the interface between the body and the world. The phenomenon of change blindness is often conceptualized in this way. People do not remember the details of what is right before their eyes because they do not need to remember what they can merely look at and see (O'Regan & Noë, 2001). Similarly, Ballard and colleagues (Ballard, Hayhoe, Pook, & Rao, 1997) have shown that in tasks in which people are asked to rearrange arrays of squares, they off-load their short-term memory to the world (when they can). This off-loading in the interface between body and world appears to be a pervasive aspect of human cognition and may be critical to the development of higher-level cognitive functions or in the binding of mental contents that are separated in time.

Smith (2005) has recently reported evidence on how the body—and the body's continuous coupling to events in the world—may play a key role in word learning. The experimental procedure derives from a task first used by Baldwin (1993) and illustrated in Figure 6.14. The participating subjects are very young children 1.5 to 2 years of age. The experimenter sits before a child at a table, and presents the child with one object to play with and then with a second. Out of sight of the child, the two objects are then put into containers and the two containers are placed on the table. The experimenter looks into one container and says, "I see a dax in here." The experimenter does not show the child the object in the container. Later the objects are retrieved from the containers and the child is asked which one is a dax. Notice that the name and the object were never jointly experienced. How then can the child join the object name to the right object? Baldwin showed that children as young as 24 months could do this, taking the name to refer to the *unseen* object that had been in the bucket at the same time the name was offered. How did children do this? How, if

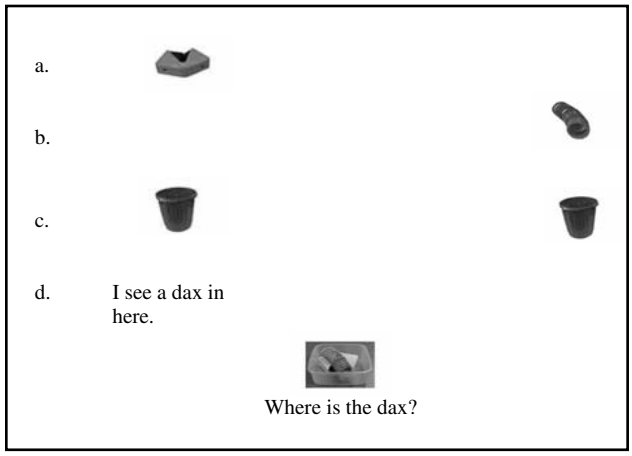

Figure 6.14 A schematic illustration of the course of events in the A-not-B task. After the delay, the hiding box is moved forward allowing the infant to reach and search for the hidden toy.

one were building an artificial device, would you construct a device that could do this, that could know the name applied to an object not physically present when the name was offered?

There are a number of solutions that one might try, including reasoning and remembering about which objects came out of which containers and about the likely intentions of speakers when they offer names. Smith showed, however, that young children solve this problem in a much simpler way, exploiting the link between objects and locations and space. What children do in this task is make use of a deep and foundationally important regularity in the world: a real object is perceptually distinguished from others based on its unique location; it must be a different place from any other object. The key factor in the Baldwin task is that in the first part of the experimental procedure, one object is presented on the right, the other on the left. The containers are also presented the same way and the name is presented with the experimenter looking into one bucket or at one location, for example, on the right. The child solves this task by linking the name to the object associated with that location. We know this is the case because we can modify the experiment in several crucial ways. For example, one does not need containers or hidden objects to get the result. One can merely present the target object on the right and have children attend to and play with it there, then present the distracter object on the left and have children attend to and play with it there. Then, with all objects removed, with only an empty and uniform table surface in view, one can direct children's attention to the right and offer the name (dax) or to the left and offer the name. Children consistently and reliably link the name to the object that had been at this location.

Young children's solution to this task is simple, a trick in a sense, that makes very young children look smarter than they perhaps really are. But it is a trick that will work in many tasks. Linking objects to locations and then directing attention to that location to link related events to that object provides an easy way to bind objects and predicates (Ballard et al., 1997). People routinely, and apparently unconsciously, gesture with one hand when speaking of the protagonist in a story, but with the other hand when speaking of the antagonist. By hand gestures and direction of attention, they link events in a story to the characters. American Sign Language formally uses space in this way in its system of pronouns. People also use space as a mnemonic, looking in the direction of a past event to help remember that event. One experimental task that shows this is the "Hollywood Squares" experiments of Richardson and Spivey (2000). People were presented at different times with four different videos, each from a distinct spatial location. Later, with no videos present, the subjects were asked about the content of those videos. Eye tracking cameras recorded where people looked when answering these questions and the results showed that they systematically looked in the direction where the relevant information had been previously presented.

This is all related to the idea of *deictic pointers* (Ballard et al., 1997; Hurford, 2003) and is one strong example of how sensory-motor behaviors—where one looks, what one sees, where one acts—create coherence in our cognition system, binding together related cognitive contents and keeping them separate from other distinct contents. In sum, one does not necessarily need much content-relevant knowledge or inferential systems to connect one idea to another. Instead, there is a easier way; by using the world and the body's pointers *to that world.*

An emerging field pertinent to these ideas of embodiment is epigenetic robotics (Zlatev & Balkenius, 2001). This field results from the mutual rapprochement of developmental psychology and robotics, with a focus on the *prolonged epigenetic process through which increasingly more complex cognitive structures emerge in the system as a result of interactions with the physical and social environment* (Zlatev & Balkenius, 2001). Epigenetic robotics emphasizes three key ideas relevant to developmental processes in biological and artificial systems:

1. The *embodiment* of the system
2. Its *situatedness* in a physical and social environment
3. A prolonged *epigenetic developmental process* through which increasingly more complex cognitive structures emerge in the system as a result of interactions with the physical and social environment

This new interdisciplinary developmental research purposely borrows the term *epigenesis* from Piaget to development determined primarily by the *interaction* between the organism and the environment, rather than by genes. Current research within this field does not just emphasize sensorimotor interactions but also social processes with particular attention to the ideas of Vygotsky (1962). Current topics of study within epigenetic robotics that should be of interest to developmental psychologists are joint attention (Björne & Balkenius, 2004), imitation (Schaal, 1999), and observational

learning (Breazeal, Buchsbaum, Gray, Gatenby, & Blumberg, 2005).

From Theory to Practice: A Dynamic Systems Approach to Research

The strength of a dynamic approach is its great generality and thus its potential application across many domains and levels of analysis. For instance, a dynamic approach to development is more a way of thinking about development than a specific theory of, say, personality or the acquisition of formal reasoning. However, a dynamic approach does suggest a powerful research strategy for investigating particular domains. We first summarize the principle steps in a dynamic strategy, and then we illustrate an application of this approach to the development of a fundamental motor skill.

Recall that the essential issues are the stability of the system, as indexed by the behavior of some collective measure of the multiple components, and the changes in stability over time. According to dynamic principles, transitions to new forms involve the loss of stability that enable the formation of new self-organized patterns. At transitions, systems may reveal which of their components is a control parameter or a critical element in change. Thelen and Smith (1994) outlined a series of explicit steps for research design, which are detailed in the following subsections.

Identify the Collective Variable of Interest. In a dynamic system, one or two variables can be identified that capture the degrees of freedom of a multidimensional system. In a development study, the goal is to describe the changes in this collective variable over time. It is not easy to find a collective variable over time or in a nonlinear, changing system. Performance measures at one age may not have the same meaning at a later age because the components of the system, and the relations between them, change. But this is a problem of any study over time, whatever the theoretical motivation.

One important criterion of a collective variable is that it should be a well-defined and observable variable, not a derived construct. Whereas "number of words in the lexicon" is operationally specific, "language processing capability" is not, because it cannot be defined outside of some other concrete behavioral measures. In some behavioral studies, the appropriate collective variable may be a *relationship*—the timing between a stimulus and a response, between movements of different parts of the body, or mutual turn taking during a social dialogue.

Characterize the Behavioral Attractor States. Before beginning a study of change, it is important to understand the preferred states of the collective variable at different points in time and over different conditions. Here is where cross-sectional studies can be very useful. Sometimes, it is most helpful to know how skilled adults or children perform the tasks under varying conditions such as differing speed, accuracy, or spatial demands. It is also critical to sample the stability of the system at different ages, to pick appropriate timescales in a developmental study. If there are big differences between 8 and 12 months, for instance, and very little change after 12 months, intensive study would be directed toward the time of rapid transition.

As we mentioned earlier, the stability of a behavioral attractor is indexed by its variability around an average value: How easily it is perturbed and how quickly the system returns to a stable configuration after perturbation. Performance that varies greatly within the same individual and is easily thrown off course indicates that the attractor state is weak. Conversely, when performance converges on a stable value, especially from different initial conditions and in the presence of distractors and other perturbations, the attractor well is deep.

Describe the Dynamic Trajectory of the Collective Variable. The heart of a dynamic analysis is a map of the stability of the collective variable. A crucial assumption in a dynamic strategy is that the individual (or the family unit) and any behavioral changes over time are the fundamental unit of study. It is common in developmental studies to compare groups of children at different ages and infer development from age-related differences in average group performance. Such cross-sectional studies are important for delimiting the boundaries of change, but they cannot inform about the processes that engender change. The essential nonlinear nature of dynamic systems means that attractors pull in trajectories from a variety of initial positions. This means that children may end up with similar behavior from very different starting points. At the same time, even very small differences in the initial conditions can lead to widely disparate outcomes (Figure 6.7). Group averages cannot disambiguate these pathways; the underlying developmental mechanisms may be profoundly different (or remarkably similar).

Thus, understanding developmental trajectories requires longitudinal study of individuals at appropriately dense sampling intervals to capture the timescale of

relevant change. In infancy, for instance, when new behaviors appear almost daily, even weekly observations may miss the critical transitions. Later in life, transitions may be relatively prolonged and much less frequent measures are needed.

Longitudinal studies are designed to probe the stability of systems over time; however, we are really testing systems over two related timescales. The obvious one is change over age or developmental time. Less explicit is the real time of the experimental task. By assessing performance over various trials and conditions within the single experimental session, we ask about the minute-to-minute dynamics. Thus, the history of the system *within the experimental session* may be very important. Effects of the number of trials and their order are also indexes of the system's stability. Does performance change after many repetitions, or is it stable whatever the preceding tasks?

Probing these two timescales is important because they must be inextricably interwoven in real life: When we observe infants and children at any point in time, their behavior reflects *both* their long-term developmental history *and* their immediate history within the task session. Likewise, developmental changes reflect children's repeated everyday experiences, which themselves modulate performance dynamics. It is useful therefore to consider the participants' *intrinsic dynamics,* or histories, as the background on which the experimental tasks are imposed: The intrinsic dynamics are the preferred stability landscapes, given previous history and organic conditions.

Identify Points of Transition. Transitions can be qualitative shifts to new forms, such as the first word spoken or the ability to do a transitive inference task, or they can be quantitative changes in the collective variable such as a shift in speed or the accuracy of a task. Transitions are critical because when a system is in transition its mechanisms of change can be identified and manipulated. Stable systems do not change; only when the coherence of the components is weakened are the components able to reorganize into a more stable form.

The branch of dynamics known as *catastrophe theory* is particularly concerned with sudden shifts from one form to another. These sudden jumps are associated with a number of *catastrophe flags* or indicators of shifts without intermediate forms. As discussed earlier, van der Maas and Molenaar (1992) have applied catastrophe theory to Piagetian conservation tasks to ask whether the shift from nonconservation to conservation can be explained by a catastrophe model. Although they did not find strong evidence for a number of the flags, the flags are useful indexes of systems in transition. The flags are:

- *Bimodal score distribution:* Performance is either on or off, without intermediate forms.
- *Inaccessibility:* Related to bimodality; intermediate states are not accessible, they are unstable and rarely seen.
- *Sudden jumps:* People switch from one form to another rapidly without intermediate states.
- *Hysteresis:* The dependence of performance on the immediately past performance. For example, responses might be different when the task is speeded up through a range of speeds as compared to when it is slowed down through the same range.
- *Divergence:* The system may respond differently to changes in different control variables.
- *Divergence of linear response:* Nonlinearity suggests that a small change in a control variable or perturbation can lead to a large effect.
- *Delayed recovery of equilibrium:* From earlier terminology, a slow relaxation time after a perturbation.
- *Anomalous variance:* Increased and unusual variability.

Identify Potential Control Parameters

The purpose of mapping the dynamics of the collective variable is to discover when systems change. The next step is to find out how and why they change. What are the organic, behavioral, or environmental factors that engender developmental shifts?

Thoughtful experimental design is needed to identify potential control parameters. In some cases, the possible agents of change are fairly obvious; for example, practice facilitates learning to ride a bicycle or doing arithmetic. But, in many instances of developmental change, the critical processes and events are nonobvious and may indeed be in components that seem at first only incidental, or so commonplace as to be overlooked. West and King's (1996) study of songbird learning, described in an earlier section, is a good example: Female cowbirds' subtle wing flicks are critical determinants of male song development. Another example is Thelen and Ulrich's (1991) description of treadmill stepping in infants, where improvements in treadmill stepping were related to overall changes in dominant muscle tone.

One way to help discover relevant control variables—in addition to informed guesses—is to actually measure changes in a number of system variables along with the collective variable. Thus, if the behavior of interest is, say, object retrieval in infants, a collective variable might be correct retrievals of a hidden object. But because retrieval performance is a collective of many other processes that may contribute to change, independent, then concomitant measures of visual attention or of memory, for instance, may reveal correlated jumps and plateaus.

Instability in the collective variable reveals points of transition. Thus, Gershkoff-Stowe and Smith (1997) mapped children's word retrieval errors as a function of the rapid vocabulary growth characteristic of the period between 15 and 24 months. During this time, individual children's retrieval of known object names showed a brief (3- to 6-week) period of disruption. Children would point to a well-known object (say, *cat*) that they had named correctly many times in the past and misname it (e.g., *duck*). This transient disruption in lexical access was temporally related in individual children to an increased rate of new word productions, suggesting that the rate of new words being added to the lexicon is the control parameter for these word retrieval processes, and, thus, the driver of developmental change in lexical access processes.

Traditionally, variability in behavioral data is a researcher's nightmare. Too much within- or between-subject variability swamps any experimental effects. Thus, researchers deliberately choose tasks to make people look alike. But behavior in real children is not like that, it is notably fragile and context dependent. Abilities seemingly come and go, and even skilled adults might perform tasks differently each time (Yan & Fischer, 2002). Dynamic systems theory turns variability from a scourge into a blessing. In dynamic systems theory, the metric is not whether a child has some static ability or unchanging concept. Rather, as systems are always in flux, the important dimension is the relative stability of behavior in context over time (van Geert, 2000). New measures of variability allow researchers to see trajectories of change over the short timescales of problem solving or over a longer developmental span. For example, Yan and Fischer (2002) tracked adults learning a new computer program and found that the performance of each person varied, but that the patterns of variability differed between novices and experts. Also, De Weerth and van Geert (2002) collected dense longitudinal samples of basal cortisol in infants and their mothers. Cortisol levels in infants decreased with age and did not show circadian rhythms, but each infant had great variability from measurement to measurement. Mothers, conversely, were individually very stable, but differed from each other more than infant to infant.

Manipulate Putative Control Parameters to Experimentally Generate Transitions. Mapping the dynamics of the collective variable and other components only provides suggestive and correlational evidence for possible control parameters. More convincing is to generate developmental transitions on a real or developmental timescale by manipulating the suggested control parameters. These simulations of developmental change work at points of transition because the system is not stable and thus is amenable to being affected by interventions.

It is of both theoretical and practical importance to know when interventions are effective in a developing system and when established behavior is so firmly entrenched that intervention is difficult. The Head Start program, for example, was targeted to the early preschool years because researchers discovered that enrichment was less potent with older children whose educational habits were already formed. Once a sensitive period is determined, developmental control parameters can be tested by providing specific interventions that may engender long-range behavioral change. For ethical reasons, these interventions are usually enrichments.

In the example discussed earlier, Titzer et al. (2003; see also Smith & Gasser, 2005) accelerated infants' abilities to retrieve objects from transparent containers by providing them with a variety of Plexiglas boxes to play with at home. Normally, 10-month-old infants have difficulty with the seemingly simple task of retrieving a toy from a Plexiglas box when the opening of the box is on the side. Although the toy is in full view, infants reach in their direct line of sight—smack into the Plexiglas—and not into the box opening. Titzer et al. reasoned that, because infants lacked experience with the properties of transparency, they relied on their usual pattern of reaching straight to what they see. The control parameter for developmental change was the repeated handling of transparent containers and learning about objects that could be seen through but not reached through. The experimenters provided 8-month-old infants with varied transparent containers and told the

parents to allow their children to play with the containers for 10 minutes twice a day, with no other specific instructions. By 9 months of age, infants in the experimental group were more facile in retrieving toys than a control group of 10 months of age who did not have enriched experience. Enriched experience pushed the system into new forms.

In a similar vein, Gershkoff-Stowe and Smith (1997) used training to investigate the disruption observed in word retrieval errors, which we described earlier. These authors reasoned that the disruption in word retrieval with accelerated vocabulary growth was the product of a lexicon crowded with many new and unstable additions. If the retrieval of words in a newly crowded lexicon is easily disrupted because word retrieval is relatively unpracticed, then naming errors during this period should decrease with practice at word retrieval. Here, the control parameter for developmental change was the repeated seeing and naming of objects by the child. These experimenters provided 17-month-olds with extra practice in producing one set of object names. When these children's rate of productive vocabulary began to accelerate, the researchers observed increased word retrieval errors for many known words but not for the words that had received extra training. This training study demonstrates how seeing and naming objects may be the cause of more stable and less perturbable lexical retrieval, and how the activity of the system itself may be the cause of developmental change.

Equally as informative as long-term interventions for testing control parameters are what Vygotsky (1962) called *microgenesis* experiments (e.g., Kuhn & Phelps, 1982; Siegler & Jenkins, 1989). The experimenters try to push children into more mature performance by manipulating possible control parameters over a shorter time period, sometimes within an experimental session. For example, Thelen, Fisher, and Ridley-Johnson (1984) tested their hypothesis that the control parameter for the "disappearance" of the well-known newborn stepping response was the rapid deposition of subcutaneous fat, making the baby's legs relatively heavy. If, they reasoned, the weight of the legs was critical for whether babies stepped or not, changing leg weights should mimic developmental changes, and indeed it did. Decreasing the mechanical load on the legs by submerging the legs in water increased stepping, and adding weights decreased the response.

We emphasize again that many developmental studies manipulate potential control parameters. Those that provide training, enrichment, or increased parental support hope to show more advanced performance; those that increase attentional or processing demands or offer ambiguous stimuli or distractions will demonstrate less skilled actions. What is different about a dynamic systems approach is the situating of these experiments in the larger context of the overall collective dynamics so that principled decisions can be made on when and what to manipulate in experimental sessions. In the previous examples, the interventions worked because the experimenters knew from other data that the children were in periods of rapid change.

In the following section, we report on a developmental study designed and conducted using these explicit dynamic systems principles. We demonstrate that a dynamic perspective revealed change processes that were not discovered from conventional approaches.

A Dynamic Systems Approach to Learning to Reach

Reaching for and grasping objects is a foundational perceptual-motor skill that is critical for normal human functioning. Normal infants first reach out and grab things they see when they are 3- to 4-months-old. At first, their coordination and control are poor; they often miss their targets, and their movements are jerky and indirect. Within a few months, they become much more skilled, and by the end of the first year, they can grab things off the supermarket shelves as they are wheeled by in shopping carts.

The pioneering work of Halverson (1931, 1933) and especially of von Hofsten (1991) has documented that, within those first months of reaching onset, infants' reaches become more accurate, straighter, and smoother. But the developmental processes involved in the emergence of the skill and its improvement have remained little understood. Reaching is a function of many component structures and processes, including the physiological, metabolic, and biomechanical properties of the muscles and joints, the state of the central nervous system, vision and visual attention, motivation, and so on. All of these elements are changing during the first year of life—some, at a rather rapid rate. What are the control parameters that move the system into new states?

To begin to understand these processes, Thelen and her colleagues designed a study of the emergence of reaching using explicit dynamic systems principles. The focus was on reaching as an emergent perceptual-motor pattern acquired throughout the soft assembly of mutually interacting with multiple components within a con-

text. All of the components are essential for the skill to emerge and improve, but one or more components may act as control parameters at different points during development. The overall design was to measure behavior repeatedly and intensively in a small number of children at multiple levels (from behavioral to patterns of muscle activation) and at multiple timescales (real time and developmental time).

The study involved four infants, Nathan, Gabriel, Justin, and Hannah, whose reaching and nonreaching arm movements were observed weekly from 3 weeks until 30 weeks, and in alternating weeks thereafter. The study tracked *multiple components* in looking at reaching performance: The kinematics (time-space parameters) of the movement trajectories, the coordination between the arms, and underlying torque or force patterns moving the joints, the patterns of muscle activation that generate the forces, and the everyday postural and motor states of the baby. In addition, the study addressed *multiple timescales.* Each week, the experimenters presented the infants with attractive objects in such a way that the reach was embedded within a larger session, and motor variables were recorded so that the transition from nonreaching movements to reaching could be captured. Thus, they recorded transitions on two timescales: (1) the real time of the trial where the toy was presented, and (2) the developmental timescale, where patterns of stability may evolve and dissolve.

Collective Variable Dynamics. The first step in a dynamic systems approach is to define a reasonable collective variable or variables—measures that capture the state of the system and its developmental changes. Previous descriptions (e.g., Fetters & Todd, 1987; Mathew & Cook, 1990; von Hofsten, 1991) suggested that improvement in reaching could be described by two measures of the path of the hand to the offered toy: Its straightness and its smoothness. A straight-hand path takes the shortest distance from the start of the movement to the target: Adults' hands move in a very nearly straight path for direct reaches. Smoothness is a measure of how often the movement starts and stops or slows down and speeds up. Infants' jerky movements have many "speed bumps" characterized by accelerations and decelerations. In contrast, adults' movements toward a direct target show only one acceleration and one deceleration.

The developmental dynamics of these two collective variables for the four infants are depicted in Figure 6.15 (Thelen, Corbetta, & Spencer, 1996). Overall, the infants became better reachers; they converged on relatively straight and smooth hand paths by the end of the first year. These performance results are consistent with previous reports showing improvement with age (von Hofsten, 1991). But the picture revealed by this dense longitudinal study is much richer, and more surprising, than that painted by previous work.

Most notably, the dynamics of reaching performance over the first year were highly nonlinear (in contrast to the seemingly linear improvement revealed by less dense and group data). First, infants differed dramatically in the age of the first transition (from no reaching to reaching). Whereas Nathan reached first at 12 weeks, Hannah and Justin did not attain this milestone until 20 weeks of age. Second, the infants showed periods of rapid change, plateaus, and even regressions in performance. All infants were poor reachers at first. But three of the four infants—Nathan, Hannah, and Gabriel—also showed an epoch where straightness and smoothness appeared to get worse after some improvement (labeled as A in Figure 6.16). Finally, there was in Nathan, Justin, and Hannah a rather discontinuous shift to better, less variable performance (indicated by T in Figure 6.16 on p. 295). Gabriel's transition to stability was more gradual, but clearly nonlinear overall. These phase shifts to different states were confirmed statistically.

The developmental course of reaching looks very different when the individual trajectories of change are plotted using dense sampling. Although all four infants converged on remarkably similar values by 1 year, they did not get there by identical means. Can these collective variables dynamics provide insight to the processes underlying the onset and improvement of reaching? Are there control variables that are common to all four infants? What accounts for their individual differences?

The First Transition: The Onset of Reaching. The longitudinal design allowed Thelen and colleagues to pinpoint with some accuracy the first phase shift, the appearance of successful reaching for and contacting the offered toy. (Note that these weeks of onset were confirmed by the more naturalist observations of these babies.) Having identified a developmental transition, the next step in a dynamic approach was to look for potential control parameters. Recall that we make strong assumptions of continuity across levels and timescales; discontinuities must arise from, and be part of, these continuous dynamics.

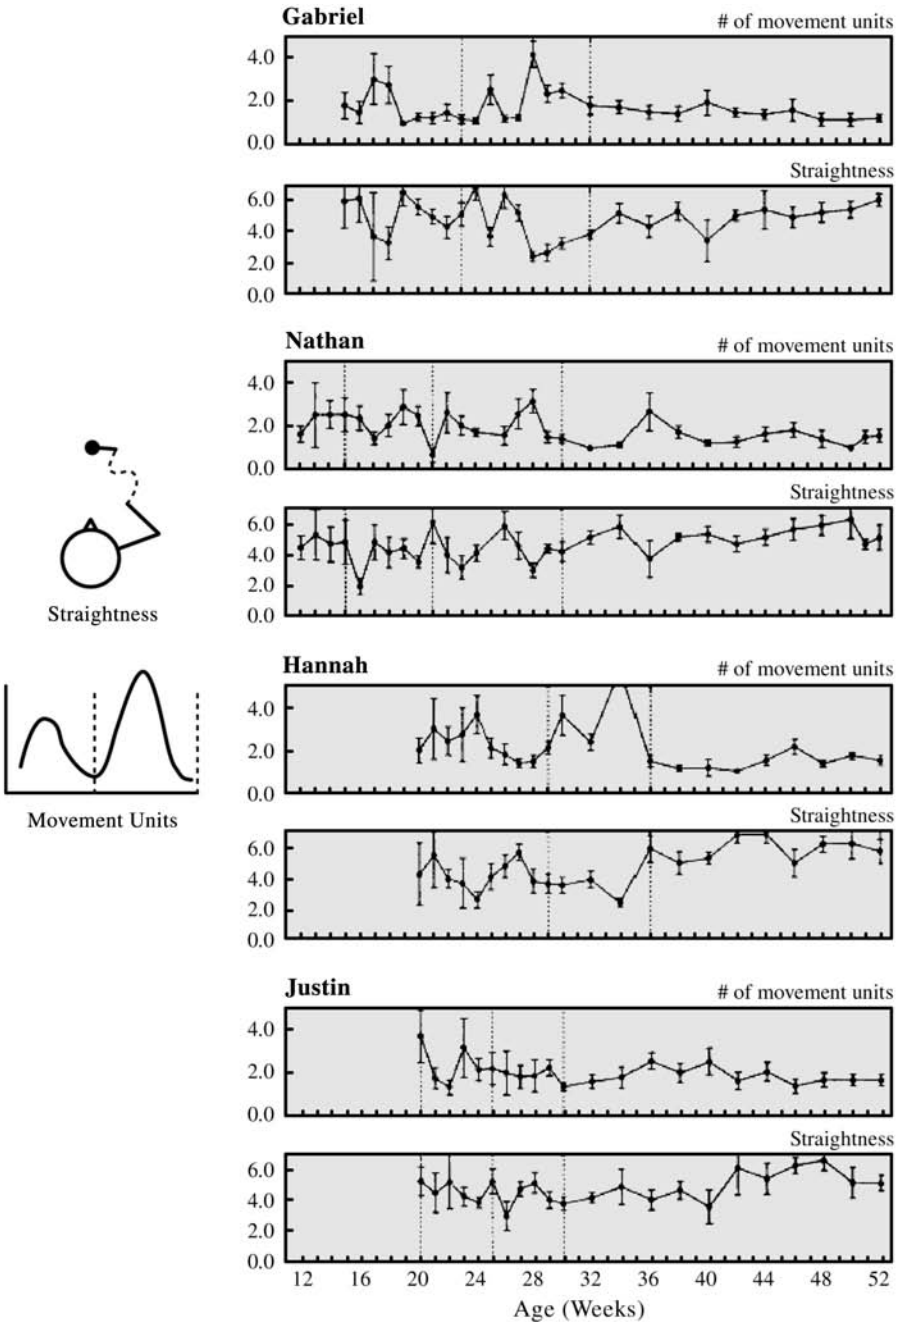

Figure 6.15 Changes in the straightness and smoothness of reach trajectories of four infants followed longitudinally over the first year. The collective variables are number of movement units (fewer = a smoother reach) and straightness index, where a value of 1 = perfectly straight from start to target. *Source:* From "The Development of Reaching during the First Year: The Role of Movement Speed," by E. Thelen, D. Corbetta, and J. Spencer, 1996, *Journal of Experimental Psychology: Human Perception and Performance, 22,* pp. 1059–1076. Copyright 1996 by the American Psychological Association. Reprinted with permissions.

What is continuous for young infants is that they are always moving their limbs, from birth and even before. Reaching, the new form, must emerge from the continuous processes of moving and perceiving that occur before infants perform the first goal-directed reach—and that continue as nonreaching arm movements even after this new behavior appears. Thelen et al. (1993) looked at the transition to first reaching as a process of infants' "discovering" a reach from among many and varied nonreaching movements.

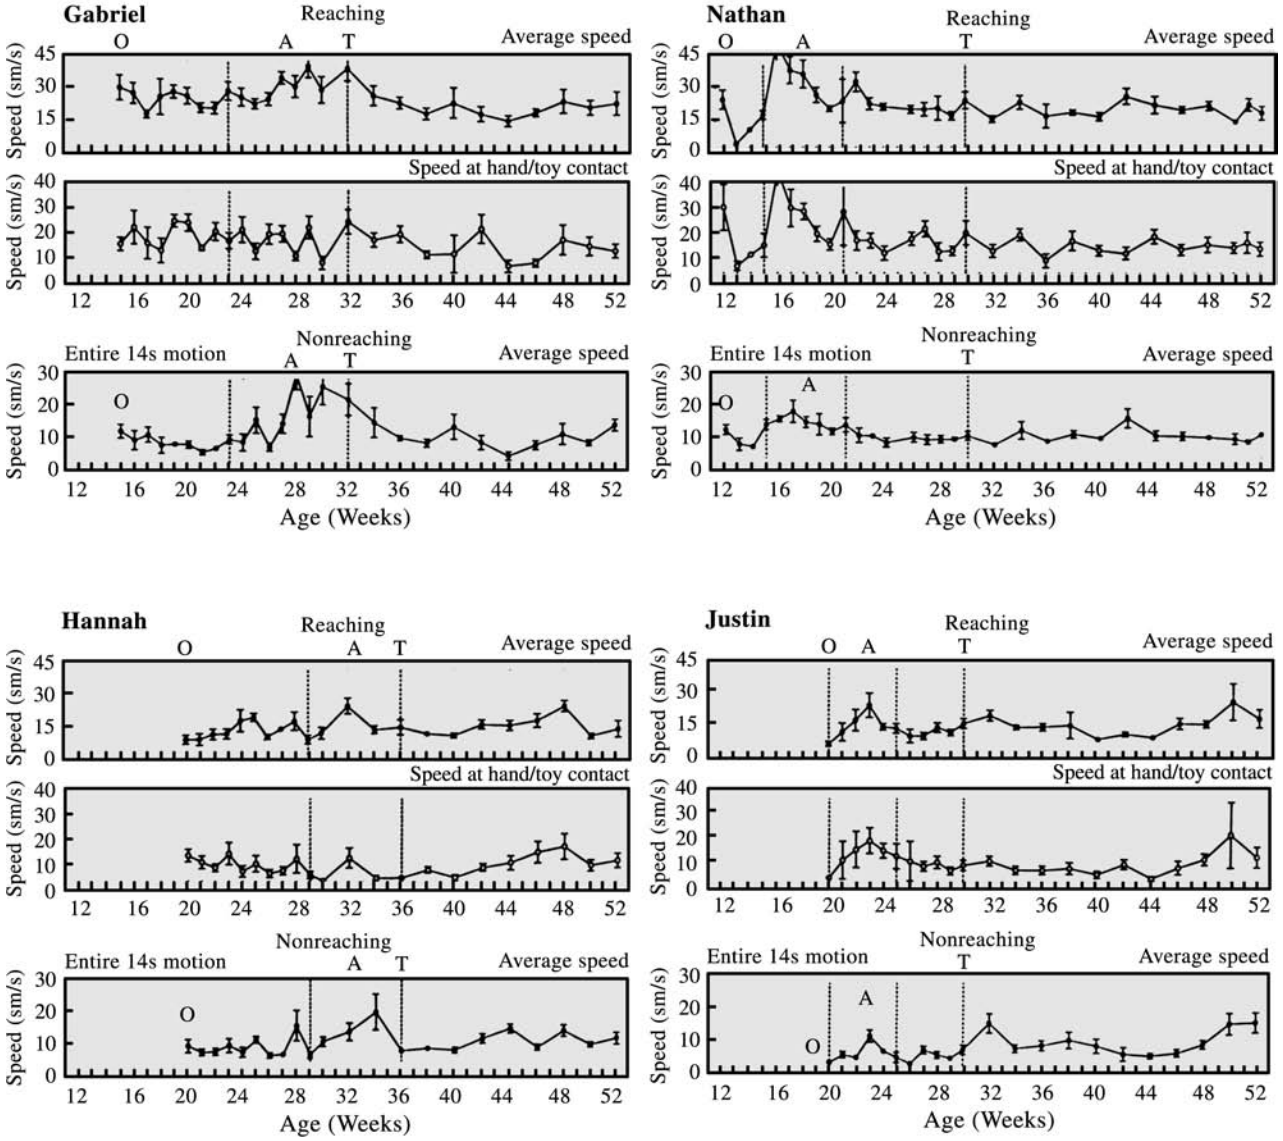

Figure 6.16 Average speed of reaching, speed at toy contact, and speed of nonreaching movements for the four infants in Figure 6.15. *Source:* From "The Development of Reaching during the First Year: The Role of Movement Speed," by E. Thelen, D. Corbetta, and J. Spencer, 1996, *Journal of Experimental Psychology: Human Perception and Performance, 22,* pp. 1059–1076. Copyright 1996 by the American Psychological Association. These authors found that the preferred states of infants' motor systems in nonreaching movements—their individual intrinsic dynamics—profoundly influenced the nature of the transition to reaching. In particular, the four infants differed in the amplitude, and especially in the vigor, of their spontaneous arm movements in the months previous to reach onset. Two infants, Gabriel and Nathan, had large and vigorous movements; the other two were quieter and generated fewer and slower, less forceful movements. The task for all the babies was the same: To get their hands in the vicinities of the desired objects. But they had different problems to solve to do this: Gabriel and Nathan had to damp down their forceful movements to gain control; Hannah and Justin had to produce more muscle force to extend their arms forward in space and hold them stiffly against gravity. Examination of the actual torques used to move the arm segments showed

that Gabriel and Nathan were using their muscles primarily to counteract the passive inertial forces generated by the rapid movements of their arms, while Hannah and Justin were using their muscles to counteract gravity.

Many components are necessary for infants to begin to reach. They must be able to see the toy (or other target) and locate it in space. And they must want to get it. The visual and motivational aspects of reaching are probably not the control parameters because other evidence suggests that infants can locate objects in three-dimensional space rather well, if not perfectly, by age 3 months, and that they grasp and mouth objects and show interest in them. More likely, selecting the correct muscle patterns and scaling the activation appropriately allow infants to fashion their first reaches from their undirected movements.

Indeed, analysis of infants' muscle synergies from electromygraphic (EMG) recordings reveal that reaching onset was associated with changes in functional muscle use. Spencer and Thelen (1995), comparing EMG patterns in reaching and nonreaching movements before and after reach onset, discovered that when reaching infants frequently recruited their anterior deltoid muscle, alone and in combination with other muscles. (This shoulder muscle raises the upper arm.) Before reaching, infants sometimes also raised their arms, but they used other combinations of muscles to do this. The ability to selectively activate and control this muscle group was associated with goal-directed movements.

Thelen and colleagues speculated that infants learn specific functional muscle patterns through experience in moving during the weeks and months before reaching actually emerges. Infants' real-time activities of moving—sensing the "feel" of their limb dynamics and perceiving the consequences of their movements—are time-locked input to the degenerate and reentrant neural nets we described in an earlier section. As a consequence, categories of limb parameters emerge from all the possible combinations that are appropriate to the spatial location of the toy.

Changes in other system components may facilitate this discovery. For example, Thelen and colleagues found that infants did not reach until they could also stabilize their heads in a midline position. Possibly, strength and control of neck and head muscles are necessary before the arm can be lifted independently. Stable head and eyes also facilitates accurate localization of the to-be-reached object in space.

Shifts in Control during the First Year. Recall that in three infants, the collective variable dynamics had a striking nonlinear course over the first year (Figure 6.15), with a distinct period of seeming instability followed by a period of stability. Recall also that the individual infants had very different intrinsic movement dynamics, especially in relation to characteristic speeds. Studies of adult reaching have repeatedly shown that the speed of movements—reflecting the amount of energy delivered to the limbs—is a critical parameter in many aspects of motor control. Faster movements are generally less accurate, probably because there is less time to make fine adjustments (Fitts, 1954). Reach trajectories may require different strategies of control and different patterns of muscle activation, depending on whether they are performed slowly or rapidly (Flanders & Herrmann, 1992; Gottlieb, Corcos, & Agarwal, 1989). Similarly, very fast movements produce much greater motion-related passive forces than slow ones do, and thus pose different problems for neural control (Latash & Gottlieb, 1991; Schneider, Zernicke, Schmidt, & Hart, 1989). Could movement speed be acting as a control parameter in these developmental shifts?

Figure 6.16 illustrates the four infants' characteristic speed of movements over their first year. Plots show average and peak speed of the reach itself, as well as speed at the start and termination of the movement. In addition, Thelen et al. (1996) reported infants' speed of *nonreaching* movements, that is, all the movements infants produced during the 14-second sampling trials when they were not reaching. This analysis revealed several remarkable results. First, infants converged on more or less similar *good* movement and contact speed; it was not functional to grab the toy either too slowly or too rapidly. Second, within this common speed solution, individual speed *personalities* or intrinsic dynamics remained, on average. For example, Gabriel was a faster mover than Hannah. Third, there was close correspondence between characteristic movement speed in reaching and in nonreaching movements. The reaches were not isolated from the ongoing preferences and habits of the babies, but were molded from those dynamics. Finally, periods of faster movements were associated with instability in the collective variables, indicating poor control.

Although the factors that led the infants to move more quickly or more slowly are as yet unknown, this overall speed variable clearly acts as a control parameter on the straightness and smoothness of the reach trajectory. Again, individual acts of reaching are fashioned

at the moment and carry with them the state of the system at that moment, which, in turn, is determined by the system's history.

Bimanual Coordination

This interplay between task and intrinsic dynamics is equally well illustrated by another aspect of infants' reaching: Whether they reach with one or two hands. Gesell (1939; Gesell & Ames, 1947) first noted that the bilateral symmetry and preference of infants was very unstable and frequently shifted from unimanual limb use to bimanual, and from strongly lateralized preference to symmetry. The four infants in the Thelen et al. (1996) study amply demonstrated these shifts. Figure 6.17 (Corbetta & Thelen, 1996) shows individual frequencies of one- or two-handed reaching. Note that, in this situation, toys could always be grasped by one hand, so two-handed reaching was not obligatory for function. Not only did individual infants have mixed preferences, but no two infants were alike in their developmental course.

As in the single-arm trajectory, Corbetta and Thelen (1996) discovered that bimanual coordination was also influenced by infants' intrinsic dynamics—in this case, whether their limbs moved in a coupled fashion in nonreaching movements as well. When infants reached with two hands, the two arms tended to speed up and slow down together in all movements; limbs were symmetrically coupled. In contrast, no such coupling was noted at times when infants preferred to use only one hand to grab the toy. Furthermore, epochs of bimanual symmetry in reaching and nonreaching were associated with *periods of higher speed movements.* Gabriel, for instance, used two hands and had coupled movements almost throughout the year, and he was the most energetic baby. Hannah, in contrast, was largely unimanual and uncoupled (and moved slowly), except for the period in the middle of the year when her movement speed increased and her movement symmetry did as well. Movement speed was a control parameter for both the efficiency of the movement and the strength of bilateral coupling.

Although the infants had an obvious task goal in reaching out to grab a toy, this dynamic act emerged from a background of ongoing movement. The state of the infants' systems was emergent from their body architecture, metabolism, and motivation, and from how they had been moving in the months before. In such a view, no one part of the system is privileged—there is no dedicated reaching code in the brain. Reaching is a pattern that self-organizes from multiple components over several timescales: The here-and-now dynamics of the task and goal, and the longer-term dynamics of the infants' history of moving and reaching.

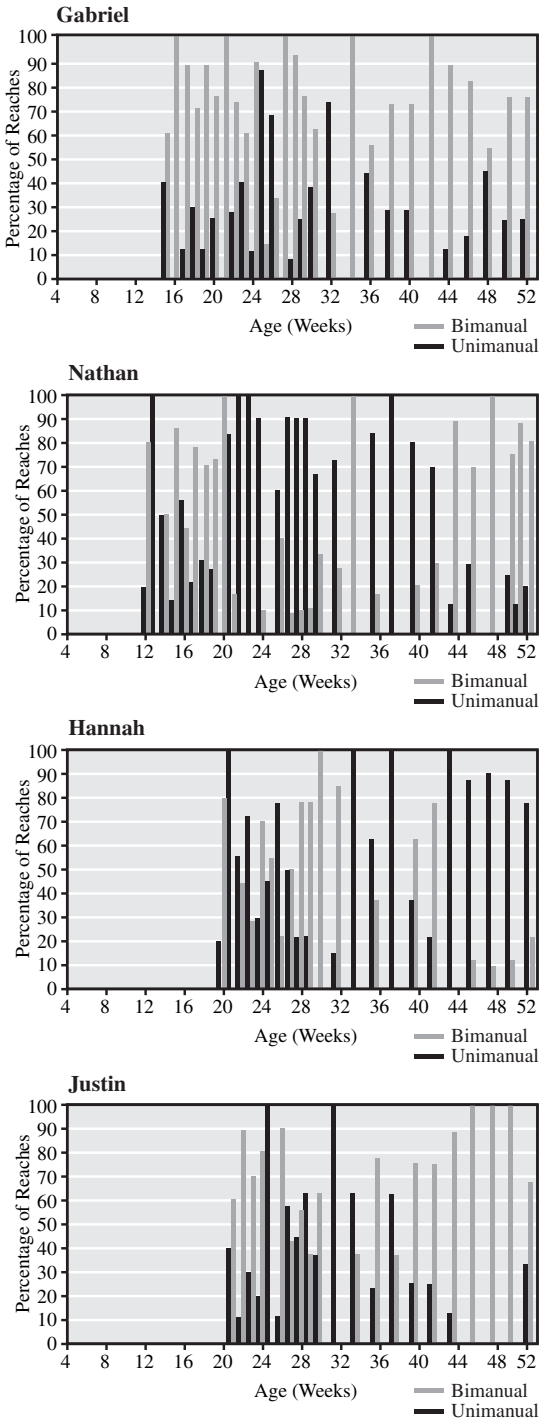

Figure 6.17 Percentages of uni- and bimanual reaches for the four infants in Figure 6.15.

A Model of Levels of Control

A dynamic view of the development of reaching revealed stagelike changes in the collective variables at the same time that reaching was embedded in the infants' continuous and ongoing intrinsic dynamics. In this section, we present a dynamic model of emergent control that reconciles these multiple levels and multiple timescales by proposing that they are dynamically *coupled.*

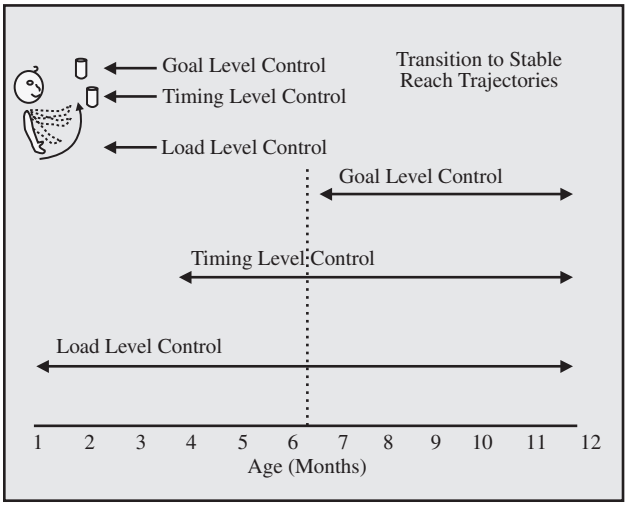

Figure 6.18 A simple model of increasing control over reaching. After Schöner (1994), we have defined control as protecting that level from perturbations from the other levels. The load level involves the internal and external forces acting on the limbs and the associated stretch reflexes. The timing level involves the generation of a trajectory and the timing of the joints and muscles to execute the trajectory. The goal level is the spatial target. Infants only gradually gain control of these levels.

What Is Skill?

It is useful here to digress briefly and ask: What is involved in controlling the arm (or any body part) for successful and adaptive movement?

According to Bernstein (Bernstein, 1996), one of the hallmarks of skilled activity is the ability to flexibly adapt movements to current and future conditions. What constitutes skilled performance is not just a repeatable and stable pattern, but the ability to accomplish some high-level goal with rapid and graceful, but flexible solutions that can be recruited online or in anticipation of future circumstances. Consider, for example, a skilled equestrian whose goal is to stay on the horse and maintain a graceful posture, while leading the horse through an intended course. Skill in this case means making minute, online adjustments in response to the horse's movements while anticipating changes in the terrain.

Indeed, in movement, as well as in cognitive or social activities, we can define skill as being able to rapidly recruit appropriate strategies that meet the changing demands of the social, task, or physical environment. For reaching, good control means being able to efficiently reach in all directions, for moving or stationary objects, when the light is bright or dim, from any posture, while our attention is focused or distracted, and so on. On further analysis, we can identify the sources of potential disruption as affecting one of three levels of control of the reach. As depicted in Figure 6.18, reaching must be stabilized first against transient mechanical perturbations—various forms of external forces acting on the moving limb in a way that would tend to push the intended trajectory off course. (We know that adults are very good at maintaining their movement trajectory in the face of little bumps against the limb; e.g., Hogan, Bizzi, Mussa-Ivaldi, & Flash, 1987.) Second, reaching must be stabilized in the face of different task demands of the timing of the movement, such as setting the coordination pattern of the various joints and muscles, and producing the time-space trajectory of the arm. Finally, reaches must be stabilized even when the global goal parameters change—when the target is unexpectedly displaced (adults make these kinds of adjustments quickly and smoothly; Jeannerod, 1988). Using Gregor Schöner's (1994) terminology, we can define these levels of control as the *load, timing,* and *goal* levels.

In ordinary adult skilled actions, these levels are not separable; that is, people perceive, think, and act as one unit in the physical world. Levels of control are revealed only through extraordinary experimental manipulations, for example, when experimenters tell participants to hold a limb position constant when they apply an external load, or to reach to a target that is suddenly displaced. Adults are able, intentionally, to isolate, protect, or control their activities at several behavioral levels. This means that, in skilled adults, the levels of control are not tightly coupled; the goal level is not a slave of the arm's biomechanics although the load level contributes to the movement. We must emphasize that these levels are strictly a function of the imposed task demands.

They do not exist anatomically or functionally in the absence of the tasks.

Development of Levels of Control

Infants, in contrast, do not start out with this ability to protect one aspect of the task against perturbations—that is, to control their actions against unanticipated (and even anticipated) bumps from the environment. Indeed, what we want to argue here is that the initial state is highly syncretic; infants' movements are initially tightly coupled to lower-level dynamics, and only through experience and organic changes does a fully protected higher-level goal dynamic emerge.

We can see very clear examples of this in early spontaneous movements of the arms and legs. As we have argued previously, when young infants inject sufficient energy into their limbs, the resulting patterns suggest the dynamics of coupled oscillators with a periodic forcing function. Such dynamics must be the collective result of simple neural patterns in combination with the springlike properties of the joints and muscles and the effects of gravity—the load-level dynamics.

In the first months of life, infants are largely the captives of these dynamics. They cannot control well, or at all, the positions of their limbs in space or the timing of the segments during movement. Thus, the first problem that infants have to solve is control of these load-level dynamics; they must begin to weaken the obligatory coupling between the load level and the higher levels of control.

By the time infants first reach and grasp, at age 3 or 4 months, they must have begun, through their repeated movements, to generate a trajectory in time and space to attain something they see. But their reaches are still not fully controllable independent of the load level dynamics. Infants often reach too fast or too slowly; they overshoot, or inject energy bursts in stops and starts, leading to the patterns of acceleration and deceleration so characteristic of early reaching. This model predicts that without good control of the arm, the reach trajectory would degrade when movements are fast. This happens because fast movements create inertial forces between the segments of the arm, which require precise control—something skilled movers have continually. And, indeed, this is what happened in the four infant reachers described earlier: When movement speed increased, reach trajectories became more jerky and less straight (Figure 6.16).

The dramatic transition to smoother and straighter reaching that we saw at around age 7 months is, we suggest, the system's discovery of a stable trajectory solution—that is, the isolation and protection of the time-space parameters of getting the felt hand to the seen toy. Thus, by this age, reaches were no longer buffeted by load-level dynamics. Infants could reach smoothly and in a relatively straight manner, and they could control the segments against their own inertial forces.

Although 8- to 12-month-old infants, under ordinary and everyday conditions, look like pretty good reachers, we can create conditions that reveal that they have not yet mastered the highest level of skill—the ability to protect the goal from the lower-level dynamics. In the following section, we report on studies where the goal level—the location and the nature of the object to be reached—was perturbed. These experiments revealed that, in this unstable period, infants were not flexible; they were held captive, so to speak, by the arm pathways they had previously produced. Their trajectory formation was good but not flexible; they were stuck in the habits of previous reaches. We focus on classic object retrieval experiments—Piaget's "A-not-B" error. A dynamic systems account challenges the traditional explanations that object retrieval tasks tap into enduring knowledge about objects. Rather, we suggest that infants show traces of obligatory coupling between the goal and timing levels of trajectory control.

The Task Dynamics of the A-Not-B Error

One of the primary tasks of infancy is to learn about the properties of objects to act on them, think about them, and, eventually, talk about them. Literally thousands of papers have been written about the nature of object representation: When and how babies come to understand the spatial and temporal permanence of objects. One signature task that has been used to measure infants' understanding of objects asks infants to retrieve a hidden object. Odd patterns of search errors and dramatic developmental changes characterize performance between the ages of 6 and 12 months. We briefly review here our dynamic systems account of one of these search errors, the classic Piagetian A-not-B error (Smith, Thelen, Titzer, & McLin, 1999; Spencer, Smith, & Thelen, 2001; Thelen, Schōner, Scheier, & Smith, 2001; Thelen & Smith, 1994).

The A-Not-B Error. We present an example of how we have used the dynamic concepts of multicausality and nested time to revisit a classic issue in developmental psychology. The question originally posed by Piaget

(1962) was "when do infants acquire the concept of object permanence?" He devised a simple object-hiding task, which has been adopted by several generations of researchers. The experimenter hides a tantalizing toy under a lid at location A and the infant reaches for the toy. This A-location trial is repeated several times. Then, there is the crucial switch trial: the experimenter hides the object at new location, B. At this point, 8- to 10-month-old infants make a curious error. If there is a short delay between hiding and reaching, they reach not to where they saw the object disappear, but back to A, where they found the object previously. This A-not-B error is especially interesting because it is tightly linked to a highly circumscribed developmental period: Infants older than 12 months of age search correctly on the crucial B trials. Why this dramatic shift?

Do 12-month-old infants know something that 10-month-old infants do not? Piaget suggested that only at 12 months of age do infants know that objects can exist independently of their own actions. Others have suggested that during that 2-month period, infants shift their representations of space, change the functioning of their prefrontal cortices, learn to inhibit responses, change their understanding of the task, or increase the strength of their representations (Acredolo, 1979; Bremner, 1985).

There is merit to all of these ideas, but none can explain the full pattern of experimental results (Smith, Thelen, Titzer, & McLin, 1999). This might be because these accounts seek an explanation in terms of a single cause when there is no single cause. We offer a formal theory, the dynamic field model (Thelen et al., 2001) to explain how the A-not-B error is the emergent product of multiple causes interacting over nested timescales. The account begins with an analysis of the looking, reaching, and memory events that comprise the task, as illustrated in Figure 6.19.

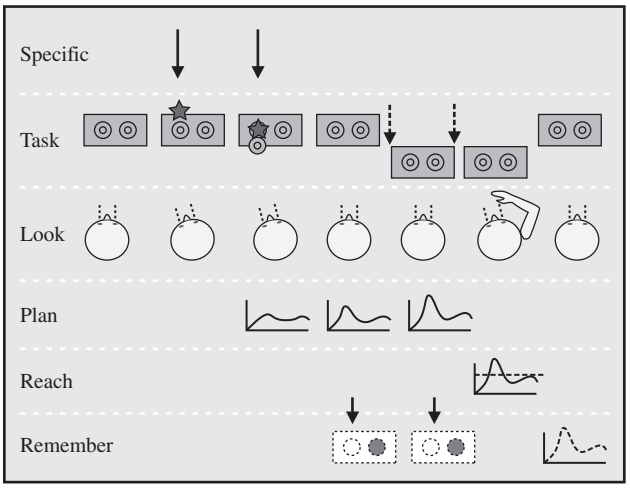

Figure 6.19 A task analysis of the A-not-B error, depicting a typical A-side hiding event. The box and hiding wells constitute the continually present visual input. The specific or transient input consists of the hiding of the toy in the A well. A delay is imposed between hiding and allowing the infant to search. During these events, the infant looks at the objects in view, remembers the cued location, and undertakes a planning process leading to the activation of reach parameters, followed by reaching itself. Finally, the infant remembers the parameters of the current reach.

Task Dynamics. The dynamic field simulates the decisions of infants to reach to location A or B by integrating, over time, the various influences on that decision. The field model is neurally inspired, of the type described and characterized analytically by Amari (1977), but it is abstract and not anatomically specific. The model has a one-dimensional activation field, defining a parameter space of potential activation states (in this case the locations of targets A and B). Inputs are represented by their location and their influence on the field. Most important, points in the field provide input to one another, which allows the field to become self-organizing. A highly activated point will exert a strong inhibitory influence over the points around it, allowing an activation to be maintained in the absence of external input.

Figure 6.20a illustrates the evolution of activation on the very first A trial. Before the infant has seen any object hidden, there is activation in the field at both the A and B locations from the two covers. As the experimenter directs attention to the A location by hiding the toy, it produces a high, transient activation at A. Then the field evolves a decision over time. When the activation peak crosses a threshold, the infant reaches to that location.

Most crucial for this account is that once infants reach, a memory of that reach becomes another input to the next trial. Thus, at the second A trial, there is some increased activation at site A because of the previous activity there. This combines with the hiding cue to produce a second reach to A. Over many trials to A, a strong memory of previous actions builds up. Each trial embeds the history of previous trials. Now, consider the crucial B trial in Figure 6.20b. The experimenter provides a strong cue to B. But as that cue

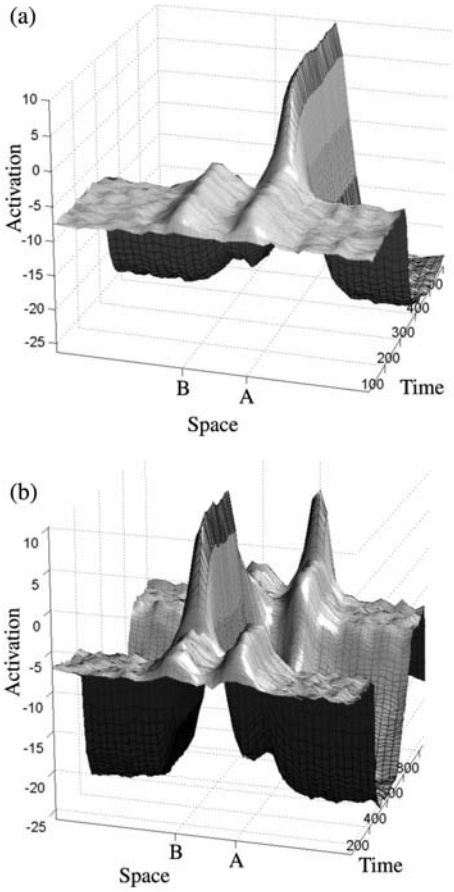

Figure 6.20 (a)The time evolution of activation in the planning field on the first A trial. The activation rises as the object is hidden and due to self-organizing properties in the field is sustained during the delay. (b) The time evolution of activation in the planning field on the first B trial. There is heightened activation at A prior to the hiding event due to memory for prior reaches. As the object is hidden at B, activation rises at B, but as this transient event ends, due to the memory properties of the field, this activation is pulled in the direction of the longer-term memories, toward A.

decays, the lingering memory of the actions at A begin to dominate the field, and, over time, to shift the decision back to the habitual A side. The model clearly predicts that the error is time dependent: There is a brief period immediately after the hiding event when infants should search correctly, and indeed they do (Wellman, Cross, & Bartsch, 1987).

Using this model as a guide, experimenters can make the error come and go. This is achieved by changing the delay, by heightening the attention-grabbing properties of the covers or the hiding event, and by increasing and decreasing the number of prior reaches to A (Diedrich, Thelen, & Smith, 2001; Smith et al., 1999). The error can occur (and not occur) even when there is no toy to be hidden (Smith et al., 1999). Directing attention to an in-view object A heightens activation at the location, and infants reach to that continually in-view object. Subsequently, when the experimenter directs attention to a different nearby in-view object B, infants watch, but then reach back to the original object A. Experimenters have also made the error vanish by making the reaches on the B trials different in some way from the A trial reaches. In the model, these differences decrease the influence of the A trial memories on the activations in the field.

One experiment achieved this by shifting the posture of the infant (Smith et al., 1999). An infant who sat during the A trials would then be stood up, as shown in Figure 6.21, to watch the hiding event at B, during the delay and during the search. This posture shift causes even 8- and 10-month-old infants to search correctly, just like 12-month-olds. In another experiment, the similarity of reaches on A and B trials was changed by putting on and taking off wrist weights (Diedrich, Smith, & Thelen, 2004). Infants who reached with "heavy" arms on A trials but "light" ones on B trials (and vice versa) did not make the error, again performing as if they were 2 to 3 months older. These results suggest that the relevant memories are in the language of the body and close to the sensory surface. In addition, they underscore the highly decentralized nature of error: The relevant causes include the covers on the table, the hiding event, the delay, the past activity of the infant, and the feel of the body of the infant.

This multicausality demands a rethinking of what is meant by knowledge and development. Do 10-month-old infants know something different when they make the error compared with when they do not? The answer is yes if we conceptualize knowledge and knowing as emergent or made at a precise moment from multiple components in relation to the task and to the immediately preceding activity of the system. What do 12-month-olds know that 10-month-olds do not? There can be no single cause, no single mechanism, and no one knowledge structure that distinguishes 10-month-olds from 12-month-olds because there are many causes that make the error appear and disappear. Instead, both 10- and 12-month-olds can be regarded as complex systems that self-organize during the task. However, just as trial dynamics are nested in task dynamics, so are task dynamics nested in developmental dynamics.

Figure 6.21 An infant sitting for an A trial and standing for a B trial.

Developmental Dynamics. The A-not-B error has been important to developmental theory because it is tightly linked to a few months in infancy. However, the neural field model suggests that the dynamics that create the error in infants are basic processes involved in goal-directed actions at all ages. Indeed, by changing the task, researchers can make preservative errors come and go in older children and adults, just as in infants.

Recently, Spencer and colleagues (2001) invented an A-not-B task that was suitable for 2-year-olds by hiding toys in a sandbox. The surface of the sand presents a uniform field, so there are no markers to indicate the two possible hiding locations. Experimenters gave toddlers many trials at location A, and then hid the toy at location B. With a delay of 10 s, the toddlers, having watched the toy being hidden at location B, still returned to location A to dig in the sand for the toy. Indeed, there are many other situations in which both children and adults fall back on a habit despite new information (Butler, Berthier, & Clifton, 2002; Hood, Carey, & Prasada, 2000). Nonetheless, in the standard A-not-B task, infants change their behavior over 2 months. In the field model, this is simulated by increasing the resting activation of the field. This makes it easier for the input from the hiding cue to form a self-sustaining peak at B to compete with the A memory. Similarly, in her model of the error (also a dynamics systems model), Munakata (1998) simulates development by stronger self-sustaining memories for the hiding event.

If self-sustaining memories drive the successes of older children, then we must ask where they come from. What are infants doing every day that improves their location memory? One possibility is their self-locomotion. Crawling appears to improve the spatial memories of infants (Bertenthal & Campos, 1990). But there are also other possibilities. Their fine motor control improves markedly during the last part of an infant's first year. Perhaps more experience perceiving objects and manipulating them improves the flexibility of infants to notice differences in the targets or to be less tied to their previous actions. Simply practicing the A-not-B task repeatedly improves performance (Diamond, 1990a). In this way, real-time activity in the task is unified with developmental time. Developmental change evolves from the real-time activities of the infant.

Implications of a Dynamic Approach. A dynamic systems theory of development helps to resolve an apparent theoretical contradiction. At a very global level, the constraints imposed by our biological heritage and by the similarities in human environments seem to result in similar developmental outcomes. All intact human infants learn to walk, progress from making the A-not-B

error to not making it, speak their native language, and form intense social relationships. But when one looks at the details of development, the picture seems far less deterministic. Children from the same family grow up to be amazingly different from one another. Children with social and economic advantages sometimes fail in life, whereas those from impoverished backgrounds succeed. Such nonlinearities might be reflected in development as stagelike shifts and might underlie the dramatic differences between 10- and 12-month-olds in the standard A-not-B task. But if development is made from real-time events, then these nonlinearities might also create individual differences. Even very small differences in beginning states and in developmental histories can amplify and lead to large individual differences. If this is so, then at the microlevel, development will be messier and very much tied to the idiosyncratic real-time activities of the infant. From a dynamic perspective, it is important to understand the processes by which the everyday activities of children create developmental change—both the universal attainments and the individual pathways.

What Is Knowing? What does all this mean for Piaget's original conclusions from watching his own children search for objects in the "wrong places"? What does all this mean for the results of Baillargeon and Graber (1988) and others who have found that infants seem to know that objects stay where they are put, in tasks in which they only watch but do not act? How does this dynamic systems account fit with Munakata, McClelland, Johnson, and Siegler (1997) and their connectionist account, in which internal representations of objects reside in one set of layers that deliver input to a separate system that acts?

One possible answer to these questions is that the A-not-B error is simply about reaching—not about the object and not about *knowing*. According to this answer, infants in the A-not-B task represent objects *independently from their actions* right from the beginning, although those representations may not, as Munakata et al. (1997) suggest, be strong enough to support goal-directed manual action. This answer divorces knowing from acting; the infant knows where the object is when it is hidden in B, but just cannot control the reach.

We believe this answer is wrong. Knowing is the process of dynamic assembly across multileveled systems in the service of a task. We do not need to invoke represented constructs such as "object" or "extended in space and time" outside the moment of knowing. Knowing, just like action, is the momentary *product* of a dynamic system, not a dissociable cause of action. Churchland (1986) put it this way:

> [B]rains are not in the business of pattern recognition for its own sake, and the nature of pattern recognition, as accomplished by brains, must be understood in the context of its role in how brains achieve motor control. Evolution being what it is, pattern recognition is there to subserve motor coordination. . . . [I]f we ignore motor control as the context within which we understand pattern recognition, we run the risk of generating biologically irrelevant solutions. (pp. 473–474)

We think to act. Thus, knowing may begin as and always be an inherently sensorimotor act. Our dynamic systems account thus stands on common ground with Piaget in the origins of thought in sensorimotor activity but also on common ground with Johnson (1987); Varela, Thompson, and Rosch (1991); Churchland (1986); and Edelman (1987) in the newer ideas of Barsalou (2005) and Glenberg and Kaschak (2002) that cognition emerges in the recurrent sensorimotor patterns that enable action to be perceptually guided.

Dynamic Systems and Other Theories of Development. How different is dynamical systems as a theory of development from other approaches? Thelen and Bates (2003) recently considered this question and their conclusions are summarized in Table 6.2. They specifically considered the following theoretical frameworks:

1. Chomsky's (1968, 1975, 1988) nativist theory of language development (which has inspired nativist theories in other domains as well—for a discussion, see Fodor, 1983)
2. E. J. Gibson's (1969) theory of perception and perceptual development (which is empiricist in emphasis)
3. Vygotsky's (1978) theory of cognitive development in a social framework (a theory that is strongly empiricist in flavor, though it is certainly a complex and interesting example of an empiricist approach)
4. Piaget's (1952, 1970) constructivist theory of cognitive development (a direct predecessor to today's emergentist approach)
5. Connectionism as laid out in Elman et al. (1996)
6. Dynamic systems as laid out in Thelen and Smith (1994)

TABLE 6.2 A Taxonomy of Developmental Theories

Theory	Chomsky	Gibson	Vygotsky	Piaget	Thelen/Smith	Elman/Bates
Emphasized mechanism of change	Maturation	Perceptual learning	Internalization	Consruction	Self-organization	Emergence/learned connections
Experience	No	Yes	Yes	Yes	Yes	Yes
External information	No	Yes	Yes	Yes	Yes	Yes
Social	No	No	Yes	No	No	No
Biological constraints	Yes	Yes	No	Yes	Yes	Yes
Brain development	No	No	No	No	Yes	Yes
Embodiment	No	Yes	No	Yes	Yes	No
Mental representations	Yes	No	Yes	Yes	No (not in traditional sense)	Yes
Dynamical systems	No	No (yes)	No	No	Yes	Yes
Formal models/simulations	Yes	No	No	No	Yes	Yes

Adapted from "Connectionism and Dynamic Systems: Are They Really Different?" by E. Thelen and E. Bates, 2003, *Developmental Science, 6,* pp. 378–391.

These six theories were compared with regard to (1) the primary mechanism of change, (2) the structuring role of external information, (3) the importance of social interaction, (4) the role of biological constraints, (5) the use of information about brain development as a theoretical constraint, (6) emphasis on sensorimotor processes, (7) emphasis on and elaboration of mental representations, (8) invocation of dynamic systems as a source of causation/explanation of structure and change, (9) use of mathematical formalisms, and (10) use of computer simulations as a tool for the study of development.

Mechanisms of Change. Chomsky invoked two related mechanisms to account for developmental change and the role of the environment: parameter setting and triggering. *Triggering* refers to the release of a preexisting behavioral option by an environmental event (not unlike the triggering of the processes that lead to male genitalia in the embryo by the genetically timed release of testosterone). *Parameter setting* is an enriched form of triggering, a process whereby children use environmental signals to select the correct parameters for their native language from an array of innate grammatical options. In elaborating these ideas over the years, Chomsky has consistently stressed that learning is highly overrated as a source of change, at least for those domains of behavior that are especially important for the species. For Gibson, the primary mechanisms of change are children's exploration of their environment and the discovery of matches between their current abilities and the affordances for action inherent in a richly structured environment. This is primarily a process of *perceptual learning,* or an increasing ability to discern relevant features in the perceptual array and thus to tune actions appropriately to them. Vygotsky built his theory on *internalization.* For Vygotsky, many of the cognitive and linguistic structures that make us human are first played out in the realm of behavioral interaction with a competent adult. By participating in social interaction, the young organism moves from incompetence to competence, internalizing the relevant structures until he or she can finally produce them on his or her own. Although this is a richer and more sophisticated form of environmental determination than one finds in many writings by many of Vygotsky's behaviorist contemporaries (American, European, and Russian), internalization is certainly a mechanism that is "pushed" from the outside. Piaget's seminal contribution was his consistent emphasis on the bidirectional nature of cognitive development, whereby children act on the world (assimilation) and then adjust their action schemata in accordance with their degree of success or failure (accommodation). The mechanism of change in connectionist accounts of development are principally changes in connection weights among subsymbolic neuron-like nodes such that the regularities in the world are incorporated *into* the internal processes that connect nodes to each other, and input to output. Some models begin with few constraining assumptions about architecture, whereas other's base their architecture on current understanding of neural pathways or as a

consequence of experience (see O'Reilly & Munakata, 2000, for a comprehensive review and tutorial). In all, however, the principal mechanism of change is incorporation of statistical regularities in the learning environment.

How does dynamic systems differ with regard to the principle causes of change? The concepts of self-organization and emergence proposed in dynamic systems theory bear a strong historical relationship to Piaget's constructivism, the emphasis on sensorimotor processes is shared with Gibsonian approaches, and a structuring role for the environment with connectionism. Contemporary dynamic systems approaches have not considered social interactions, but could in principle (see Yu & Ballard, 2004). Chomsky (and nativism) seems to be left out, but is he really? There are explicit formal theories of change in dynamic systems consistent with a triggering mechanism of change. Specifically, Yamauchi and Beer (1994) showed how the dynamics of continuous time recurrent networks can generate highly distinct patterns of sequential behavior, shifting between different attractor states, in response to an external trigger. That is, Chomsky's general idea of triggers and parameter settings could well be realized in a dynamic systems framework as a mechanism of change.

The Structuring Role of External Information. This dimension is strongly correlated with the mechanisms of change just described, although it is not quite the same thing. Nativist theories tend to downplay the structuring role of external information, while empiricist theories tend (by definition) to view the environment as a primary source of structure. Thus for Chomsky, the environment plays a limited role and acts primarily through triggering. Indeed, Chomsky has continually emphasized the paucity of the environment. For Vygotsky, in contrast, the social environment is a critical source of structure, internalized by the child through social interaction. Likewise, for Gibson, the child does not need to build complex mental structures to represent the environment because the environment is already rich in information, waiting only to be discovered. In this regard, Piaget continually emphasized the structured nature of the world in which the child exercises his or her minimal innate sensorimotor schemata, using information about a mismatch between his or her intentions and realization (disequilibrium) to motivate change. However, the endpoint of cognitive development (formal operations) reflects a long series of transformations and reorganizations, resulting in structures that cannot be detected directly in the outside world. External information is critical to connectionism because the incorporation of statistical regularities in the world is the principal mechanisms of change in those theories. External structure is critical to dynamic systems theories because the world, the specific task at hand, and a history of interaction in that world, is one of many causes organizing the system. However, in dynamic systems, a change in external structure may result in a completely different endpoint, but the endpoint itself is not contained in the environment. This then is a shared point with nativism: However, whereas nativism sees the main cause as the constraining properties of the system itself; dynamic systems sees the history of a complex system of many interacting internal and external components.

Importance of Social Interaction. Of the six theories summarized in Table 6.2, Vygotsky's theory is the only one that has taken social interaction seriously as a source of structure in cognitive development. Chomsky denies that social factors play any important structural role in language development, and Gibson does not assign any privileged status to social factors. Piaget acknowledged the importance of social factors in the construction of the mind (particularly in his works on language and culture—see Piaget's remarks on Vygotsky's views in Piaget, 1986), but did not study social processes. Thelen and Bates acknowledge that, to date, dynamic systems have failed to recognize social factors as a source of structure in developmental process.

The Role of Biological Constraints. Of the six theories compared in Table 6.2, Vygotsky's is the only one that had little or nothing to say about the role of biological constraints on development. Thelen and Bates suggest that this may be more a result of the issues of main interest to Vygotsky than a principled denial of the role of biology. All contemporary serious developmental theories acknowledged the role of biology. Theories differ from to stronger (nativist) to weaker (most connectionist) in the role of biology in determining specific outcomes. Dynamic systems in its multicausal, multilayered, *historical* approach sees biology and environment as continually meshed and inseparable. It makes no sense to ask which is most important or most determining.

Brain Development as a Source of Constraints. Thelen and Bates note that none of the four classic

theorists—Piaget, Gibson, Vygotsky, Chomsky—made much use of information from developmental neurobiology. But to be fair, there was far less useful information available in the first 50 to 60 years of the twentieth century. In the last 20 to 30 years, there has been an explosion of information about plasticity, activity-dependent factors in brain development, and the bidirectional roles of both genes and environment in brain development (see especially Chapter 5 of Elman et al., 1996; Chapter 5 of Thelen & Smith, 1994). Much of this information is incompatible with strong nativist theories (which emphasize a rigid form of biological determinism), and highly compatible with the kind of dynamic approach to development that we espouse. Still, the serious incorporation of advancing knowledge about neural development into general developmental theories has not yet happened. This is an important limitation on dynamical systems as yet developed.

Sensorimotor Bases of Higher Cognition. Piaget's emphasis on the sensorimotor bases of higher cognition is the linchpin of his theory, and may be viewed as his most creative and important contribution. The same point is explicitly disavowed by Chomsky (who is committed to a grammar that is autonomous from the rest of mind, much less the body itself). It is implicit in Gibson's theory, but for Thelen and Bates, not because of Gibson's strong critique of mentalism (see following), the idea was never fully developed. Vygotsky also gave these factors little role once language learning and socialization came into play. Current connectionist theories like most cognitivist theories give little attention to the role of the sensory-motor system. Dynamic systems theory, with its emphasis on perceptual-motor development, stands strongly in the tradition of Piaget in espousing the fully embodied mind.

Mental Representations. In their discussion, Thelen and Bates give representation to all theoretical perspectives but Gibson, noting that while some dynamic systems theorists eschew representation (Smith et al., 1999; Thelen & Smith, 1994), others embrace it (Spencer & Schoner, 2003). However, what one concludes depends on what one takes representation to mean. In the strong traditional sense, representation means Newell, Shaw, and Simon's (1957) physical symbol system: internally represented propositions that operate as symbols (with a syntax and a semantics) *within* a computational system. This is representation in the sense of Chomsky, Piaget, and Vygotsky among others. Then, there is representation-like: Any internal event in the system with some stability (or recurrence) that the *theorist* can point to as corresponding to some regularity in behavior. This is "representation" in the sense of connectionism and Thelen and Bates. Under this definition, it is hard to imagine a theory that does not have representations (because any internal regularity that corresponds to a behavioral regularity counts).

Dynamics as a Source of Structure and Change. Developmental theory should be about time: how real time events literally make (create) change. Dynamic systems, as a theory of development, represents an effort to implement insights from dynamic systems theory in physics, mathematics, and biology to a theory about change over time. This is the very core of the enterprise. Because dynamic systems is itself a late twentieth century movement, it is not surprising that these ideas had little influence on the four classic developmental theories. However, modern-day Gibsonians like Turvey, Kelso, and Shaw (Kelso, 1995; Turvey, 1977; Turvey, Shaw, Reed, & Mace, 1981) have been pioneers in using dynamic systems to explain aspects of perceptual and motor functioning in adult humans. Similarly, connectionist models as nonlinear neural networks are nonlinear dynamical systems (see especially Elman et al., 1996, Chapter 4); they embody the principles and phenomena that define dynamic systems theory. Although not all practitioners of connectionism are aware of the extent to which this is the case, and not all connectionist models have much to say about the interplay of real-time activity and the slower dynamics of learning and developmental change, Thelen and Bates conclude that connectionism and dynamic systems share, at base, the very same ideas about the nonlinear dynamics of change, sensitivity to initial conditions, and the sudden catastrophic transformations (including U-shaped behaviors) that can take place after gradual increments along some quantitative parameter. However, the mathematics of dynamic systems provides a way of studying, describing, and explaining change in general, including as we noted earlier, trigger-like and parameter-setting processes such as those proposed by Chomsky.

Mathematical Formalisms and Simulations. Formally specified theories have played an important role in Chomsky's and J. J. Gibson's theories, parts of Pi-

aget's theory, connectionism, and dynamical systems. Formal mathematical theories will become increasingly important in developmental psychology. Theories, which are merely strings of words (often ill-defined ones at that), can lead to debates about "what is really meant" and to confusions about the predictions that do or do not follow from some claim. Mathematical specification of theoretical claims and predictions derived from simulations are clearly the future for developmental theories of all persuasions.

SUMMARY

The point of Thelen and Bates's exercise was to situate dynamic systems in the larger landscape of developmental theories. As should be evident, dynamic systems is a powerful framework in which many different ideas—from triggers to associative learning to embodiment to socialization—may be realized. Dynamic systems is not so much in opposition to these other perspectives but a new way of unifying the many threads that comprise developmental change. What dynamic systems *adds* to this current landscape is both an emphasis on understanding development as a complex system of nested dynamics, and a complex system of self-organizing interactions at many levels of analysis, including those between the brain and the body, and between the body and world.

CONCLUSION: WHY DYNAMICS?

The major contribution of a dynamic approach to development is the potential to bring theoretical coherence to a field that has been beset by dialectics: Nature versus nurture, learning versus maturation, continuity versus discontinuity, structure versus process, perceptual versus conceptual, symbolic versus presymbolic, and so on. The danger of such either-or thinking is not that good studies have not been done, or cannot be done, but that the point of the enterprise, understanding change, can be forgotten. Only the framework and language of dynamics can erase these dualities and shift the focus to *how* the developing system works.

The promise of dynamics is realized through the assumptions of coupling and continuity. Coupling means that all components of the developing system are continually linked and mutually interactive in the individual and between the individual and the environment. Continuity means that processes are seamless in time and cumulative; mental and physical activity are assembled in the moment and always as a function of the system's history. Actions done in this moment, in turn, set the stage for behavior in the next second, minute, week, and year. With this formulation, it makes no sense to ask what part of behavior comes from stages, mental structures, symbol systems, knowledge modules, or genes because these constructs do not exist in timeless, disconnected form. There is no time and no level when the system ceases to be dynamic.

Dynamics is the language of stability and change, and a dynamic approach frames developmental questions about when systems are stable or change, and what makes them change. The power of dynamics is that these issues can be posed at many levels and timescales. The system is dynamic all the way down and all the way up! We can ask meaningful developmental questions at the neural, physiological level, or individual or social behavior level. Because dynamics seeks to be construct free, there is a real potential for integrating levels of analysis. Likewise, we can probe the system as it changes over the time of a single event, an experimental session, more extended training, or what we consider the *developmental* timescale of weeks or months. That dynamics is a framework and a language rather than a specific theory of the development of *something*—language, peer relations, visual perception, adolescent adjustment, and so on—is both a strength and a weakness. The strength is the potential for viewing many traditionally separate domains as subsumed under the same dynamic processes. The weakness is equally apparent. A dynamic approach does little of the real work. It suggests a way of thinking, a strategy for collecting developmental data, and hopefully, some analysis and modeling techniques that have broad generality. (That's not too bad!) The approach is not a substitute for the hardest part of understanding development: Collecting good data and using both descriptive and experimental methods. There are grave pitfalls in collecting data without clear theoretical assumptions, but it is equally dangerous to spin theories, verbal or mathematical, without a constant dialogue with data. For example, thinking dynamically allowed us to reinterpret the A-not-B error and generate new predictions, but only trudging back to the laboratory gave substance to the theorizing. These experiments hold promise for new theoretical insights, and so forth.

CHAPTER 7

Dynamic Development of Action and Thought

KURT W. FISCHER and THOMAS R. BIDELL

Human activity is both organized and variable, dynamically changing in principled ways. Children and adults are flexible and inventive in their action and thought, adapting old ideas to new situations and inventing concepts, formulating plans, and constructing hypotheses while participating in a wide variety of cultural practices. Few developmentalists today would disagree, as, for half a century, psychologists have been accumulating a wealth of evidence on the constructive, self-regulating, and culturally contextualized nature of human psychological processes. If *psychological function*—the way people act—is constructive, dynamic, and culturally embedded, then *psychological structure*—the organization or pattern of activities—is equally so. Yet remarkably, the most widely used conceptions of psychological structure and its development do not reflect this dynamic, constructive, and contextualized picture of psychological processes. The opposite is true: The major models of development describe psychological structure in static, formal terms. Concepts like universal stages, innate linguistic modules, and innate cognitive competencies portray psychological

Preparation of this chapter was supported by grants from Ms. and Mrs. Frederick P. Rose and the Harvard Graduate School of Education.

organization as fixed and unchanging, insulated from variation in context and feedback from activity.

The hallmark of the dynamic nature of human behavior is its pervasive variability: People act differently in different situations, with different people, in different emotional states. Faced with the large and growing corpus of research evidence for *variability* in activity and development, researchers guided by static models have been continually surprised to find that children's performance is nowhere near as stable as the static conceptions predict. A child who can solve an arithmetic problem (or a social problem) one day or in one situation frequently cannot solve the same problem the next day or in a different but apparently similar situation. Different children of precisely the same age often cannot perform the same cognitive tasks—sometimes in relation to cultural contexts or family environment, sometimes for reasons that are harder to explain. Even from moment to moment, a person performs a task differently as she or he adapts to variations in the situation, social context, or emotions of self and others. Indeed, when the data of cognitive developmental research is taken as a whole, variability in the level of psychological performance is the *norm,* not the exception.

The task of developmental science is to detect and describe patterns in this variability and to propose models to account for data patterns that reflect both stability and variability. We show how the concepts and methods of dynamic structural analysis provide a framework and tools for analyzing this variability and detecting the order in it—key findings such as the emergence of qualitatively new cognitive abilities or the transitions from one behavior to another.

In our view, performances vary so greatly because psychological structure is not static but naturally produces variability in activity and development arising from people's constructive self-organization of their own psychological structures in relation to situations, other people, meaning systems, and their own bodies. Far from being a problem, patterns of developmental variability are the key to understanding the organization of these dynamic systems and the constructive processes by which human agents create new interrelations and thus new structures. The complexity of these systems is not something to be controlled for but to be described and understood. The patterns of variability that arise from the particular ways in which cognitive systems are organized are the key to understanding that organization and thus to understanding psychological structure. Tools from dynamic systems analysis provide ways of embracing the variability to find the order in it.

With this chapter, we present a framework for conceptualizing psychological structure in dynamic systems constructed by human agents. We show how this model describes and explains patterns of developmental variability in terms of the structures human beings build. The chapter begins with an introductory overview of dynamic structuralism as a general approach to development, elaborating a theoretical model of psychological structure as the dynamic organization of self-constructed, socially embedded skills and activities (actions and thoughts). We contrast this position with traditional static views of psychological structure, which dominate scientific dialogue in what amounts to a modern synthesis of traditionally opposed viewpoints of nativism and empiricism. These static views derive from reductionist scientific theory inherited from the Cartesian tradition in philosophy, which leads to systematic misunderstanding of the nature of psychological structure and blatant failures to explain the extent of developmental variability.

The dynamic framework and research tools specifically crafted for analyzing development and learning provide a research methodology for the study of psychological structures including both their variability and the order in the variation. These concepts and tools apply to both long-term development and short-term microdevelopmental variations in the building of dynamic structures, providing powerful methods for testing dynamic hypotheses about variation, change, and stability. Broad in scope and applicability, the dynamic structural model and methodology elucidate relations between cognitive, social, emotional, and neurological development—which all work together in the activities of human beings in all their rich complexity.

DYNAMIC STRUCTURALISM

One reason psychological structure has so often been treated as static is that theorists have confounded structure with form. *Structure* refers to the *system of relations* (Piaget, 1970) by which complex entities such as biological organisms and psychological activities are organized. There are systematic relations, for instance, between the nervous system and the cardiovascular system such that each supports and responds to the other. The relations between these systems are in a constant balance or equi-

librium, which can only be maintained by constant activity on the part of each subsystem. Thus, systems of relations—structures—are necessarily dynamic.

Form is an *abstraction from structure*—a fixed pattern that can be detected in a dynamic structure. An orange has cellular and tissue-level structure, which lead to its cohesion in a spherical shape. The structure of the orange is dynamic, emerging developmentally, maintaining a dynamic equilibrium for a time, and then decaying. The concept of sphere, on the other hand, is an abstract form that we apply to describe one characteristic of the dynamic structure: the shape it produces. Beyond the orange, the concept of sphere is an ideal form that applies across myriad realities. The fact that this formal concept is unchanging across many situations is what makes it useful in describing similarities in many different objects such as balls, plums, or planets.

A structure/form problem arises when an abstraction used to describe reality is confounded with the reality described. People commonly expect patterns of phenomena in the world to conform to their underlying abstractions, instead of determining which patterns fit an actual object or experience. In personality and social relations, people commonly expect others to fit the stereotype of, for example, a shy, introverted person or a mother (Greenwald et al., 2002). Similarly, in science, researchers who focus on the sphere form may be surprised that baseballs, basketballs, and soccer balls are so different from one another, and researchers who focus on innate knowledge may be surprised to find that a 3-year-old really does not understand the numbers 1, 2, and 3 even though an infant can distinguish arrays of 1, 2, and 3 dots (Spelke, in press). For the sphere, the logical fallacy is obvious: The spherical shape is an abstraction of a common pattern across different objects, not an independently existing form that somehow dictates what the objects should be like. The same fallacy applies to the stereotypes and the nativist explanation of number.

This form fallacy has frequently led to perplexity among scientists and educators who expect patterns of thought and action to conform to an independently existing form such as stage, cognitive competence, or core knowledge. Scholars have been puzzled when a child reaches a certain stage or competence for one task or situation and he or she does not evidence the same ability in other tasks or situations, as if an underlying abstract logic could determine an individual's performance in the real world (Piaget, 1985). The attempt to preserve formal conceptions of structure in the face of ever growing evidence of variability in cognitive performance has led developmental theorists into pointless arguments over, for example, which of many varying performances represent an individual's "real" logical ability, or at what age children "really" acquire a concept like object permanence. We demonstrate later how the confounding of form with structure has led to an explanatory crisis in developmental science with ever more tortured attempts to explain the pervasive evidence of variability in static conceptions of structure as form. (We also see hopeful signs that the field is shifting to deal more centrally with the dynamics of variation.)

Dynamic structuralism offers an alternative to static conceptions of structure, starting with the recognition of the complexity inherent in human psychological development and the central role of the person in constructing dynamic systems of action and thought. Instead of trying to eliminate or get beyond the complexity of relations among systems, dynamic structuralism uses the tools of contemporary developmental science to analyze patterns in the complexity—how the constructive activity of human agents leads to new relations among systems of action and thought. The analysis of the dynamic structures of human behavior provides a way of simplifying without discarding complexity, identifying the essential relations among systems, and explaining activities and developmental pathways in terms of those essential system relations. Dynamic structuralism thus differs from the classic structuralism of Piaget (1983), Chomsky (1995), and others, which isolates structure from the variability of mental dynamics, treats it as static, and attempts to explain development in terms of the static forms.

Variability in the Middle of Things: An Example of Representing Social Interactions

Focusing on the pervasive variability of human activity, dynamic structuralism analyzes the patterns of stability and order in diverse patterns of activity in the variation (Bidell & Fischer, 1992; Fischer, Yan, & Stewart, 2003; Siegler, Chapter 11, this *Handbook,* Volume 2; Thelen & Smith, Chapter 6, this *Handbook,* this volume; van Geert, 1998). As in the study of ecology, the analysis begins *in medias res,* in the middle of things. Starting in the middle of things means that people's activities are embodied, contextualized, and socially situated—understood in their ecology (Bronfenbrenner & Morris,

Chapter 14, this *Handbook,* this volume; Cairns, 1979; Gibson, 1979) as well as their structure. People act and understand through their bodies acting in the world, not through a disembodied mind or brain. The brain and nervous system always function through a person's body and through specific contexts composed of particular people, objects, and events, which afford and support the actions. People act jointly with other people within culturally defined social situations, in which activities are given meaning through cultural frames for interpretation (Rogoff, 1990). Action in context is the center of who people are and how they develop (Brandtstädter, Chapter 10, this *Handbook,* this volume; Lerner & Busch-Rossnagel, 1981).

Starting in the middle of things with embodied, contextualized, socially situated individual and joint activity requires two major steps: (1) to describe basic structures or organizations of activities in context and (2) to characterize how those structures vary as a function of changes in key dimensions of person, body, task, context, and culture. Whether the focus is on knowledge, action, emotion, social interaction, brain functioning, or some combination, the dynamic structural approach puts the person in the middle of things and frames the person's activity in terms of multiple components working together. The maturity or complexity of people's behavior varies widely and systematically from moment to moment and across contexts, states, and interpretations or meanings. Each individual shows such variations, in addition to the wide variations that occur across ages, cultures, and social groups.

Consider, for example, the wide variation documented for children's stories or narratives about positive and negative social interactions (Fischer & Ayoub, 1994; Hencke, 1996; Rappolt-Schlichtman & Ayoub, in press; Raya, 1996). The developmental level, content, and emotional valence of a child's stories vary dramatically as a function of priming and immediate social support, emotional state, and cultural experience. For example, the activities of 5-year-old Susan demonstrate some of the variations in both developmental complexity and emotional organization that have been documented in research. First, she watches her counselor act out a pretend story with dolls: A child doll named after Susan makes a drawing of her family and gives it to her father, who is playing with her. "Daddy, here's a present for you. I love you." Then the daddy doll hugs the girl doll and says, "I love you too, and thanks for the pretty picture." He gives her a toy and says, "Here's a present for you too, Susan." When asked, the girl promptly acts out a similar story of positive social reciprocity, making Daddy be nice to Susan because she was nice to him.

Ten minutes later, the counselor asks the girl to show the best story she can about people being nice to each other, like the one she did before. Instead of producing the complex story she did earlier, she acts out a much simpler story, making the Daddy doll simply give lots of presents to the child doll, with no reciprocal interaction between them. There is no social reciprocity in the story but only a simple social category of nice action.

A few minutes after that, when the girl has spontaneously shifted to playing at fighting, the counselor shows her another nice story about father and child. This time, when the girl acts out her story, she switches the content from positive to negative with energetic aggression. The girl doll hits the Daddy doll, and then he yells at her, "Don't you hit me," slaps her in the face and pushes her across the room, showing the violence that often appears in the stories of maltreated children. The girl doll cries and says she is scared of being hit again. Note that, despite the shift to negative affect, Susan sustains a story involving social reciprocity: The Daddy doll hits the Susan doll because she had hit him, and she becomes afraid because he had hit her.

Then Susan becomes agitated; yelling, she runs around the room and throws toys. When the counselor asks her to do another story, she makes the dolls hit and push each other with no clear reciprocity and no explanation of what is happening. With her distress and disorganization, she no longer acts out a complex aggression story but is limited to stories of repeated hitting, even when she is asked to produce the best story she can. She uses a simple social category of mean action.

What is the "real" story for the child? Does she represent relationships between fathers and daughters as positive or negative? Is she capable of representing reciprocity, or is she not? These are the kinds of questions that are often asked in child development, but these questions assume an opposition that makes no sense. Susan plainly shows four different "competences"—positive reciprocity, positive social category (without reciprocity), negative reciprocity, and negative social category. Depending on the immediate situation, her emotional state, and the social support from her counselor, she demonstrates each of these four different "abilities." Her four skills vary strongly in both emotional valence and developmental level (complexity) with the different skills linked to the social context, her emotional state, and her relationship with her father and her counselor.

Different contexts for assessment routinely produce such substantial variations, although most developmental theories and methods do not deal with this variability. Children (and adults) show distinct levels of competence under different conditions, even for a single domain such as stories about nice and mean social interactions between peers (A. Brown & Reeve, 1987; Fischer, Bullock, Rotenberg, & Raya, 1993). Figure 7.1 shows the best (most complex) performances of eight 7-year-old children who were acting in (a) several contexts in which an interviewer provided high social support for complex stories, such as prompting the gist of the plot, and (b) several contexts providing no such support. As the context shifted, the children's competence for representing mean, nice, or nice-and-mean social interactions shifted dramatically and systematically. Every individual child showed a similar pattern of shifting across conditions—competence at step 6 or 7 for high-support conditions, and competence at step 2, 3, or 4 for low-support conditions. This variation is an example of *developmental range,* the spread between competence with high support and competence with little support. With both positive and negative stories, Susan demonstrated a developmental range varying from interactions with social reciprocity to interactions based on a single, nonreciprocal category. For example, she showed a higher competence of social reciprocity when the interviewer first demonstrated a story of nice reciprocity for her and a lower competence of nonreciprocal social interaction when she later made up a story without the interviewer's demonstration. Labeling her as having or understanding social reciprocity misrepresents the range of her competence, as does labeling her as having only a nonreciprocal social category.

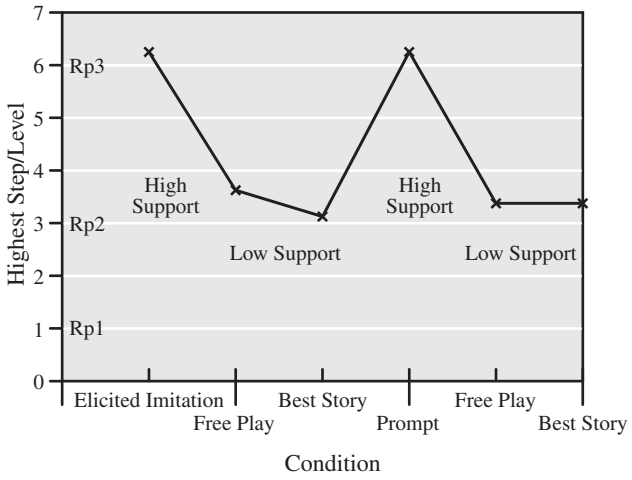

Figure 7.1 Variation in competence for stories as a function of social-contextual support. In the high-support assessments the interviewer either modeled a story to a child (Elicited Imitation) or described the gist of a story as well as some content cues (Prompt), and then the child acted out or told a similar story. In the low-support assessments the interviewer provided no such support but either asked for the best story the child could produce (Best Story) or let the child make up a number of stories in free play with the most complex story determining the child's "competence" for this context (Free Play). Children had performed similar stories several times before the assessments graphed here. The y-axis indicates steps in the assessed developmental sequence, as well as skill levels (Rp1 to Rp3), which will be explained later. *Sources:* From "The Dynamics of Competence: How Context Contributes Directly to Skill" (pp. 93–117), by K. W. Fischer, D. H. Bullock, E. J. Rotenberg, and P. Raya, in *Development in Context: Acting and Thinking in Specific Environments—The Jean Piaget Symposium Series,* R. H. Wozniak & K. W. Fischer (Eds.), 1993, Hillsdale, NJ: Erlbaum; and "The Effects of Development, Self-Instruction, and Environmental Structure on Understanding Social Interactions," by E. J. Rotenberg, 1988, *Dissertation Abstracts International, 49*(11), p. 5044B.

Depending on their emotional state, children also show different emotional valences in their representations, just as Susan did in her shift to negative stories. Maltreated children often shift the content of stories from positive to negative, and, when they become agitated, the sophistication of their negative stories deteriorates and remains low until they become calmer (Ayoub & Fischer, in press; Buchsbaum, Toth, Clyman, Cicchetti, & Emde, 1992).

These kinds of variations need to be center stage and the focus of developmental analysis. Only by including these variations as a function of context, culture, state, and other key contributors to behavior can scholars build an effective framework for explaining the many shapes of human development. Dynamic structuralism provides concepts and tools for founding developmental explanation and description of these variations, and it encourages the building of theory and method that capture the rich complexity that is the legacy of the human species.

Dynamic Nature of Psychological Structure

What is psychological structure? Why is it important in explanations of development? The answers depend on assumptions about the nature of the mind and its relation to other biological, psychological, and social phenomena. Psychological structure is the organizational property of dynamic systems of activity, and analysis of dynamic structure starts with assumptions that are fundamentally different from the traditional view of

structure as static form. The concept of structure in stage theory and related viewpoints equates form with structure and thus founders on the "discovery" of variability in development (as do most other traditional psychological concepts). The continued dominance of the structure-as-form paradigm has prevented an adequate resolution of the crisis of variability in developmental theory.

To build successful models of dynamic psychological structure, it is essential to understand how dynamic structure differs from static form. An essential first step is to focus simultaneously on variability and stability. Indeed, the neglect of variability helps ensure that models remain static, missing the sources of order in the variation and treating structures as static forms. Any adequate account of psychological structure must explain not only the stability that allows systems to function and maintain themselves over time and space but also the wide variability that arises from the dynamics of self-organizing systems. Models of psychological structure must specify mechanisms by which activities are organized dynamically in relation to multiple influences that are biological, psychological, and social.

In this section, we illustrate how a dynamic structural framework deals with variability and stability simultaneously and thus introduces powerful explanations of development, including cognition, social interaction, emotions, and even brain development.

Dynamic Structure in Living Systems

All living systems—whether biological, psychological, or social—must be organized to function. A living organism that becomes sufficiently disorganized dies. A disorganized society collapses. A disorganized mind leaves a person helpless in the face of everyday problems. This organizational aspect of living systems is what we call *structure,* a dynamic patterning and relating of components that sustain the organized activities that define life and living things.

To say that a system is structured or organized implies that specific relations exist among its parts, subsystems, or processes. In the human body, for example, the respiratory, circulatory, digestive, metabolic, and nervous systems must all function in very specific relations to maintain the overall functioning and health of the organism. Similarly in a complex society, the economic system, judiciary, political/electoral system, and government must maintain specific relationships to sustain the society. In this way, dynamic structure exists only where relationship exists, and relations among the parts of a system provide its specific organization.

To flourish, living systems must be more than just organized. They must be dynamic. Systems must constantly move and change if they are to carry out their functions and maintain their integrity and their interrelations with other functioning systems. A system that becomes static—unable to change and adapt to varying conditions—will quickly perish. Social, psychological, or biological systems must be able to stretch the limits of their current patterns of organization, and even to actively guide and reorganize the relations that constitute their structure. An organism or society that becomes inflexible and incapable of adaptive response to variations in its environment will die as surely as one that becomes disorganized. Thus, structure must be distinguished not only from disorganization but also from static form, which really is the antithesis of structure. Structure is fundamentally dynamic because it is a property of living, changing, adapting systems. Susan demonstrated this dynamic adaptation in her variable representations of social interactions with her father and counselor. Dynamic variation is a fundamental property of human action and thought.

The human mind is a specialized living system that participates in and with other bodily, environmental, and social systems. The specialized function of the human mind is to guide and interpret human activity in relation to the world of people and objects. The activity takes places *in medias res,* in the middle of things, not in the person alone or in the brain. The objects and people in the physical and social world of the actor are actually part of the activity.

Moreover, living systems are *agentive*—self-regulating and self-organizing, adapting and changing as a consequence of goal-oriented activity, as in Susan's activities (Bullock, Grossberg, & Guenther, 1993; G. Gottlieb, 2001; Kauffman, 1996). In seeking its goals, a living system is involved in multiple relations with other living and nonliving systems, and they are part of one another's dynamics.

This agency and interaction lead naturally to variability in systems. If systems were static, they would be unchanging; but because they move and change, they give rise to patterns of variability. The more complex a system, the more relations are entailed by its structure and the greater the variability it is likely to display. Human beings show more variability in activity than lizards,

rats, or monkeys. This variability can easily elude overly simple theoretical models that ignore the dynamic complexity and interrelationships of living systems.

Variation and Order in Development: The Constructive Web

People unknowingly ground their concepts and activities in metaphoric frames that give meaning (Lakoff & Johnson, 1999). Concepts and theories in science derive from metaphoric frames in the same way as everyday concepts, except that research systematically tests their grounding in observation and action. Traditional static conceptions of development in psychological structure are closely related to the widespread cultural metaphor of a ladder. Development is conceived as a simple linear process of moving from one formal structure to the next, like climbing the fixed steps of a ladder. It matters little whether the steps of the ladder are conceived as cross-domain stages, levels of a domain-specific competence, or points on a psychometrically based scale. In each case, the beginning point, sequence of steps, and endpoint of the developmental process are all linear and relatively fixed, forming a single ladder. With such a deterministic, reductionist metaphor, it is difficult to represent the role of constructive activity or contextual support because there appears to be no choice of where to go from each step. The richness of children's development, including the variability in their skills across contexts, is simply lost with the ladder metaphor. Development means just moving to the next step—an overly simple theory that clearly does not capture the variability that Susan showed in her stories about nice and mean interactions.

A more dynamic metaphor for development, which includes variability as well as stability in development, is the constructive web (Bidell & Fischer, 1992; Fischer et al., 2003). The metaphor of a web is useful for dynamic models because it supports thinking about active skill construction in a variety of contexts and for diverse variations. Unlike the steps in a ladder, the strands in a web are not fixed in a determined order but are the *joint product* of the web builder's constructive activity and the supportive context in which it is built (like branches, leaves, or the corner of a wall, for a spider web). The activity of an agent in constructing a web is particularly clear. For example, a given strand may be tenuous at first, dependent on surrounding strands for external support, and like the spider, the person can reconstruct it until it becomes a stable part of the web. Also, unlike most spider webs, human developmental webs are constructed jointly by multiple agents, not by an individual alone, although most psychological research examines individuals isolated from their social networks. We show how people often join together to construct parts of their developmental webs.

The separate strands in a web represent the various pathways along which a person develops. The strands in a web can start in a number of places, take a variety of directions, and come out at a range of endpoints, all determined by active construction in specific contexts. The several strands composing one line may be constructed in a different sequential order from the strands composing another line in a different section of the web. At the same time, there is order in the web, including similar orderings of spatial positions for some strands, separations and junctions of strands, and related starting and ending points for some strands. Using the constructive web as a metaphor for devising models of development facilitates the unpacking of variability relating to constructive activity and context, which are conflated in the image of a linear ladder of static structures.

Figure 7.2 depicts an idealized constructive web. The lines or strands represent potential skill domains. The connections between strands represent possible relations among skill domains, and the differing directions of the strands indicate possible variations in developmental pathways and outcomes as skills are constructed

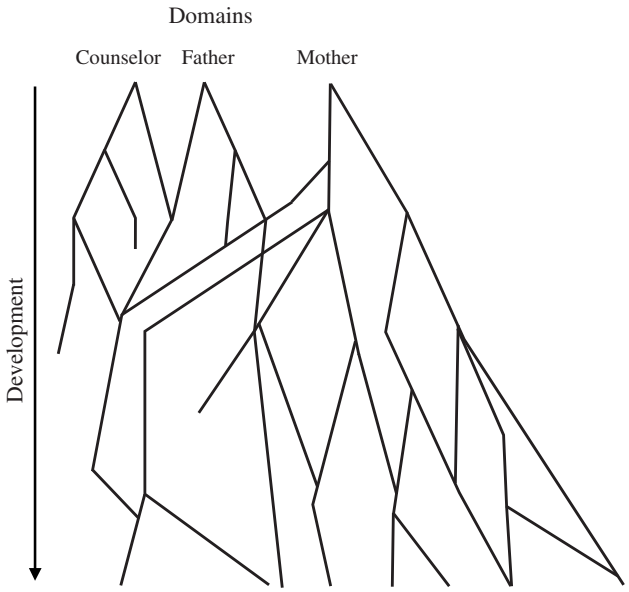

Figure 7.2 Development as a constructive web.

for participation in diverse contexts. Groupings of strands represent domains of skill, such as mother, father, and counselor, for each of the three clusters of strands. Within each strand, people's activities also vary, demonstrating a developmental range (like Susan's) varying between high competence with contextual support and lower competence without it (Fischer, Bullock, et al., 1993; Fischer et al., 2003). In the discussion that follows, the web metaphor is articulated to facilitate analysis of variability in the development of dynamic skills.

DYNAMIC STRUCTURE IN COGNITIVE AND EMOTIONAL DEVELOPMENT

To explain both variability and stability in development and learning, an alternative framework is needed to replace the structure-as-form paradigm as a basis for research and interpretation. Static conceptions of psychological structure must be replaced with dynamic ones such as the constructive web. Reified notions of structures existing separately from human activity must give way to a new understanding of structure as the dynamic organization inherent in the activity itself. Such a framework is emerging in dynamic systems theory, which is influencing a variety of fields and a growing number of researchers. (This volume shows the extent of the growth of dynamic systems in human development, with a majority of chapters taking a dynamic systems perspective.)

Common in many dynamic systems models is a shift in the treatment of order and variation from being dichotomized to being intrinsically related (Hua & Smith, 2004; Kelso, 1995; Port & van Gelder, 1995; van Geert, 1998). Phenomena that were once viewed as random or chaotic are now seen as organized in complex ways that lead to specific patterns of variation. Descriptions and models of the activity and change start with analysis of relations between organization and variability in specific phenomena. For instance, the jagged patterns of seacoasts—seemingly erratic jumbles of random erosions—can be closely modeled with fractal geometry, revealing an intrinsic organization to a geologic process of erosion and sedimentation once thought of as disorderly. By recognizing that organization is related to variability, geologists and mathematicians have been able to create models of the dynamic organization of the erosion process that can predict and explain the variability observed in the changing coastline (Kruhl, Blenkinsop, & Kupkova, 2000). Similarly, biologists model the structures of evolution of living organisms (Kauffman, 1993) and the dynamics of brain functioning and development (e.g., Marcus, 2004; Polsky, Mel, & Schiller, 2004; Spruston & Kath, 2004).

Full realization of the potential of dynamic systems analysis requires not only connecting nonlinear dynamic concepts to psychological processes but also building explicit dynamic models of those processes. Global concepts can be powerful and useful, but ultimately they must be tested out as models with explicitly defined properties. Only with such models can researchers determine whether the processes they hypothesize in fact produce the dynamic patterns of development and variation that they expect (Fischer & Kennedy, 1997; Thelen & Smith, Chapter 6, this *Handbook,* this volume; van der Maas, 1995; van Geert, 1998; van Geert & van Dijk, 2002). Happily, computer-based tools including spreadsheets such as Excel can be readily used to build explicit dynamic models and test them against empirical data.

From a dynamic systems viewpoint, psychological structure is the actual organization of systems of activity. It is not a separately existing entity, such as a logical stage dictating behavior, or a preformed linguistic or cognitive capacity awaiting actualization, but instead is a property of human activity systems. Because real systems of activity are dynamic—constantly moving, adapting, and reorganizing—they must be dynamically structured. Variability is a natural consequence of system dynamics, and because systems are organized, the variability is not random but patterned, as evident in the variable stories that Susan told. Just as geologists have modeled the structures of coastal evolution and biologists have modeled the structures of evolution of living species, developmental scientists can build models of the dynamic structures of development and learning in human action and thought.

To move beyond a general call to dynamic structural analysis and model the dynamics of development successfully, scholars need specific psychological constructs that support analyzing structures behind variation for particular research problems. There is not one correct construct for a dynamic approach to psychological structure. A number of contemporary constructs are useful for this purpose because they have been developed specifically to facilitate analysis of variation and organization of activities in context. The concept of script, for example, focuses on the organization and variation in everyday activities for storytelling, narratives, goals, and recall for scripted activities in specific contexts (Fischer, Shaver, & Carnochan, 1990; Nelson,

1986; Schank & Abelson, 1977). The concept of strategy has a long history of illuminating variations in the organization of problem-solving activity (Bruner, Goodnow, & Austin, 1956; Siegler & Jenkins, 1989; Siegler, Chapter 11, this *Handbook,* Volume 2). Concepts such as apprenticeship (Rogoff, 1990), environmental niche (Gauvain, 1995), and setting (Whiting & Edwards, 1988) facilitate analysis of the dynamic social organization of activities across contexts.

A construct that we find especially useful for facilitating a dynamic approach to psychological structure is *dynamic skill;* it provides a useful way of integrating many of the necessary characteristics of dynamic psychological structure into a single, familiar idea (Fischer, 1980b; Fischer & Ayoub, 1994; Fischer, Bullock, et al., 1993). This construct is based on concepts that were central to the cognitive revolution of the late 1950s and 1960s (Bruner, 1973; Gardner, 1985), the ecological revolution of the 1960s and 1970s (Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; Gibson, 1979), and the emotive revolution of the 1980s and 1990s (Campos, Barrett, Lamb, Goldsmith, & Stenberg, 1983; Frijda, 1986; Lazarus, 1991). These revolutions have emphasized, for example, the importance of goals, self-regulation, organism-environment interaction, bias or constraint, and the social foundations of activity. Most importantly, Piaget (1970) and Vygotsky (1978) insisted on activity as the basis of cognitive structures, defined as systems of relations among activities.

In the following discussion, we explicate the construct of dynamic skill, using it to articulate essential characteristics of psychological structures. We show how the dynamic analysis of structure can both predict and explain specific patterns of developmental variability, focusing on three key types of variability frequently observed in developmental research: (1) sequence, (2) synchrony, and (3) range. In subsequent sections, we show how these dynamic characteristics differ from those in static views of structure, and we describe key methodology for studying the dynamics of change, microdevelopment in learning and problem solving, development of emotion, and the role of brain functioning in development of cognition and emotion.

Psychological Structure as Dynamic Skill

In ordinary English usage, the term *skill* both denotes and connotes essential characteristics of the dynamic organization of human activities (Bruner, 1973; Welford, 1968). Skill is the capacity to act in an organized way in a specific context. Skills are thus both action-based and context-specific. People do not have abstract, general skills, but they have skills for some specific context: a skill for playing basketball, another for telling a children's story, or yet another for interpersonal negotiation. Skills do not spring up fully grown from preformed rules or logical structures. They are built up gradually through the practice of real activities in real contexts, and they are gradually extended to new contexts through this same constructive process (Fischer & Farrar, 1987; Fischer & Immordino-Yang, 2002; Granott, Fischer, & Parziale, 2002).

The concept of skill also helps to conceptualize the relations among various psychological, organismic, and sociocultural processes and to cut through artificial dichotomies between mind and action, memory and planning, or person and context. A skill—such as telling children stories about emotional interactions with other children—draws on and unites systems for emotion, memory, planning, communication, cultural scripts, speech, gesture, and so forth. Each of these systems must work in concert with the others for an individual to tell an organized story to specific children in a particular context, in a way that it will be understood and appreciated. The concept of dynamic skill facilitates the study of relations among collaborating systems and the patterns of variation they produce and inhibits treating psychological processes as isolated modules that obscure relations among cooperating systems. To see how, let's consider some of the characteristics of skills.

Integration and Interparticipation

Skills are not composed atomistically but are necessarily integrated with other skills. The skill of playing basketball demands that many other skills, such as running, jumping, and visual-motor coordination, all be integrated to function in a coordinated way. Integrated skills are not simply interdependent but *interparticipatory.* True integration means that the systems participate in one another's functioning. Atomistic models allow for simple interdependence: The stones in an arch, the trusses in a bridge, the modules in a serial computer comprise atomistic systems in which parts are interdependent but do not obviously participate in each other's functioning.

In contrast, the components of living systems not only depend on one another but participate in one another. Although at first this concept may seem counterintuitive, there are many obvious examples in familiar processes such as human cellular or organ systems. Any

system in the human body is composed of multiple subsystems whose boundaries defy definition. The cardiovascular system, for example, participates in the functioning of every organ system, because every organ depends on receiving oxygenated blood. At the same time, the cardiovascular system includes components from the nervous system, the muscular system, and so forth, so that these other systems in turn participate in the circulatory system. It makes little sense to think of any of these systems as functioning outside the context of the other systems: Living systems die when cut off from the other systems with which they interparticipate. For living systems, conceptions of structure must reflect the interparticipation of one system in another.

Systems of activities are central parts of living systems, especially in complex systems such as human beings. Activities organize into skills, which have many interparticipating components. When Susan creates a story of social reciprocity between the positive actions of the doll Susan and her doll father, the actions of each character affect each other intimately and reciprocally—they participate in each other. Skills normally involve this interparticipation of components.

Context Specificity and Culture

Skills are context-specific and culturally defined. Real mental and physical activities are organized to perform specific functions in particular settings. The precise way a given skill is organized—its structure—is essential to its proper functioning, as well as specific to that skill at any moment. Good basketball players do not automatically make good baseball players; good storytellers in one culture do not automatically have their stories understood and appreciated in other cultures.

The context specificity of skills is related to the characteristics of integration and interparticipation because people build skills to participate with other people directly in specific contexts for particular sociocultural systems. In turn, people internalize (Cole, 1996; Wertsch, 1979) or appropriate (Rogoff, 2003) the skills through the process of building them by participating in these contexts; and as a result, the skills take on cultural patterning. Similarly, component systems such as memory, perception, emotion, and even physiological regulation all participate in the culturally patterned skills. The context specificity of skills thus implies more than simply a fit with an environment. Even systems like perception or memory, which are often thought of as being isolated from sociocultural systems, are linked to them through the skills in which they participate; research shows how pervasive and deep the connections are (Greenwald et al., 2002; Mascolo, Fischer, & Li, 2003).

Self-Organization, Mutual Regulation, and Growth

Skills are self-organizing. Part of the natural functioning of skills is that they organize and reorganize themselves. These self-organizing properties go beyond maintenance to include growth of new, more complex skills. One of the goals of developmental science is to analyze the processes of organization and change, which skills undergo with development and learning. Unlike mechanical systems that must be built and maintained artificially through an external agency, the agency that creates and maintains skills (and living systems in general) resides in the activities for both individual activity and social interaction. Construction and maintenance of skills involves both self-regulation and mutual regulation with other people, because components interparticipate. In an obvious example from human biology, as people increase their activity level, their increased use of energy and oxygen evokes increases in their rates of breathing and metabolism. No outside agency is involved in adjusting the controls for this interparticipation of motor systems with respiratory and metabolic systems. The living system actively adjusts itself to maintain its own integrity.

In skills, the components regulate each other in the same way. Susan's and her father's mean actions toward each other mutually affected the other's mean actions, creating adaptations in content, organization, and emotional tone (quality and intensity). Skills are not fixed abilities but constantly adapting, regulated activity structures. As Susan, her father, and her counselor act together, they develop new skills together, coordinating activities that were previously relatively independent to form newly integrated wholes. Through coordination and mutual regulation, they organize their activities into qualitatively new, integrated systems, with sequences of coordinations and regulations that build on each other.

Dynamic structuralism provides concepts and tools for taking hold of this adaptive variability to uncover the order behind the variations. One of the central discoveries is a common scale of hierarchical complexity that orders the variations.

A Common Ruler for Skill Development

A key ingredient for advancing developmental science is common rulers (scales) for measuring change and varia-

tion in activity, similar to the Centigrade or Fahrenheit scale for temperature and the meter or foot for length. These scales should be grounded in properties of natural response distributions and applicable across tasks and domains. However, psychological measurement has produced mostly arbitrary scales based on one situation such as those for intelligence, achievement, and personality tests. They do not use naturally occurring response distributions but statistical models assuming stable (static) ability and normal distributions (van Geert & van Dijk, 2002; Wahlsten, 1990), and they assess behavior in one situation, the test. A more useful scale allows measurement of different skills in various situations and is not tied to one situation or assessment instrument. Temperature and length can be measured in many ways in virtually any situation.

Fortunately, the measurement problem has now changed with the discovery of a common scale for behavioral complexity that captures a central dimension of both long-term development and short-term change (Commons, Trudeau, Stein, Richards, & Krause, 1998; T. L. Dawson & Wilson, 2004; Fischer, 1980b; Fischer & Immordino-Yang, 2002). Research with various methods has produced evidence for the same scale, marked by clusters of discontinuities such as sudden changes in growth patterns and gaps in Rasch scaling. Analysis of growth curves has documented these patterns (Fischer & Rose, 1999; van Geert, 1998), and Rasch (1980) scaling of interview and test data has shown remarkably consistent evidence of the same patterns of discontinuity (Dawson, 2003; Dawson, Xie, & Wilson, 2003), forming a scale of at least 10 levels of hierarchical complexity, as shown in Figure 7.3. The scale relates to the outline of developmental stages that Piaget (1983) described, but the levels on the scale are better grounded empirically, and performance varies across the scale instead of being fixed at one point at each age. The scale also has important similarities to those suggested by Case (1985), Biggs and Collis (1982), and others. Interestingly, discontinuities in growth of brain activity seem to follow the same scale, as described later in the chapter (Fischer & Rose, 1996).

Many developmental scientists have posited stages, some of which match some of the levels (Biggs & Collis, 1982; Case, 1985; Halford, 1982; McLaughlin, 1963), but these alternatives have not been based on clear empirical criteria for what constitutes a stage or level—and what does not (Fischer & Silvern, 1985). Typically, these investigators have merely described a sequence of posited cognitive reorganizations without specifying empirical criteria for stages or levels, except for loosely defined "qualitative change" and an approximate developmental sequence.

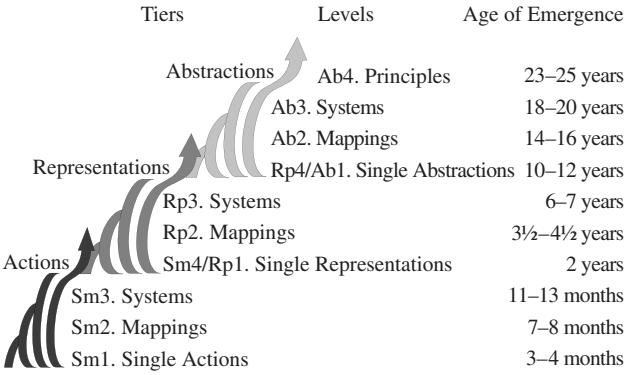

Figure 7.3 Developmental cycles of levels and tiers of skills. Development proceeds through 10 levels of skills grouped into three tiers between 3 months and adulthood. The ages of emergence are for optimal levels, the most complex skill that a person can perform with social-contextual support, based on research with middle-class American or European children. They may well differ across social groups. There is some evidence for an additional tier of innate action-components in the first few months of life. *Sources:* From "A Theory of Cognitive Development: The Control and Construction of Hierarchies of Skills," by K. W. Fischer, 1980b, *Psychological Review, 87,* pp. 477–531; and "The Big Picture for Infant Development: Levels and Variations" (pp. 275–305), by K. W. Fischer and A. E. Hogan, in *Action in Social Context: Perspectives on Early Development,* J. J. Lockman & N. L. Hazen (Eds.), 1989, New York: Plenum Press.

The skill scale in Figure 7.3 begins with sensorimotor actions, which are coordinated through several complexity levels to eventually form representations, which are in turn coordinated through several levels to form abstractions, which continue to develop into adulthood. The larger growth cycles of actions, representations, and abstractions are called *tiers* (left column of the figure), and the specific changes marked by clusters of discontinuities are called *levels* (middle column). The ages in the right column indicate when skills at a level first emerge under conditions that support optimal performance. Each level has a characteristic skill structure, as shown in Figure 7.4, and similar structures recur in each tier, reflecting a dynamic cyclical growth process. The structures begin with single sets organized as actions, representations, or abstractions. A person coordinates and differentiates these sets to form mappings, which in turn are coordinated and differentiated to form systems.

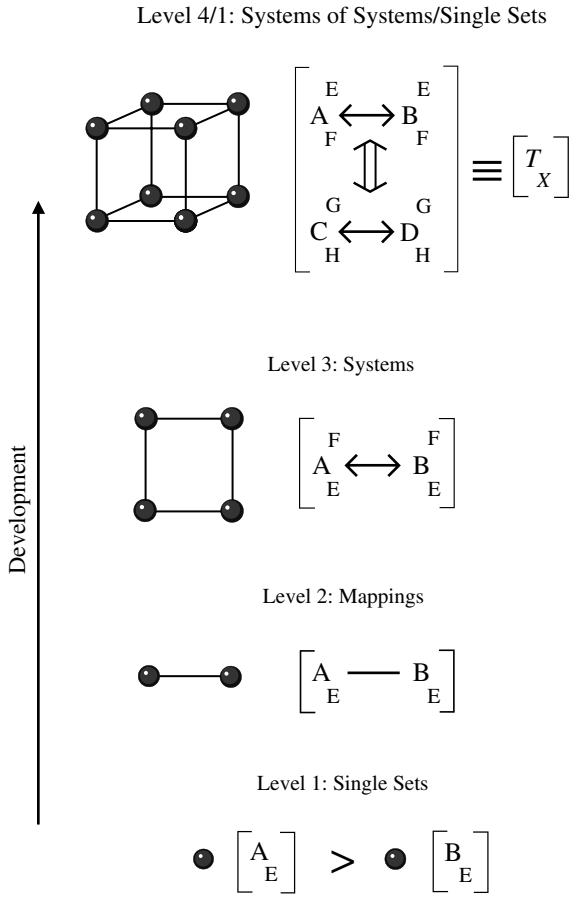

Figure 7.4 Cycle of levels of development for a tier: cube models and skill structures. The fourth level marks the culminating structure for a tier and the formation of a new unit for the next tier, as shown by the two skill formulas for Level 4/1: Level 4 actions form Level 1 representations, and Level 4 representations form Level 1 abstractions.

In skill formulas, brackets mark a skill structure; and each letter denotes a skill component, with a large letter designating a main component (set) and a subscript or superscript a subset of the main component. A line connecting sets (—) = A mapping relation, a single-line arrow (↔) = A relation forming a system, a double-line vertical (⇕) arrow = A relation forming a system of systems, and a greater than symbol (>) = A shift from one skill to another without integration. Such shifts between skills can occur at every level, although for simplicity a shift is shown only at the first level. For skill formulas in later figures and text, bold letters = Sensorimotor actions, italic letters = Representations, and script letters = Abstractions.

At the fourth level of each tier, the person coordinates and differentiates systems to form systems of systems, thus constructing a new unit that begins the next tier—a single set of a new type. At the tenth level, the person constructs single principles, and there is as yet no evidence for further levels marked by clusters of discontinuities beyond single principles (Fischer et al., 2003).

Contrary to static approaches to development and learning, the levels on the scale do not indicate the use of one psychological structure or module across domains, like one of Piaget's (1985) generalized logical structures or Chomsky and Fodor's (1983) modules. People do not use the same structure across situations, but they build skills along the same scale. The processes of growth and variation produce skills that fit a common scale across tasks and domains, but the skills used differ, being dynamically adapted to context, emotional state, and goal. The complexity of separate activities varies in similar ways for different contexts and states. Think of temperature, for which physicists discovered a common scale over the last several hundred years. The same scale can be used to measure the temperature in the sun, Antarctica, a refrigerator or furnace in New York, a person's mouth, or the bottom of the ocean. Thermometers measure with a common scale across radically different situations and methods, even with great differences in the ways that heat and cold occur.

In this way, skills are organized in multilevel hierarchies that follow the scale in Figures 7.3 and 7.4. People construct skills through a process of coordination, as when 5-year-old Susan built stories about emotionally loaded social interactions that coordinated multiple actions into social categories and then coordinated social categories into reciprocal activities. Susan used a skill hierarchy in which individual pretend actions (Sm3 systems of actions) were embedded in social categories (Rp1 single representations), which were in turn embedded in socially reciprocal activities (Rp2 representational mappings). Existing component skills, controlling activities in specific contexts, were intercoordinated to create new skills that controlled a more differentiated and integrated range of activities. In the newly integrated skills, the component skills still functioned as subsystems in the new skill as a whole. They also could still be used alone, as when Susan dropped back to simpler actions with less contextual support or with emotional upset. We use representations of positive and negative social interactions to ground the explanation of dynamic skills and to illustrate how the skills in the diagrams both develop in the long term (macrodevelopment or ontogenesis) and vary from moment to moment (microdevelopment).

The skill hierarchy in the scale embodies the principles of self-organization and interparticipation of dynamic

systems. As skills become integrated and differentiated at later levels, the component skills subordinate themselves to new forms of organization and mutual regulation. The very process of creating new skills through self-organizing coordination leads to a multileveled hierarchical structuring of living skills. Indeed, "hierarchy" in this sense has a special meaning. Computer programs, for example, can be arranged hierarchically in the sense that lower-level outputs feed higher-level procedures, but this organization does not typically involve interparticipation and self-organization.

Generalization through Construction

Susan built her skills for representing positive and negative social interactions in one context, but she naturally tried to generalize those skills across related contexts—for example, using the skills for representing interactions with her father to build representations of interactions with her counselor. The process of skill construction through coordination is closely related to skill generalization, and the complexity scale can illuminate both. Generalization of mental and physical activity involves specific building of generalized skills driven by the goal-oriented activity of an individual or ensemble (a few people working closely together), especially for socially constructed domains such as literacy, mathematics, and science. Generalization in these domains is not a predetermined, innate outcome waiting for development to catch up with it, as some nativists would have it (Baillargeon, 1987; Fodor, 1983; Spelke, 1988). Several mechanisms of generalization of dynamic skills through coordination, differentiation, and bridging from simple to complex have been specified with some precision (Fischer & Farrar, 1987; Fischer & Immordino-Yang, 2002; Siegler & Jenkins, 1989). Studying microdevelopment is an especially powerful way of analyzing processes of dynamic generalization, as we describe in a later section to illuminate how learning general knowledge takes a long time.

Building a Constructive Web for Positive and Negative Social Interactions

The complexity scale combines with the constructive web in Figure 7.2 to support analyzing psychological structure in dynamic terms. Unlike the traditional ladder of development, the web highlights integration, specificity, multiple pathways, active construction, and other central properties of skill development (Bidell & Fischer, 1992; Fischer et al., 2003). Building a web is a self-organizing process in which a person coordinates and differentiates various activities along the complexity scale. The strands in a web are the joint product of the person's constructive activity and the contexts in which skills are built, including the other people who coparticipate in building them.

We use stories about nice and mean social interactions to illustrate properties of the constructive web and its relation to dynamic properties of cognitive and emotional development. Telling a story or narrative is a fundamental human activity. To produce a specific story or narrative, a child needs to organize activities in a scriptlike way, following specific patterns of sequencing of events (Bruner, 1990; Fischer et al., 1990; Ninio & Snow, 1996; Schank & Abelson, 1977). This organization helps impart meaning to the narrative, as with 5-year-old Susan's stories about interaction between a girl and her father. Without this script organization, the story becomes a meaningless jumble; for example, it becomes unclear who is being nice to whom and why, or who is hurting whom and why. Yet the organization of the storytelling activity must also be flexible, so that a storyteller can create new versions for changing situations and people, thereby communicating different ideas and feelings, as Susan changed her stories in relation to her emotional state and to the contextual cuing and support she received from the adult interviewer.

Like other skills, the complexity and organization of story skills varies widely with the dynamics of the constructive activity, including story complexity, emotional state, and social-contextual support from other people. The skill scale illuminates this variation by providing a ruler for analyzing and comparing these variations. When 5-year-old Susan is in a positive mood and has support from her counselor, she organizes a complex story about positive interactions. A few minutes later when she is emotionally stressed, she no longer produces a complex positive story, even with support from the counselor, but instead tells an equally complex negative story. When the counselor does not provide contextual support, Susan can organize only a simpler positive or negative story. In addition, the form of narrative organization varies across cultural groupings and discourse communities because individuals construct different narrative skills to participate in different culturally patterned communicative activity. Susan's

stories fit her cultural community, but would have to be reorganized to fit others.

Webs and Biases

Figure 7.5 shows a developmental web for stories about positive and negative social interactions in American children of diverse ethnicity and social class (Ayoub & Fischer, in press; Fischer & Ayoub, 1994). When children play, they commonly act both nice and mean to each other, and like 5-year-old Susan, they readily act out and tell stories about positive and negative interactions between peers. The web has three distinct strands

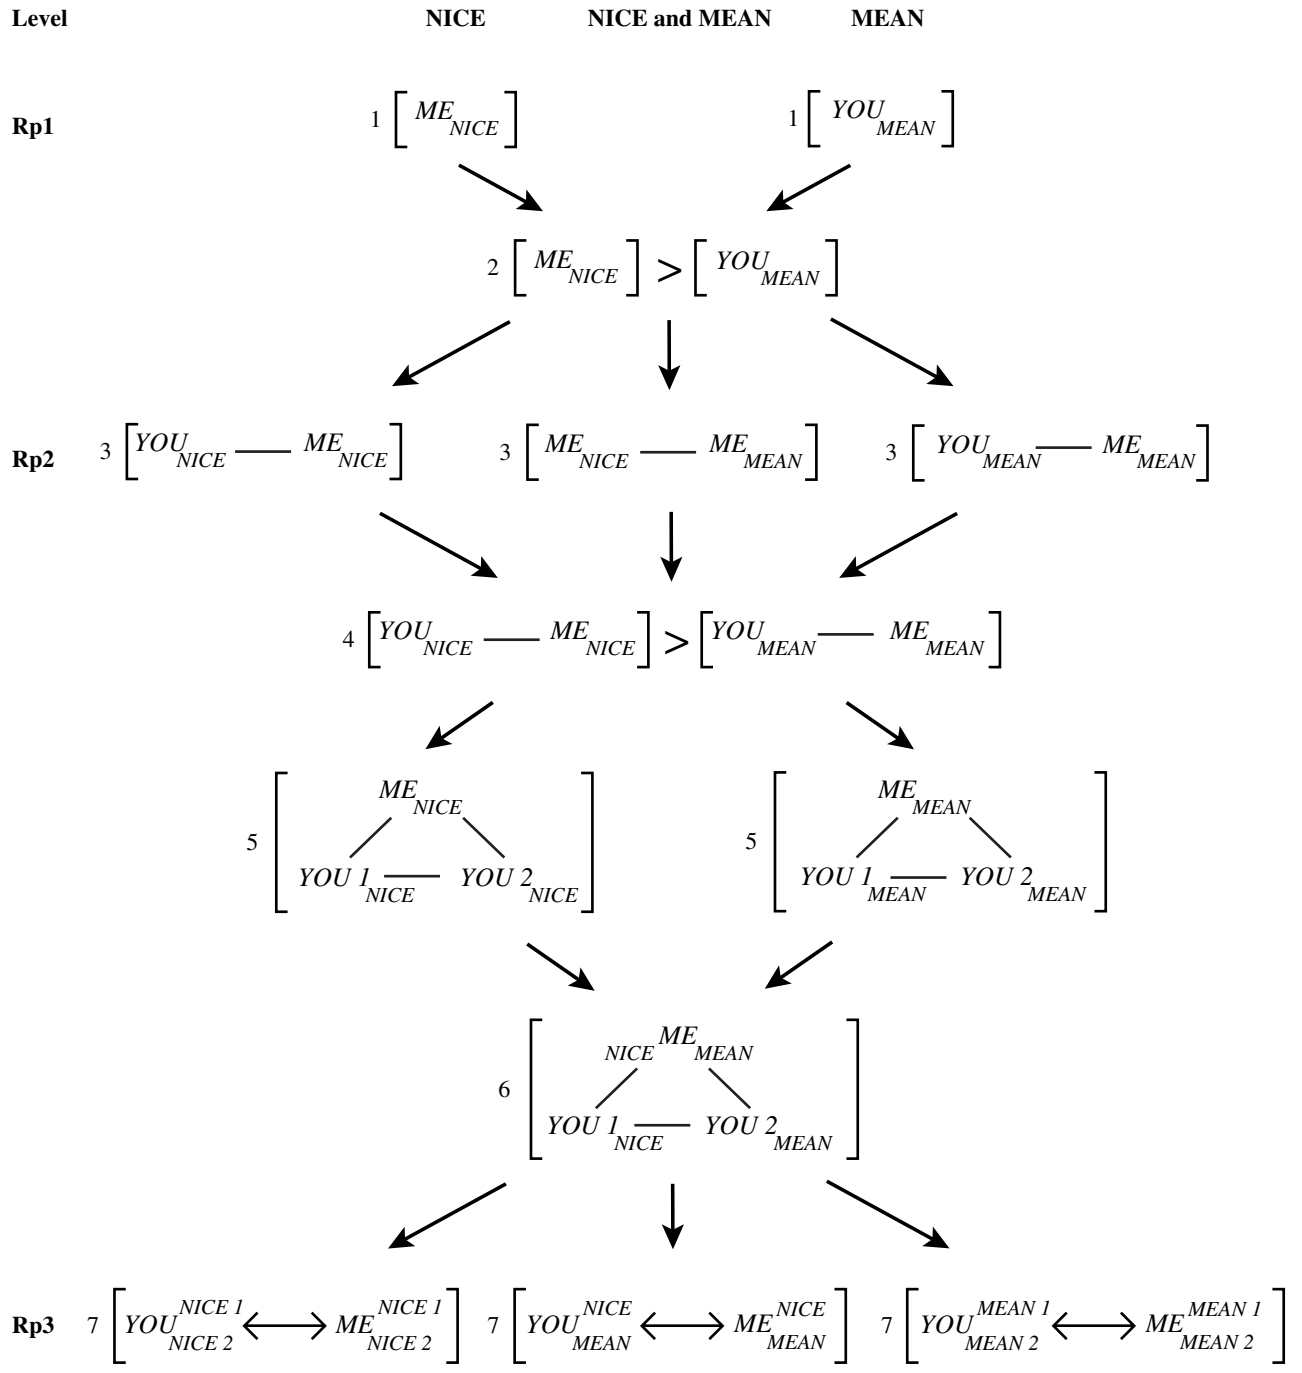

Figure 7.5 Developmental web for nice and mean social interactions. The numbers to the left of each set of brackets indicate the step in complexity ordering of the skill structures. The words inside each set of brackets indicate a skill structure. The left column designates the first step at each skill level.

organized by emotional domains of different valence—nice on the left, mean on the right, and the combination of nice and mean in the middle. The tasks are ordered in steps by skill complexity, marked by the numbers next to each skill structure. There are normally multiple steps per level, marking the distinct points in the construction process that can be discriminated for a particular situation, which can vary in number. The levels are indicated in the left-hand column.

In the research, children between 2 and 9 years of age told stories about two or three boys or girls playing together, with each story reflecting one of the three emotional domains. One character usually had the name of the child telling the story, and the others represented his or her friends or siblings; in some studies, the characters had the names of unknown children. In a separate assessment, children also told similar stories about parent-child interactions.

Later steps generally involve more inclusive skills, constructed by the coordination and differentiation of lower-level components. For example, in step 3, the story involves a mapping between two instances of niceness (or meanness), similar to the reciprocity stories of Susan: One doll acted mean (or nice) to a second doll who because of the first doll's action, acted mean (or nice) in return. In Figure 7.5, each diagram of *YOU* or *ME* acting *NICE* or *MEAN* represents a story with a certain skill structure, varying across the three skill levels of single representations, mappings, and systems. The structure

$$\left[YOU_{NICE} \text{ —— } ME_{NICE} \right] \qquad (1)$$

represents a mapping for reciprocity: If you are nice to me, I will be nice to you. Vertical arrows between specific story structures in Figure 7.5 indicate developmental sequencing for those stories, as when steps 3, 4, and 5 in the left column form part of a pathway along the strand for nice. The skill formulas focus on the central elements that children had to control in the nice/mean stories: roles (you or me), emotional valence (nice or mean), and relations between roles (shifts without coordination, mappings, and systems). Like structures in any living system, these elements subsume many additional components hierarchically within them such as actions, perceptions, feelings, goals, and social expectations.

Thus, each step in Figure 7.5 represents a different level of skill at conceptualizing relations among social interactions. Children's stories develop along strands for each of the content domains of nice, mean, and nice-and-mean in combination. When stories are parallel from left to right, they emerge at approximately the same time in development. Their development also shows many connections among the strands.

In accord with the general tendency for researchers to neglect within-person variation and emphasize between-person variation, people sometimes misunderstand this developmental web, interpreting it to mean that different children are developing along each strand. To the contrary, each child develops simultaneously along each of the strands in the web in Figure 7.5. That is, each child is simultaneously developing understandings about positive valence (how nice interactions occur), negative valence (how mean interactions occur), and combined valence (how nice and mean can be combined in an interaction). When the three strands are all closely parallel, with no clear bias toward one or the other, then the web looks like Figure 7.5, with complexity as the primary determinant of developmental ordering. Steps of the same complexity are parallel in the web, independent of valence.

One characteristic of emotions, however, is that people typically show biases in their actions and thoughts. Biases toward certain action tendencies are one of the defining characteristics of emotions, as is discussed in the later section on Emotional Development. Emotional biases often have strong effects on a developmental web; they shift relations between strands, and they change developmental orderings. For the nice-and-mean web, one far-reaching emotional bias is a general favoring over time of one pole of evaluation—toward positive (nice) or negative (mean). One of the most strongly established findings in social psychology is that most people show positive biases in their activities and evaluations, especially for attributions about themselves (Higgins, 1996; Osgood, Suci, & Tannenbaum, 1957). Figure 7.6 shows a global bias toward the positive.

Although positive biases are pervasive, there are also many instances of negative biases. Powerful biases toward the negative can be produced by trauma such as child abuse (Ayoub, Fischer, & O'Connor, 2003; Westen, 1994) and by implicit attitudes (Greenwald et al., 2002). When children show a strong and persistent bias toward the negative and against the positive, their entire developmental web is shifted (biased) in the opposite direction than in Figure 7.6—toward the negative pole. That is, mean interactions are understood earlier than nice ones, and the combination of

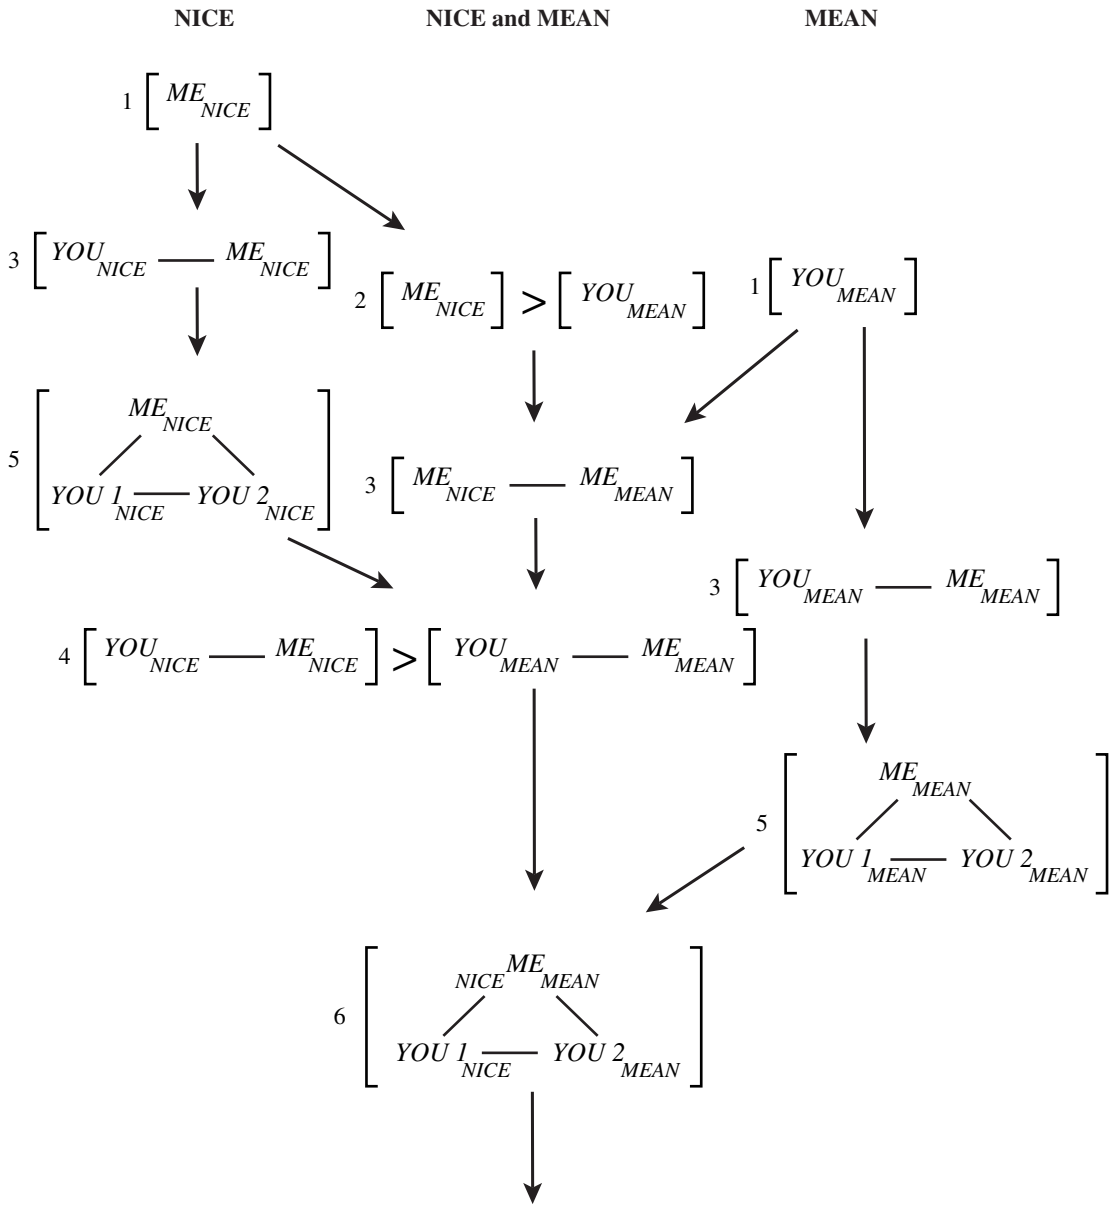

Figure 7.6 Developmental web biased toward nice interactions. This web includes only the first two-thirds of the skills from the web in Figure 7.5.

nice and mean is delayed as well. A number of abused children and adolescents show an alternative developmental pathway based on this bias toward the negative (Fischer et al., 1997; Rappolt-Schlichtman & Ayoub, in press). Besides the long-term effects of experience, there are short-term within-person effects as a function of context, mood, and similar factors, as when being in a negative mood leads to a bias toward negative stories. In this way, developmental webs can be useful for representing variations in developmental pathways not only between people but also within a person over time.

Modeling Nonlinear Dynamic Growth in a Web

Besides the representations of weblike relations between steps and strands like those in Figures 7.2 and 7.5, various tools can be useful for analyzing different properties of development. One example that can be particularly powerful is mathematical modeling of growth functions (Singer & Willett, 2003). Each strand in a web

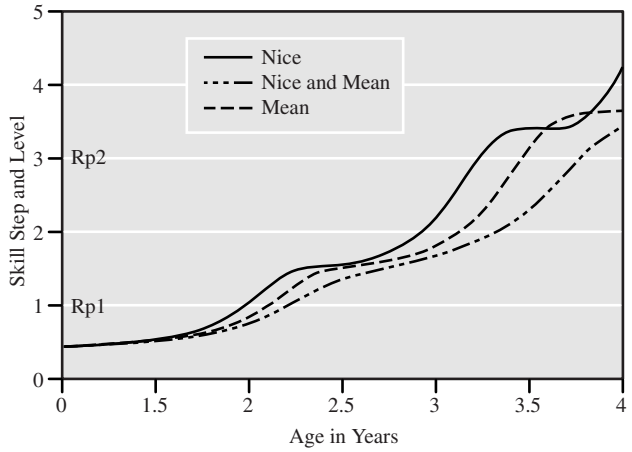

Figure 7.7 Growth functions showing a bias toward nice interactions. Skill Step refers to the complexity ordering in Figure 7.5. Level refers to the level of hierarchical complexity in Figure 7.3.

can be described in terms of its growth function, which in this case is represented by a nonlinear dynamic growth model (Fischer & Kennedy, 1997; van Geert, 1991, 2003). Figure 7.7 shows an example of growth curves produced by the model for each of the three strands.

The growth model includes a global positive bias like that in Figure 7.6, and under certain conditions, it also produces stagelike jumps in development, which are discussed in the next section. Complexity scaling provides the metric for quantifying growth of the strands, with scaling tools provided by dynamic skill theory. The graph clearly represents the bias toward positive valence and away from negative and combined valences, emphasizing the quantitative advantage of the nice strand over the others. The graph also highlights the fits and starts in growth and the relations between them—something that is not evident in the web diagram. However, this quantitative graphing de-emphasizes the ordering relations among specific story structures, which are clearly marked in Figures 7.5 and 7.6. Different tools for analysis of developing activity structures capture different properties of the structures, and no single tool captures all important aspects.

How Dynamic Skills Explain Variability in Development

The characteristics of skills, including the weblike process of skill construction, can help both explain and predict patterns of variability that have eluded traditional static accounts of psychological structure. In this section, we show how three basic forms of systematic developmental variability—(1) complexity level, (2) sequence, and (3) synchrony—can each be explained by the characteristics of dynamic skills. In a subsequent section, we consider issues of methodology and measurement used in the precise description and prediction of variability in development.

Developmental Range: Optimal and Functional Levels

Children (and adults) routinely perform across a range of skill levels, like Susan telling stories about nice and mean at two different levels with her counselor. A fundamental error stemming from static conceptions of psychological structure is that each individual is treated as "possessing" one fixed level of structure, either across domains or in a domain, as if cognition were a sealed bottle with a fixed level of liquid in it. From this point of view, an individual's behavior is expected to be homogeneously consistent with the fixed level of cognition such as the number of items that a child can sustain simultaneously in working memory. Deviations from this fixed level then seem mysterious and appear to call for complicated explanations. Often the deviations are ignored, as researchers mistakenly use methods that sum across individuals, activities, and contexts and treat true variations in level as errors of measurement (Estes, 1956; Fischer, Knight, & Van Parys, 1993; Skinner, 1938; van Geert & van Dijk, 2002).

A person possesses different competences in different contexts and emotional states. The types and complexities of organization found in dynamic skills are always changing because (a) people constantly vary their activities as they adjust to varying conditions and coparticipants, and (b) people commonly reorganize their skills to deal with new situations, people, and problems. For instance, a tennis player plays at top level one day—after a good night's rest, on an asphalt court, against a well-known opponent. The same player plays at a much lower level the next day, with a bad night's sleep, on a clay court, against a new adversary. This reduction in the player's skill level is a real change in the organization of activity, not a departure from some underlying stage or competence that is the "real" thing. The person unconsciously changes the actual relationships among the participating systems of perception, motor anticipation, motor execution, memory (for instance, of the other player's strengths), and so on. These relations

constitute the dynamic structure of skill. The level of organization of tennis skills varies because coordination among the systems is different on the 2 days. To posit any additional layers of abstract competence or stage structure to explain this variation is unnecessary, as it is accounted for by the dynamic properties of real activity systems.

Comparable variations in skill level occur in most skills, from playing tennis to interacting socially, planning a party, and reasoning about scientific or literary questions. Vygotsky (1978) spoke of the zone of proximal development (ZPD) and the variation between performances as a result of presence and absence of scaffolding by an expert. Our research has documented an important principle of variation in this zone: the developmental range introduced earlier, which is the interval between a person's best performances with and without social contextual support in some domain. Susan showed a developmental range in her construction of stories about nice and mean interactions.

In a study of nice and mean stories, 7-year-old children telling stories under conditions of high and low social-contextual support showed a consistent developmental range, repeatedly changing to a high level with support and a lower level without it, as shown in Figure 7.1 and Table 7.1 (Fischer, Bullock, et al., 1993). A typical 7-year-old produced a highest story at step 3 (Level R2, representational mappings) under low-support conditions but achieved step 6 (Level Rp3, representational systems) under high-support conditions. The interval between these two developmental levels (a child's developmental range for this domain) is indicated in Table 7.1, which is based on the data in Figure 7.1. The highest skill level when functioning independently (under low support) for a given domain is referred to as the *functional level.* The highest level with high-support conditions is the *optimal level.*

The interval of variation for a given skill can extend even farther, as suggested in Table 7.1. Social support often goes beyond prompting or modeling to actual coparticipation in a task (also called *scaffolding*), where, for example, an adult takes on acting out the role of one of the dolls in a story with a child. With scaffolding, the level of task performance can be extended several steps upward because psychological control of the activity is shared with an expert. In contrast, circumstances such as emotional stress, fatigue, distraction, or interference by a coparticipant can lead a person's skill level to fall below his or her functional level.

Developmental range seems to characterize performance across most tasks, ages, and cultures, and it grows larger with age, at least through the late twenties (Fischer, Bullock, et al., 1993; Fischer et al., 2003). Most people experience the developmental range directly when they learn something new with a teacher or mentor. With the prompting of the teacher, they understand a new concept or control a new skill at a relatively high level. Without the prompting, their level of skill drops precipitously such as when they leave the classroom and try to explain the new concept to a friend who knows nothing about it.

A study of Korean adolescents' conceptions of themselves in relationships illustrates the striking gap that commonly occurs between optimal and functional levels, as shown in Figure 7.8 (Fischer & Kennedy, 1997; see also Harter & Monsour, 1992; Kennedy, 1991). In this study, adolescents participated in the Self-in-Relationships Interview (SiR), which assessed developmental level under two conditions (described in more detail in the section on Methodology of Dy-

TABLE 7.1 Developmental Range of a 7-Year-Old Telling a Story with Varying Social Support

Step	Skill Level	Performance Level	Social Support
1	Rp1		
2			
3	Rp2	Functional level	None
4			
5			
6	Rp3	Optimal level	Priming through Modeling, etc.
7			
8	Ab1	Scaffolded level	Direct participation by adult
9			

Note: Functional and optimal levels are upper limits on performance, which show stability for a task. Scaffolded level involves a range of performance indicated by the vertical line on the left, with the specific step depending on the nature of the scaffolding in combination with the 7-year-old's skill.

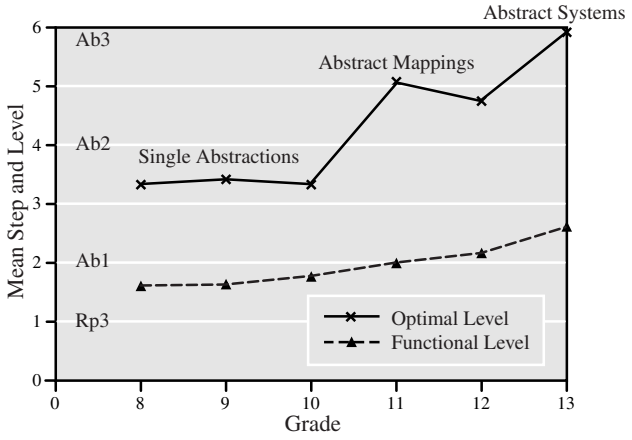

Figure 7.8 Range of developmental levels for Self-in-Relationships Interview in Korean adolescents.

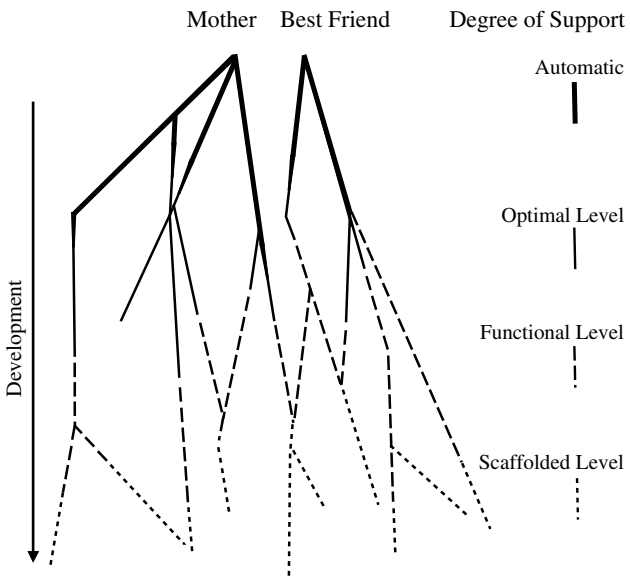

Figure 7.9 Developmental range of a web for two relationships.

namic Structural Analysis). For the optimal-level condition, high support involved the construction by each adolescent of a detailed diagram of his or her own descriptions of self in several different relationships such as with mother, father, sibling, best friend, and teacher. The diagram as well as the interview questions supported optimal performance by prompting key components of skills. For the functional-level condition, low support involved a relatively open-ended interview that was similar to most traditional assessments of self for adolescents; they were simply asked to describe what they were like in each relationship and how their descriptions related to each other. There was no prompting of key skill components.

The constructive web provides another useful way of portraying variability in developmental level. Figure 7.9 represents a developmental web for an individual's conceptions of self in two important relationships, mother and best friend. Along each strand the heavy solid line indicates a well established, highly automatized skill for a given context. An individual's performance drops to this level in circumstances of high stress, fatigue, or interference. The thinner solid strand represents the functional level of independent control under normal conditions for this context—a level of skill organization that is well established but less automatic. The optimal-level skills indicated by the dashed lines are still under construction, occurring when the person receives modest contextual support such as modeling or prompting. Finally, the dotted lines indicate a skill level that the individual has recently begun to construct, in which the person can hold the component skills in an integrated structure only if there is direct scaffolding, coparticipation of a more capable partner.

From this perspective, it is easy to see why skill levels vary over a wide range. The variation is a direct consequence of the active, constructive, and context-embedded nature of human activity. As Figures 7.8 and 7.9 suggest, adolescents' conceptions of themselves in relationships are not fixed capacities but multilevel structures of dynamic skills under construction. Skills early in a particular developmental sequence are better integrated and more stable across time and conditions than skills more recently constructed or just starting to be constructed. Variability in the organization of a person's skill at holding in mind and organizing the events and characteristics of a social relationship are a natural consequence of these constructive dynamics. There is no need to invoke explanations in terms of formal stage structures or hidden competences hovering over and guiding activities. Variability is explained by constructive dynamics. The task is to build theoretical models and methods for describing and analyzing these dynamics.

The Dynamics of Stages and Developmental Synchrony

Besides explaining sources of variability in level, the concept of dynamic skill also provides a framework for facilitating analysis of processes of change in constructive dynamics. Specifying the conditions that lead to

variability, as in developmental range, allows the control and use of the conditions to analyze patterns of change. We have employed this control of conditions to illuminate a classic argument about processes of change, the stage debate (Bidell & Fischer, 1992). Traditionally the dialogue about stage has not always been informative, amounting to assertion without accommodation:

Stage proponent: "There are stages of cognitive development."
Nonstage proponent: "No, there are no stages."
Stage proponent: "Yes, there are."
Nonstage proponent: "No, there aren't."

Instead of arguing about whether stages exist, dynamic skill analysis provides tools for specifying the conditions for stagelike change and those for continuous, nonstagelike change. Stages both do and do not exist, depending on the dynamics of the conditions of activity!

In the study of Korean adolescents, dynamic skill theory was used to predict the conditions and age intervals when growth shows discontinuous jumps in level versus smooth change. High-support conditions were predicted to produce two discontinuities marking the emergence of two new levels of coordination of abstractions. Figure 7.8 shows the predicted difference in growth functions: Optimal-level growth spurted twice, at grades 11 and 13, which are comparable to the ages of optimal-level spurts found in research with American and Chinese samples (Cheng, 1999; Fischer & Kennedy, 1997; Harter & Monsour, 1992; Wang, 1997). Researchers using the skill theory framework have observed similar patterns in other types of skills, in age groups ranging from preschool to adulthood (e.g., Corrigan, 1983; Fischer & Hogan, 1989; Fischer et al., 2003; K. Kitchener, Lynch, Fischer, & Wood, 1993). In each case, the developmental spurt is associated with a major transition in skill level such as the transitions to abstract mappings and abstract systems under optimal conditions in Figure 7.8. When optimal and functional levels are lumped together, this discontinuity is masked because the developmental function produced is effectively an average of two different developmental functions, a process that inevitably masks the true growth functions. In addition, there is much evidence of other kinds of discontinuities such as gaps in Rasch scaling and changes in brainwave patterns at similar points along the hierarchical complexity scale (Dawson, 2003; Dawson et al., 2003; Fischer & Rose, 1996).

As this and many other examples demonstrate, the developmental level of behavior varies with assessment context, coparticipant, state of arousal, emotional state, and goal, just to name a few of the most obvious sources of variation. Some researchers have argued that these variations demonstrate an absence of developmental stages (Brainerd, 1978; Flavell, 1982; Thelen & Smith, 1994), but these arguments overlook the order in the variability. The organization of behavior develops systematically, and it also varies from moment to moment. These facts are contradictory only for overly simple concepts of stage and variation. Real behaviors—and real neural networks as well—function not at a single level but in a range or zone (A. Brown & Reeve, 1987; Fischer, Bullock, et al., 1993; Grossberg, 1987; Vygotsky, 1978). Research to test for stagelike change must take this range into account and analyze which parts of the variation show stagelike characteristics and which do not. Only then will the field move beyond endless arguments in which protagonists focus on only part of the variation and thus draw half-baked conclusions.

The separation of optimal and functional is one example of the way a dynamic skills framework permits the prediction and explanation of patterns of variability that have typically been ignored or explained away by theories relying on static stage or competence models of psychological structure. Although researchers may differ with the specific interpretation given to a phenomenon like the discontinuities in optimal level, the constructive-dynamic framework described here makes it possible to debate the issues empirically, by providing concepts and research methodologies to control and manipulate variations in the developmental process. (These methodologies are described throughout this chapter; see also the section on Methodology.)

An important part of "stage" is the expectation of high developmental synchrony. Stage theories predict high stability across contexts in the level of performance an individual will display. The idea of a "hard stage," an underlying logical system pervading the mind at a given stage (Kohlberg, 1984; Piaget, 1985), implies that a given person should perform logically equivalent tasks at the same time regardless of state or context—say, Piaget's tasks of conservation of liquid and classification of shapes in matrices. It is as if Piaget touched children's heads on their seventh birthday, and instantly they were transformed into concrete operational thinkers. This strong "point synchrony" (simultaneous development of new levels across domains) is seldom empirically supported (Fischer & Bullock, 1981). Instead, children and

adults show a high degree of variability in levels across tasks and contexts, even with tasks that are logically similar. For example, children who understand tasks for conservation of number frequently fail tasks for conservation of liquid even when the procedures and questions are similar.

On the other hand, there is evidence of real developmental synchrony as well when dynamic concepts are used to analyze how and when synchrony does and does not occur. Equivalent concepts show what is sometimes called "interval synchrony," appearing not at the same time but within a relatively short time interval of each other. Moreover, this interval is much smaller for concepts about closely related topics measured in similar tasks, especially when there is a clearly defined conceptual structure that is ecologically valid (T. L. Dawson & Gabrielian, 2003; K. Kitchener & King, 1990; Pirttilä-Backman, 1993). The disparity in intervals between concepts drops as differences in content, context, and concept are reduced. Case and his colleagues (1996) have even shown that, with a well-defined central conceptual structure, teaching the structure increases the degree of synchrony across domains to the point that it sometimes accounts for approximately 50% of the variability—a remarkably large effect indicating high interval synchrony. Lamborn, Fischer, and Pipp (1994) demonstrated that development of understanding of specific moral concepts such as honesty and kindness related closely to relevant social problem-solving skills but not to other problem-solving skills.

The combination of systematic variability and synchrony is hard to explain with static concepts of psychological structure such as stage or competence. Piaget and other hard-stage theorists initially waved away evidence by arguing that different tasks posed different forms of resistance to structures of logic. The resulting *decalages* (time gaps) were said to result from different kinds of resistance, but the processes by which resistance functioned were never explained (Kohlberg, 1969; Piaget, 1971).

The principles of constructive dynamics explain patterns of variation in stage patterns and synchrony in a straightforward manner:

- Skills are constructed hierarchically by integrating earlier skills into a more inclusive whole.
- Skills vary across multiple levels for each individual depending on context, goal, state, support, and other factors. An important example is the developmental range.
- Skills are constructed for participation in specific tasks and contexts and over time can be generalized to others through specific generalizing activity (Case et al., 1996; Fischer & Farrar, 1987; Fischer & Immordino-Yang, 2002).

Even in the simple diagram of two domains in Figure 7.9, it is obvious that among the functional, optimal, and scaffolded levels, some skills will be the same across domains, and others will be different for the same domain. Taken together, these principles help explain how interval synchrony occurs as well as how people build general skills. This process is elaborated later in the section titled: Building Structures: Transition Mechanisms and Microdevelopment.

The scale for hierarchical complexity in Figures 7.3 and 7.4 provides a metric for assessing greater or lesser synchrony, moving beyond all or none arguments. For many related skills, levels do not show complete asynchrony but are relatively close even when they differ. The growth functions for nice and mean in Figure 7.7 illustrate how the same growth curves can simultaneously show similarities and differences in the ages of change. Stepping back to look at the broad sweep of change makes the synchronies evident; stepping close to look at the details of change highlights the disparities. Each new skill at a higher level is built from similar lower-level skills: Each extension of a skill to a new level is a constructive generalization constrained by the component skills available. There is no need to invoke pervasive logical structures or innately determined formal constraints to account for interval synchrony in development. The dynamics of the construction of skills in context explain both the variability and the synchrony found in patterns of variation.

Variability in Sequence of Acquisitions

Another form of variation involves the sequence in which skills for a given task or context are constructed, often called *developmental sequences* or *pathways.* Although evidence of variation in specific developmental sequences has been taken as evidence against hierarchically constructed stages (Brainerd, 1978; Gelman & Baillargeon, 1983), a dynamic structural analysis illuminates when sequences occur and when they do not, whereas stage and competence theories are hard pressed to account for observed patterns of variability and stability in sequences.

An examination of the evidence shows a familiar pattern: There is high variability in developmental

sequences, but this variability is neither random nor absolute. The number and order of steps in developmental sequences vary as a function of factors like learning history, cultural background, content domain, context, coparticipants, and emotional state. In addition, the variability in steps appears to be contingent on the level of analysis at which the sequence is examined (Dawson & Gabrielian, 2003; Fischer, 1980b; Fischer et al., 2003).

Developmental sequences tend to appear mainly at two levels of analysis: (1) large-scale, broad sequences covering long times between steps, relatively independent of domain, and (2) small-scale, detailed sequences found within particular domains. Large-scale sequences appear to be relatively invariant. Children do not, for instance, exhibit concrete operational performances across a wide range of tasks, and then years later begin to exhibit preoperational performance on related tasks. On the other hand, small-scale sequences have often been found to vary dramatically (Ayoub & Fischer, in press; Wohlwill & Lowe, 1962).

Typically, variation in small-scale sequences is associated with variation in task, context, emotion, coparticipant, or assessment condition. For instance, Kofsky (1966) constructed an eleven-step developmental sequence for classification of objects based on Inhelder and Piaget's (1964) concrete-operational thinking and used scalogram analysis to rigorously test the sequence. Her predicted sequence followed a logical progression, but it drew on an assortment of different tasks and materials to evaluate each step. The results showed weak scalability with several mini-sequences.

Other sources of variation in small-scale sequences include cultural background, learning history, learning style, and emotion. Price-Williams, Gordon, and Ramirez (1969), for instance, examined the order of acquisition of conservation of number and substance in two Mexican villages. The villages were comparable in most ways except that in one village the children participated in pottery making from an early age. Children of the pottery-making families tended to acquire conservation of substance (tested with clay) before conservation of number, while nonpottery-making children showed the opposite tendency.

Affective state can also powerfully affect developmental sequences (Ayoub & Fischer, in press; Fischer & Ayoub, 1994). For example, inhibited and outgoing children show different sequences in representing positive and negative social interactions, especially those involving the self. Inhibited children often show the positive bias in Figure 7.6. Extreme emotional experiences such as child abuse often lead to highly distinctive developmental sequences for representing self and others in relationships, as we discuss in the section on Emotions.

Furthermore, the failure to consider variation in sequences from factors such as learning style, disability, or cultural difference leads to combining undetected variations, with the result that task sequences erroneously seem to scale poorly (Fischer, Knight, et al., 1993). As soon as they are resolved into alternative sequences, they scale well. For example, a sequence of six tasks related to reading single words scaled weakly when tested on a sample of poor readers in first to third grades (Knight & Fischer, 1992). In each task, a child dealt with an individual word, reading it directly (Reading Production), reading it through matching it with a picture (Reading Recognition), producing a word that rhymes with it (Rhyme Production), recognizing a word that rhymes with it (Rhyme Recognition), naming the letters seen in the word (Letter Identification), or describing what the word means (Word Definition). Use of a scaling technique for detecting alternative sequences showed the existence of three different well-ordered sequences in the sample. Subsamples of poor readers showed sequences that reflected their specific reading difficulties.

The constructive web framework provides a tool for rethinking these patterns of variation in the constructive dynamics of skill development. Alternative developmental pathways can often be traced for different groups of children such as the three pathways for good and poor readers. When the standard metaphor of the developmental ladder is used, children are compared only in relative progress or delay on a single progression from low to high performance on a single sequence. As long as only a single pathway is considered, there seems only one remedial choice: to work to speed up the apparently delayed group along the "normal" pathway.

Figure 7.10 shows the three weblike pathways that the students take through the series of reading tasks. For each group, the order of acquisition for the six tasks was tested using *partially ordering scaling,* a statistical technique that is based on the logic of Guttman scaling (Krus, 1977; Tatsuoka, 1986). A line between two tasks means that the ordering is statistically reliable. A comparison of the three developmental pathways shows that the poor readers are not delayed with respect to a universal sequence, but actually follow *different* pathways of acquiring these skills. Normal readers all showed one

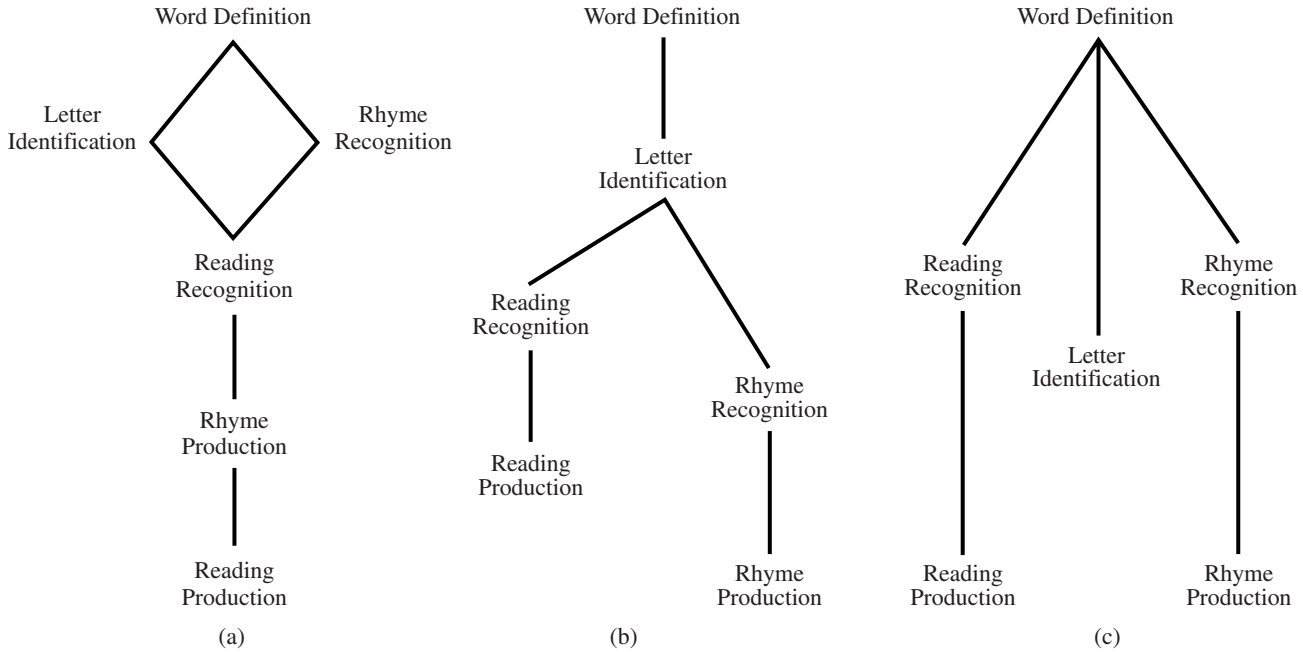

Figure 7.10 Developmental pathways of good and poor readers. The normative pathway for most good readers is shown in (a: Pathway 1: Normative developmental pathway for reading single words), whereas the two less integrated pathways followed by poor readers are shown in (b: Pathway 2: Independence of reading and rhyming), and (c: Pathway 3: Independence of reading, letter identification, and rhyming). From "Growth Cycles of Mind and Brain: Analyzing Developmental Pathways of Learning Disorders," by K. W., Fischer, L. T. Rose, and S. P. Rose, in *Mind, Brain, and Education in Reading Disorders,* K. W. Fischer, J. H. Bernstein, & M. H. Immordino-Yang (Eds.), in press, Cambridge, England: Cambridge University Press; From "Learning to Read Words: Individual Differences in Developmental Sequences," by C. C. Knight and K. W. Fischer, 1992, *Journal of Applied Developmental Psychology, 13,* pp. 377–404.

main pathway (a), but poor readers showed two other pathways different from the normal one (b and c).

This map of alternative pathways suggests a different remedial educational strategy. Instead of attempting to speed up development in poor readers, teachers can help channel children following divergent pathways into alternatives that converge on the goal of skilled reading (Fink, in press; Wolf & Katzir-Cohen, 2001). By providing environmental support, teachers can channel development, building bridges from the known to the unknown instead of providing frustrating repetitive encounters with the unknown. This approach is being realized most fully in educational efforts for children with learning disorders and handicaps (Fischer, Bernstein, & Immordino-Yang, in press; Rose & Meyer, 2002) and also in some work with maltreated and aggressive children (Ayoub & Fischer, in press; Kupersmidt & Dodge, 2004; Watson, Fischer, & Andreas, 2004).

From this perspective, the tool of mapping alternative developmental pathways is especially important for the study of development among children of differing socioeconomic groups, cultures, ethnicities, or races, and children with learning or psychological disorders. Against the backdrop of a developmental ladder based on White, middle-class norms, children from different social groups are frequently seen as exhibiting deficits in development. Within the web metaphor, many developmental differences become alternative pathways instead of deficits, and curricula, interventions, or therapies can be created based on these alternative pathways.

Research methods should allow detection of alternative sequences instead of forcing all children to either fit or not fit one sequence. Remarkably, much research on development has treated sequences not as variable phenomena to be explained but as fixed milestones in a ladder. In the early 1970s, Flavell (1971) and Wohlwill (1971) called for more research on variation in sequences, but this call has only recently begun to be taken seriously. Most neo-Piagetian developmental theories and domain theories still differentiate only gross stages, ignoring completely branches in sequences and variations among steps, with a resulting overgeneralization of the

uniformity and universality of cognitive and emotional development.

In summary, the organization of human action, thought, and emotion shows wide, systematic variation that can be measured, analyzed, and explained in hierarchically organized systems of contextually embedded activity. Patterns of variation in developmental level, synchrony, and sequence are all consistent with a constructivist, dynamic systems interpretation of psychological structure. In light of the pervasive evidence of cognitive variability, it seems surprising that the most prominent models of psychological structure have been and continue to be based on static conceptions such as stage, competence, and innate core knowledge. To understand why these static conceptions of structure continue to dominate and how dynamic views of psychological structure move beyond them, we consider the history and origin of static conceptions of psychological structure and their shortcomings as explanatory tools in the next section.

THE CRISIS OF VARIABILITY AND THE CARTESIAN SYNTHESIS IN DEVELOPMENTAL SCIENCE

The failure of developmental theory to recognize the dynamic and constructive nature of psychological structure has led to an explanatory crisis in developmental science. At the heart of this crisis is the problem of how to account for the tremendous variability in developmental phenomena, which during the past 30 years has increasingly moved from the background to the foreground of developmental research and theory (Bidell & Fischer, 1992; Damon, 1989; Siegler, 1994; Chapter 11, this *Handbook,* Volume 2; Thelen & Smith, Chapter 6, this *Handbook,* this volume).

The static stage structure, which dominated theories of cognitive development from its inception through the early 1980s, proved incapable of accounting for the massive evidence of (a) both wide-ranging variation and sometime consistency within and across individuals in the age of acquisition of logical concepts across domains and contexts, (b) systematic sequences in acquisition of many of these concepts and their components, and (c) variation from high to low synchrony in development of concepts under various conditions. By the mid-1980s, the inability of stage theory to account for this combination of variability and consistency led many scholars to virtually abandon stage theory as a framework and to launch a series of alternative accounts of psychological structure and its origin.

Many of these alternative accounts attempt to explain variability without departing from the static structure-as-form metaphor, but they have consistently come up short. Traditional Piagetians tried to package up variability in the concept of "decalage," which simply means a gap in ages of acquisition across tasks or individuals, and then mostly ignored it, thus renaming variability but not explaining it. Other theorists introduced a separation between competences or underlying structures that remain static and performances or surface manifestations that can vary. However, the separation of action from competence in competence-performance and nativist models introduces a major mystery about what interferes with the expression of competence and creates an inability to explain how psychological organization directs action and how structures adapt to a range of environmental and cultural contexts.

Why do developmental theorists cling to static structural models? The most important reason, we propose, is the pervasive influence of the Cartesian epistemological tradition in the history of Western psychological thought (Descartes, 1960; Gottlieb, Wahlsten, & Lickliter, Chapter 5; Overton, Chapter 2; Valsiner, Chapter 4, this *Handbook,* this volume). The Cartesian method conceptually isolates mental systems from their natural context of interrelations with the biological and cultural systems of which they are a part. This intellectual methodology of isolating an object of study from interrelationships with other phenomenon was successful in the early history of the natural sciences, but it obscures the complexity and dynamism of mental activity. It leads to systematic distortions when applied to the question of mental organization or psychological structure.

In this section, we review the Cartesian framework and the empirical debate surrounding the concept of "stage structure," showing how this debate led to the discovery of variability in level, synchrony, and sequence, and why the formal view of structure was unable to predict or explain this variability. We then argue that three major theoretical movements since stage theory—(1) domain specificity theory, (2) nativist competence theory, and (3) competence/performance theory—have also proved inadequate in accounting for variability in structural development because they too have failed to move beyond the Cartesian structure-

as-form paradigm. In the subsequent section, we describe a set of methods for moving beyond these approaches to do research that deals with variability more powerfully within a dynamic structural framework, including an outline of how to turn theories about developmental process into specific mathematical models that can be tested against growth patterns of individual children and adults.

The Cartesian Dualist Framework

The debate over nature-versus-nurture explanations of the origin of knowledge assumes the Cartesian framework, which is accepted by both sides—nature/nativist and nurture/empiricist. Grounded in the dualism of mind and world, the two sides necessarily imply one another. The nativist-rationalist tradition and the empiricist-learning tradition are two sides of the same Cartesian coin. The nativist branch of the Cartesian framework explains the origin of psychological structure as preformed innate structures such as concepts. The empiricist branch explains it as experience stamping its shape on the natural mind. Psychological structure, conceived as innate form, implies some outside input to be stored and manipulated. Environmental information conceived as preexisting packets of knowledge requires some sort of preexisting receptacle or organizing structure in the mind to receive, contain, and organize them. In this framework, only two explanations for the origin of psychological structure seem possible—nature or nurture—and they become the basis for the two branches of Cartesian epistemology.

The Cartesian tradition in philosophy and science brings with it the methodologies of reduction and reification. These methods, which have been profitably employed in many areas of science, result in systematic misconceptions when applied to dynamic processes like development of action, thought, and emotion. The dynamic organization of human mental activity is abstracted from the living systems of which it is a property and treated as a separately existing "thing," giving birth to the conception of static structure. The reification of psychological structure as a separately existing static form leads scientists down false paths in trying to understand the origins and development of psychological organization. Instead of seeking to understand the constructive, self-organizing processes by which children build new relations among contextually embedded mental activities, theorists have been led into the futile nature-nurture debate about whether statically conceived psychological structure is somehow insinuated in the genome or is built up through analysis of perceptual-motor experience. These reductionist assumptions support static views of structure and limit the explanatory power of developmental theories.

The Cartesian method, emerging in the seventeenth century philosophy of René Descartes (1960) and others, gave science a powerful analytical tool to sort out the complexity of the world and focus on one aspect at a time for study. This tool, known as Cartesian reductionism, derives simplicity out of complexity by isolating one aspect of a process from its relations with other aspects of the process or from related processes, to be studied independently. Descartes tried to extract mind from nature by creating a dualism in which a separately existing mental structure receives impressions from the outside world through the sensory apparatus. Descartes's famous dissection of the cow's eye, revealing the image projected on the retina, supported his view that innate structures are fed with sensory images from the environment. Similarly, in his logical empiricism the philosopher John Locke (1794) asserted that some preexisting logical structure is required to explain how environmental input leads to higher order knowledge. Locke saw that the simple mechanism of association of sensory impressions could not account for higher-order knowledge involving induction, deduction, and generalization. Like Descartes, Locke's account of knowledge acquisition involved a dualist conception in which a preexisting psychological structure receives and processes sensory input from the outside.

Although Cartesian reductionism has been and will continue to be an indispensable tool of scientific analysis, its strength—the isolation of phenomena from complex relations—is also its weakness (Wilson, 1998). When Cartesian reductionism is used exclusively as an analytic method, it eliminates an essential characteristic that needs to be understood—the interrelations of psychological systems both internally among component processes and externally with other systems. Understanding relations is a requisite for understanding change and variation in developmental or historical phenomena. In the real world, it is the interrelations among systems and processes that effect movement and change. The gravitational relation between the earth and the moon is key to sustaining the moon's orbit, which generates the changing cycles of the moon seen on earth. To ignore the gravitational relation between

earth and moon would preclude understanding the source of this pattern of variability, and in turn its explanation of an orbital system. The reductionist approach can be highly efficient for restricted scientific purposes such as isolating a particular strain of bacteria that causes a human disease. It is problematic in studying any complex phenomenon involving relations among elements and systems such as the problem of how some bacteria evolve more virulent strains in the modern context of changing natural and social ecology, growing poverty and hopelessness in many locales, and overuse of antibiotics. The structure grows dynamically out of the relations among varying systems, neither from a static innate structure nor a static environmental structure stamped on the mind.

The exclusive use of reductionism as an analytical method fosters the related problems of reification and dualism, both arising from the neglect of relations in theoretical constructs. Without an account of the relations among systems that can explain movement and change, abstractions such as mind, thought, and structure appear static and isolated from other constructs such as body, action, or function. These static abstractions reify the phenomena they refer to, treating dynamic processes as frozen objects. The self-organizing, goal-directed activity of the human agent is ruled out of the accounts of development.

Moreover, because the relations between such reified processes are lost, they seem isolated, separate, and even opposite to one another. This seeming opposition of reified abstractions is the basis for the classic Cartesian dualisms separating mind from body, thought from action, and structure from function. Since the time of Descartes, such dualist assumptions have become ingrained in the mainstream of Western scientific thought in general and psychological theories in particular. The result has been static accounts of psychological phenomena and their origins and sterile debates that explain mental processes by one or another reified abstraction such as faculties, associations, stimulus-response bonds, innate concepts, or stages. While such single-construct explanations have generated intense debate, they have been notoriously limited in accounting for a broad range of developmental data.

The Tacit Modern Synthesis in Psychology: Nativism and Empiricism Together

The result of the debate that has continued for more than a century between empiricist and nativist theories of development is the emergence of a tacitly shared model—a kind of modern synthesis in psychology—that is neither strictly empiricist nor strictly nativist but simply Cartesian in its assumptions. The emerging model is an amalgam of a sort of logical empiricism with a version of maturationism. According to this view, infants are supplied innately with core knowledge systems that provide them with *predetermined* representations of certain aspects of the world such as numerosity and object permanence (Carey & Spelke, 1996; Hauser, Chomsky, & Fitch, 2002; Spelke, 2000). However, these initial representations must be extended by learning processes. Learning processes typically are characterized through a logical analysis of perceptual-motor input leading to inductions and generalizations growing from core knowledge. Debate continues about whether core knowledge systems change qualitatively over time or simply remain in place into adulthood, which mechanisms lead from innate representations to new forms of knowledge, and what roles perceptual analysis and learning mechanisms play in such changes. Yet the framework of the debate remains firmly grounded in Cartesian assumptions.

With respect to the origins and development of knowledge, the debate between empiricism and nativism—and the emerging modern synthesis—starts with a core set of shared dualist assumptions: The mind is isolated from its environmental context, thought is divided from action, and the way the mind is organized (psychological structure) is separated from the way it operates in the world (cognitive function).

Early empiricists tried to explain the origins of knowledge in sensory impressions of the environment with little reference to the role of the active person and mind. In classic empiricist theories, the role of organization in the mind is minimal (a "blank slate" in the extreme), and it is shaped by environmental contingencies. Links or associations between ideas are generated by whatever happens to co-occur: A person sees red and apple at the same time, so she or he remembers red-apple. In the behaviorist version of associationism, the mind is reduced to almost no role at all, and behavior is organized directly by environmental contingencies through the stimulus-response bond (Skinner, 1969). Contemporary empiricist theories tend to rely on an information processing metaphor in which sensory information from the environment is parsed by perceptual analysis into basic knowledge units that can then be recombined into higher level knowledge (Newell & Simon, 1971). However, common to all empiricist theories of mental development is a dualist separation of

mind from environmental context, a concomitant reification of the mind as a container or mechanistic processor, and a dualist separation of mental structure from mental content.

Information processing theories, in the empiricist tradition, have focused on the input and storage of information, building the analysis of cognitive structure on a model of information flow in a computer. These theories came late to the problem of where cognitive structures come from and how they change over time. A few information processing theories have posited qualitative hierarchies of cognitive structures (Anderson et al., 2004; Klahr & Wallace, 1976; Pascual-Leone, 1970), but they have provided only sketchy accounts of the origins of these structures and the mechanisms of transition from one structure to another.

Despite years of vociferous debate with empiricists, nativists share this set of dualist assumptions but privilege them in different ways (Fischer & Bullock, 1984; Overton, Chapter 2, this *Handbook,* this volume). Nativists and the closely associated rationalists also start from an acceptance of mind-environment, mind-body, and thought-action dualisms. The difference with empiricists is that the structure of the mind is primary instead of the structure of the environment. Nativists accept the dualism of inner structure and outer sensory information, but they simply assign them different roles. Instead of filling up preexisting mental containers with experience, the nativist role for sensory information is to provide inputs, which trigger the emergence or activation of preexisting psychological structures such as the syntax of language or the properties of objects. The dualist separation of psychological structure from its contextual relations with human activity has led to the reification of psychological structure and the inevitable conclusion that the structure must be innate. The outside world provides grist for the cognitive mill, or sometimes a triggering stimulus to kick off a new level of maturation, but plays a minimal role in the development of the psychological structures themselves.

When a dynamic system is approached statically, the complex relations by which it is organized and by which it develops are lost. The inescapable fact that it is *organized* is abstracted and reified as static form. When psychological structure is conceived as static form, with no activity and no inter-systemic relations to explain its origin and development, it appears to have an existence of its own, separate from the reality from which it is abstracted. Therefore, psychological structure must be innate, according to this argument.

The reification of dynamic structure as static form in the Cartesian tradition has earlier roots in Western culture (Pepper, 1942) extending back at least to Plato (1941) 2,000 years ago. His doctrine of ideal, universal forms provides a particularly clear example of how concepts and ideas are seen as independent of the mind. These forms exist independently of the imperfect material world, which evolves toward them. They are transferred to each newborn infant, who gradually remembers them with maturity. In the eighteenth century, Kant (1958) argued that we inherit preexisting cognitive structures or categorical imperatives, which determine how we make sense of our experience. In recent times, Chomsky (1965) and Fodor (1983) have argued for predetermined linguistic structures called *modules* that impose specific patterns on our learning of languages and concepts. Following Chomsky's lead, contemporary neo-nativists have posited innate structures determining such developmental achievements as number concept, object concept, and Euclidian geometry (Baillargeon, 1987; Fodor, 1983; Spelke, 1988).

Because both the empiricist and the nativist versions of the Cartesian tradition share the same dualist, static conception of psychological structure, neither has really challenged the other on the *nature* of psychological structure. However, the debate over how much emphasis to place on innate structures versus learning has forced each side to examine, rethink, and revise its theories. As theorists on both sides of the empiricist-nativist debate have attempted to revise their models to meet these challenges they have naturally turned to models within their shared Cartesian framework, and thus have increasingly adopted elements of each other's theories. While still emphasizing the importance of perceptual input, empiricism-based theories have come to rely on nativist conceptions about the origins of psychological structure to help explain how that input gets organized and how its organization changes over time. On the nativist side, theorists have increasingly come to depend on various functional-learning and perceptual-analysis mechanisms to explain how innate structures can lead to knowledge and conceptual change.

At first glance, bringing together two opposing tendencies into a more integrated model may seem like progress toward a more comprehensive theory. The resulting amalgamated model, however, does not take us beyond the Cartesian framework of dualism and therefore does not offer a way beyond the static conceptions of psychological structure—a way to explain how structure emerges from the interrelated activity of people

with their world and each other. For this reason, the Cartesian synthesis is not any more successful in explaining the broad data of variability in cognitive development. Linking static conceptions of psychological structure to mechanistic information processing models does not provide us with better explanations for variability in cognitive performance than either tradition did on its own. Understanding why Cartesian models—whether empiricist, nativist, or a combination of the two—have trouble explaining variability requires considering in more depth the static conceptions of psychological structure inherent in this tradition and the explanatory limitations they carry with them. This analysis lays the foundation for understanding how dynamic structuralism provides a path to analyzing the dynamics of structure in development starting from activities in context.

The Structure-as-Form Paradigm

Because the Cartesian tradition has been the dominant framework for scientific theories in general and psychological theories in particular, reductionism and reification have been the rule rather than the exception in conceptions of psychological structure. The prominence of these modes of thought in the Western intellectual tradition has encouraged the confounding of dynamic structure with static form. Accordingly, the structure-as-form model has tended to serve as an unconscious foundational metaphor (Lakoff & Johnson, 1999; Pepper, 1942) or paradigm (Kuhn, 1970) for scientific accounts of the organizational properties of natural and social systems, especially in psychology (Overton, Chapter 2; Valsiner, Chapter 4, this *Handbook,* this volume).

It is no easy matter to move beyond the static metaphors for structure, which language and cultural practices strongly support and which people typically use unaware. A dramatic, pervasive example is the conduit metaphor for communication (Lakoff & Johnson, 1980; Reddy, 1979). In ordinary discourse about communication of knowledge, people use this metaphor, talking as if the mind is a container for knowledge and as if things that they know are discrete objects. They treat communication as the transfer of knowledge objects from one person to another, as if static objects are being sent through a conduit such as a pipe or telephone line. This metaphor often leads to the belief that telling someone an item of information (giving them an object) is sufficient to communicate it and even to teach it. If a course or a chapter covers a concept, for example, then the student or reader is assumed to have been given that object. If they fail to demonstrate the knowledge specified by that object, they are taken to be ineffective learners (stupid, inattentive, or lazy). Research shows that students do not learn effectively from such presentations, but they require experience with acting on and manipulating the material to understand it (Crouch, Fagen, Callan, & Mazur, 2004; Schwartz, 2000; Schwartz & Fischer, 2005). This static metaphor (and others as well) omits the constructive nature of learning, knowing, and understanding from the assumed structure of communication and education, and their social nature is minimized too.

The conceptualization of structure as form treats structure as a static property of knowing that can be separated from the knowing activities themselves, just as the conduit metaphor separates objects of knowledge from activities of knowing. Imagine trying to remove the structure from the Golden Gate Bridge, gather it up somehow, and ship it off to someone else, who would add it to a pile of steel, which would quickly arise to form a replica of the San Francisco landmark. Even more absurd would be trying to extract the structure from the tightly coordinated, self-organizing, physicochemical processes of a living cell and then to apply it to a blob of inert chemical components in hope of generating a new cell. Structure is an inseparable quality of real dynamic systems, and it emerges as they develop (are constructed). In reality, structure cannot be separated from its role as the organizational property of dynamic systems.

In the study of development, three static conceptions of psychological structure have predominated, all of which have used static forms to explain dynamic structures. In many developmental theories, including Piaget's (1983, 1985) stage theory, activities take the form of abstract logical structures. In many linguistic and cognitive theories, activities take the form of preformed quasi-logical rules, typified by Chomsky's (1957, 1995) theory of innate linguistic competences and its corollary theories of innate cognitive competences (Baillargeon, 1987; Fodor, 1983; Spelke, 1988). In many traditional empiricist theories in Anglo-American psychology, activities take the form of linear input-output rules, as typified by linear models in statistics, information processing, and behavior genetics (Anderson et al., 2004; Horn & Hofer, 1992; Plomin, DeFries, McClearn, & Rutter, 1997). This linear form of theory is especially prominent in approaches that focus on domain speci-

ficity, the separation of knowledge into distinct parts tied to domains of experience.

Despite well-publicized disagreements among these three frameworks, they derive their core assumptions from the structure-as-form paradigm, portraying psychological structure in abstract forms existing separately from real self-organizing human activities. In stage theory, psychological structure is seen as a universal abstract logic imposing itself on the developmental trajectories of every person. Although Piaget believed that activity is the basis of knowledge and development, the base metaphor for his stage theory of cognition is successive stages of logic that determine specific cognitive performances across contexts and domains of knowledge and are relatively unaffected by the contexts of those performances. Similarly, nativist competence theories project a universal preformed code, blueprint, or set of instructions that somehow exists separately from the activities that it will someday engender. Like Platonic forms, these blueprints lurk among the genes, awaiting the right moment to impose order on behavior.

The experimental/psychometric framework also bases its core assumptions on structure as form, but there the structure is hidden behind standard methods and paradigms for explanation. The assumed linear combinatorial structures of dichotomies—person and environment, input and output, heredity and experience, domain x versus domain y—are embedded in research designs, statistical techniques, and theoretical concepts, but their implicit assumptions about structure are seldom acknowledged (Bronfenbrenner, 1979; Fischer & Bullock, 1984; Gottlieb, Wahlsten, & Lickliter, Chapter 5; Overton, Chapter 2; Thelen, & Smith, Chapter 6; Valsiner, Chapter 4, this *Handbook,* this volume; Wahlsten, 1990; Wittgenstein, 1953). Person and environment are partitioned into separate groups of factors instead of being treated as dynamic collaborators in producing activities. Much of modern biology has assumed similar reductionist, reifying notions of structure as form (Goodwin, 1994; Gottlieb, 2001; Kauffman, 1996).

The dominance of the structure-as-form paradigm in cognitive developmental theory has forced scholars to choose among these three inadequate notions of structure—stages, innate structures, and linear information processes. Instead, structure needs to be conceived dynamically. Psychological structure exists as a real organizational property of dynamic systems, just as the structure of the human skeletal system and the human circulatory system are real and distinguish humans from other animals. The structure is a property of the self-organizing systems that create it—the dynamic organization exhibited by self-organizing systems of mental and physical activity, not a free-floating ghost of competence or logic that dictates behavior to its human machine. Before we explicate concepts and methods of dynamic structure, however, we need to ground our argument with analysis of key problems with the static conceptions of structure that pervade developmental and psychological science.

The Stage Debate and the Discovery of Variability in Cognitive Development

The strength of the stage structure concept, as with all structure-as-form models, is its account of stability in development. Skills exhibit patterns of stability both in the ways they function and the ways they develop. What would account for such stable patterns in the functioning and development of cognition? Piaget's (1983, 1985) conception of formal logical stages addressed this question with what seemed to be a powerful and reasonable explanation: Individuals construct logical structures that preserve the organization of their interpretive or behavioral activities to be applied again at later times or in different situations. The existence of these structures accounts for the ability to apply the same concept or skill across many situations. Similarly, the emergence of concepts in specific sequences is accounted for by the fact that the logical structures underlying the concepts are constructed gradually, so that a partially complete logic would give rise to one concept (e.g., one-to-one correspondence) and the later completion of the logical structure would give rise to a more extensive and logically complete concept (e.g., conservation of number). Piagetian stage theory places all human cognitive activities into a sequence of abstract logical forms, but it has proved incapable of explaining the vast array of deviations from stage predictions (Bidell & Fischer, 1992; Flavell, 1971; Gelman & Baillargeon, 1983).

However, the strength of the stage structure concept was also its greatest weakness: Whereas universal logical structures accounted elegantly for stability, they offered hardly any explanation for variability in the functioning and development of cognition. Because the stage concept equated psychological structure (the organization of dynamic mental activity) with static form (formal logic), it provided no model of the real psychological mechanisms that might lead to variability and change in development. The idea of a fixed logical structure underlying all of a

child's conceptions at a given stage seems to explain observed consistencies in the form of children's thinking, but it predicts much, much more consistency than children show, and it has proven incapable of explaining departures from the predicted consistency.

Departures from the consistency predicted by stage theory proved to be more the norm than the exception as proliferating replication studies introduced a myriad of variations on Piaget's original tasks and procedures. On the one hand, opponents of Piaget's theory, doubting the reality or usefulness of formal stage structures, focused their research on identifying conditions in which stage theory predictions failed. In contrast, supporters of Piaget's constructivist view tried to validate the purported products of development—stage sequences, timing of cognitive achievements, and universality. These researchers focused a great deal of attention on demonstrating conditions in which stage predictions were empirically supported. Today, many researchers still continue along these independent paths, mostly ignoring or dismissing findings of people from the other camp.

The outcome of this protracted and often heated empirical debate has been the discovery of remarkable variability in every aspect of cognitive development studied. As researchers implemented variations in the nature of task materials, complexity of tasks, procedures, degree of modeling, degree of training, and methods of scoring across a multitude of replication studies, a consistent pattern of variation emerged (Bidell & Fischer, 1992; Case, 1991b; Fischer, 1980b; Halford, 1989; Lourenço & Machado, 1996). To the extent that studies closely approximated the assessment conditions used by Piaget, the findings were similar to those he had reported. When tasks and procedures varied greatly from Piaget's, the findings also varied greatly within certain limits.

A classic example of this pattern of variation is found in research on number conservation. In Piaget's theory, number conservation (the ability to conceptually maintain the equality of two sets even when one set is transformed to look much larger than the other) was seen as a product of an underlying stage of concrete operational logic. In the original number conservation studies, Piaget and Szeminska (1952) had used sets of 8 or 10 objects each and had identified 6 to 7 years as the typical age of acquisition for this concept. In one group of replication studies, Gelman (1972) showed that the age of acquisition for number conservation could be pushed downward from Piaget's norms if the task complexity was simplified by (a) reducing the size of the sets children had to compare and (b) eliminating the requirement for verbal justification of conservation judgments. Under these conditions, Gelman reported that children as young as 3 to 4 years of age could answer conservation questions correctly. Fortunately, the debate about number eventually produced important new discoveries spelling out developmental pathways for the early construction of number actions and concepts (Case et al., 1996; Dehaene, 1997; Spelke, in press).

As replication studies proliferated, this seesaw debate over age of acquisition of logical concepts was extended to other dimensions of psychological structure where researchers produced similar patterns of variability as a function of assessment conditions. These included variability in the three central characteristics we have described (developmental level, synchrony in level across domains or contexts, and sequence of development in a domain or context).

The growing empirical documentation of variability in development posed severe problems for the concept of formal stage structures. If concepts such as conservation of number are supported by underlying logical structures, then why wouldn't the logical structure manifest itself in most if not all situations? Why would a child show logical thinking one moment and in the next moment, appear to have lost it? If cognitive development consists of the emergence of successive forms of underlying logic, why wouldn't developmental sequences remain the same across domains, contexts, and cultures? The formal concept of stage structure could offer no specific explanation for this pattern of variability, but only the label of decalage.

In one sense, victory in the stage debate went to the skeptical. By the mid-1980s, the inability to account for the dramatic departures from stage theory's predictions of cross-domain, cross-individual, and cross-cultural consistency had resulted in a general flight from stage theory as an explanatory framework (Beilin, 1983). In a more important sense, however, there was no winner because neither side had offered a workable explanation of the patterns of variation the debate uncovered. What concept of psychological structure would explain the fact that cognitive performance varies so greatly with changing conditions and yet also exhibits great consistency under other conditions?

Explaining Variability versus Explaining It Away

From the perspective of the history of science, one might think that the discovery of new patterns of variability would be met with excitement and theoretical ad-

vance. After all, a central task of science is to discover and account for variability. Theories are constructed and reconstructed to interpret the range of variation observed and to search for patterns of order within this range. Indeed, an essential criterion of sound scientific theories is that they account for the full range of variability observed in a phenomenon of interest.

However, change in scientific theories is rarely that simple. Evidence that threatens a prevailing worldview or paradigm can lead to attempts to assimilate the discrepant findings into the current paradigm, either by denying their relevance or by advancing alternative explanations within the dominant paradigm (Hanson, 1961; Kuhn, 1970). Responses to the discovery of variability in development have followed this pattern, returning to the prevailing Cartesian framework and building minor modifications to account for portions of the observed variability. Instead of attempting to fully describe the range of variability and explain the reasons for the observed patterns, responses have tried to explain away variability through a variety of theoretical maneuvers that include ignoring variability, accepting variability without explaining it, and focusing on selected effects of variability to support existing theory with minor adaptations. Each of these theoretical responses to variability has served to preserve some version of the Cartesian framework and the structure-as-form paradigm in the face of the new evidence and has led to the modern Cartesian synthesis, despite the fact that most of the evidence of variability remains unexplained.

Reasserting Stage Theory

Piaget, Kohlberg (1969), and other stage theorists at first mostly ignored variability, treating it basically as a nuisance or as error of measurement. Differences across domains, tasks, contexts, and coparticipants in phenomena such as age of acquisition, synchrony, and developmental sequence were said to represent varying forms of resistance to the operation of underlying logical structures. Although Piaget later acknowledged the inadequacy of this position and experimented with alternative logic frameworks (Piaget, 1985, 1987; Piaget & Garcia, 1991), he never found an alternative concept of structure that would predict and explain when and how performance varies. (The discovery of the scale of hierarchical skill levels, shown in Figure 7.3, came from analyzing patterns of variation in growth curves, demonstrating the usefulness of analyzing variation for understanding stages.)

Several scholars have emphasized Piaget's belief in the importance of *decalage* and other forms of variation (Beilin, 1983; Chapman, 1988; Lourenço & Machado, 1996), but recognizing that phenomena need to be explained is not the same as explaining them. Piaget and other stage theorists have not specified the processes by which cognitive stage structures and environmental resistance interact to make one kind of task develop later than another in general. They have dealt even less adequately with variations across individuals in the order and timing of acquisition of skills and variations within an individual related to tasks, context, social support, and experience. In short, stage theory has provided no explanation for most observed patterns of variation in developmental level, synchrony, and sequence (Bidell & Fischer, 1992; Edelstein & Case, 1993).

Domain Specificity Theory

As evidence of variability grew and the inadequacy of the classic stage concept became clear, the theoretical crisis deepened. With stage theory losing its potential to generate interesting and credible research and with no clear alternative model of psychological structure available except for Chomskian nativism, some framework was needed as a basis for the continued empirical study of development. *Domain specificity* theory emerged as a way of freeing the field from its dependence on stage theory without demanding a new commitment to any particular model of psychological structure. According to domain specificity theory, psychological processes are not organized in universal structures, but within limited domains such as spatial, linguistic, or mathematical reasoning, or for groups of similar tasks such as problem solving, analogical reasoning tasks, and theory of mind (Demetriou, Christou, Spanoudis, Platsidou, 2002; Hirschfeld & Gelman, 1994; Turiel & Davidson, 1986; Wellman, 1990). The structures in these domains are often referred to as modules, indicating separate, distinctive structures of brain and behavior (Fodor, 1983). In education, domain specificity became a major theme through the influence of Howard Gardner's (1983) theory of "multiple intelligences," leading to curricular revisions in schools around the world.

Description of development and learning within important domains has great value for both developmental science and education, but many scholars have stopped with the domain description. They thus avoid having to explain patterns of variability—for example, the differences and similarities in age of acquisition across

different logical concepts such as number and theory of mind. Instead, they simply assert that cognition is organized locally and so cross-domain relations do not have to be explained. This theoretical stance simply acknowledges the fact of variability and sidesteps a systematic account of its origins.

In some ways, this acknowledgment has represented an advance for a field once dominated by stage theory with its assumption of a single logic that catalyzes change across all aspects of the mind. However, to the extent that domain specificity creates the illusion of having solved the problem of variation, it is an unfortunate theoretical detour. Developmental scientists need to explain why clusters of many (structurally equivalent) concepts emerge in different domains around the same time, showing interval synchrony (Case, 1991b; Fischer & Silvern, 1985). They need to explain how an individual who is working within a single domain and task exhibits one skill level when working alone, but a distinctly higher level when working with the support of a helpful adult (Fischer, Bullock, et al., 1993; Rogoff, 1990). Although domain specificity theory provides important recognition of developmental variability, it offers no explanation of variability across domains and within individuals.

Neo-Nativism

An important response to the evidence of variability has been the neo-nativist movement (Carey & Gelman, 1991; Fodor, 1983; Spelke, 1988), which represents a major theoretical alternative to stage theory within the structure-as-form paradigm. Researchers taking this perspective have used ingenious experiments to uncover surprising capacities of infants and young children and have led to the creation of the modern Cartesian synthesis. With the rejection of the concept of structure as stages of formal logic, the other predominant concept of structure—innate formal rules—seems to be the only remaining alternative within the structure-as-form paradigm. Unfortunately, the concept of innate formal rules has the same fundamental limitation as its sister concept of formal logic: As a static conception of structure, it cannot adequately account for the variability that arises from dynamic human activity (Fischer & Bidell, 1991).

Neo-nativist researchers have focused on selected effects of cognitive variability that seem to support the existence of innate competences within prominent domains such as number, space, language, object properties, and theory of mind (Carey & Spelke, 1994). For the most part, they have not attempted to deal with the extensive variability found in performance. Indeed, the modern father of this movement, Noam Chomsky (1965, 1995), specifically rejects the evidence of variability in language, asserting that it is illusory and that all people "really" speak the same fundamental language. The Chomskian theory of linguistic competence accounts for human linguistic behavior on the basis of a set of innate rules, only a few of which have been specified. Despite almost 50 years of effort, nativism has been notoriously unable to account for either the variations of human languages (Chinese is different from English!) or the highly variable everyday communication skills that individuals develop in a language within and across diverse settings (Lakoff, 1987; Ninio & Snow, 1996; Slobin, 1997). Nevertheless, the nativist approach has had great appeal to many developmental scientists because of its important discoveries about children's early abilities.

The basic paradigm for neo-nativist research is to design tasks that drive ages of acquisition much lower than traditional Piagetian norms (Baillargeon, 1987; Spelke, 1988, in press). Nativist researchers introduced techniques for simplifying Piagetian task materials and procedures, requiring only minimal activity from a child or providing modeling, training, and other forms of support for more complex activity. They have shown great ingenuity in discovering capacities of young infants and children, demonstrating strong violations of Piaget's age norms for various logical concepts. Their neo-nativist argument is that cognitive structure must be innate because acquisition of certain concepts can be demonstrated at very young ages. However, this *argument from precocity* takes into account only half the evidence for variability—the downward half (Fischer & Bidell, 1991; Halford, 1989). It treats the earliest age as the "real" age for a concept's emergence, ignoring evidence of wide variations in age of acquisition both upward and downward.

A good example of the focus on early age instead of variation is the extensive research on infants' acquisition of knowledge of objects, especially object permanence (objects continue to exist even when they have been displaced and are not perceived) and object tracking. Researchers have used the procedure of dishabituation, which is designed to assess preferences for stimuli without requiring much behavior. Infants are shown a stimulus until they are used to it (habituated), and then they are shown an altered stimulus. If they show increased attention to the new stimulus (dishabituation), the conclusion drawn is that they have noticed the difference.

A well-known case is Baillargeon's research on object permanence in young infants (Baillargeon, 1987, 1999). To appreciate the problems with focusing on only selective aspects of variability, it is useful to place this study in the context of Piaget's (1954) original findings and interpretations regarding infant object permanence. Piaget described a six-stage sequence in infants' construction of object permanence, which subsequent research confirmed with some revision and clarification (McCall, Eichorn, & Hogarty, 1977; Uzgiris & Hunt, 1987).

Piaget offered a constructivist interpretation of his observations: a simple activity-based mechanism to explain transitions from one stage to another. By *coordinating* early sensorimotor activities on objects to form new, more comprehensive action systems, infants gradually construct more inclusive understandings of what they can do with objects and therefore how objects can behave. For instance, by coordinating the sensorimotor actions for looking at and grasping objects at Stage 2, infants of about 5 to 6 months of age move to a new Stage 3 structure for dealing with objects—visually guided reaching, in which they simultaneously hold and observe an object. Piaget described an especially important transition at stage 4, when infants of about 8 months coordinate different visually guided reaching skills into a system for searching out objects that have been displaced or hidden. For instance, infants coordinate two skills (what Piaget called "schemes"): reaching for a rattle to grasp it, and reaching for a cloth that is covering the rattle to remove it. With this stage 4 coordination, they can begin to understand how objects come to be hidden by other objects and why hidden objects remain available to be retrieved. Later stages in this understanding extend to late in the second year of life, when infants become able to search exhaustively for hidden objects in many possible hiding places.

In contrast to Piaget's model of gradual construction of object permanence, Baillargeon focused on the lower end of the age range and a simple looking task. Infants from 3 to 5 months of age were habituated to the sight of a small door that rotated upward from a flat position in front of them, tracing a 180% arc away from them to lie flat again on a solid surface. They were then shown two scenes with objects inserted behind the rotating door. In the possible event, the door swung up but stopped at the object. In the impossible event, the object was surreptitiously removed and the door was seen to swing right through the space the object had occupied, as if it moved through the object. Infants as young as 3½ to 4½ months dishabituated to the impossible event significantly more than they did to the possible, and Baillargeon took this behavior as evidence of object permanence. She concluded that infants acquire object permanence 4 to 5 months earlier than the age of 8 months that Piaget had reported.

This argument from precocity is straightforward: If behaviors associated with a conceptlike object permanence can be found much earlier than in prior research, then the concept in question must be present innately. Similar evidence has led to claims of innate determination for a growing list of concepts, including object properties, space, number, and theory of mind (Carey & Gelman, 1991; Saxe, Carey, & Kanwisher, 2004; Spelke, 2000). Based on the static Cartesian model, these claims have important limitations centered on the failure to consider the full range of variability involved in developmental phenomena.

The crux of the problem is a simplification that ignores the gradual epigenetic construction of activities that vary in complexity. Baillargeon's task and procedure were dramatically different from the more complex method of assessment used by Piaget. In place of independent problem solving in which the infant must actively search for an object hidden in several successive places, Baillargeon substituted a simple look toward one of two displays. This procedure simplifies the task so greatly that it shifts from a conceptual task to one of perceptual anticipation. Indeed, on a computer a neural-network model of the situation can solve a similar task with a simple visual strategy and no coordination of object characteristics with spatial location (Mareschal, Plunkett, & Harris, 1999).

Baillargeon and other nativists claim that the object concept appears very early, even though the more complex behaviors described by Piaget still develop at the usual later ages, as shown by overwhelming evidence. The selective focus on one early age for one behavior obscures the constructive mechanisms of development and makes it seem that the concept of object permanence has suddenly leaped up, fully formed, at 3½ months of age. Within this framework, innate concepts emerge abruptly in the first few months of life, and development disappears. How could such early development arise except through innate concepts? The answer to this question is another question: How do skills develop through a long sequence of increasingly complex

object-related activities of which the looking behavior is only the beginning?

Competence/Performance Models

Nativists and many other cognitive scientists answer by distinguishing between competence and performance. The modern version of the competence/performance distinction was proposed by Chomsky (1965) in an effort to explain why his theory of innate linguistic rules could not predict the wide range of variability observed in actual language usage. Chomsky argued that innate language rules existed separately from the performance of specific acts of communication. The rules governed which communication practices are possible but not which ones will actually take place in a given situation. Many developmental scientists, faced with the similar problem of explaining why formal Piagetian conceptions of logic do not predict observed patterns of variability in cognitive performance, adopted this distinction (Flavell & Wohlwill, 1969; Gelman, 1978; Klahr & Wallace, 1976; Overton & Newman, 1982).

Competence/performance theories based on the Piagetian and Chomskian models portray cognitive structures as fixed rule sets in the mind/brain that specify behaviors but are somehow impervious to or independent of the contexts of the behaviors. The structures exist somewhere in the background and serve a limiting function: They determine the upper limit on the range of actions possible at a given time, but they leave open the specific action that will take place. For example, in arithmetic, the counting behavior of a preschool child arises from a mathematical competence such as being able to directly perceive numbers of objects of 1, 2, or 3. When a child fails to count, say, three pretzels accurately, the failure is explained by some interference such as memory failure or distraction (Greeno, Riley, & Gelman, 1984; Spelke, in press). A skilled person can indeed mess up a performance here and there because of memory failure or distraction, but when the 3-year-old fails almost all tasks for counting three objects, what sense does such an explanation make?

These models dismiss variability in cognitive and language performance by asserting that fixed competence is differentially expressed because of intervening cognitive processes (vaguely specified) or as a result of unanalyzed environmental resistance to the competence, as Piaget suggested for decalage. Although most nativist theories assume such a framework, some competence/performance theories do not require that psychological structures exist innately, but only that they are firmly separated from the actions that instantiate them. The dynamics of construction of activities leading to wide variation are lost in the muddy mediators that somehow prevent competence from being realized in activity. Such conceptions of disembodied structure seem not too distant from the humorous idea of bottling up the structure of the Golden Gate Bridge. Why is it necessary to posit separate levels of structure, existing somewhere (it is unclear where) outside the real activity in question? Why not model the organization of the actual mental and physical activity as it exists in its everyday contexts?

In short, domain specificity, nativist, and competence/performance models share the same fatal limitations as the logical stage models they were meant to replace. Although the newer models do not make the cross-domain claims that stage models did, they retain a conception of psychological structure as static form existing separately from the behavior it organizes. Whether such static forms are seen as universal logics or domain-specific modules, they offer accounts only of stability in the organization of behavior while ignoring or marginalizing variability. The challenge for contemporary developmental science is not to explain away evidence of variability in performance. Instead, scholars need to build dynamic models of psychological structure, using concepts such as skill, hierarchical complexity, contextual support, and developmental web to build methods for analyzing and explaining both the variability and the stability in the organization of dynamic human activity.

The Constructivist Alternative

The constructivist alternative takes as its starting point what the Cartesian framework rules out: the constructive agency of a human being acting in the context of relationships among systems—biological, psychological, and sociocultural. As we have shown in the opening sections of this chapter, the dynamic structural framework provides a straightforward, comprehensive alternative to the conundrums created by the Cartesian synthesis and the related structure-as-form paradigm. Human knowledge is neither passively received from the environment nor passively received from the genome. Instead, people construct knowledge through the active coordination of action systems beginning with the earli-

est sensorimotor activities of newborns, influenced by environmental and genetic systems. By coordinating the systems of activity (including perceptual activities) through which they participate in the social and physical worlds, infants create new relations among these systems and thus new potentials for acting in and understanding the world. These new relations among action systems constitute psychological structures—the organizational aspect of human knowledge, which we refer to as skills. They exhibit both wide variations and patterns of order within the variations.

Dynamic systems research provides the framework for this alternative account, drawing on traditions that have developed outside of or as an alternative to the Cartesian tradition. Important concepts and methods come from epistemological constructivism and related sociocultural/sociohistorical theory (Cole, 1992; Rogoff, 2003), traditional systems theory (Dixon & Lerner, 1992; von Bertalanffy, 1976), dynamic systems theory (Thelen & Smith, 1994; Chapter 6, this *Handbook,* this volume; van der Maas & Molenaar, 1992; van Geert, 1991), and the developmental science group (Cairns, Elder, & Costello, 1996; Cairns, Chapter 3; Valsiner, Chapter 4, this *Handbook,* this volume). These traditions, while differing in many ways, share a constructivist focus on action, interrelatedness, and complexity of psychological, biological, and sociocultural systems. From this perspective, the person is the primary agent of cognitive change, constructing new kinds of relations among psychological systems with biological and cultural systems (Bidell & Fischer, 1996; R. Kitchener, 1986). These relations are organized in particular ways that give rise to specific patterns of performance, and they are complex and variable because they are living systems.

People construct the skills of human understanding and action through their diverse bodies, the variable physical world, different sociocultural relations, and distinct developmental histories, thus producing highly variable activities. If this variability is ignored, it acts as noise disguising the nature of developmental processes and thus misleading researchers and educators. However, if the tools of developmental analysis are used to control and manipulate conditions contributing to variability, then the systematicity of the variability can be uncovered and it becomes a key to understanding the nature of psychological structure. In the next section, we discuss some of the methodological tools by which developmental variability can be used to understand and describe the development of dynamic psychological structure.

METHODOLOGY OF DYNAMIC STRUCTURAL ANALYSIS

To overcome the limitations of structure as static form, we need to articulate a framework for dynamic development, which includes a set of methods that embody dynamic concepts. Classical research methods use static notions, indicating the age when a competence emerges (really, the mean or modal age for one context and one group), forcing growth into linear models, and partitioning analysis of activities into dichotomies such as heredity and environment or input and output (Anderson et al., 2004; Horn & Hofer, 1992; Plomin et al., 1997; Wahlsten, 1990). Most importantly, effective research needs to be designed so that it can detect variability and, in turn, use the variability to uncover sources of order or regularity in development.

Effective research should be built with designs, measures, analytic methods, and models that can detect variations in growth patterns. Research must be designed to deal with variability, or it is doomed to fail to provide an adequate analysis of development. This chapter focuses on activities in which people coordinate and differentiate lower-order components to form higher-order control systems, which encompasses most activities of interest to developmental and educational researchers. The components of these control systems range from neural networks to parts of the body, immediate contexts (including objects and other people), and sociocultural frameworks for action. Moment by moment, people construct and modify control systems, and the context and goal of the moment have dramatic effects on the nature and complexity of the systems. Frequently, people do the construction jointly with others. To go beyond static stereotyping of development and learning, research must deal directly with these facts of variation. Research must be designed to deal with the wide range of shapes of development that occur for different characteristics of action and thought in diverse contexts and conditions.

Developmental regularities can be found at several levels of analysis, from brain activities to simple actions, complex activities, and collaborations in dyads or larger groups. In analyzing these developmental regularities, it

is important to avoid a common mistake. No one regularity applies to all characteristics of developing activity or all levels of analysis. The same developmental regularities will not be found everywhere. That is an essential principle of the variability of human activity.

In one major realization of this principle, development has many different shapes! Some behaviors and brain characteristics show continuous growth, others show clusters of spurts and drops, still others show oscillation, and some show growth followed by decay (Fischer & Kennedy, 1997; Siegler, Chapter 11, this *Handbook,* Volume 2; Tabor & Kendler, 1981; Thatcher, 1994; Thelen & Smith, Chapter 6, this *Handbook,* this volume; van Geert, 1998). Ages of development likewise vary dynamically, even for the same child measured in the same domain: Assessment condition, task, emotional state, and many other factors cause ages to vary dramatically. There are no legitimate *developmental milestones,* stones fixed in the developmental roadway in one position. Instead, there are *developmental buoys,* moving within a range of locations affected dynamically by various supports and currents.

It is remarkable how pervasively researchers ignore or even deny variations in shape and age of development. Scholars committed to a continuous view of development typically ignore the spurts and drops in many developmental functions, insisting that development is smooth and continuous despite major evidence to the contrary. Physical and psychological development are both routinely graphed with smooth curves, as in the charts in a pediatrician's office, even though research on individual growth consistently shows patterns of fits and starts in virtually all aspects of physical growth (Lampl & Johnson, 1998). The distortion is just as pervasive in psychological development. For example, Diamond's (1985) findings of linear growth of memory for hidden objects in infancy are frequently cited, even though replications by others with the same tasks and measures show nonlinear, S-shaped growth (Bell & Fox, 1992, 1994). Many data sets show powerfully nonlinear individual growth as the norm in infant cognitive and emotional development as well as development at later ages (Fischer & Hogan, 1989; McCall, Eichorn, & Hogarty, 1977; Reznick & Goldfield, 1992; Ruhland & van Geert, 1998; Shultz, 2003).

In a similar manner, at the other pole of argument, scholars committed to stage theory often ignore the evidence for continuous growth, even in their own data. For example, Colby, Kohlberg, Gibbs, and Lieberman (1983) asserted that their longitudinal data on moral development showed stages in growth even in the face of clear evidence that growth was gradual and continuous (Fischer, 1983). In the same way for age, scholars routinely talk as if there are developmental milestones at specific ages, despite the massive evidence of variability in age of development with variations in conditions of assessment (Baron-Cohen, 1995; Case, 1985; Spelke, in press). Common claims, for example, are that object permanence develops at 8 months in Piagetian assessments, conservation at 7 years, and combinatorial reasoning at 12 years, although no such statement is tenable without more specification because the ages vary greatly with task, support, and so on. Classic research on reflexes in very young infants even demonstrates variability in the ages at which they emerge and disappear (Touwen, 1976).

Starting in the Middle of Things: Implications for Design

To study development *in medias res*—in the middle of things—research designs need to be broadened so that they capture the range of variation and diversity of human activities in real-life settings. If development is assessed with an instrument that places all behavior on a single linear scale, for example, then nothing but that linear change can be detected. The limitations of most classical research arise from assumptions that restrict observation and theory to one-dimensional analysis. When those assumptions are changed, research opens up to encompass the full range of human activity. By limiting developmental observation and explanation to one-dimensional processes, the static assumptions have stymied investigation of the richly textured dynamic variations of development. To do research that facilitates multidimensional-process explanation requires building research designs that go beyond one-dimensional assumptions to provide for detection of the dynamics of variability (Edelstein & Case, 1993; G. Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume; Lerner, 2002; Thelen & Smith, 1994, Chapter 6; Valsiner, Chapter 4, this *Handbook,* this volume; van Geert & van Dijk, 2002).

Here are four important one-dimensional assumptions that are typically incorrect and that are embodied in research designs that implicitly assume static structure. These all need to be avoided in designs for assessing the dynamics of change by addressing variability and diversity.

1. *Single-level, single-competence assumption—not.* At any one moment, a person functions at a single cognitive stage or a single level of complexity and possesses a single competence. Contrary to this one-level, one-pathway assumption, people function at multiple developmental levels concurrently, even within the same situation (Fischer & Ayoub, 1994; Goldin-Meadow & Alibali, 2002; Siegler, Chapter 11, this *Handbook,* Volume 2). In development, a person moves through a web of connected pathways composed of multiple strands (domains or tasks), each involving variation within a range or zone of developmental levels, as illustrated in the webs in Figures 7.2 and 7.9. Assessments must include multiple pathways and multiple conditions so that the full range of levels and competences can be detected.
2. *Single-shape assumption—not.* Each developmental pathway shows essentially similar linear or monotonic shapes. Contrary to this linearity assumption, developmental pathways or strands take many different shapes, which frequently include reversals in direction—not only increases but also decreases, as illustrated in Figure 7.11. Individual people normally grow in fits and starts both physically and psychologically, as we described in the introduction to this section. In development, these fits and starts seem to be especially prevalent and systematic when people are functioning at optimum or when they are building a new skill in microdevelopment. Developmental pathways or strands for individual activities move through nonlinear dynamic patterns of change, seldom showing straight lines. In long-term development, there are periodic movements to a lower level (regressions), especially after developmental spurts (Fischer & Kennedy, 1997). In microdevelopment, backward movement to a low-level skill is common before construction of a new skill (Granott & Parziale, 2002), as we discuss in the section on Microdevelopment.
3. *Single-person assumption—not.* People develop and learn individually, and they sometimes interact and affect each other. Contrary to this individualist assumption, people do not usually function solo, but instead from birth they act in a fundamentally social way, working together in ensembles that distribute a task across several collaborating partners (Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume; A. Brown & Palincsar, 1989; Scardamalia & Bereiter, 1999; Vygotsky, 1978). Studying development socially is not only more realistic, but it can also make the processes of development more transparent. When people work together, communicating about what they are doing, the internal processes of learning and thinking become externalized, and the processes of social collaboration and interference become evident (Fischer & Granott, 1995).
4. *Single context assumption—not.* The most effective research typically focuses on one task and variations on it or one context for assessment. Contrary to this uniformity assumption, research needs to combine multiple tasks and assessment contexts so that it can capture the range of levels and competences, pathways, and social interactions that characterize development (Bronfenbrenner, 1993; Campbell & Stanley, 1963; Fischer, Knight, et al., 1993). To accurately describe people's developing activities, research must be designed with an array of assessment conditions and an array of tasks within conditions.

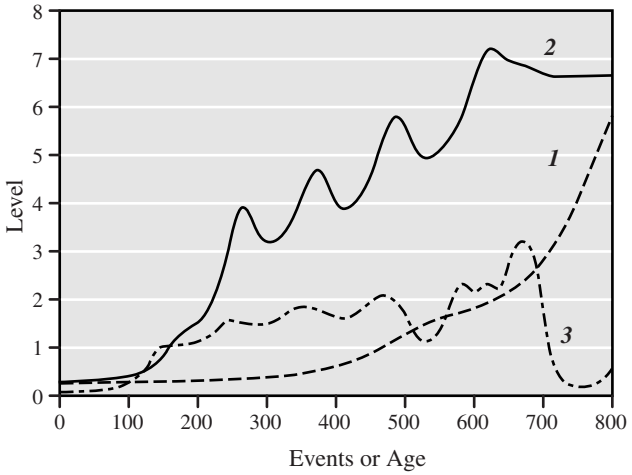

Figure 7.11 Three different growth curves based on the same growth model. The growth curves are all generated by the same nonlinear hierarchical model of development of self-in-relationships used in this chapter, but variations in the values of the parameters in the equations produce vastly different shapes. The same growth processes produce essentially monotonic growth (Grower 1), growth with stagelike spurts and drops (Grower 2), and fluctuating change (Grower 3).

Guidelines for Developmental Research

To analyze and understand natural variations in development as well as consistencies across variations, research needs to move beyond these limiting assumptions. Analyzing the dynamics of change requires

methods that allow detection of variations in development and learning:

- People develop along multiple concurrent pathways in a web.
- From moment to moment people function across a range of different levels and competences.
- People develop in the long run and learn in short time periods according to diverse shapes of growth, including the complex nonlinear fits and starts in many growth curves.
- People learn and develop in social ensembles, and research should reflect this fundamentally social nature of development.
- People act differently in different tasks and conditions, and so research needs to include a range of tasks and conditions to detect the full range of variability in action and thought.

Only through analyzing the natural variability in development and learning can researchers come to understand the consistencies inside the variation.

Putting together all these contributions to variation can seem daunting, but it need not be. A few straightforward guidelines in designing research and analyzing observations facilitate uncovering the variation and diversity of development. Investigators should focus on (a) using well-designed clocks and rulers to measure change and variation, (b) studying several tasks and domains to determine the generality and variation in pathways, (c) varying assessment conditions to uncover the range of variability in level and content, and (d) investigating diverse sociocultural contexts to discover the effects of different cultural groups on development. No one study can investigate all sources of variation at once, but investigators can make sure that several sources are evaluated in each study. Also researchers need to situate their findings within a conceptual map of the multiple sources of dynamic development, avoiding the pitfall of reductionist description, which assumes that one study captures the important sources of variation.

Clocks, Rulers, and Repeated Measures

Detection of variation in developmental shapes requires both good clocks and good rulers to measure change. To capture either smooth growth or fits and starts requires a clock that can detect the speed of change. Ages or events need to be sampled frequently enough to provide several assessments for each period of increase and decrease. Otherwise, the shape of growth cannot be detected. Also, the distribution of ages or times of assessment must be chosen carefully so that estimates of changes in item or response distributions are not distorted by biases in time sampling. Much developmental research uses clustered ages such as groups of 2- and 4-year-olds clustered tightly around the mean ages of 2 and 4. This design assumes the importance of mean differences and provides a bad clock for development, because it represents only a few of the many points along the time scale from 2 to 4 years. If major reorganizations of activity are hypothesized to occur, for example, every 6 months in the early preschool years as Case (1985) predicted, then assessments must take place at least every 2 or 3 months to reliably detect the periods of reorganization, and the distribution of ages across 2- or 3-month intervals should be uniform, not clustered at the mean age.

Capturing the shapes of development requires a good ruler as well, one that provides a scale sensitive enough to detect the ups and downs of growth. The best assessments provide a relatively continuous developmental scale of increasing complexity, such as the Uzgiris and Hunt (1987) scales to assess infant development and the scales for nice and mean social interaction (Ayoub & Fischer, in press; Fischer, Hencke, & Hand, 1994). It is crucial to avoid scales that combine items in a way that forces growth into a particular function, as when intelligence tests force test data into scales that show linear increase with age.

A single task seldom makes a good ruler because it provides such a limited sample of behavior. Better is a series of tasks or a grouping of tasks that forms coherent developmental scales. A series of tasks can be used to assess either (a) a Guttman-type developmental scale measuring one linear pathway in a developmental web (Guttman, 1944), like the Uzgiris-Hunt scales, or (b) branching pathways like the tasks for nice and mean interactions and those for reading single words in Figures 7.5 and 7.10. Through analysis of profiles across tasks, a good ruler can be created for either pathway. A particularly useful method is Rasch scaling, which is based on a sensible, nonlinear (logistic) developmental model and allows detection of Guttman scales as well as branches (Bond & Fox, 2001; Dawson, 2003; Rasch, 1980). The discovery of the general ruler for hierarchical skill development came from research assessing performance profiles with these and related methods, as

discussed in the section titled A Common Ruler for Skill Development.

Table 7.2 shows a set of profiles for defining the simplest developmental pathway in the development of reading words—Figure 7.10 (a), the pathway for normal readers, which includes only one simple branch (Knight & Fischer, 1992). The sequence is determined by the ordering patterns for every pair of tasks. For most profiles in this simple sequence, every task is passed up to a certain point in the table from left to right, and then all tasks are failed thereafter, which is characteristic of a Guttman scale. Branching is indicated by profiles that show variations in this simple pattern, such as Step 2b in Table 7.2, where there is a failed task in the middle of a string of passes. Based on analysis of performance across tasks for each word, a child is assigned a profile in Table 7.2, and therefore a step in the pathway, even when assessment is at a single time rather than longitudinal. The table shows pass/fail tasks for simplicity, but multistep scales can be used, with scaling tested by tasks earlier in a sequence having higher scores than those later.

Profile analysis can detect webs as simple as the one for normal readers in Figure 7.10 (a), or as complex as the one for nice and mean social interactions in Figure 7.5. The logic of analysis is the same for branched webs as for linear Guttman scales, and sequencing is determined by the ordering patterns of all pairs of tasks. Indeed, the same set of tasks can define different webs for different children. For example, different sets of profiles for the tasks in Table 7.2 define the unintegrated webs for poor readers in Figure 7.10 (b) and (c), such as the web in which the three domains of identifying letters, reading words, and rhyming words are all independent.

An important characteristic to keep in mind when devising tasks to build rulers for change is the similarities and differences among tasks. Simple ordering like that in Table 7.2 is typically eliminated by differences in content or procedure between tasks. When researchers have attempted to build scales using distinctive tasks to assess different steps, the task differences have wiped out scaling of steps (Kofsky, 1966; Wohlwill & Lowe, 1962). A good, simple Guttman-type ruler uses tasks that include only variations in complexity or difficulty, with minimal differences in content and procedure. Differences between distinctive tasks are captured by having separate Guttman rulers for each set of tasks (each domain). In a similar way, measuring the temperature of a refrigerator in New York requires a different thermometer from measuring the temperature of the surface of Mars. Rasch analysis can also facilitate using a common scale across tasks and domains (Bond & Fox, 2001; Dawson et al., 2003), as it has helped test the generality of the ruler for skill complexity, showing simultaneously the *same scale* across domains and large domain effects.

Another method for devising a ruler uses groupings of similar tasks to assess a scale. For example, in early language development, Ruhland and van Geert (1998) grouped words into syntactical classes based on Dutch children's spontaneous speech to form a sensitive developmental scale. With pronouns, for example, they found a large growth spurt late in the second year, as shown in Figure 7.12. Other groupings that have proved useful in studies of development have included arithmetic problems of similar complexity (Fischer, Pipp, & Bullock, 1984) and explications of dilemmas about the bases of knowledge called reflective judgment (K. Kitchener et al., 1993). Scales based on such groupings of similar tasks can be used to specify the shapes of development in various domains and to compare relations among development across domains or levels in individual subjects or groups. Like scalogram analysis, they also provide a way of testing developmental functions with

TABLE 7.2 Task Profiles for Normative Developmental Sequence for Reading Words

Step	Word Definition	Letter Identification	Rhyme Recognition	Reading Recognition	Rhyme Production	Reading Production
0	–	–	–	–	–	–
1	+	–	–	–	–	–

cross-sectional designs. For example, this method can test for both spurts and bimodal distributions on emergence of developmental levels or growth of separate strategies for approaching a task (Siegler, 2002). The design must included separate groups of tasks for each level or strategy. The grouping method, however, does not provide a sensitive index of the intervals in a scale between points of discontinuity, or levels.

Rasch analysis fills this need, providing powerful tools for assessing the steps and intervals along a scale as well as discontinuities (Bond & Fox, 2001; Rasch, 1980). Only recently have researchers begun to realize its potential for assessing developmental scales and determining the distances between items along a scale. Most investigators have used it to determine whether items in a domain fit a single Guttman scale and what the distances are between items along that scale, and it can also be used to assess for several independent scales or branches in a web. Rasch scaling provides one of the most convincing sources of evidence for the scale for hierarchical complexity of skills shown in Figure 7.3 (Dawson, 2003; Dawson et al., 2003).

The three techniques for combining tasks to form developmental scales (Guttman scaling, groupings of similar tasks, and Rasch analysis) provide a repeated-measures assessment that has many of the desirable characteristics of longitudinal assessment, even when there is only a single session. Through analysis of task profiles and distributions, each person can be tested to determine whether he or she follows a particular developmental pathway or growth function. Contrary to the conventional wisdom that development can only be effectively assessed longitudinally over months and years, these repeated-measures assessments can provide powerful tools for describing and testing developmental pathways and growth functions. They can also be combined with longitudinal designs, where they provide even more powerful tools for assessing development.

General Structure across Tasks in a Domain

Task differences are typically controlled for and systematically manipulated in developmental scales. However, task differences are important in their own right. Task is one of the most powerful sources of variability in behavior, as documented by thousands of psychometric and experimental studies across many decades (Fleishman, 1975; Mischel, 1968). An accurate portrait of development requires assessment of different tasks and domains to capture patterns of variation in developmental pathways and growth functions.

One of the most common hypotheses in cognitive and developmental science is that behavior divides into domains, which are built on general psychological structures. That is the core of the domain specificity framework and of neo-nativist explanations. However, evidence for generality in a conceptual structure is relatively rare in the research literature, where careful tests of generalization are infrequent (Fischer & Immordino-Yang, 2002). Many abilities that have been described as general competences seem not to be coherent abilities at all but instead summary variables, with at best weak correlations among items. Examples include the hypothesized domains of theory of mind, metamemory, visual thinking, and ego resiliency, for each of which there is no clear evidence of a central generalized structure that generates common activity across a wide array of tasks. For example, ego resiliency has been posited as a broad characteristic of effective people and it has been subjected to extensive longitudinal study by Jack and Jeanne Block (Block, 1993). Research on this general competence in Dutch and American children indicates that ego resiliency does not affect relevant specific competences such as school achievement and social preference (Harter, 1999; van Aken, 1992). That is, it does not show a generalizing relation with specific skills, which would indicate a common structure applied across tasks. Ego resiliency may be a useful social construct, but it does not seem to be a central psychological structure that organizes various activities together in development.

One convincing case of a general structure in a domain is the central conceptual structure documented by Robbie Case and his colleagues (1996). It provides a model for defining a general structure and testing its generality. Assessment of the development of a general concept of number requires an array of tasks that all require the use of that concept. Case and his colleagues have constructed such a task array for the elementary number line, which represents number as quantitative variation along a line. This representation constitutes what they call a *central conceptual structure* for number in young children, a framework for thinking about number that facilitates numerical understanding across many situations. Tasks like reading the time on a clock, counting gifts at a birthday party, and doing simple arithmetic problems in school all make use of this same structure. Discovery of general conceptual structures like the number line would be a strong boon for educators, greatly streamlining their efforts to teach children the basic concepts and skills required by modern society.

From approximately 4 to 8 years of age, children build the central conceptual structure for number. When instructors and curriculum explicitly teach the structure, children evidence a major improvement in performance across a wide array of number tasks but not for tasks in other domains such as understanding social interactions. The change amounts to as much as 50% of the variance in test scores, which is a remarkably large effect. The use of many tasks allowed Case and his colleagues to determine how general the structure is—where children apply it and where they do not. Note also that along with the general change across number tasks, the researchers still found large task effects and considerable developmental variation in level. The generality of the structure operates within this substantial variability.

In the behavioral sciences, researchers commonly wish to generalize from their data to the development of a domain, but the two standard methods preclude legitimate generalization by artificially reducing variation instead of analyzing it. First, in the "psychometric method," commonly used in intelligence, education, and personality testing, many tasks are summed and only the summary scores are considered. A boy's IQ score is 116, or the college entrance test score for a young woman is 575. Most of the variation in each person's performances on the tasks is ignored. Second, in the "experimental method," commonly used in experimental psychology and neuroscience, a researcher analyzes one task by varying a parameter and calculating mean performance differences for specific values of the parameter. Variations in performance in the task other than the means are treated as error variance and not analyzed further. Also, variations among diverse tasks are ignored because only one task is examined.

The psychometric strategy is evident in ability theories, where researchers study some hypothesized general ability such as spatial intelligence or verbal intelligence (Demetriou et al., 2002; Sternberg, Lautrey, & Lubart, 2003). The evidence for the coherence of these supposedly modular abilities is modest in comparison to Case's evidence for a central conceptual structure for number. Most tasks or items that measure each ability or intelligence have only minimal variance in common, with correlations between pairs of items typically accounting for approximately 4% of the variance (an average correlation of .2 between individual items).

Educational researchers have regularly thrown up their hands in dismay that they have found so little generalization or transfer of concepts to tasks that are distinct from those taught (Salomon & Perkins, 1989). For example, when instructors teach a concept such as gravity, evolution, or working memory, they commonly find that even intelligent students have difficulty using the concept in tasks different from those explicitly taught in class. The reason for the difficulty of this far generalization (use of knowledge in tasks far from the original object of learning) is that the construction of generalized skills requires time and effort (Fischer & Immordino-Yang, 2002). Furthermore, even with a strong conceptual structure like Case's number line, generalization is not perfect. For a weak structure such as spatial intelligence or ego resiliency, generalization should not be expected. Learning is not a simple transmission of information through a conduit from one person to another or from one task to another.

Researchers using the second strategy, experimental manipulation of a task, typically restrict their investigations to one task and variations of it. Their intent is to control for extraneous sources of variability, such as task effects, but at the same time, they wish to generalize about broad abilities or concepts such as object permanence (Baillargeon, 1999), the concept of number (Spelke, in press), or working memory (Diamond, 1985). Unfortunately, the cost of restriction to a single task (or even two) is an absence of generalizability of results beyond that task.

When researchers use different tasks to assess a domain, they typically find very different portraits of development for each task. Indeed, many of the central

debates in the study of development center on issues of task difference. When do children really understand object permanence? When do children control the syntax of their native language? When can people think logically? Such questions cannot be answered without examination of many distinct tasks that index the domain of interest. Analysis of the dynamics of variability then becomes possible.

Multiple Assessment Conditions and Social Support: Developmental Range

Even for a single task, a person typically shows vastly different competence with variation in social-contextual support, as demonstrated by the developmental range. Other powerful sources of variation for an individual person in a single task include emotional state, coparticipant, and familiarity with the task and situation. To capture these sources of variation, research should include multiple conditions designed to evoke different levels of performance in each person. It is not legitimate to ignore these variations and claim broad application of a developmental analysis based on one assessment task and condition.

Recall the study of Korean adolescents' conceptions of self-in-relationships, which documented the power of variation in developmental range—the contrast between conditions of unassisted performance (low support) and priming of a task (high support; Fischer & Kennedy, 1997; Kennedy, 1991). The upper limit on individual performance under these two conditions changes powerfully, as shown in Figure 7.8. The gap is robust and cannot be removed by simply increasing training, practice, or motivation. The developmental range illustrated in Figure 7.1 documents this robustness for another domain—nice and mean stories. Performance on these stories shifted repeatedly up to optimal level with high support and down to functional level with low support, and the gap did not lessen with practice, instruction, and motivational manipulations (Fischer, Bullock, et al., 1993).

For a high-support procedure to produce optimal-level performance, it must be designed to sustain appropriate performance and minimize interference. Tasks should be straightforward and well defined, procedures should be familiar to participants, and there should be no incompatible emotional state. Most important, the context should prime high-level functioning, with social priming by a more knowledgeable person often proving especially effective. Successful priming procedures have included demonstrating a task and asking people to imitate it, explaining the gist of a task, and providing a prototype of an effective solution.

The Self-in-Relationships (SiR) Interview illustrates an effective, flexible high-support procedure. Participants built their own tool for priming themselves—a visual representation of themselves in relationships. In addition, an interviewer asked structured questions to prime high-level functioning. First, participants were asked to describe several characteristics of themselves in relation to each of a series of designated people (listed in Figure 7.13). They wrote each description on a Post-It paper and indicated whether it was positive, negative, or of mixed valence. Then they arranged the descriptions on an 18-inch circular self-diagram, placing each self-description within one of three concentric circles that ranged from most important (inner circle) to least important (outer circle). Each student grouped descriptions together on the diagram and indicated relations between groups or individual descriptions. Once the diagram was created, the interviewer asked specific questions to assess four distinct developmental levels from the skill scale. For example, the level of abstract mapping of self-understanding was assessed by asking each student to explain the relation (mapping) of two salient abstract self-descriptions to each other, such as attentive and overjoyful in Figure 7.13.

The SiR was designed to assess functional as well as optimal levels of self-understanding. The low-support condition was given at the start of a session and assessed a person's functional level through the traditional "spontaneous" procedure (McGuire & McGuire, 1982). Without any diagram or supportive questions, participants were asked first to describe what they were like with each of the designated people, to indicate whether any characteristics seemed to go together, and to note those that were opposites. Then they moved on to the high-support condition.

Scholars have often claimed that the collectivist nature of Far Eastern cultures leads people to have no clear self-concept, in contrast to people in the West (Fischer, Wang, Kennedy, & Cheng, 1998; Markus & Kitayama, 1991). Research with traditional Western low-support assessments has seemed to show that the self-descriptions of people in Far Eastern countries are indeed primitive and simple, and that there is little developmental change in concepts of self during adolescence.

This claim illustrates the limitations of one-condition assessments, which ignore the effects of contextual sup-

port on the variability of levels of self-complexity. Because Eastern cultures typically discourage a focus on self in conversation, people are likely to show low levels of self-description unless they are given strong social-contextual support for describing themselves. That explains why the difference between optimal and functional levels was so dramatic in the Korean study (see Figure 7.8). Under low-support conditions, Korean adolescents did indeed show simple, primitive self-descriptions, which they presumably also show in much of their public conversation. High-support conditions, on the other hand, produced complex self-descriptions, comparable in

developmental level to those of U.S. adolescents, although emerging about a year later. The gap between optimal and functional levels appears to be larger in Korean youths than in their U.S. counterparts, probably because of the Korean devaluation of focusing on self.

Sociocultural Variation and Frames of Meaning

A powerful source of variability in developmental pathways is sociocultural context, as reflected by differences across nations, ethnic and racial groups, and social classes (Cole, 1996; Rogoff, 2003; Valsiner, 2001; Whiting & Edwards, 1988). To capture the range of variation in human development, researchers need to assess developmental pathways in distinct cultural groups. Doing research in a different culture usually requires working with a native of that culture to ensure that the research engages the meaning systems of the culture instead of misrepresenting them.

One major dimension of disagreement in developmental science involves generalizing findings to all human beings versus emphasizing cultural differences. Dynamic structural analysis requires analyzing this source of variation instead of assuming either universality or cultural difference. Diverse social groups value different activities, teach different contents, prescribe different roles and norms, and practice different child-rearing practices. A method of raising children that is common in one culture (e.g., Western parents' placing their infants in a separate bedroom to sleep) may be more than unusual in other cultures (the Gusii of Kenya consider Western sleeping arrangements abusive; LeVine, Miller, & West, 1988).

Yet some characteristics turn out to be universal or at least common across many cultures, and others vary greatly (Fischer et al., 1998). The optimal skill levels in development of self-in-relationships, for example, look similar in China, South Korea, Taiwan, and the United States. Also, people tend to view themselves in predominantly positive terms across the same cultures, as is evident with the Korean girl in Figure 7.13 (note the distribution of pluses and minuses). On the other hand, the emotion of shame differs greatly across cultures. Fundamental in Chinese and many other Asian cultures, it develops early in children's speech, is highly differentiated with many different words for shame situations and reactions, and pervades adults' discourse and emotion concepts. That same emotion is treated as being much less important in the United States and Great Britain, where it develops late in children's speech and is minimized in the emotional concepts of most middle-class adults (Li, Wang, & Fischer, 2004; Shaver, Wu, & Schwartz, 1992).

Developmental researchers need to explain such similarities and differences by examining major sources of variation, such as task, assessment condition, emotional state, and culture. Then they need to characterize the variations effectively, relating their findings explicitly to concepts about development and variation. Traditionally, theories of development and learning have been replete with complex conceptions of change and variation processes, but there has been no way to test adequately the process claims, to determine whether the processes specified actually produce the growth patterns predicted. That deficit no longer exists.

Building and Testing Models of Growth and Development

Developmental theories require complex, sophisticated tools for analysis, going beyond the models of linear main effects that have dominated the behavioral sciences. Methods based on nonlinear dynamics, including both dynamic growth models and neural networks, provide powerful ways of representing and analyzing the dynamics of change. These dynamic methods mesh naturally with developmental theories to allow developmental scholars to begin to capture the complexities of human development (Fischer & Kennedy, 1997; Shultz, 2003; Thelen & Bates, 2003), and they can be easily programmed on computers with common software such as Excel.

With these new tools for building models of change, the claims of virtually any theory can be explicitly tested in what van Geert (1994) calls "experimental theoretical psychology." Developmental or learning processes can be represented in equations, and computers can be used to run experiments by varying parameters to test whether the growth functions that the models produce fit theorists' predictions and empirical findings. A model of growth defines a basic growth function or set of functions for each specified component, which is called a "grower." These growth models can simulate not only quantitative growth, such as complexity level, frequency of an activity, or preference but also qualitative developments such as emergence of a new stage, coordination of two strands into one, or splitting of a strand into branches.

One important kind of nonlinear dynamic model represents networks in the brain and nervous system. Re-

searchers have built many neural network models to depict and analyze processes of learning and adaptation that involve coordinating and differentiating activities at one or two levels of complexity (Bullock et al., 1993; Elman et al., 1996; Grossberg, 2000; van der Maas, Verschure, & Molenaar, 1990). For example, word inputs are compared to infer how to make a past tense verb in English. Visual scanning and object characteristics are integrated to infer how an infant looks for objects of a particular type following a specific path. Or visual input and arm-hand control are integrated to produce visually guided reaching.

An important characteristic for evaluating the models is whether they reflect the real architecture of the activities that they represent. Many models use global, generalized programs to analyze the development or learning of an activity. Although these generalized approaches make models easier to design, their structure typically does not closely match the architecture of the real activities. Models that have been constructed specifically to fit the real architecture of the behavior, social interaction, or nervous-system network being modeled have been more successful. For example, the adaptive resonance theory of neural networks has been used to construct models that carefully match the architecture of the nervous system, the body, and the senses (Raizada & Grossberg, 2003). A model of eye-hand coordination is based closely on how eye, hand, and related cortical networks are actually built (Bullock et al., 1993). Many models have paid much less attention to the specific architecture of the activity being modeled. A question to ask in evaluating a model is whether it plausibly reflects the architecture of the activity of interest.

Nonlinear Dynamic Models of Growth and Development

For decades, systems theory and nonlinear dynamics have been popular as broad theoretical interpretations of development (Sameroff, 1975; von Bertalanffy, 1976), but the tools needed for precise developmental analysis were missing. When the computer revolution began to produce a powerful array of new dynamic modeling tools, investigators began with models of a few tractable psychological problems, especially involving motor coordination (Bullock et al., 1993; Thelen & Smith, 1994). Now there is an explosion of dynamic systems research, including diverse models for analyzing activity and its development (e.g., Case et al., 1996; Fischer & Kennedy, 1997; Hartelman, van der Maas, & Molenaar, 1998; Shultz, 2003; van Geert, 1998). Our focus in this chapter is on models of hierarchical growth of action, thought, and emotion. We define basic growth processes for psychological growers and how they are connected in a developmental process.

An important consequence of these new tools is that they lead to more powerful and precise definitions of growth, development, and learning. Traditionally, these three terms for patterns of change have been defined restrictively in terms of directional change, usually, linear increase (Willett, Ayoub, & Robinson, 1991; Wohlwill, 1973). In dynamic structural analysis, they are defined instead by specific *models of change processes*—any systematic mechanism of change, resulting in not only linear increase and decrease but also complex patterns such as increase occurring in successive jumps and dips, or oscillation between limits. Equations specify these growth processes systematically and predict a family of growth curves, often of many different shapes. In common usage, *growth* is the most general term, *development* tends to be used for systematic increase over long time periods, and *learning* typically means short-term increase based on experience. We expect the meanings of the terms to be revised over time as a result of the more precise definitions of change in dynamic models. The most important point for our purposes is that growth, development, and learning are no longer identified by the shape of any one particular curve. There is no need for restrictive definitions such as monotonic increase.

Logistic Growth

The best starting point for growth models is usually logistic growth because most growth processes in biology show this kind of growth. Figure 7.14 shows three examples of logistic growth, all produced by the same basic equation, which generates the S-shaped curve that typifies much simple growth. Note that even this simplest curve is not linear. The model is called *logistic* because the equation includes log values (squares or higher powers of the grower's level).

Many basic growth processes involve this form of growth, where the change at a given time is derived from three parameters: (1) the prior level of the grower, (2) the growth rate of the system, and (3) a limit on the system's growth, called the *carrying capacity.* The term *level* refers to some quantity that a grower has reached, potentially involving a wide array of different characteristics such as developmental level, frequency of response, or amount of activity. In many of our

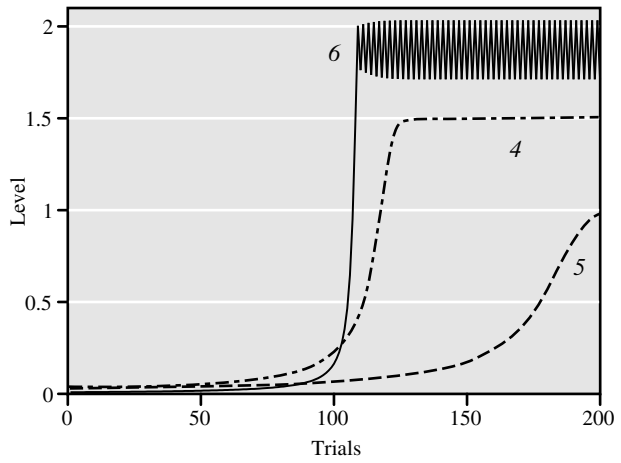

Figure 7.14 Three forms of simple logistic growth.

examples, level *(L)* refers to the complexity of an activity along the skill complexity scale in Figure 7.3, as applied to the development of self-in-relationships (Fischer & Kennedy, 1997). Models have also been built for other domains such as King and K. Kitchener's (1994) reflective judgment, which develops through seven stages that show growth curves similar to those for self-in-relationships (K. Kitchener & King, 1990; K. Kitchener et al., 1993).

By itself, without connection to other growers, the equation produces mostly S-shaped growth, as with Growers 4 and 5 in Figure 7.14. Even without connection, however, there is significant variation in the growth curve, as illustrated by the turbulence in Grower 6 as it nears its carrying capacity. The three growth curves in Figure 7.14 all derive from the same equation, and only values of the growth parameters differ.

Logistic growth equations can take several different forms, and van Geert (1994) recommends the following as the best starting point for modeling hierarchical growth for an action, thought, or emotion, designated as Grower B:

$$L_{B_{t+1}} = L_{B_t} + R_B \frac{L_{B_t}^2}{K_B^2} - R_B \frac{L_{B_t}^3}{K_B^3}$$

$L_{B_{t+1}}$ is the level of Grower B, with subscript t indicating the previous trial, and t+1 indicating the current trial. R_B is the rate of growth of B, specifying the amount of change that occurs in each trial. K_B is the carrying capacity of B, which is the limit on growth that is characteristic of this particular system in this situation.

The equation is divided into three terms, which together produce the level of B in the current trial. The first term is the level in the previous trial. Next is the growth term—the growth rate times the square of the level in the previous trial divided by the square of the carrying capacity. With modest growth rates, this factor produces an increase on each trial. Level is divided by carrying capacity to base growth on a *ratio* with the system's capacity instead of its absolute value, because of an assumption that the level operates as a function of the capacity.

The growth term in this logistic equation squares the ratio of level to carrying capacity, in contrast to a simpler form of the equation, which uses the ratio without squaring. The squared form of the equation seems to represent psychological growth processes more accurately, and that growth depends on the person's prior level in two simultaneous ways: (1) current understanding is built on earlier understanding, and (2) level affects the probability of encountering situations that promote growth. van Geert (1994) elaborates this argument and shows that this form of the growth equation fits individual growth curves better than the squared equation. The growth curve for pronoun use by the Dutch child Tomas in Figure 7.12 fits this version of the equation well, but not the nonsquared version (Fischer & Kennedy, 1997; Ruhland & van Geert, 1998).

The third term provides a form of regulation based on the limits of the system. Without some limit, the level will eventually explode to ever larger quantities. In real biological systems, there is always some limit, based on the availability of food, space, energy, and the like. The regulation term subtracts an amount to limit the system based on its carrying capacity and keeps it from exploding. The amount subtracted is the product of the growth term (the second term in the equation) multiplied by the ratio of the level to the carrying capacity. The result is the cubing of level, which leads to this equation being called the *cubic* logistic equation. (The simpler equation is called the *squared version.*) When the current level is low in relation to carrying capacity, little is subtracted; but when the current level rises, the amount subtracted becomes larger. As the level approaches the carrying capacity, the amount subtracted becomes large enough to cancel out growth, and thus the level approaches the carrying capacity as a limit. This growth process does not always produce smooth S-shaped growth, however. When the growth rate is high, the level can show turbulent fluctuations as the level approaches the carrying capacity, illustrated by Grower 6 in Figure 7.14. Note, in

Figure 7.12, that Tomas's development of pronoun use also evidenced this turbulence as his use grew rapidly to a high level. Turbulence is a common property of dynamic systems when they grow very rapidly.

Growth can be characterized with other kinds of equations, most obviously with differential calculus instead of the difference equations that we are using. Differential equations assume that feedback for change is instantaneous and continuous in time, whereas difference equations assume that feedback occurs between discrete events such as social encounters or learning situations. The assumption of discrete events seems appropriate for most psychological development and learning. Also, differential equations are mathematically complex and difficult to work with, whereas difference equations can be used easily in any computer spreadsheet program by using recurrent trials (similar to what is required for calculation of mortgage payments). van Geert (1994) provides step-by-step guidelines on how to use a spreadsheet program to build a dynamic model. Singer and Willett (2003) describe another class of growth models based on linear assumptions, and they also provide step-by-step guidelines for use.

Connections among Growers

Any single activity is affected by many different components and influences coming together. In a growth model, each component (grower) is represented by a growth function, and all growers can be connected within the set of growth functions. Modeling a grower starts with a growth function like the first equation, and connections are built around that function. The connections range from strong to weak to nonexistent, and the ways that they affect growth take many different forms. Connections between growers can involve aspects of the person acting alone, or they can be between people, as in a teacher-student relationship (van Geert, 1998).

Different combinations of components can produce different growth curves. With dynamic systems, however, even the same combinations can produce widely different growth functions. Shapes as diverse as monotonic growth, successive stagelike change, and chaotic fluctuation can all arise from the same set of equations. Growth curves 1, 2, and 3 in Figure 7.11 all arise from the same nonlinear hierarchical model of development of self-in-relationships for five relationships, each with five developmental levels (Fischer & Kennedy, 1997). Despite the great differences in their shapes, only the values of the parameters in the equations differ. The same growth processes produce virtually monotonic growth (Grower 1), growth with stage-like spurts and drops (Grower 2), and fluctuating change (Grower 3).

The strongest form of connection among growers is hierarchical integration, where each successive step within a strand in the developmental web builds on the previous step. In one example of such integration, two strands come together to form a new single strand such as when an adolescent girl compares herself in two relationships. The 15-year-old Korean girl represented by the diagram in Figure 7.13 compared what she was like at school (being attentive, enjoying school) with what she was like with her best friend (feeling valuable, being overjoyful). She built a mapping for those characteristics of the two relationships. The model of the strand for each relationship uses a skill scale of five hierarchical growers built successively on each other—Growers A, B, C, D, and E. A grower later in the sequence starts only after the level of the immediately prior grower, the prerequisite, has become sufficiently strong and frequent for a person to begin to build on it. When the girl coordinates her characteristics at school with those relating to her best friend, she is coordinating two strands, each with five hierarchical growers forming a five-level scale.

In this prerequisite connection, the prior grower must reach some specified level *P* before the later grower can begin to change:

$$L_{B_{t+1}} = L_{B_t} + P_{B_t}\left[R_B \frac{L^2_{B_t}}{K^2_B} - R_B \frac{L^3_{B_t}}{K^3_B}\right]$$

P_{B_t} is the *precursor function* for Grower B at time *t* based on the level of the prerequisite Grower A:

$$\text{If } L_{A_t} < p,\ P_{B_t} = 0;\ \text{If } L_{A_t} > p,\ P_{B_t} = 1$$

Before Grower A has reached its prerequisite level *p* at time *t,* such as .2, precursor P_B is 0, and Grower B does not grow. When Grower A reaches .2, precursor P_B becomes 1 and Grower B starts to grow. Specification of the precursor function can be more complex than simply one trial at .2. For example, Grower A might need to stay at .2 for some number of events or trials before Grower B starts to grow; or two different prerequisite Growers, A_1 and $A_{2,}$ might both have to reach a specified level.

In addition to strong hierarchical connections among growers, there are also weaker connections, both within and between strands. These weak connections can be difficult to detect at any one moment, but in growth models they often cumulate, either from repeated action over many occasions or from multiple connections working together at the same time. These weak connections then become powerful determinants of the shapes of growth.

One common kind of weak connection is competition, in which growth in one component or strand interferes with growth in another. For example, trying to relate two opposing characteristics of the self, such as feeling comfortable and feeling uneasy, may interfere with earlier understandings of the characteristics themselves. Another common connection is support, in which growth in one component or strand promotes growth in another. Understanding how the real me is shy can facilitate the girl's understanding of why she is awkward with a boyfriend (Rom for Romantic in Figure 7.13). Connections of competition and support occur both between successive growers (levels within a strand) and between domains (relationships or strands). We use within-strand between-level connections to illustrate the processes. Fuller explications are available from van Geert (1994) and Fischer and Kennedy (1997).

As grower C begins to grow along the strand, it competes with grower B, as with feeling comfortable and feeling uneasy. In this model, the competition process is the product of a competition parameter times the change in Grower C on two successive trials divided by the level of C on the prior trial. This term is subtracted from the growth equation for Grower B:

$$-Cb_{C\rightarrow B}\frac{L_{C_t}-L_{C_{t-1}}}{L_{C_t}}$$

where $Cb_{C\rightarrow B}$ is the parameter specifying the strength of the competitive effect of Grower C on Grower B. The competition parameter specifies the strength of the competition effect. Large values of parameters of competition and support can cause major perturbations in growth, including crashes and explosions. Ordinarily, the values are small, which reflect the weakness of these connections.

In this model, the competition is a function of the change in the level of Grower C relative to its prior level, not the level by itself. The rationale for this form of competition is that the amount of change involved in growth is posited as the major source of competition, not the absolute level of skill. For example, when an adolescent is working to construct an abstract mapping for comparing her feelings of being comfortable with her mother to her feelings of being uneasy, her new understanding is likely to disrupt her prior understandings temporarily until she can work on the understanding for a while. In addition, the time and effort she spends on building that understanding competes with further learning of her skill at the prior level because that time is used up. That is how Grower C competes with Grower B as a function of the change in level, not the absolute level itself.

Support of Grower B by Grower C in this model takes a different form—the product of a support parameter times the level of Grower C divided by the carrying capacity of C. This term is added to the growth equation for Grower B:

$$+Sb_{C\rightarrow B}\frac{L_{C_t}}{K_C}$$

where $Sb_{C\rightarrow B}$ is the parameter specifying the strength of the supportive effect of Grower C on Grower B. For example, when an adolescent relates the shyness of her "real me" with her awkwardness with a boyfriend, the relating of the two characteristics can facilitate the separate lower-level understandings of the shyness and the awkwardness. This support from higher growers turns out to be important in producing developmental spurts in growth curves. For many parameter values, it promotes the occurrence of growth patterns like the succession of spurts seen in Figures 7.7 and 7.11 and thus helps explain empirical findings of successive spurts in growth curves like that for the self-in-relationships study.

Addition of the between-level support and competition processes to the second equation provides this connected growth model for Grower B:

$$L_{B_{t+1}}=L_{B_t}+P_{B_t}\left[R_B\frac{L_{B_t}^2}{K_B^2}-R_B\frac{L_{B_t}^3}{K_B^3}+Sb_{C\rightarrow B}\frac{L_{C_t}}{K_C}-Cb_{C\rightarrow B}\frac{L_{C_t}-L_{C_{t-1}}}{L_{C_t}}\right]$$

Each successive level in the hierarchy involves a similar growth equation, and together the equations for the five levels constitute a growth model for one strand of self-in-relationships. The complete model includes five separate relationships (strands), each with connections of support and competition among them as well, and the between-

strand competition and support are defined differently from those within level (Fischer & Kennedy, 1997).

These various connections among growers have powerful dynamic effects on the shapes of growth and development. The confluence of multiple types of connections turns out to be important for determining the many shapes of development.

Equilibration, Disturbance, and the Shapes of Development

If the self-in-relationships model is correct, it should produce growth curves like those obtained in the self-in-relationships study for optimal and functional levels, as well as a number of other kinds of growth curves of interest to generate questions for further research. Processes such as equilibration, disturbance, regression, and turbulence can be explored with the model.

The empirical results for development of self-in-relationships in South Korea include a striking difference between optimal and functional levels, as shown in Figure 7.8, where the measure is the highest level obtained for the entire interview. Under optimal conditions, students showed relatively rapid growth as well as two successive spurts in understanding. Under functional conditions, they underwent very slow, monotonic growth.

The model produced growth patterns similar to the empirical ones, with analogous differences between the levels and shapes for high- and low-support assessments. Figure 7.15 presents growth curves generated by the model under high- and low-support conditions. Note that the contextual support referred to in high and low support is different from the support between growers in the model. Contextual support is not included directly in the model, but is varied through the parameter of growth rate. All parameter values for the curves in the figure are the same, except that high-support growers have a high rate and low-support growers have a low one. With differences in rate alone and no other differences among the equations, the shapes shift from strongly stagelike hierarchical growth to more mono-tonic and variable growth. All the high-support curves approximate the empirical curve for self-in-relationships under high support. The low-support curves for relationship 3, which has the slowest growth rate, approximates the empirical curve for low support. Included in the variability of some of the low-support curves is a jump or drop, which presumably represents likely growth patterns when the growth rate is a little higher than it was in the Korean sample. In general, low rates produce relatively monotonic growth, and high rates produce a series of discontinuities (spurts and drops).

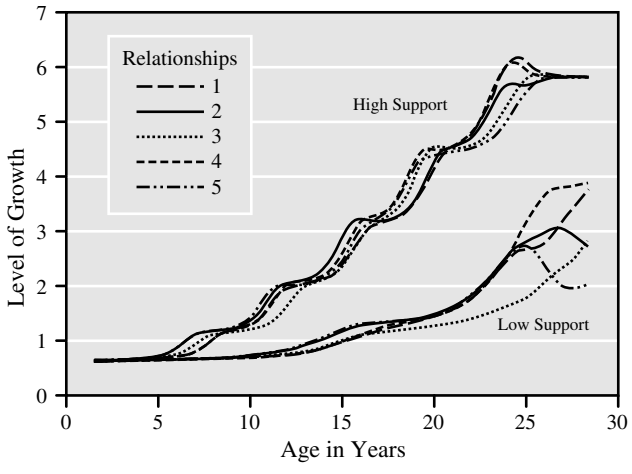

Figure 7.15 Growth model for development of self-in-relationships: Optimal and functional levels for five relationships and five hierarchical levels.

This change from growth through a series of discontinuities to growth that is variably monotonic defines a broad set of the growth patterns for the model, but the model also produces other patterns. For example, in Figure 7.11, which shows curves generated by the same model, Growers 1 and 2 represent similar variation from discontinuous to more monotonic growth. However, Grower 3 represents a more unstable pattern, which is common when the growth curves are less stable or equilibrated.

According to Piaget (1985) cognitive development is usually equilibrated—regulated to produce a series of successive equilibria (times of stability) marking the stages in his developmental hierarchy. Spurt-and-plateau growth patterns like those for high-support growers in Figure 7.15 show an equilibration process, in that the growers for different domains tend to seek the same levels—what is referred to as an *attractor* in nonlinear dynamics, because there seems to be something pulling the curves toward a common place. For example, when one grower moves higher than the others, which can be construed as a disturbance from equilibrium, it is pulled back toward the common level. At the same time, the growers for functional level do not show any clear attractor—no tendency to seek the same level.

This pattern is also called U-shaped growth because of the decrease after each spurt—which scholars have often puzzled about (Strauss, 1982). The U shape

is especially dramatic in Grower 2 in Figure 7.11. In these dynamic growth models and in empirical research on optimal levels, peaks of growth are often followed by drops. By experimenting with the full range of possible values of the parameters in the model, Fischer and Kennedy (1997) determined that the support among multiple domains (relationships) in the model caused this pattern through growers catalyzing each other's growth and thus producing an overshoot beyond the carrying capacity of the system. Such complex effects from connections among growers are one of the hallmarks of dynamic systems.

Orderly equilibration is a quality of one class of hierarchical growth curves, but there are many forms that show no such order. Besides curves like those for low support in Figure 7.5, many growth functions spread disturbances throughout a system of growers. Sometimes, these disturbances lead to growth patterns like the one shown in Figure 7.16, which we call the Piaget effect. When Piaget (1950) criticized efforts to speed up children's early development, he suggested that pushing them beyond their natural levels was like training animals to do circus tricks. Instead of contributing to their normal growth, it could lead to stunted long-term development like what happens in some circus animals. The model and growth parameters in Figure 7.16 are the same as those for optimal levels in Figure 7.15, except that Domain 2 was given a special one-time boost to its growth rate at the second level, analogous to special training to produce precocity. The boost caused Domain 2 to immediately grow to higher levels than the other domains, but over time the other domains grew more and

Figure 7.16 The Piaget effect: Disturbance of development caused by early speeding up of growth.

Domain 2 ended up at a much lower level. Also, the five domains stopped showing equilibration with each other and instead spread out across a wide range of levels. In this way, a short-term boost in one grower disturbed the entire system, changing the growth patterns of all the growers it was connected with.

The Piaget effect is still an orderly pattern. Sometimes, the growers in this and related hierarchical models show much wilder disturbances, including crashes, explosions, and turbulent vacillations, analogous to the turbulence produced by the simple logistic growth formula with Grower 6 in Figure 7.14. In this way the same growth processes produce a full range of shapes of development from monotonic growth to stagelike equilibrated growth to disturbed growth and turbulent variation. Some of the growth functions of these hierarchical growth patterns even seem to fit the properties of catastrophe and chaos (van Geert, 1994). These are truly nonlinear systems, and they provide a powerful tool for facilitating description and analysis of the many shapes of human development.

Van der Maas and Molenaar (1992) hypothesize that developmental reorganizations marked by shifts to a new skill level reflect an especially important property of change according to catastrophe theory—hysteresis, in which during a time of major change the point of jumping to a higher or lower level shifts depending on the direction of variation in a control parameter. For example, the temperature at which water freezes when heat is removed differs from the temperature at which ice melts when heat is added. Candidates for hysteresis effects in psychological development include contextual support and emotional state. With changes in these factors, shifts to higher or lower levels would vary more dramatically during a time of transition between levels than later when the level had been consolidated.

A wide array of nonlinear dynamic tools is available for tying down developmental processes and analyzing change, and much work remains to be done to apply them to analysis of development and learning. Many of them were devised in biology to deal with the ecology of species interactions and the dynamics of long-term evolution (Holland, 1992; Kauffman, 1996; Wolfram, 2002). A few scholars have even begun to apply nonlinear concepts to social phenomena such as how people work together to construct their own development (Fogel & Lyra, 1997; Nowak, Vallacher, Tesser, & Borkowski, 2000). A particularly promising area for advancing

methods and theories of development is the study of transition mechanisms in microdevelopment of both individuals and social ensembles.

BUILDING STRUCTURES: TRANSITION MECHANISMS, MICRODEVELOPMENT, AND NEW KNOWLEDGE

Because the study of development is the study of change, any adequate account of the development of psychological structures must provide credible explanations of the transition mechanisms by which a constructive agent develops from structures at a given level to more complex, inclusive, and differentiated structures. Recent advances in methods for task analysis in general and microdevelopmental analysis in particular have moved the field beyond the vague descriptions of transition mechanisms of the past. The outlines of a constructivist model of task- and context-specific developmental transitions are emerging. This methodology promises to provide answers to a key question that cognitive scientists have puzzled over: How do people construct new knowledge, building novel understanding out of existing skills (Granott et al., 2002; Gruber, 1973)?

The study of transition mechanisms is closely associated with the concept of microdevelopment (also called microgenesis). *Microdevelopment* is typically defined as the study of developmental change over short time periods, spanning minutes, hours, days, or weeks rather than months or years. Studying processes of change over short periods produces fine-grained data about the course of transitions as they occur (Granott & Parziale, 2002), which is not possible with the widely spaced observations of traditional cross-sectional and longitudinal developmental studies.

Relations between Micro- and Macrodevelopment

An important advantage of dynamic structural analysis is that it provides a way of relating short-term and long-term change. Past approaches have tended to take either long-term development or short-term microdevelopment (learning) as central, either reducing one type of change to the other or emphasizing one and neglecting or dismissing the other (Piaget, 1950; Skinner, 1969). They have been caught in the problematic unidimensional assumptions about developmental methods and concepts that we outlined earlier.

Microdevelopment is the set of short-term processes by which people construct new skills for participation in specific contexts, which Vygotsky (1978) called "proximal processes." Macrodevelopment describes the larger-scale processes in which many local constructive activities in different contexts and domains are gradually consolidated, generalized, and related to form the big, slow changes of development over long periods.

The image of the developmental web in Figure 7.9 illustrates this approach to micro- and macrodevelopment. The microdevelopmental processes by which specific skills are constructed in specific contexts are represented by the strands of the web shown under construction (dashed and dotted lines). At any given time, many strands are under construction, and the strands follow different developmental pathways for different contexts and with different coparticipants. The shifts from optimal to functional and from functional to scaffolding levels begin at different developmental points along the scale on each strand and span several levels in the developmental range for that strand, as shown in Figure 7.9 as well as Table 7.1 and Figures 7.1 and 7.8.

Stepping back a bit, scanning across the developmental web presents a broad picture of macrodevelopment. Whereas each small piece of each strand entails microdevelopment, the collection of processes involved in constructing the web as a whole constitutes macrodevelopment, which is not simply an atomistic heap of many microdevelopmental processes but the cumulative process in which all the micro processes participate. In this sense, micro and macro processes are intrinsically related and interdependent in a way that is analogous to the molecular and subatomic worlds. Neither can exist without the other, but neither can be reduced to the other. At the microdevelopmental level of analysis, we find some phenomena that do not appear at the macrolevel, and vice versa.

An important macrodevelopmental phenomenon is the clustering of discontinuities with developmental levels, the intervals in which jumps, drops, and reorganizations in skills co-occur across strands (domains), labeled "emergence zones" in Figure 7.17. This phenomenon captures the kernel of truth in stage theories—what allows people experienced with children to predict accurately, before they have ever met a child, most of the skills the child will be able to use. Examined up close (microdevelopmentally) the web shows enormous variability in performance, but examined from a distance, there is relative

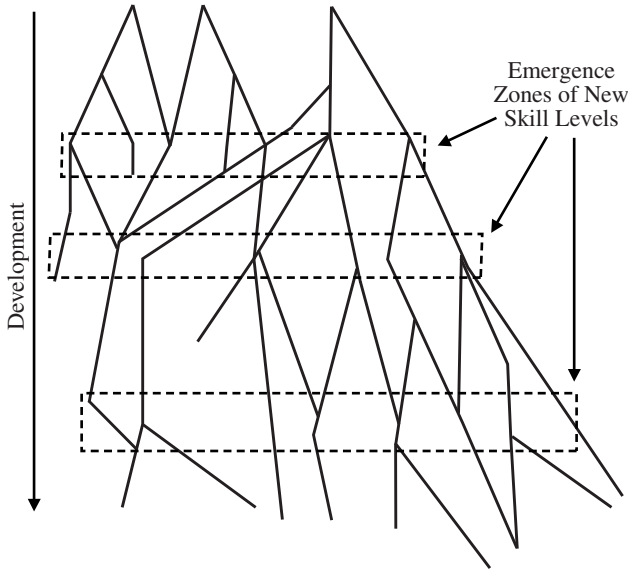

Figure 7.17 Developmental web with concurrent discontinuities across strands. The boxes show three zones of concurrent discontinuities. Additional zones occur earlier and later in the web.

consistency in emergence of a level. For example, understanding of self-in-relationships spurts in individual adolescents at approximately 15 to 16 and 19 to 20 years in macrodevelopment, but microdevelopmental analysis of changes over hours, days, and weeks shows each individual gradually constructing these new skills.

The clustering of discontinuities in macrodevelopment arises not from a mysterious underlying stage structure but from the dynamics by which people build skills through the integration of earlier components in a gradual process with constraints. The constraints include sociocultural meanings and settings (Rogoff, 2003; Whiting & Edwards, 1988), biological changes in neurological and anatomical supports for skills (Carey & Gelman, 1991; G. Dawson & Fischer, 1994; Fischer & Rose, 1996), and the limits that available time places on the speed and scope of skill construction. These same dynamics also cause the opposite pattern—major disparities in ages of skill emergence in some domains under some circumstances, as shown in Figures 7.10, 7.15, and 7.16.

Developmental clustering is a macrodevelopmental phenomenon that does not appear directly in microdevelopment. Yet it arises from the combination of microdevelopmental processes in many contexts leading to clusters of discontinuities for each developmental level. Conversely, macrodevelopmental constraints limit microdevelopmental processes at any given time because people build on skills they have accumulated over time and have upper limits on complexity reflected in functional and optimal levels. Full understanding of developmental transitions thus requires studying the relations between micro- and macrodevelopment.

Construction Processes: From Micro to Macro

A major obstacle to studying the relations between micro- and macrodevelopment has been an absence of research methodologies for including both levels of analysis in one study. Conceptual frameworks and research methodologies for the study of short- and long-term change have grown up independently. On the one hand, macrodevelopment has been studied mainly in terms of the broad structural models of Piaget (1983, 1985), Werner (1948), and the experimental/psychometric approach focusing on input and output (Horn & Hofer, 1992; Klahr & Wallace, 1976). Typically, research has used cross-sectional or longitudinal methods to describe the successive forms of psychometrically scaled performance or mental structure at widely spaced points over the life span. Such approaches make no reference to the everyday short-term functional adaptations that lead to long-term changes.

On the other hand, microdevelopment has been studied as a process of relatively immediate functioning in adaptation to specific environments. Whether such adaptations are conceived as individual learning (Bandura, 1977; Skinner, 1969) or as internalization of between-person control (Rogoff, 1990; Vygotsky, 1978), researchers taking functional approaches have done little analysis of long-term structural change.

Contemporary task-analytic methods make it possible to overcome this methodological divide and study the ways that short- and long-term reorganizations relate within a common framework (Goldin-Meadow, 2003; Granott & Parziale, 2002; Miller & Coyle, 1999; Siegler & Crowley, 1991). Common scales and concepts make it possible to describe psychological organization in terms of executive control structures for specific tasks, contexts, and collaborations, thus relating micro- and macrodevelopment. The skill complexity scale makes it possible to use the same scale (Figure 7.3) to analyze both microdevelopment and macrodevelopment. Researchers can relate changes in children's short-term performance on a task, such as problem-solving efficiency, strategies, and errors, directly to

changes in hierarchical organization of control structures for performance.

This research has led to advances in our understanding of (a) the central transition mechanism of co-occurrence or shift of focus, (b) gradual construction of new structures through building, repetition, and generalization as evidenced in the shapes of growth curves, (c) microdevelopment from novice to expert in a domain, and (d) the process of bridging by which people bootstrap themselves to higher-level new skills.

Shift of Focus in Transitional States

A fundamental mechanism of transition in hierarchical integration is co-occurrence or shift of focus (Fischer, 1980b). Research across dozens of different tasks in several laboratories have converged on this common microdevelopmental phenomenon: When individuals are beginning to develop a new skill, they shift between two different representations or two different strategies, each of which is only partly adequate to the task (Bidell & Fischer, 1994; Goldin-Meadow, 2003; D. E. Gottlieb, Taylor, & Ruderman, 1977). Piaget (1952) and Baldwin (1894) described transitions as involving *groping,* in which children search intuitively for ways of combining and differentiating skills in a new form. For example, just before coming to understand conservation of liquid in containers of different shapes, children often represent the height of the liquid verbally while simultaneously representing the width in gesture (or vice versa). A few days or weeks later, they have integrated the two dimensions to form a skill for conservation, taking a major step in an important macrodevelopmental achievement. Goldin-Meadow and her colleagues (1993) have shown that such dual representations dependably indicate a transitional state in the development of skills such as conservation and mathematical equivalence. This transition process occurs in emotional development as well where opposites such as nice and mean routinely co-occur in children's activities when they are working on integrating these opposites (Fischer & Ayoub, 1994; Harter & Buddin, 1987).

Many transitions involve such construction of new skills from co-occurring components, although many also involve a change in the mixture of skills or strategies applied to a task (Siegler & Jenkins, 1989). The diverse studies of co-occurrence provide a new before-and-after picture of transitions: At first, a person concurrently uses less adequate skills for a given task, and that co-occurrence instigates groping to differentiate and integrate the skills to form a new hierarchically inclusive skill that is more adequate to the task.

Shapes of Growth Curves in Construction and Generalization of New Skills

Microdevelopmental analysis illuminates the real-time process of coordination and differentiation of the co-occurring skills to form a new skill. Individual growth curves are analyzed, not combinations of standardized data from many students (Estes, 1956; Fischer, 1980a; Granott & Parziale, 2002; Siegler & Crowley, 1991; Yan & Fischer, 2002). Changes in learning and generalization can be analyzed and compared across skills and tasks, tracing, for example, the progress of generalization of new knowledge to different tasks and contents by individual students or ensembles. Commonly, the progress of learning can be directly detected, including the nature of construction of a skill and the generalization of that skill to new situations. The skill complexity scale in Figures 7.3 and 7.4 greatly facilitates the research by providing a common scale for comparison of growth of diverse skills.

A key tool for analysis is the shapes of growth curves. In everyday learning activities, people produce complex growth patterns, with activities that differ widely in complexity, varying from moment to moment within a range that does not show simple upward progression. With the insights of dynamic systems theory, many cognitive scientists recognize that complex trajectories capture the true shapes of learning and development. Real-time trajectories do not move along a straight line, but instead they typically fluctuate up and down within a range that reflects constraints.

Analysis of growth curves shows a prototypic pattern for building and generalizing a new skill: People build a skill and then repeatedly rebuild it in a wavelike pattern of construction and reconstruction, not in a straight line or monotonic upward progression. Encountering a new task or situation, people first move down to a low level of complexity as illustrated in Figure 7.18, using basic skills similar to those of young children. They then gradually build a more complex skill for coping with the task by repeatedly rebuilding it with variations (Fischer et al., 2003; Granott, 2002). That is, when they encounter some change in the narrow context, their skill collapses and they regress back to a low level and then rebuild the skill again in this new context. With naturally occurring changes in context or state, their skill collapses over and over, and they adapt and rebuild it each time in a different way. This pattern is often called

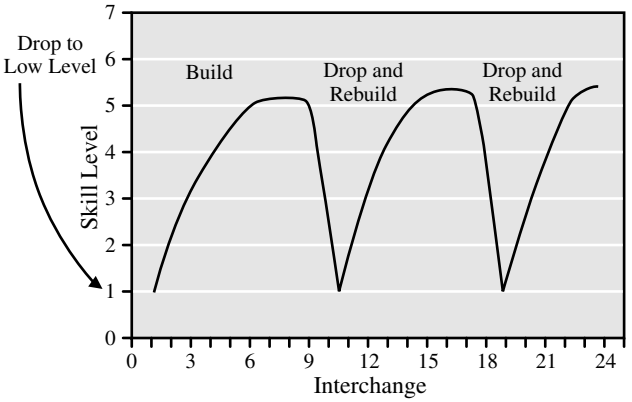

Figure 7.18 Building a new skill through repeated reconstruction, or scalloping. *Source:* From "Adult Cognitive Development: Dynamics in the Developmental Web" (pp. 491–516), by K. W. Fischer, Z. Yan, and J. Stewart, in *Handbook of Developmental Psychology,* J. Valsiner and K. Connolly (Eds.), 2003, Thousand Oaks, CA: Sage.

"scalloping," as in Figure 7.18, because it builds gradually and then drops, forming the approximate shape of a scallop shell. Through this slow process, people gradually build a more general skill that they can sustain across a set of variations in context. Scientists have described this process extensively for infants and young children, where it is called a "circular reaction," (Piaget, 1952; Wallon, 1970), but it occurs at all ages in new learning situations (Fischer & Connell, 2003).

Figure 7.19 illustrates this phenomenon in a dyad of graduate students learning a new skill in a study by Nira Granott (1994, 2002). Ann and Donald were trying to understand a Lego robot that changed its movement in response to light. (The study was done when Lego robots were under development at the Media Laboratory at MIT before they were available in toy stores.) Ann and Donald knew nothing about how the robot worked or what it responded to. They tried to figure out what it was and how it functioned. Beginning at a very low level of complexity in understanding the robot, they worked closely together over a period of half an hour to gradually build a more complex shared understanding of the robot. Their understanding of how the robot moved across the floor fluctuated in skill complexity, as shown in Figure 7.19, starting from primitive egocentric actions that confused the robot's properties with their own actions and moving to complex representational systems that specified the robot's concrete characteristics.

Instead of a single upward trend toward a more adequate understanding, Ann and Donald's skill was fragile, building and collapsing several times, as illustrated by the panels marked by dashed vertical lines in Figure 7.19. Seemingly small changes in the situation led to collapse of their skill to low levels, marked by egocentric actions that confused their own activities with properties of the robot. After each collapse they rebuilt their understanding again. After their initial growth of skill (first panel: Start), a wire fell out of the robot, and they unknowingly placed it back in a different socket, producing a different response in the robot. With this change in the robot, their skill level plummeted, and they began again (second panel: Redo Wire 1). Then someone else joined them and asked what they were doing. In response to the need to explain their actions, their skill collapsed to a low level again, which they gradually built up again over several minutes (third panel: Summary). After finishing their explanation they purposely removed a wire from the robot and placed it

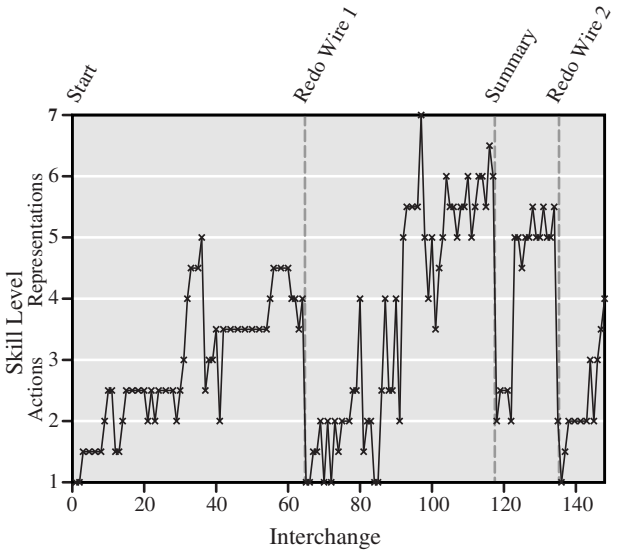

Figure 7.19 Microdevelopment of understanding a Lego robot: Repeated reconstruction of skill. A dyad, Ann and Donald, worked together to understand a Lego robot that changed movement in response to light. Their joint problem solving involved repeated reconstruction, as they moved through four construction episodes in a half hour. *Source:* From "Microdevelopment of Co-Construction of Knowledge during Problem-Solving: Puzzled Minds, Weird Creatures, and Wuggles," by N. Granott, 1994, *Dissertation Abstracts International, 54*(10B), p. 5409; and "How Microdevelopment Creates Macrodevelopment: Reiterated Sequences, Backward Transitions, and the Zone of Current Development" (pp. 213–242), by N. Granott, in *Microdevelopment: Transition Processes in Development and Learning,* N. Granott and J. Parziale (Eds.), 2002, Cambridge, England: Cambridge University Press.

in a different socket. Once again their skill collapsed and had to be rebuilt (fourth panel: Redo Wire 2).

Notice that this study involved a dyad working together, not separate individuals solving a problem. Many studies of microdevelopment benefit from analyzing learning in such social situations. Not only is the social setting more natural and ecologically valid, but it provides a richer source of data for analyzing learning. Collaboration makes the learning process more visible, as students communicate in ways that externalize the learning process (verbal exchanges, gestures, joint activities). Individuals working by themselves do much less externalization of learning, making it more difficult for researchers to study how they learn.

In summary, repeated building and collapse with changes in the situation show the fragility of new skills, which are usually difficult to generalize (Fischer & Immordino-Yang, 2002; Salomon & Perkins, 1989). Minor changes in the situation cause the skill to fall to a low level and require reconstruction, as shown in the scalloping model in Figure 7.18. We propose that this process of repeated rebuilding is an essential mechanism for creating a generalizable skill.

Learning Takes a While: Growth from Novice to Expert

Building new, generalizable skills usually takes a long time, especially for domains that are taught in school and valued in society such as literacy, mathematics, science, and art. Becoming an expert in a field typically requires 5 to 10 years of learning (Ericsson & Charness, 1994; Gardner, 1993; Hayes, 1985). Creating new general knowledge in a field likewise takes a long time, as when Darwin built the outline of the theory of evolution over a period of 8 years (Gruber, 1981), and then spent the rest of his life generalizing and differentiating it for dozens of topics in biology. Becoming an expert on a task or in a smaller domain may be accomplished in weeks or months, but it still takes time.

Novices and experts show distinct patterns of microdevelopment in their approach to a task, and as people move from novice to expert they produce an intermediate pattern that is equally distinctive. In a microdevelopmental study of graduate students learning to use a computer to calculate simple statistical operations such as the mean of a data set, students showed the three patterns in Figure 7.20 (Fischer et al., 2003; Yan, 2000; Yan & Fischer, 2002). Novices produced erratic, chaotic growth curves, shifting frequently between high and low skill levels as shown in the top row. Students with intermediate skill showed the scalloping pattern, building and sustaining a more complex skill for more than one interchange, as illustrated in the middle row, as well as Figures 7.18 and 7.19. Experts often began at a low level but moved quickly to a skill level appropriate for the task at hand and mostly remained there except for occasional brief drops with mistakes or confusions.

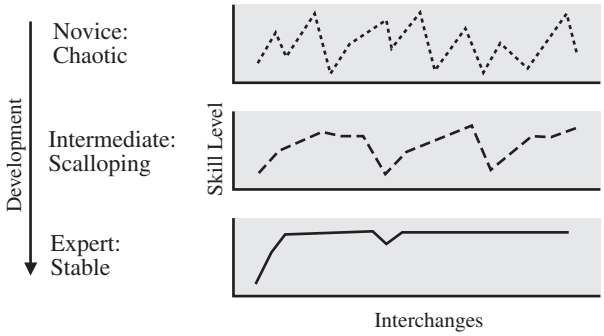

Figure 7.20 Growth curves for novice, intermediate, and expert skill use. *Source:* From *Dynamic Analysis of Microdevelopment in Learning a Computer Program,* by Z. Yan, 2000, Unpublished Doctoral Dissertation, Harvard Graduate School of Education, Cambridge, MA; and "Always under Construction: Dynamic Variations in Adult Cognitive Development," by Z. Yan and K. W. Fischer, 2002, *Human Development, 45,* pp. 141–160.

Across four assessments during the one semester course, approximately 40% of the students progressed from novice to intermediate patterns or from intermediate to expert. (Some of the students also showed backward movement from intermediate to novice patterns, apparently becoming confused as the course progressed from simpler to more challenging tasks.) Patterns of growth curves in learning and problem-solving situations thus provide straightforward ways of assessing how people build skills in the short term as well as how those skills relate to long-term development and expertise.

Multiple Dimensions of Learning and Development

Uncovering patterns of microdevelopment like those in Figure 7.20 requires observing the strands along which people are learning new skills. Growth commonly occurs along multiple concurrent strands and threads within strands, some of which show learning and some of which do not (Fischer & Granott, 1995). A given activity does not occur only on one dimension or at one developmental level but at different levels along different cognitive and emotional strands.

In the robot study, for example, Ann and Donald showed two separate but related strands intertwined in the same activity—understanding the robot and verbal communication with each other—which produced strikingly different patterns of growth. In contrast to the scalloping pattern for understanding the robot, the verbal strand showed a consistently higher level of skill and no systematic change over the course of the session, as shown in the top, dashed line in Figure 7.21 (which shows interchanges for only the first panel from Figure 7.19). Ann and Donald maintained effective representational communication during their joint problem solving but showed no systematic growth in the complexity of that communication. At the same time, their understanding of the robot (which was evident through their communication) did show systematic change, forming a scalloping pattern. A superficial analysis of the verbal interactions between Ann and Donald would have missed the process of understanding the robot and showed a relatively flat, stable trajectory in their representational communication, with some fluctuation but no learning. Activity involves multiple, simultaneous strands (dimensions) that are genuinely distinct aspects of the same activity, and in a learning situation only some of these strands demonstrate systematic change.

An important ancillary point is that these students were capable of higher levels of skill than they showed in either strand. Based on their performance in graduate courses and their ages, they were capable of using complex abstract skills, at least mappings at Level Ab2 and systems at Level Ab3, but they did not show these levels in their activities with the robot. People use the skill levels that are required for a task and do not employ the higher levels of which they are capable unless the situation demands it.

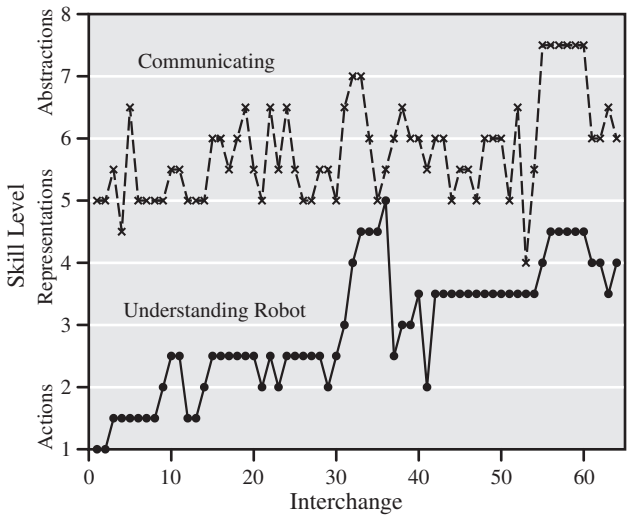

Figure 7.21 Two strands in Ann and Donald's first problem-solving sequence. *Source:* From "Beyond One-Dimensional Change: Parallel, Concurrent, Socially Distributed Processes in Learning and Development," by K. W. Fischer and N. Granott, 1995, *Human Development, 38,* pp. 302–314.

Detecting the dynamic nature of learning in microdevelopment requires (a) finding the strands or threads that are growing and (b) distinguishing them from the ones that are merely varying without growing. Methods that recognize the multiple levels of functioning in an activity facilitate distinguishing these different threads and thus uncovering microdevelopment. With such methods, it becomes possible to see how people build skills from low levels and how they rebuild them repeatedly to generalize and consolidate them. Generally, the complex webs of macrodevelopment derive from these microdevelopmental strands, which grow, join, and separate to produce nonlinear long-term development of skill and understanding.

Bridging: A Process of Building New Knowledge

One of the mysteries of learning has been that people somehow build knowledge that is *new* for them. That is how different people end up with very different knowledge. The origins of new knowledge have puzzled philosophers for centuries (Kant, 1958; Plato, 1941) and continued to puzzle twentieth-century scholars (Fodor, 1975). When people appear to have no knowledge of, say, a Lego robot's functioning, how can they build new knowledge of the gadget? How can they build new knowledge out of nothing?

The reason for this dilemma lies (again) in the limitations of the paradigm of structure-as-form. People do not build new knowledge from nothing! It only seems that way because scholars assume that people function at only one level of knowledge. In fact, people function at multiple levels, and so they can use one level of functioning to direct their activities at another level. They can build up new knowledge by using old knowledge from other contexts to bootstrap themselves (Dunbar, 2001; Kurtz, Miao, & Gentner, 2001).

One important way that people do such bootstrapping to build knowledge is the process of *bridging* in which people direct the construction of their own knowledge by functioning at two levels simultaneously (Case, 1991a; Granott et al., 2002). They unconsciously establish a target skill or understanding, which lies unconstructed beyond their current level of functioning, and

they use it as a shell for constructing understanding. The shell functions like a grappling hook for mountain climbers, pulling activities up toward the target level. Often the shell is based on an analogy or metaphor, like the frameworks for meaning that Lakoff (1987) and other cognitive linguists have described. Teachers and other people can also provide bridging shells for learners such as Case's number line metaphor as a central conceptual structure for arithmetic in young children (Case et al., 1996).

In the process of bridging, the target shells that people build are often partial and fuzzy, but they provide a framework that directs the search for new knowledge. People then use their activities to gradually fill in components of the shell until they have moved themselves to a higher level of understanding for the new task in context. Experts presumably use bridging shells, too, but ones that are less fuzzy and more articulated for relevant domains and that facilitate rapid skill building and problem solution, as in the third row of Figure 7.20.

An example from a second dyad working with a Lego robot illustrates how bridging works (Granott et al., 2002). Kevin and Marvin did not know that their robot responded to sound. When they began their explorations of the robot, they played with it for a few minutes, exploring what happened. After a few minutes, they showed their first case of bridging—a vague reference to undefined cause and effect that provided an outline around which to build a skill: Marvin placed his hand around the robot in different positions to see what would happen, and Kevin said, "Looks like we got a reaction there."

The term reaction suggested cause and effect, action and re-action, but Kevin gave no specifics because he did not yet know enough. It was not clear what in Marvin's action (or in something else) was the cause or how the robot's movement changed in reaction. The two students did not know even that the robot responded to sound, and they had not yet detected relevant patterns in the robot's movements. Still, the idea of reaction did imply a causal connection, content unknown. Through it, Kevin and Marvin set up a bridging shell that effectively posited two unknown variables, *X* and *Y,* related to each other:

$$\underset{\text{Shell}}{\left[\ (X) \overset{\text{Reaction}}{\text{——}} (Y)\ \right]} \qquad (2)$$

Parentheses around the letters in the formula indicate that the components were unknown for Marvin and Kevin. This shell linked action *X* with response *Y* as a reaction to *X.* The shell was still devoid of content, but it marked an existing unknown causal relation. Bridging follows the basic structures of skill development except that some components of the shell start out unknown or partially known, like algebra in action. The number and nature of unknown components differ with developmental level.

Through construction of a shell, bridging operates like the pillars on an overhead highway that is under construction. The pillars have been put in place, but they do not yet carry the roadway that will eventually be built on top of them. Just as the horizontal beams and the concrete between the pillars are still missing, the content—the specific cause and effect—in Kevin's brief statement is missing. Like the empty pillars, the bridging shell traces the target causal mapping and prepares a frame for building it. Although the bridging shell is currently hollow or empty, Kevin and Marvin will organize new experiences with the shell and thus introduce meaning to it.

After Kevin and Marvin introduced the reaction shell, they continued to play with the robot and observe how it reacted. A few minutes later, they had built a causal relation, saying: "When it comes over here and as soon as it gets underneath part of the shadow there, it starts changing its behavior." This statement specified an elementary causal connection between the robot's coming under the shadow and its change in behavior and thus filled in the first instances of *X* and *Y* in the skill shell:

$$\left[\ \begin{matrix}\textbf{UNDER}\\ \textbf{SHADOW}\end{matrix} \overset{\text{Reaction}}{\text{——}} \begin{matrix}\textbf{CHANGES}\\ \textbf{BEHAVIOR}\end{matrix}\ \right] \qquad (3)$$

The bridging shell defined by reaction guided Kevin and Marvin to formulate a first causal relation or hypothesis indicating that a shadow produces a change in the robot's behavior. After this beginning use of the bridging shell, Kevin and Marvin elaborated it to grope their way to what eventually became a relatively sophisticated, partially stable understanding of the robot.

In overview, microdevelopmental analysis richly captures the dynamics of activity, development, and learning. When people construct skills at new levels of complexity for a given task or situation, the more complex skills are initially tenuous and only become relatively stable gradually over long periods. Working socially as well as individually, people juxtapose or shift between relevant component skills, and they move

gradually through processes of coordinating these components to form higher-level skills. To facilitate their own skill construction, they build shells at higher levels to bridge or bootstrap themselves to new knowledge. Over time, they build and rebuild each skill again and again with each small change in task and context until they consolidate their performance to form a skill of some generality. Once new skills are consolidated, people can use them as bases for further constructive activity, including generalizing to new situations and building additional coordinations. Even when skills are consolidated, of course, they are not uniformly available at will. They remain subject to the many dynamically interacting factors that make up human activity.

Microdevelopmental analysis of learning and problem solving makes especially evident the great variability in the structures of human activity from moment to moment. Another traditional domain in which variability is prominent is emotional development. Traditionally, emotion has been treated as separate from cognition (another instance of reductionist distortion), but the revolution in emotion research in the last 25 years has radically changed that view. Emotion and cognition are not in fact separate but are two sides of the same coin. Indeed, microdevelopment and emotion are two of the domains leading the way in moving beyond the structure-as-form paradigm to create dynamic structuralism.

EMOTIONS AND THE DYNAMIC ORGANIZATION OF ACTIVITY AND DEVELOPMENT

Emotions show powerfully how dynamic structural analysis illuminates human activity and its development. In the past 25 years, emotions have reclaimed center stage in the study of human action and thought, after decades of neglect in the mid-twentieth century during the eras of behaviorism and cognitivism (Damasio, 1994; Frijda, 1986; Lazarus, 1991; Scherer, Wranik, Sangsue, Tran, & Scherer, 2004). Scholars have constructed a new framework for understanding emotion that belongs in the center of the new dynamic structuralism, combining traditional concerns about both structure and function in a single analytic system. The general framework is typically referred to as the "functional approach" because of its emphasis on the adaptive (functional) role of emotions in human activity. Consistent with dynamic structuralism, however, the functional focus is combined with structural analysis, so a more appropriate label would be the functional-structural or functional-organizational approach to emotions (Fischer et al., 1990; Mascolo et al., 2003; Sroufe, 1996). We illustrate the use of several interrelated kinds of structures to analyze emotional functioning, including information flow, script, categorical hierarchy, dimensional split, developmental level, developmental web, and dynamic growth curve. No single analysis by itself can capture all the important aspects of the organization and functioning of emotions—which is typical of dynamic phenomena.

Emotion and Cognition Together

Contrary to common cultural assumptions, emotion and cognition operate together, not in opposition to each other. The official journal of the International Society for Research on Emotion is entitled *Cognition and Emotion* to reflect this point. *Cognition* generally refers to the processing and appraising of information, and *emotion* refers to the biasing or constraining effects of certain action tendencies that arise from appraisals of what is beneficial or threatening to a person (Frijda, 1986; Lazarus, 1991; Russell & Barrett, 1999). Thus, cognition and emotion are two sides of the same coin as characteristics of control systems for human activity. Emotion is together with cognition at the center of mind and activity.

Analysis of emotion highlights the role of the body and social world. Minds are not merely brains that happen to be in bodies. People's minds are parts of their bodies, and their mind-bodies act, think, and feel in a world of objects and other people. This ecological assumption is fundamental to the dynamic structural framework and applies to analysis of all human activity. Emotions are one of the most important organizing influences on people's mind-bodies in context—fundamental biological processes that shape action and thought. Contrary to common parlance and much classic theory, emotions are not merely feelings or inner experiences of individuals but integral parts of human activity, shaping action and thought, and founded in social interactions.

In the history of psychology, a distinction has often been made between emotion and affect, with emotion referring to biologically driven reactions and affect emphasizing individual experience and meaning (T. Brown, 1994). By these definitions, modern functional/structural analysis deals with affect rather than emotion, but recent researchers' emphasis on biological factors has led to general preference for the term *emotion.* In this modern meaning, emotion is used in a broad sense to include the classical meaning of affect. We use emotion

and affect interchangeably to refer to the broad ways in which activities are organized by action tendencies arising from people's appraisals.

Adaptation and appraisal are two fundamental concepts in emotion. They are captured in the basic definition of emotion process: People act in contexts where their activities are embedded in events (*in medias res*). Emotions arise from appraisals of the events based on each person's many specific concerns (goals, needs). An emotion is an action tendency (constraint, bias) that arises from an appraisal and molds or structures a person's activities to shift the state of affairs toward his or her goals and needs. The central process in emotion is the action tendency, the way that an emotion organizes activity. Actions, thoughts, experiences, physiological reactions, and expressions of body and voice are all organized by the action tendency of an emotion.

When people feel ashamed, for example, they want to be evaluated positively in some context, but instead someone judges them negatively for something they did or said or for some characteristic of theirs, especially something that indicates a serious flaw (Tangney & Dearing, 2002; Wallbott & Scherer, 1995). They typically lower their eyes, conceal their face, blush, and stay quiet. They try to escape or hide, and they may try to blame others for the event or characteristic. Subjectively, people feel uncovered, small, or heavy, and they focus on their shameful flaw. Emotion refers to this entire process, including appraisal, social context, physical reactions, activities, and subjective experiences, but especially the action tendency that organizes the shame reaction.

The processes of emotion are diagramed in Figure 7.22, which presents a schema for the information processes that many emotion theorists propose (Fischer et al., 1990; Frijda, 1986; Lazarus, 1991). For the situation in which people are acting, they detect a *notable change* (first box on the left in Figure 7.22), involving some difference in the situation or some violation of expectations. For a case of shame, people may notice that they have acted poorly or broken some rule, or they may observe someone expressing contempt or disgust toward them.

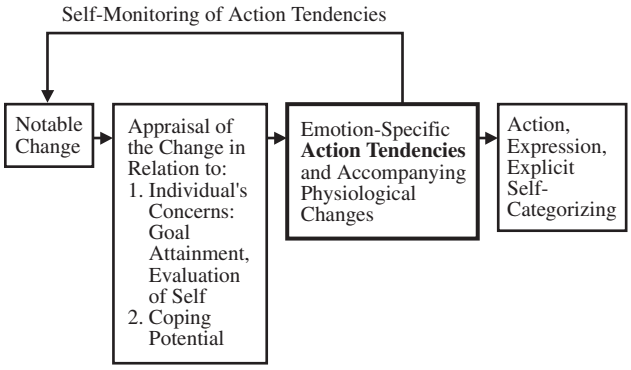

Figure 7.22 Emotion process.

They then appraise the situation for its affective meaning—its significance in their own specific concerns (second box). Despite the cognitive, conscious, deliberate connotations of the word *appraisal,* this process typically occurs unconsciously and quickly. One result of the appraisal is a general positive or negative evaluation of whether the situation promotes or hinders goal attainment or wish fulfillment (promoting accomplishments or preventing troubles) according to Higgins and his colleagues (1996). Situations that compromise people's concerns produce negative emotions such as shame, fear, sadness, and anger. Those that promote people's concerns produce positive emotions such as pride, joy, and love or affection.

A person also appraises the situation for coping potential, how well he or she can deal with or change the emotion-producing aspects of the situation. When circumstances are desirable, a person may try to sustain or further them or may simply enjoy them. When circumstances compromise a goal or need, a person assesses what can be done to change the situation—undoing, altering, or escaping from the negative circumstance. Appraisal that a negative situation can be undone or altered leads to emotions such as anger or guilt. An appraisal that it cannot be undone or changed leads to sadness or shame. Appraisal that it can be escaped leads to fear or shame.

Each appraisal produces an action tendency (third box in Figure 7.22), a pattern of activity based on evaluation and coping potential that is an unconscious plan of action for the situation. Each emotion has a prototypic, often preemptive, action tendency, which takes over control of activity. People tend to act in a certain way and to perceive and interpret events according to specific biases, and their bodies change physiologically to prepare for the planned actions.

Beyond early infancy, people also engage in self-control efforts in which they try to alter their own perceptions and actions. For shame, action tendencies include trying to hide or escape from observation, lowering the head or covering the face, feeling small and exposed, and becoming preoccupied with the negative action or characteristic. Self-control efforts include

trying to change the negative action or characteristic, deny or disguise it, or blame someone else for it.

The boxes in Figure 7.22 suggest an approximate order for these emotion processes, although they typically occur in parallel and cannot be separated as fully as the boxes may imply. The implications of separateness and sequentiality are a limitation of information-flow analysis. After a person has fully developed an emotion, the processes become seamless and automatic. Emotions appear to occur unconsciously, washing over us autonomously, despite the fact that the processes are complex and derive from a long period of development. The heart of the emotion is the action tendency, which is indicated with darkened lines in Figure 7.22.

In addition to the sequence of processes from left to right, there is a feedback loop in which older children and adults appraise their own affective reactions and move back through the entire set of emotion processes, reacting emotionally to their own emotion and exerting efforts at self-control. This loop often results in an emotion about an emotion, as when a person becomes angry about feeling ashamed or becomes afraid about feeling love or affection.

Organizing Effects of Emotions

The ways that emotions organize activities are powerful and pervasive. Among the structural descriptions used to characterize these organizing influences are: (a) scripts for prototypical organizations for particular emotions, (b) categorical hierarchies, and (c) dimensions for relating emotions to each other.

These empirically derived descriptions of the organizing effects of emotions illustrate especially well how biology and experience work together in human development (Damasio, 2003; Fischer et al., 1990). Nativist theorists often emphasize the constraints or biases that genes place on human action and thought (Carey & Gelman, 1991; Spelke, 2000). At the extreme, nativist researchers look for the early or "first" emergence of some piece of knowledge or emotion, and then claim that this early development shows that the knowledge or emotion is innately present from an early age. Such an approach neglects the developing organization of human activity, reducing analysis to description of a few innate elements, as we discussed earlier. Emotions and emotional development show powerfully how biological constraints dynamically affect the developing organization of activities as they are constructed through experience and culture. Emotions are a paradigm of how the dynamics of development can produce simultaneously both "basic" categories and complex behavioral organizations (Camras, 1992; Russell & Barrett, 1999).

Scripts

A useful way of describing the organization of emotions is with prototypical emotion scripts—descriptions of the prototype or best case of the antecedent events and reactions involved in a common emotion such as anger, fear, love, or shame (Mascolo et al., 2003; Shaver, Schwartz, Kirson, & O'Connor, 1987). These kinds of scripts have been used extensively in cognitive psychology to describe a standard sequence of events that many people share—the prototype or best instance of a certain category (Schank & Abelson, 1977). Prototypic emotion scripts are inferred from stories that people tell about emotions, characteristics that people attribute to emotions, and reactions that people show in emotion-inducing situations.

In a standard format for scripts, antecedents describe the notable change in the situation that evokes an emotion, responses describe the action tendencies that the emotion produces, and self-control procedures describe the ways that people attempt to change or limit the emotion. Tables 7.3 and 7.4 present prototypes for the nega-

TABLE 7.3 Prototypical Script for Adult Shame

Antecedents: Person's Flaw, Dishonorable or Deplorable Action, Statement, or Characteristic
A person acts in a dishonorable way, says something deplorable, or evidences a characteristic that is disgraceful or flawed.
Someone witnesses this action, statement, or characteristic and judges it negatively.
Responses: Hiding, Escaping, Sense of Shrinking, Feeling Worthless
The person tries to hide or escape from observation or judgment, feels small, exposed, worthless, and/or powerless.
The person lowers the head, covers the face or eyes, or turns away from other people. Sometimes he or she strikes out at the person observing the flaw.
He or she is preoccupied with the negative action, statement, or characteristic as well as with negative evaluation of self more generally.
Self-Control Procedures: Undoing and Redefinition
The person may try to change the negative action, statement, or characteristic, or deny its existence, or disguise it.

Fischer, 2004, *Cognition and Emotion, 18,* pp. 767–797 and *Self-Conscious Emotions: The Psychology of Shame, Guilt, Embarrassment, and Pride,* by J. P. Tangney and K. W. Fischer (Eds.), 1995, New York: Guilford Press.

TABLE 7.4 Prototypical Script for Adult Love

Antecedents: Other Person's Attractiveness, Meeting of One's Needs, Good Communication, Sharing of Time and Special Experiences
The individual finds another person attractive, physically and/or psychologically.
The other person meets some of the individual's important needs.
The two communicate well, which fosters openness and trust; they have spent much time together and shared special experiences.
Responses: Feeling Happy and Secure, Wanting to Be Close, Thinking about the Other Person
The individual feels warm and happy and tends to smile, especially when thinking of the other person or being with him or her.
The individual thinks about the other person, wants to be with him or her, to spend time together (not be separated), to make eye contact, to hold, kiss, and be intimate (psychologically and/or sexually), and to express positive feelings and love to the other.
The individual feels more secure and self-confident, and accentuates the positive side of events.
Self-Control Procedures: Not a Salient Issue
(Suppression of love is possible in the interest of decorum or the avoidance of embarrassment, guilt, or rejection, but such self-control efforts are not prototypical, at least in the United States.)

Based on "Is Love a 'Basic' Emotion?" by P. R. Shaver, H. J. Morgan, and S. Wu, 1996, *Personal Relationships, 3,* pp. 81–96; and "Emotion Knowledge: Further Exploration of a Prototype Approach," by P. R. Shaver, J. Schwartz, D. Kirson, and C. O'Connor, 1987, *Journal of Personality and Social Psychology, 52,* pp. 1061–1086.

tive emotion of shame and the positive one of love. The main organizing influences (action tendencies) for shame are to hide, escape, feel exposed, and become preoccupied with the cause of the shame. The main organizing influences for love are to feel happy and secure, to want to be close to the loved one, and to think about the loved one. Control procedures are typically important for negative emotions such as shame but minimal or nonexistent for positive emotions such as love, because in the prototypic situation there is no desire to avoid or eliminate the positive emotion. Real-life occurrences of emotions are inevitably more complex than simple prototypes, and control procedures do occur with positive affects as well, depending on the variable circumstances of the specific occurrence.

Families of Emotions, Dimensions, and Cultural Variations

Human beings experience many different emotions, and scholars have sought to find an organization underlying all these variations, relying on facial expressions, emotion words, personality types, and various other data to infer relations among emotion types or categories. In general, most categories function through prototypes, forming family resemblances related by similarities to best instances (prototypes). The study of knowledge was revolutionized in the late twentieth century by the realization that most categories function in terms not of exclusive logical definitions but of overlapping prototypes, which organize categories into basic families (Lakoff, 1987; Rosch, 1978; Wittgenstein, 1953). Emotions fit this organization just like most other categories.

One of the striking findings about emotion categories has been the similarity of basic families for emotion words with those for emotional expressions in face, voice, and action. The convergence across these components of human activity is remarkable, as illustrated by the prototypic families for emotion words in English, Indonesian, Italian, and Chinese shown in Figure 7.23 (Shaver, Murdaya, & Fraley, 2001; Shaver et al., 1992). The six emotion families of anger, sadness, fear, shame, love, and happiness also appear in many analyses of facial expressions for basic emotions (Ekman et al., 1987), along with a few additional emotion categories such as disgust and surprise. (The additional categories are not basic families but subordinate items within one of the families in Figure 7.23.)

Besides the basic categories of emotion families, there are higher degrees of abstraction in which families and emotions are related through superordinate categories or dimensions such as positive-negative evaluation. There are also lower degrees of abstraction, in which families divide into subordinate categories, and then the subordinate categories subdivide further into lower-level categories and eventually specific emotion words. For example, in Figure 7.23 clusters of Chinese emotion words form the subordinate categories of sorrowful love and unrequited love in the Sad Love family and the subordinate categories of guilt/regret and shame in the Shame family.

At higher degrees of abstraction, emotion categories fall along several dimensions defining an emotion space. The most prominent dimension is usually evaluation of positive-negative or approach-avoidance. That is why evaluation appears in the emotion process model in Figure 7.22 as part of people's first appraisal—whether an event is good or bad for them. This superordinate dimension represents one of the three dimensions that have been found in many different research traditions going back to the beginnings of experimental psychology in the nineteenth century, long before the framework for prototype

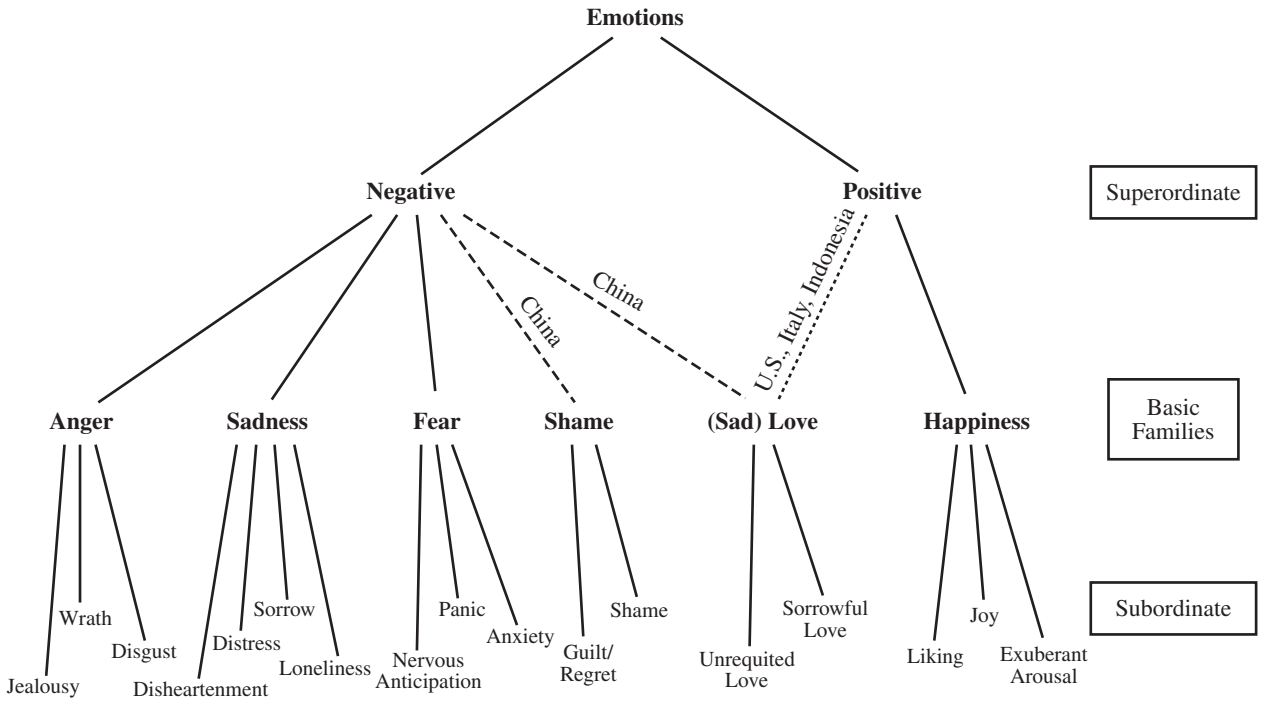

Figure 7.23 Hierarchy of emotion categories. This hierarchy represents the organization of emotion families in Chinese based on the findings of Shaver and his colleagues. Results for the United States, Italy, and Indonesia are also represented. For subordinate categories, the diagram lists only the largest categories from the Chinese sample. Dashed lines indicate findings that held for only the Chinese sample; dotted lines those for only the United States, Italian, and Indonesian samples. *Source:* From "Structure of the Indonesian Emotion Lexicon" by P. R. Shaver, U. Murdaya, and R. C. Fraley, 2001, *Asian Journal of Social Psychology, 4,* pp. 201–224; "Cross-Cultural Similarities and Differences in Emotion and Its Representation: A Prototype Approach" (Vol. 13, pp. 175–212), by P. R. Shaver, S. Wu, and J. C. Schwartz, in *Review of Personality and Social Psychology,* M. S. Clark (Ed.), 1992, Newbury Park, CA: Sage.

analysis was devised (Osgood et al., 1957; Schlosberg, 1954; Wundt, 1907).

The classic dimensions have been replicated with similar findings across many different methods, data sets, and cultures, although there are some important variations in the exact nature of the dimensions. The three general dimensions are (1) evaluation of positive-negative or approach-avoidance, which usually accounts for approximately half the variance and is shown in Figure 7.23, (2) activity or active-passive, and (3) engagement or self-other. Although dimensions (2) and (3) are not shown in Figure 7.23 because of graphical limitations, they are nevertheless present in the hierarchy as additional superordinate categories.

The basic emotion families and the dimensions of emotions are similar across cultures, probably because they reflect fundamental characteristics of the human species. In this sense, nativist arguments are correct: Emotion categories have an important species-general (hereditary) component (Ekman et al., 1987). In the studies that produced the hierarchy in Figure 7.23, Shaver and his colleagues began with a standard dictionary in each language, asking informants to pick words that involved emotions (Shaver et al., 1992, 2001). Then they used the selected words with another set of informants, who sorted the words into categories. Hierarchical cluster analysis of the sortings produced the dimensions, basic families, and subordinate families. Chinese, Indonesian, Italian, and American/English showed five common emotion families—anger, sadness, fear, love, and joy—as well as the three affective dimensions. Other researchers examining different cultures have found groupings of emotions in similar families and dimensions (Fontaine, Poortinga, Setiadi, & Markam, 2002; Heider, 1991). Claims that emotions differ fundamentally across cultures do not take these broad family groupings into account.

Alongside cultural similarities, however, cultural differences are strong and important. The hierarchies for China, Indonesia, Italy, and the United States illustrate those differences. First, the Chinese organization of love was substantially different from the Ameri-

can/Italian/Indonesian one. In the latter languages, love was categorized as a fundamentally positive emotion; while in Chinese love was sad and negative, as shown by the two main subordinate categories of sorrowful love and unrequited love. In contrast, the American subordinate categories were primarily positive, including words such as fondness and infatuation. The Chinese and American constructions of the basic family of love are clearly different.

An even greater difference was that the Chinese showed a sixth emotion family, shame, which existed in the U.S. study as only a small subordinate cluster in the sadness family, not as a separate basic family. This finding demonstrates a powerful cultural difference—an entirely different emotion family, presumably reflecting important cultural experiences (Benedict, 1946; Kitayama, Markus, & Matsumoto, 1995; Li, Wang, & Fischer, 2004). Shame is much less salient in the United States (and in many other Western cultures) than it is in China and some other Eastern cultures.

Li et al. (2004) followed up this finding by analyzing the categorical organization of the shame family in Chinese, using a method similar to Shaver's. They worked with Mandarin speakers from mainland China to identify 113 words clearly involving shame. Hierarchical cluster analysis of subjects' sortings of these words produced the hierarchy outlined in Figure 7.24. The primary superordinate dimension was self/other (one of the three common dimensions of emotion), and there were six families of shame words, with several subordinate categories for most of the families. The English names for each family and subordinate category were chosen carefully to portray the Chinese meanings, but it is difficult to capture in English the connotations of many of these Chinese emotion concepts. Interestingly, one of the families that seems familiar to U.S. culture is guilt, but it was the least differentiated shame family in Chinese, showing no clear discrimination of subordinate categories despite including an ample number of words (13).

Generally speaking, the organization of emotion concepts seems to have broad similarities across cultures, but cultural experiences simultaneously lead to powerful differences in specific emotion concepts and important variations in basic emotion families. Emotion concepts—and emotions more broadly—are not simply innate or entirely variable across cultures. Emotion organization is constrained by broad species characteristics at the same time that it involves very different

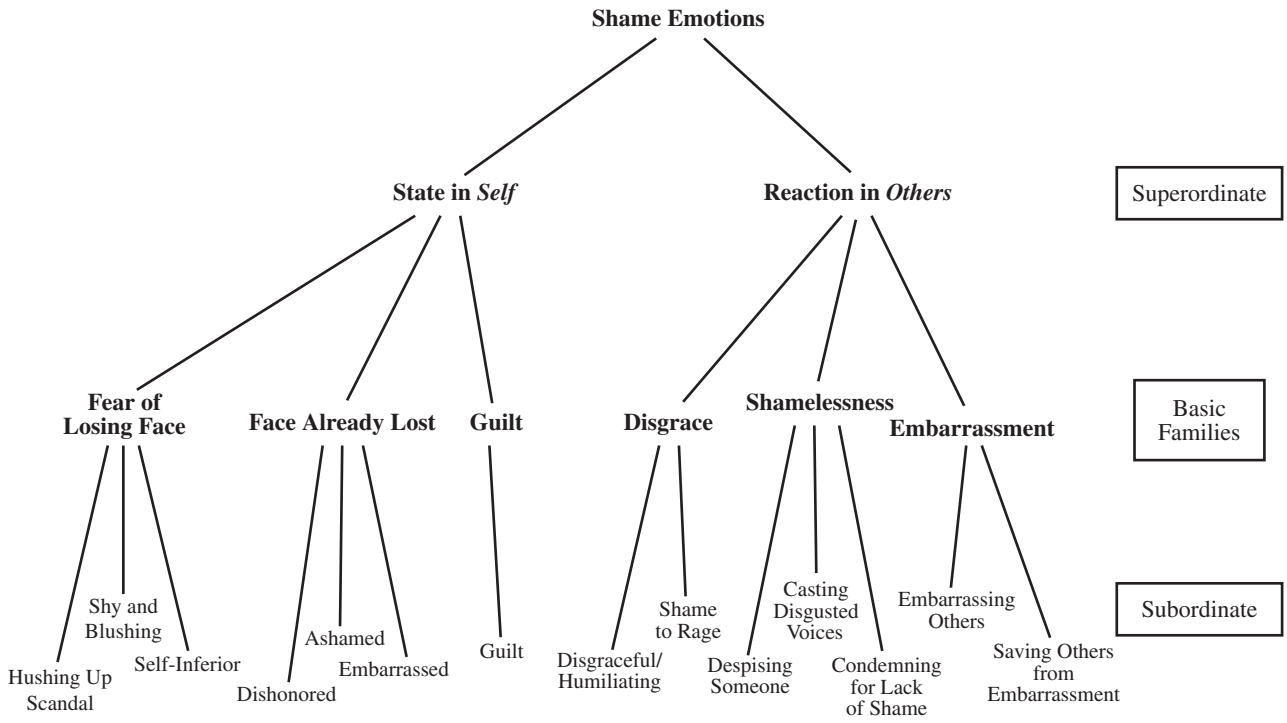

Figure 7.24 Hierarchy of shame categories in Chinese. This hierarchy shows the organization of shame categories in Chinese. For subordinate categories, only the first degree of categories is shown. *Source:* From "The Organization of Shame Words in Chinese," by J. Li, L. Wang and K. W. Fischer, 2004, *Cognition and Emotion, 18,* pp. 767–797.

structures across cultures and individuals. Techniques that focus on the variations in emotion facilitate not only description of individual variability and cultural diversity but also detection of shared characteristics of emotions across individuals and cultures.

Emotionally Organized Development

The action tendencies produced by emotions shape activities not only at the moment they occur but also as they develop. Emotional experiences have powerful effects on the shapes of developmental webs, whether they are governed by cultural norms or by more individual life events such as trauma. Research on emotional development has mostly focused on these consistent, one-way effects of emotional experiences. Frequent affective experience of a given type shapes development of a person or ensemble along a particular pathway. The general positive bias illustrated in Figures 7.6 and 7.7 is one example: People generally are biased toward the positive, particularly for attributions about themselves (Greenwald et al., 2002). Other repeated affective experiences such as recurring feelings of shame, consistent love from a caregiver, or recurring abuse lead people to develop along a globally different pathway shaped by these affective organizations. Dynamic research tools facilitate the analysis of ways that these emotions shape development.

One-Way Effects on Developmental Webs for Shame and Honor

In one broad persistent effect, people develop a strand in their developmental web that would have been minor or nonexistent without the emotional experiences. The development of a distinct sixth family for shame in China illustrates how cultural shame experiences can lead to development of an additional major branch in people's developmental web for emotions (Mascolo et al., 2003). In China and in many other Asian cultures, children experience shame and shaming repeatedly as a normal part of their socialization (Benedict, 1946; Heider, 1991; Shaver et al., 1992). As a result, they learn many shame words, they develop well-differentiated scripts and categories for shame, and they represent shame as an essential part of their everyday life: $ME_{ASHAMED}$ and $YOU_{ASHAMED}$. In U.S. culture, in contrast, many children experience much less shaming while having other negative experiences as part of their socialization. As a result, most U.S. children do not use shame words in their early vocabulary, nor do they develop well-differentiated scripts and categories for shame. Instead, they develop other negative affective scripts and categories such as ones for anger, aggression, sadness, and depression (Ayoub & Fischer, in press; Luborsky & Crits-Christoph, 1990; Noam, Paget, Valiant, Borst, & Bartok, 1994; Selman, Watts, & Schultz, 1997).

In the web metaphor for the structure of development, the American experience with shame promotes little growth of this branch of affective development. The shame family develops minimally, at least for concepts and conscious experiences of shame. (Scheff & Retzinger, 1991, argue that in America, shame continues to shape activity and experience, operating unconsciously because of its fundamental biological nature in human beings.) The Chinese experience with shame, on the other hand, produces rich growth of the shame branch of affective development, with differentiation of many subsidiary branches to form the multidimensional hierarchy in Figure 7.24.

Along with shame also goes highly differentiated development of honor and respect, which are the opposites of shame in China, unlike U.S. culture, where pride is considered the opposite of shame. This elaborate development of shame and honor leads to developmental pathways not seen in most people in English-language cultures such as the Chinese emotions of self-harmonization and social honor. Chinese children focus on succeeding in their efforts in school and other activities but always remaining modest about their achievements. The goal is to bring social honor to their family through their achievements: "My family is honored even though I am unworthy of your praise." Development of the strand for self harmonization and social honor in China contrast with development of the strand for pride in the United States, where the focus is on the child as the achiever rather than on the family (Mascolo et al., 2003).

Attachment, Working Models, and Temperament

Two domains where emotional-development research has been extensive are attachment and temperament. In both cases, the model of emotions is that they have a persistent, one-way effect on developmental pathways. According to attachment theory, children's and adults' relationships, curiosity, and general emotional security depend on the nature of their early close relationships with caregivers, usually mothers and fathers. According

to traditional temperament theory, babies are born with emotional constitutions that produce a specific pattern of emotional reaction, which pervasively affects their development and tends to remain similar from infancy to adulthood.

Attachment theory characterizes three major developmental pathways based on babies' affective experience in close relationships: secure (type B), insecure avoidant (type A), and insecure anxious/ambivalent (type C; Ainsworth, Blehar, Waters, & Wall, 1978; Shaver & Clark, 1996). A fourth pathway is sometimes added—disorganized (type D), which is associated with abuse and trauma (Cicchetti, 1990; Lyons-Ruth, Alpern, & Repacholi, 1993; Main & Solomon, 1990). For each pathway, children develop a working model of close relationships founded on their early experiences with their mothers or other caregivers (Ayoub et al., 2003; Bretherton & Munholland, 1999; Sroufe, 1996). Each child's internal working model follows a straightforward emotion script for interactions in a close relationship, with one or two emotions dominant in the script.

According to the theory, the working model pervades children's later development, especially in close relationships but also in many other aspects of life. Babies who grow up in a secure relationship build their working models primarily around the emotion of love, trusting that their mothers will be present to take care of them when needed and will allow them independence to explore and learn about the world. Babies who grow up with an avoidant attachment build their working models primarily around a combination of love and fear of rejection, learning that although their mothers usually take care of them, they often reject their babies' affection or closeness. Babies who grow up with an ambivalent attachment build their working models primarily around a combination of love and anger, learning that although their mothers usually take care of them, they often restrict their actions severely or behave inconsistently, making their infants hypervigilant about attachment and angry at restriction. Babies who grow up with a disorganized attachment respond inconsistently with their caregivers and frequently have a history of maltreatment, which we analyze in a later section. Several longitudinal studies have found some stability in attachment pathways, with moderate correlations in attachment type over years as well as clear evidence of changes in many children (Cassidy & Shaver, 1999; Fraley & Shaver, 2000; Schore, 2003; Waters, Merrick, Treboux, Crowell, & Albersheim, 2000).

Only a few studies have examined the development of children's working models directly, perhaps because attachment theory treats working models as relatively fixed after infancy. Luborsky analyzed pretend stories created by 3- and 5-year-old middle-class Anglo-American children in response to story stems about emotionally loaded situations with family or friends (Luborsky et al., 1996). In this privileged sample, the dominant working model (which Luborsky calls "core relationship theme") was positive and secure: A child wished to be loved and understood or to feel good and comfortable. The other people in the children's stories understood the child and were helpful when help was needed. The child responded confidently and was, in turn, helpful and constructive.

Some research has examined working models of relationships in adult psychotherapy patients, defining how people build on dominant emotions to form an unconscious script about relationships. The script is like a working model, but it has major negative elements connected to the patient's psychological problems, and so it is called a *core conflictual relationship script* (Luborsky, 2001; Luborsky & Crits-Christoph, 1990; Noam, 1990; Selman & Schultz, 1990). Scripts include key wishes or concerns, typical responses by others to those wishes, and one's own actions in response to the others. For example, depressed patients often wish to be loved and close with others, to be accepted and understood, but they see others as rejecting and opposing them more often than loving and accepting them. Their response to the rejection is to feel depressed and helpless (a dominant emotion of sadness), as shown in the script for depression in Table 7.5. Fischer and Ayoub have also analyzed working models in maltreated children, which

TABLE 7.5 Core Conflictual Relationship Script for Depression

Wish or concern: A person wishes to be accepted, loved, and understood in a close relationship.

Other's response: Someone else who potentially could be in a close relationship with the person rejects or opposes him or her even while intermittently showing some love and acceptance.

Self's response: The person reacts with depression, disappointment, and a sense of helplessness. The dominant emotion is sadness, accompanied by various other emotions in the sadness family.

Based on "The Only Clinical and Quantitative Study since Freud of the Preconditions for Recurrent Symptoms during Psychotherapy and Psychoanalysis" by L. Luborsky, 2001, *International Journal of Psychoanalysis, 82,* pp. 1133–1154; and *Understanding Transference: The CCRT Method,* by L. Luborsky and P. Crits-Christoph, 1990, New York: Basic Books.

are discussed in the section on Emotional Splitting and Dissociation.

Research on temperament shows a similar pattern to attachment: modest long-term stability from the school years through adulthood in several dimensions of temperament, especially introversion/inhibition and anxiety/neuroticism (Costa & McCrae, 1997; Kagan & Snidman, 2004). The most extensive research involves introversion/inhibition in which a person is wary of novel situations, especially new people; it contrasts with extroversion or outgoing social behavior. This dimension demonstrates moderate correlations from infancy through childhood and during adulthood, which includes moderate stability on average as well as clear evidence of changes in many children (just like attachment style).

Theories of attachment and temperament mostly posit persistent, one-way influences of emotions, shaping development along one emotion dimension. Structural analysis provides powerful tools for capturing these one-dimensional effects, as illustrated in Figures 7.6, 7.7, and 7.13. These tools also point the way to going beyond one dimension to examine dynamic, complex effects, which typify most of emotional development.

Dynamic Shifts of Positive/Negative Biases in Webs

The tools for dynamic structural analysis facilitate moving beyond one-emotion analyses to more differentiated, textured depictions of the organizing effects of emotions on development. Emotional development involves multiple emotions, and emotional biases shift in different situations and at different points in development. Children change their understandings of themselves and their social world, and families, communities, and life situations shift in values and expectations over time.

The pervasive positive bias in development related to self illustrates well the possibilities of a more dynamic, multidimensional analysis of affective biases. Positive and negative emotions act dynamically in development, pulling this way and that—not always in the same direction. In research on development of emotions in self-concepts and social relationships, for example, children have shown developmental shifts in their orientations toward positive and negative (Fischer & Ayoub, 1994; Hand, 1982). In one longitudinal study, 3-, 4-, and 5-year-olds told stories about themselves and other children in nice and mean social interactions, as in Figure 7.5 (Hencke, 1996): Most 3-year-olds showed the opposite of the positive bias in older children and adults—a clear negative bias. At age 3 stories about ME_{MEAN} were

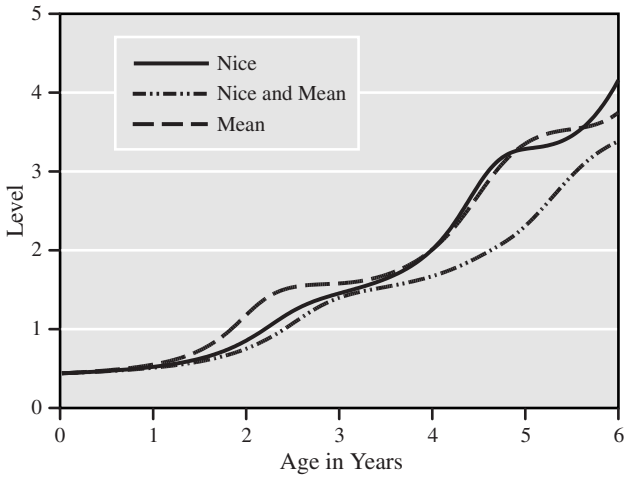

Figure 7.25 Growth functions showing a shifting bias from initial negative toward later positive interactions.

understood better than ME_{NICE} and preferred. As one 3-year-old said, "Can we do more of these mean stories? They're more fun!" Within a few years, however, the children's negative bias disappeared and was replaced by the usual positive bias, which gradually became stronger. This dynamic shift from a negative bias to a positive one is represented in the growth model in Figure 7.25.

Developmental Shifts in Emotions about Self in Family Roles

Such shifting affective biases are pervasive in development. In a general developmental principle, each new level brings with it specific emotional reactions and distortions, and many of these emotions change as children develop to higher levels. For example, the research literature illustrates transient emotional defensiveness in early development, based on children's developing (mis)understanding of themselves and their social roles. For the behavioral role of baby, ME_{BABY}, preschoolers show early skill at acting out the baby role in pretend play, even before the role of mother, ME_{MOTHER} (Pipp, Fischer, & Jennings, 1987). As they reach the age of 3 years or so (and firmly identify as *not a baby*), however, many of them become unable to act out the baby role, even though they are now capable of acting out many other simple roles such as mother, child, doctor, and patient (Watson, 1984). Other cases of emotional defensiveness affecting performance in 3-year-olds include African American children categorizing themselves as White even though they can accurately categorize other people as Black or White (Clark & Clark, 1958; Fischer,

Knight, et al., 1993; Spencer, Brookins, & Allen, 1985) and young boys categorizing themselves as large (old) even though they can accurately categorize other children as small or large (Edwards, 1984). These biases seem to be early versions of the self-promoting bias that pervades human mental life and that changes in form as children's understandings and emotions grow (Greenwald et al., 2002).

Generally, children participate in the social relationships and roles that they experience in their lives, and various emotional implications of those relationships and roles emerge for them depending on their skill development. A classic example of such emotion effects is the Oedipus conflict, which Freud (1955) originally described but which has been the subject of little developmental research except for global cultural comparisons (Spiro, 1993). According to Freud, preschool children develop a desire to replace their same-sex parent in order to assume a romantic relationship with their opposite-sex parent. Freud built a large theoretical edifice around this emotional conflict in the nuclear family.

Watson and Getz (1990), who studied the Oedipal phenomena empirically in middle-class White U.S. families, found that children did show a surge of Oedipus-type emotionally organized behaviors from 3 to 4 years of age. For example, one 4-year-old girl said to her father, "Daddy, kiss me a hundred times more than you kiss Mommy." Oedipal behaviors then declined sharply at ages 5 and 6. The researchers explained the emergence and decline of Oedipal activities, in terms of not castration anxiety and similar violent fantasies that Freud attributed to young children, but developing understanding and emotions about family roles. The first understanding of the special love *relationship* defined by husband and wife roles emerges at age 4 when children map representations of mother and father into a relationship concept. This new skill leads them to want to assume the special role with their opposite-sex parent. As a girl named Johanna comes to understand the special roles of her parents (Jane and Walter) as partners,

$$\left[JANE_{MOTHER} \text{ —— } WALTER_{FATHER} \right] \qquad (4)$$

she wants to take on the role of her mother so that she can have the special love relationship with her father:

$$\left[JOHANNA_{MOTHER} \text{ —— } WALTER_{FATHER} \right] \qquad (5)$$

That is why she says things like, "Daddy, kiss me a hundred times more than you kiss Mommy."

This understanding globs together or condenses parental and spousal roles, treating the mother role as including the wife role and the father role as including the husband role. When the roles are differentiated and coordinated in a representational system, children see that they cannot assume the parental role for themselves (becoming their own father or mother), and they see other limitations as well such as that they are too young to marry their parent and that people are not supposed to marry other family members. This emerging, more complete understanding of role relationships in the family leads the child mostly to lose the wish to replace the same-sex parent, unless there are role confusions in the family such as incest (Fischer & Watson, 2001). She comes to understand the intersection of spousal and parental roles in practice in the family:

$$\left[JANE^{WIFE}_{MOTHER} \longleftrightarrow WALTER^{HUSBAND}_{FATHER} \right] \qquad (6)$$

Development of Emotional Splitting and Dissociation

Emotions powerfully shape development, and one of the most pervasive effects on developmental pathways is emotional splitting, in which people routinely split positive and negative into separate elements that can be combined (Ayoub et al., 2003; Fischer & Ayoub, 1994; Harter, 1999). The positively biased web for development of nice and mean in Figure 7.6 illustrates one instance of splitting: Two-year-old children commonly split self and other, representing themselves as nice and someone else as mean, ME_{NICE} and YOU_{MEAN}. They have difficulty putting the two opposite representations together to see that each person (self and other) can be both nice and mean.

With time, children develop from splitting toward integration in particular domains. By the grade school years, most children become able to coordinate affects across the positive-negative split in many social situations, as when they represent themselves and other people as simultaneously nice and mean in the stories at steps 6 and 7 in Figures 7.5 and 7.6. For example, in one story, Jason comes up to Seth on the playground, hits him on the arm, and says, "I want to be your friend. Let's play" (a combination of mean and nice actions).

Seth responds with appropriate reciprocal nice and mean actions: "I would like to be your friend, but I don't play with kids who hit me." Younger children who are asked to act out or explain stories of this kind commonly split them into two separate stories, one about being nice and a second about being mean. The skills in the middle column (Nice & Mean) in the webs involve various steps in integration across the positive-negative split.

Splitting is a special case of the more general category of dissociation in which activities are separated even though they should be coordinated by some external criterion. Emotional splitting involves separation along the positive-negative dimension, or more generally, between affective opposites (e.g., smart and dumb, grown up and child). Dissociation typically refers to a stronger separation of elements along dimension(s) besides positive-negative evaluation. The mind is naturally fractionated, as represented by the separate strands in developmental webs. Consequently, splitting and dissociation are pervasive in human activity.

The terms *dissociation* and *splitting* are often used narrowly to refer to motivated separation in psychopathology such as dissociating the self into multiple personalities, or splitting family and friends into good and bad people (Breuer & Freud, 1955; Putnam, 1997). Yet splitting and dissociation occur normally and routinely as a result of lack of coordination of skills or experiences that are naturally separate (Feffer, 1982; Fischer & Ayoub, 1994). There need be no pathology. People normally split their world into good and bad, smart and dumb, or us and them. In many instances, they strongly dissociate themselves from people, beliefs, and feelings that they disapprove of. Experimental research has established clearly that various forms of active dissociation occur normally, especially during dreaming, hypnosis, and extreme religious experiences (Foulkes, 1982; Greenwald et al., 2002; Hilgard, 1977). Splitting and dissociation are normal parts of human development.

Tools for dynamic analysis of development provide insights into both normal and pathological splitting and dissociation. The development of positive and negative shows natural positive-negative splitting, as shown in the nice/mean webs in Figures 7.5 and 7.6 and the SiR Interview in Figure 7.13. In severe emotional trauma, splitting and dissociation are magnified and play an important role in adaptation to the trauma.

Children subject to severe abuse frequently cultivate skills of dissociation to adapt to their horrendous situations (Putnam, 1997; Terr, 1991). For example, 8-year-old Shirley used dissociation to cope with her father's abuse of her (Canadian Broadcasting Corporation, 1990). Shirley's father repeatedly raped her in her bed in the basement of their home, and he beat her up if she ever resisted his advances. To cope during the rape, she concentrated on a small hole in the wall above her bed, dissociating from her body and feeling that she put herself into the hole. Inside the hole, she could get through the trauma without major distress and without angering her violent father. One day, her father raped her upstairs in the main house instead of in the basement. Without the hole in the wall to support her dissociation, she began screaming and fighting her father. He lost his temper, knocked her unconscious, and then continued with the rape. (Although the father was never arrested for his crimes, Shirley did eventually find help, and she became a competent adult crusading to stop child abuse.)

In a situation like Shirley's, dissociation was an adaptive achievement in which she created a coordination to actively dissociate, building skills to keep herself from experiencing the full pain of the trauma. By 4 to 6 years of age, children first demonstrate active dissociation of a few components from one another, as when Shirley put herself in the hole in the wall (Fischer & Ayoub, 1994):

$$\left[ME\text{-}SHIRLEY_{IN\ HOLE} \dashv\!\!\blacksquare\!\!\vdash SHE\text{-}SHIRLEY_{RAPED} \right] \quad (7)$$

The block on the line relating the two Shirley roles denotes that the coordination is dissociative. With development, people can construct more complex, sophisticated dissociative coordination, actively separating multiple components.

Although research is still young on the developmental pathways of abused children, available data guide an initial sketch of the pathways, including disorganized attachment—(type D) described earlier. In severely abused or neglected children, the organization of development along the positive-negative dimension is powerfully affected. For many maltreated children, the normal positive bias in representations disappears at a young age to be replaced by the opposite—a negative bias, in which the tilt in Figures 7.6 and 7.7 is shifted to the negative side. Instead of focusing their representations of self and important relationships toward the positive, many maltreated children characterize the self in

pervasively negative terms, endlessly acting out and talking about negative events and interactions.

The findings from one study demonstrate how powerful this reversal can be. It creates an alternative developmental pathway based on a negative self bias. A group of adolescent girls hospitalized for depression and conduct disorder (acting out) described themselves in the SiR Interview (Figure 7.13), which was designed to produce rich self-descriptions (Calverley, Fischer, & Ayoub, 1994; Fischer et al., 1997). In one part of the interview, they indicated the importance of various self-characterizations, and in another part they indicated whether the self-characterizations were positive or negative. Instead of the usual positive bias shown by adolescents in this interview, the girls who had experienced severe and prolonged sexual abuse showed a pervasive negative bias in their feelings about themselves in relationships, as shown in Figure 7.26. Depressed girls in the same hospital who had not been sexually abused showed no negative bias but a clear positive bias instead. Contrary to many clinical claims, the abused girls did not function at low developmental levels in their self-representations; they produced levels comparable to those of the nonabused girls and to adolescents of similar ages in other populations. Their self-descriptions were negative, but not primitive. The abused girls were developing along a distinctive pathway, not failing to develop.

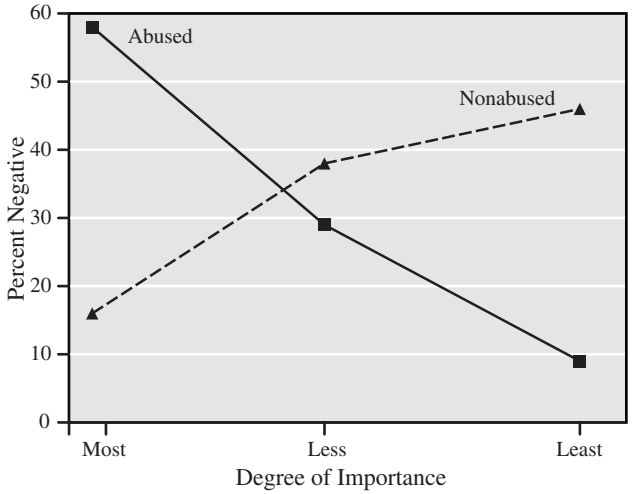

Figure 7.26 Importance of negative self-representations in abused and nonabused depressed adolescent girls. *Source:* From "Complex Splitting of Self-Representations in Sexually Abused Adolescent Girls," by R. Calverley, K. W. Fischer, and C. Ayoub, 1994, *Development and Psychopathology, 6,* pp. 195–213.

These traumatic environments produce distinct developmental pathways that are powerfully shaped by the experiences of abuse and trauma (Ayoub & Fischer, in press). Children growing up in such environments often produce remarkably sophisticated dissociation, which like Shirley's dissociation, demonstrate great developmental complexity. Figure 7.27 describes an early developmental pathway for a boy named John, who was growing up in a situation of hidden family violence where there is a rigid, socially maintained dissociation between public good and private violent worlds. In private, his father treated him tyrannically, abusing him physically whenever he disobeyed. In public, his father treated him as a good child whom he was proud of. In general, the parents maintained a consistent public image as good citizens and neighbors and model members of the community, but at home they were violent and abusive.

As John developed working models of close relationships, he constructed his own version of the private-public dissociation that his family maintained. He built increasingly complex and generalized representations of tyrant-victim relationships in private and model-family relationships in public (Ayoub et al., 2003; Fischer & Ayoub, 1994). Figure 7.27 illustrates three major levels in this development between 2 and 7 years of age for the first three levels of the representational tier (Rp1 to Rp3). At the first level, John represented himself in his private and public roles with his father, but did not maintain a firm dissociation between the two (as indicated by the permeable line dividing the domains). At the second level, he built role relationships, connecting his own and his father's roles and dissociating public and private more firmly. The third level brought a

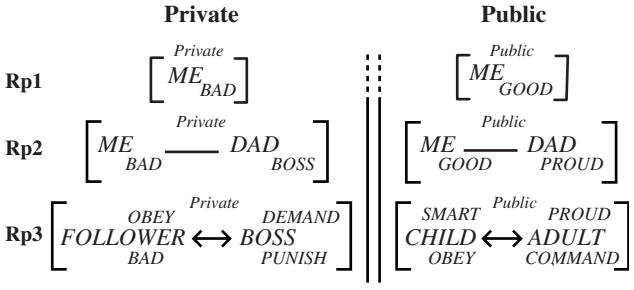

Figure 7.27 Development of dissociated representations (Rp) of private and public relationships in hidden family violence. The double line between columns indicates dissociation of the private and public pathways.

clear generalization of those roles beyond his relationship with his father—relationships with other adults and children.

These results do *not* mean that only abused or traumatized children show emotional splitting and dissociation. These are normal processes that everyone shows under many circumstances. Abuse produces different developmental pathways in which the person's working models of relationships are organized powerfully by the abuse, yielding characteristics such as a negative bias and a sharp dissociation between public good and private violent relationships. Tools for dynamic analyses of development provide ways of detecting these distinctive pathways and avoiding the common error of characterizing complex forms of dissociation and splitting as developmentally primitive.

In summary, emotions act as biasing forces that shape development along particular pathways, including normative emotional splitting of positive and negative in representations of self and others. When children have severe emotional experiences such as abuse, their emotional reactions contribute to shaping their development along unusual pathways that are built on their emotion-laden relationships. Developing understandings affect emotional reactions through changing appraisals, which lead to consequences at certain points in development, such as emotional reactions in 4-year-olds similar to those that Freud attributed to the Oedipus conflict. Emotions thus constitute a prime example of the usefulness of dynamic structural concepts and methods for analyzing how different components work jointly to produce development.

Emotion and cognition work together, affecting each other's development so extensively that they are difficult to separate. In the big picture of macrodevelopment, many of the large developmental reorganizations occur concurrently for emotion and cognition. Through dynamic structural analysis, it has become possible to build the first detailed models of how these changes in emotion and cognition relate to brain development.

JOINING NATURE AND NURTURE: GROWTH CYCLES OF PSYCHOLOGICAL AND BRAIN ACTIVITY

The dynamic structural framework provides powerful tools for detecting regularities in development. Without these tools, regularities are often swamped by the variability of human activity. Dynamic analysis has been especially useful in dealing with variability in the search for relations between psychological and brain development, producing the first specific models of relations between brain and activity in development—hypothesized growth cycles linking developmental levels of cognition and emotion with growth of cortical functioning (Fischer & Rose, 1994; Thatcher, 1994). Using dynamic analysis, researchers have uncovered rich new findings and built the first detailed models of relations between brain and psychological development.

Most developmental research fails to deal with the facts of variability, but neglecting those facts is especially perilous for research on relations between brain and behavior. Development has many different shapes! Some activities and brain functions show continuous growth, while others show various discontinuities. Research on relations between brain and behavior needs to start with analyzing different growth patterns to find relations amid all the variability. The varying shapes provide tools for unpacking growth processes in brain and activity. If the variations are left out, the research is doomed to become swamped by the combined variability in brain and behavior development.

Epigenesis of Action, Feeling, Thought, and Brain

Today, scientists assume that growth of the brain relates closely to growth of action, thought, and emotion; yet the empirical basis for this belief remains limited because there are few studies that directly assess relations of brain and behavior development. In a few narrow domains, research on neural systems has uncovered close relations between particular brain components and developing behaviors, especially for the visual system (Hubel & Wiesel, 1977) and some aspects of language (Deacon, 1997). For connections between brain changes and development of action, thought, and emotion more generally, speculation is rampant, but evidence is missing.

Happily, research is beginning to change this situation, with new epigenetic analyses of the dynamics of brain-behavior development. Research shows complex patterns of nonlinear, dynamic growth instead of monotonic growth (Fischer & Rose, 1994; Rakic, Bourgeois, Eckenhoff, Zecevic, & Goldman-Rakic, 1986; Shultz, 2003; Thatcher, 1994; Thelen & Smith, Chapter 6, this *Handbook,* this volume; van Geert, 1998). The tools for

dynamic growth analysis open ways to illuminate the epigenesis of brain-behavior relations.

Between behavior and brain, there are important commonalities that facilitate the search for regularities, including patterns of epigenetic change. Epigenesis is development through qualitative changes like those from egg and sperm to fertilized cell, embryo, newborn infant, and, eventually, adult human being. After the historical debate about the nature of embryological development was settled in favor of epigenesis, as opposed to quantitative growth of a preformed human being, the epigenetic conception was extended not only to brain development but also to cognitive and emotional development (Erikson, 1963; Hall, 1904; Piaget, 1983; Werner, 1948). The analysis of growth functions suggests a straightforward correspondence between patterns of epigenesis in brain and behavior.

From a dynamic perspective, each structure in epigenesis emerges as a result of the self-organizing activity of previously developed systems through coordination of component processes, as described in the earlier section on Dynamic Structure. Such systems are hierarchically organized, with the component systems fulfilling both separate functions and functions that are part of the larger system. The key for developmental science is to unpack the specific principles and cycles in this epigenesis that illuminate the development of brain, action, thought, and emotion.

The growth cycles of brain and behavior involve a long sequence of epigenetic coordinations, extending from before birth well into adulthood. Cognitive and emotional development combine with brain development in a collaboration connecting neural networks with actions, feelings, and thoughts. There is no separation of nature and nurture, biology and environment, or brain and behavior but only a collaborative coordination between them. "Between nature and nurture stands the human agent whose unique integrative capacities drive the epigenesis of intelligence and organize biological and environmental contributions to the process" (Bidell & Fischer, 1996, p. 236).

Principles for Understanding Growth Patterns of Brain and Behavior

Analyzed in terms of dynamics of growth and especially discontinuities, developmental curves for many characteristics of brain and behavior show remarkable similarities that seem to relate to their common foundation in hierarchical, epigenetic growth shared by neural networks and optimal levels in behavior. Investigation of these common growth patterns in both psychological and brain activity gives evidence for two recurring growth cycles. We first explicate five principles described by Fischer and Rose (1996) to describe their model of brain/behavior growth cycles, which was strongly influenced by the work of Thatcher (1994) and van Geert (1991, 1994).

Both brain activity and optimal cognitive functioning show nonlinear dynamic growth, often developing in fits and starts, which is characteristic of human physical growth in general (Lampl & Johnson, 1998). Growth speeds up and then slows down, demonstrating spurts, plateaus, drops, and other discontinuous shifts in growth patterns. For some types of growth, the fits and starts are systematic, and for others they are disorderly, showing the variability that is typical of dynamic systems affected by many different factors, as illustrated in Figure 7.11. For certain properties of brain activity and for the optimal levels of cognition and emotion, the fits and starts are systematic and form clusters of discontinuities at particular age intervals. Understanding the systematicity, however, requires understanding the variability. The principles for the dynamic structural framework range from clusters of discontinuities to processes of variability and regularity in growth functions.

> *Principle 1: Clusters of Discontinuities in Growth of Brain and Behavior.* Development of both brain activity and psychological activity moves through a series of clusters of discontinuities (spurts, drops, and other forms of abrupt change) indicating levels of reorganization of control systems for action, thought, and feeling. An important focus for analyzing discontinuities is the leading edge of change such as the onset and peak of a spurt.

A broad array of evidence indicates a sequence of discontinuities in development of brain and behavior marking a succession of levels and reflecting basic growth processes, as was discussed in the section on the Common Ruler for Skill Development. The growth patterns for different variables are not identical but variable, showing the normal diversity of dynamic systems. At the same time, the processes of development (what Piaget, 1985, called "equilibration") produce important regularities across growth curves, as shown by the dynamic model for linked growers in Figure 7.15.

Principle 2: Concurrence of Independent Growers. Developing behaviors and brain activities that are mostly independent (belonging to different domains or strands and localized in different brain regions) commonly show discontinuities that are approximately concurrent. The dynamics of the person's growing control systems produce concurrent changes across a number of independent psychological and brain activities.

In the web for multiple developing domains, discontinuities occur in concurrent clusters across domains, as marked by the clusters for optimal level in Figure 7.15 and the emergence zones in the web in Figure 7.17. Note, however, that the same growth curves also show relative independence of the growers. When small portions of the curves are viewed up close, as in Figure 7.27, the same growers that show clustering in Figure 7.15 are evidently independent, because the short-term concurrence across growers is not strong. Most developmental research takes this up-close, short-term view, instead of the distanced, long-term perspective. Clusters of discontinuities coexist with relatively independent growth in dynamic systems, with the (weak) linkages among growers often evident only in the long-term perspective.

A frequent error in the study of development is to assume that clusters of spurts or other discontinuities reflect a single coherent mechanism such as growth in a memory module that controls all the growers in common. Many traditional cognitive theories posit such a single mechanism of working memory or short-term memory, which acts as a bottleneck limiting development in all domains (e.g., Case, 1985; Halford, 1982; Pascual-Leone, 1970). Such single-process explanations do not fit the evidence. Growers that cluster can be independent of each other, with the clusters produced by dynamic regulatory processes, as in Figure 7.15. For example, synaptic densities in diverse cortical regions in infant rhesus monkeys develop through approximately concurrent spurts and drops, even though the regions are clearly separate and function mostly independently (Bourgeois & Rakic, 1993; Rakic et al., 1986).

Because of the many ways that a dynamic system can produce concurrent discontinuities, analysis of the processes underlying concurrence requires research designs for analyzing growth processes and dynamic variability. Growth must be investigated under diverse conditions that incorporate assessment of variability, and growth processes should be represented in explicit dynamic growth models (Fischer & Kennedy, 1997; Thelen & Smith, Chapter 6, this *Handbook,* this volume; van Geert, 1991, 1998). For investigations of relations between brain and behavior, these designs should include analyses of domain specificity of behavior and localization of brain function. Contrary to common assumptions, concurrence does not at all contradict domain specificity or localization.

Principle 3: Domain Specificity of Activities and Localization of Brain Functions. Relations between growers in various domains and brain regions can be analyzed through comparison of individual growth functions for those domains and brain regions. The complex shapes of the growth functions provide a tool for determining which growth functions vary together and thus which skills and brain regions grow together.

For example, many activities in distinct domains exhibit concurrent growth at approximately 8 months of age, including spatial skills such as search and locomotion, verbal skills such as imitation and intonation, and social skills such as recognizing familiar caregivers and striving to stay near them—shown by separation and stranger distress (Ainsworth et al., 1978; Bertenthal, Campos, & Kermoian, 1994; Campos et al., 2000; Uzgiris & Hunt, 1987). Many infants start to search effectively for toys or cookies hidden successively under different covers, imitate simple intonation contours and syllables that they hear spoken by their caregivers, and show consistent distress at their mother departing and at strangers appearing. These three different sets of activities belong to distinct domains and involve distinct cortical networks. They show globally parallel changes, but determination of whether they are tightly connected requires dynamic analysis of growth patterns.

Growth functions can differentiate which of these activities go together with development of specific brain regions. Bell and Fox have compared growth functions for these behaviors with those for cortical activity as measured by the electroencephalogram (EEG; Bell, 1998, 2001; Bell & Fox, 1992, 1994). Individual infants showed strongly overlapping concurrence for some domains and regions, but only loose and imprecise concurrence for others. For example, infants who demonstrated a spurt in search skills between 8 and 12 months produced a concurrent spurt in EEG activity (power) in the frontal cortex, but not elsewhere; they also showed growing connections between frontal and occipital/parietal

cortex as measured by EEG coherence. In contrast, infants who did not demonstrate clear spurts in search skills produced no growth spurts for cortical activity.

By relating dynamic variations in growth functions, researchers can move beyond the difficulties of comparison across domains and regions. They can use similarities in growth functions to analyze development of brain-behavior relations, detecting when concurrent discontinuities mesh across behaviors and cortical activities, and when they do not mesh. Clusters of discontinuities seem to reflect emergence of new organizations of brain and behavior, new action control systems linked to neural networks. Discontinuities in EEG activity, cortical connectivity, and psychological activity demonstrate concurrence and reflect the emergence of new control systems and neural networks.

Principle 4: Emergence of Neural Networks and Action Control Systems. With each developmental level, a new kind of control system for action emerges, supported by growth of a new type of neural network linking several brain regions and built on lower-level skills. Across different brain regions and skill domains, similar (independent) networks and control systems emerge concurrently. They produce clusters of discontinuities in characteristics of cortical activity and optimal level. Careful analysis of growth functions allows detection of correspondences beyond global concurrence between cortical regions and skills.

After emergence, the new systems undergo a lengthy period of consolidation during which they are tuned gradually to form efficient behavioral-neural control systems. Eventually, another new type of control system starts to grow, and another developmental level and cluster of discontinuities begins. In this way, the growth cycle creates the hierarchy of psychological and brain development.

Principle 5: Cycles of Discontinuities Forming Levels and Tiers. The development of a series of increasingly complex networks and control systems forms two dynamic cycles, one forming developmental levels, and the other, higher-order one, grouping levels into tiers and thus forming a cycle of cycles.

The cycles comprise a cascade of growth changes that move through brain areas and psychological domains systematically and cyclically—a growth process systematically altering neural networks as it moves. There are no all-or-none changes, occurring everywhere at once as suggested by classical conceptions of stage. The cycles may involve a number of different neural processes such as synaptic growth and pruning across cortical regions (Huttenlocher, 2002; Rakic et al., 1986), dendritic growth (Marrs, Green, & Dailey, 2001; Scheibel, Conrad, Perdue, & Wechsler, 1990), the formation of myelin to insulate neurons and thus produce faster neural impulses and improved coordination (Benes, 1994; Yakovlev & Lecours, 1967), and diverse other processes that improve communication among brain regions.

Cycles of Reorganization in Development

These principles specify a model for growth along the developmental scale for psychological activity in relation to brain activity—10 levels between 3 months and 25 years of age, as shown in Figure 7.3 for optimal levels. (An additional three levels are hypothesized for the first 3 months of life, Fischer & Hogan, 1989.) The levels on the scale are supported by an array of evidence of discontinuities and growth cycles for both behavior (action, thought, and feeling) and brain (anatomical growth and cortical activity). The ages for appearance of each level are highly variable, except under optimal assessment conditions. At the age of emergence, most people can first control several skills at the new level of complexity, and by hypothesis they are growing a new kind of neural network in diverse brain regions, evidenced by clusters of discontinuities in neural activity. Even under optimal conditions, however, exact age of emergence varies across individuals and domains (see Figure 7.28).

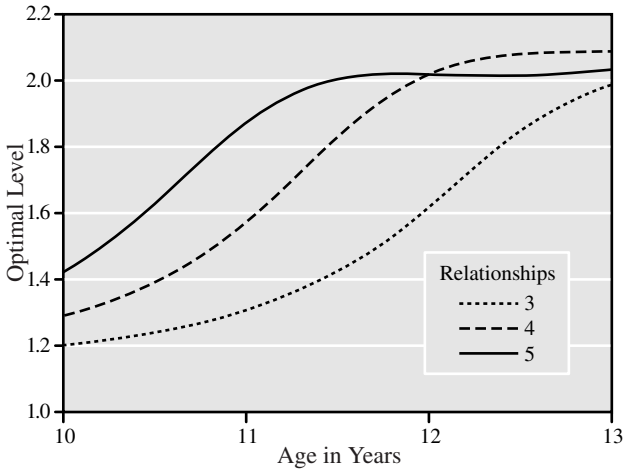

Figure 7.28 Close-up view of optimal level for three growers in the model of Self-in-Relationships (Figure 7.15).

Development takes place in three different grains of detail—step, level, and tier. At the finest grain at which developmental ordering can be detected, skills form a sequence of microdevelopmental *steps,* separated by relatively short time intervals and small differences in complexity. In dynamic skill theory, the steps are predicted and explained by a set of rules for transforming skills via coordination and differentiation such as the shift of focus rule discussed in the section on Microdevelopment. Most steps are simply points along a strand in a developmental web of skill construction and do not involve discontinuities.

The intermediate grain of detail is developmental *level,* with each level emerging in a cluster of discontinuities in behavior and brain activity, marking emergence of a new kind of control system and network, and therefore a capacity to construct a new kind of skill. Assessment of fine-grained steps greatly facilitates detection of levels by providing detailed rulers and clocks for amount and speed of change, as described in the section on Methodology.

At the broadest grain, levels form the cycles of reorganization called *tiers,* defined by a cycle of four increasingly complex levels, as shown in Figure 7.3. With the start of a tier, skills are simplified by being reorganized into a new unit of activity: actions, representations, or abstractions, respectively (as well as reflexes, by hypothesis, in early infancy). Skills within a tier grow through four levels, from single units to mappings to systems and finally to systems of systems, which initiates the next tier. Development of a new tier brings an unusually strong form of discontinuity, producing radical alterations in brain and psychological activity. For example, late in the second year, children move into the representational tier, beginning to show complex language, independent agency (as in representing ME_{NICE} and YOU_{MEAN}), and a plethora of other radical behavioral changes, as well as major spurts in frontal and occipital-parietal activity. Likewise, at 10 to 12 years, children combine multiple concrete representations to form the first abstractions and begin another new tier.

A new tier requires melding together complex systems to forge a new unit—an achievement that necessitates neural glue to cement the components together. We hypothesize that the prefrontal cortex provides much of this glue, in consonance with the general functions of frontal cortex (Damasio, 1994; Gray, Braver, & Raichle, 2002; Thatcher, 1994).

Hierarchical Growth of Action and Thought

Hierarchical skill growth has a characteristic pattern of spurts and plateaus (sometimes drops), illustrated for the growth model in Figure 7.15. Research on cognitive development commonly shows this specific pattern of growth, as illustrated for a study of reflective judgment in Figure 7.29 (Fischer & Pruyne, 2002; K. Kitchener et al., 1993). The Reflective Judgment Interview, devised by K. Kitchener and King (1990), elicits arguments about knowledge for complex dilemmas such as determining the truth based on conflicting news reports. In an optimal-level assessment, students showed general increases in level between 14 and 28 years, with spurts centered at approximately 16, 20, and 25 years of age. Many other findings, such as the evidence for discontinuities in the development of self-in-relationships for Korean adolescents in Figure 7.8, manifest similar patterns for optimal conditions.

Besides hierarchical growth, correlations among behaviors also show discontinuities with the emergence of skill levels. For example, longitudinal analysis of infant

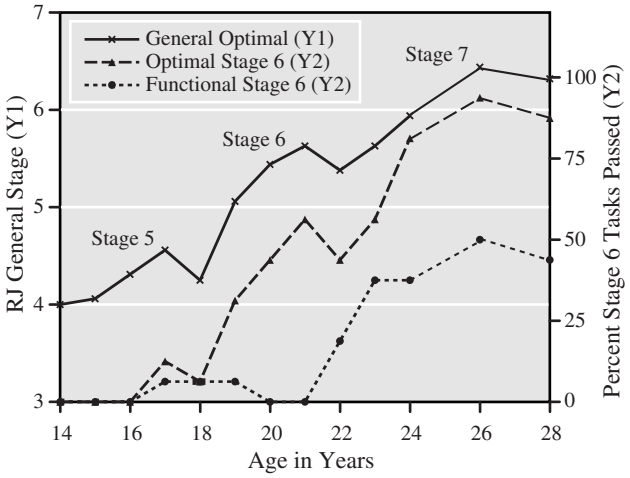

Figure 7.29 Development of reflective judgment: Optimal and functional levels. Performance at optimal level spurts on emergence of Stages 5, 6, and 7 of reflective judgment, but functional level performance shows slower, more gradual increase. The top line (solid) shows the general score for reflective judgment across all tasks. The two dotted lines show percentage of correct performance for the subset of tasks assessing Stage 6, which is the beginning of true reflective thinking. The upper dotted line shows optimal level for Stage 6, and the lower line shows functional level. *Source:* From "Developmental Range of Reflective Judgment: The Effect of Contextual Support and Practice on Developmental Stage," by K. S. Kitchener, C. L. Lynch, K. W. Fischer and P. K. Wood, 1993, *Developmental Psychology, 29,* pp. 893–906.

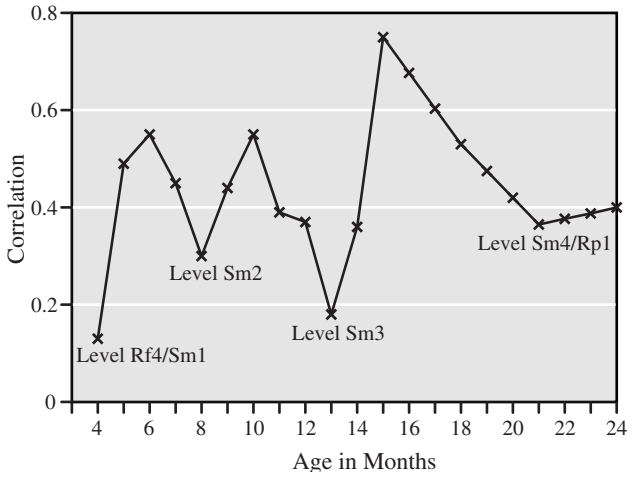

Figure 7.30 Changes in stability of infant behavior scores for girls in the Berkeley Growth Study. *Source:* From "Transitions in Early Mental Development," by R. B. McCall, D. H. Eichorn, and P. S. Hogarty, 1977, *Monographs of the Society for Research in Child Development, 42*(3, Serial No. 171).

test performance at three ages in infancy from the Berkeley Growth Study showed sharp drops in correlations among test items at approximately 8, 13, and 21 months of age, as well as a rise from low stability at 4 months, as shown in Figure 7.30 (McCall et al., 1977). These changes match other evidence for discontinuities at similar ages (for instance, Fischer & Hogan, 1989; Ruhland & van Geert, 1998; Uzgiris & Hunt, 1987).

The clear evidence for discontinuities must be understood dynamically: Most activities do not exhibit clear discontinuities at these ages because level varies dynamically with optimal support, emotional state, task demands, and many other factors. Discontinuities occur consistently only in activities that at a minimum (a) increase in complexity with development and (b) are assessed under conditions that support optimal performance (the person's optimal level). Subtler measures of discontinuity tend to show gaps in scales at the same points even without high support, but the relations with age are then highly variable (Dawson-Tunik, 2004).

Growth Cycles in Brain

One of the most remarkable characteristics of the evidence for brain development is the similarity in growth curves with cognitive development. Brain growth shows the same series of discontinuities, fitting the hierarchical growth curve for psychological development. Many of the data have been reviewed by Fischer and Rose (1994) and Thatcher (1994), especially for cortical activity, synaptic density, and head growth. They find that the majority of studies provide globally supportive evidence, but are limited by age sampling that is too infrequent to provide precise estimates of growth functions. The studies with more frequent sampling of age show clear, strong cyclicity of brain growth, with a series of discontinuities at specific age periods, listed in Figure 7.3. Here are a few strong examples involving the EEG, which measures electrical activity in the cortex. The measures showing the clearest developmental change involve the amount of energy in electrical waves, which is called power. Relative power is assessed for a region and wave band by dividing its energy by another measure of energy such as the total energy in the EEG.

In infancy, discontinuities in EEG power appear at ages similar to those for psychological development—approximately 3 to 4, 6 to 8, 11 to 13 months, and 2 years (Hagne, Persson, Magnusson, & Petersen, 1973). For example, a study of relative power for occipital EEG in Japanese infants found spurts at approximately 4, 8, and 12 months, as shown in Figure 7.31 (Mizuno et al., 1970). During childhood and adolescence discontinuities cluster at approximately 2, 4, 7, 11, 15, and 20

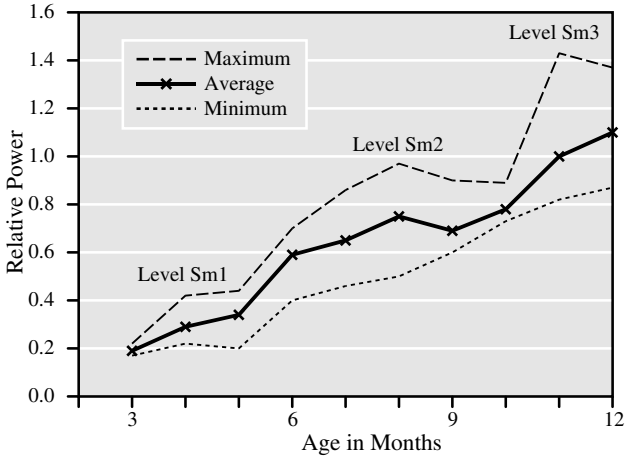

Figure 7.31 Development of relative power in occipital EEG in Japanese infants. Relative power is the ratio of power for the band from 7.17 to 10.3 Hz to power for the band from 2.4 to 3.46 Hz. *Source:* From "Maturation of Patterns of EEG: Basic Waves of Healthy Infants under 12 Months of Age," by T. Mizuno et al., 1970, *Tohoku Journal of Experimental Medicine, 102,* pp. 91–98.

years (Somsen, van 't Klooster, van der Molen, van Leeuwen, & Licht, 1997; Thatcher, 1994). Figure 7.32 portrays development of relative power from a classic Swedish study, with spurts at approximately 2, 4, 8, 12, 15, and 19 years (Hudspeth & Pribram, 1992; John, 1977; Matousek & Petersén, 1973).

Thatcher's (1994) massive study of development of EEG coherence illustrates not only the existence of discontinuities at appropriate age regions, but also other shapes for growth curves with different forms of discontinuity. Coherence is a measure of correlation between wave patterns in different cortical regions, so that high coherence indicates that two regions have similar EEG wave patterns and are therefore connected and communicating with each other. With development, coherence for any pair of EEG sites typically oscillates up and down, and these oscillations show growth cycles, moving through cortical regions in a regular pattern. In addition, the oscillations evidence discontinuities that relate to developmental levels, in which the oscillation pattern abruptly shifts to a different period. At approximately 4, 6, and 10 years, the period of oscillation shifts dramatically, and the relations of patterns of oscillation across brain regions shift from in-phase to out-of-phase, or vice versa. These patterns provide powerful clues for analyzing development of brain-behavior relations.

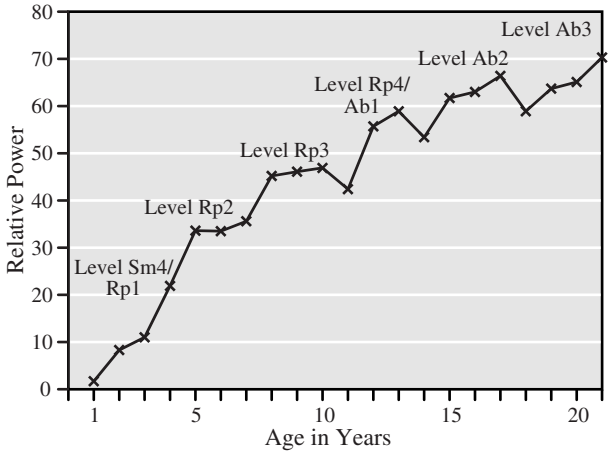

Figure 7.32 Development of relative power in alpha EEG in occipital-parietal (O-P) area in Swedish children and adolescents. Relative power is the amplitude in microvolts of absolute energy in the alpha band divided by the sum of amplitudes in all bands. *Sources:* From *Functional Neuroscience: Vol. 2. Neurometrics,* by E. R. John, 1977, Hillsdale, NJ: Erlbaum; and "Frequency Analysis of the EEG in Normal Children and Adolescents" (pp. 75–102), by M. Matousek and I. Petersén, in *Automation of Clinical Electroencephalography,* P. Kellaway and I. Petersén (Eds.), 1973, New York: Raven Press.

The cycles of coherence suggest not only a series of discontinuities but a growth cycle in connectivity among cortical regions for each level (Fischer & Rose, 1994; Immordino-Yang & Fischer, in press; Thatcher, 1994). Surges and drops in connectivity as measured by EEG coherence cycle through brain regions in repetitive patterns. The leading edge of growth moves in a systematic pattern around the cortex, showing one full cycle for each level, as diagramed in Figure 7.33. The connections are typically led by the frontal cortex, beginning with long-distance connections between frontal and occipital regions for both hemispheres. Then growth moves systematically around the cortex, extending through the right hemisphere and then through the left. For the right hemisphere, growth begins with long-distance, global connections and then contracts toward more local ones. In the left hemisphere, growth begins with more local connections and expands toward more distant ones. Growth moves systematically through cortical areas until it encompasses networks everywhere in the cortex. The cycle thus explains how independent networks manifest concurrent growth spurts in a general age period.

There is much exciting research to be done to test out these models of brain-behavior development and their implications for relations between brain change and behavioral development. It is important to remember, however, that they are dynamic systems, which means that they will not follow uniform shapes for growth. They will show variations from the simplified growth functions in Figure 7.15 and various figures in this chapter. They will also show important variations across individuals, tasks, states, and contexts, as predicted by the growth processes in the dynamic model.

CONCLUSION: DYNAMICS OF STABILITY AND VARIABILITY IN DEVELOPMENT

The proper focus for understanding human action, thought, and feeling is the organization of human activities and their many variable shapes. Activities form coherent patterns—dynamically varying structures that people actively construct at every moment, using not only their brains but also their bodies; the objects and people around them; and the roles, norms, and values of their culture. Dynamic structuralism analyzes human activities in all their complexity, combining concepts

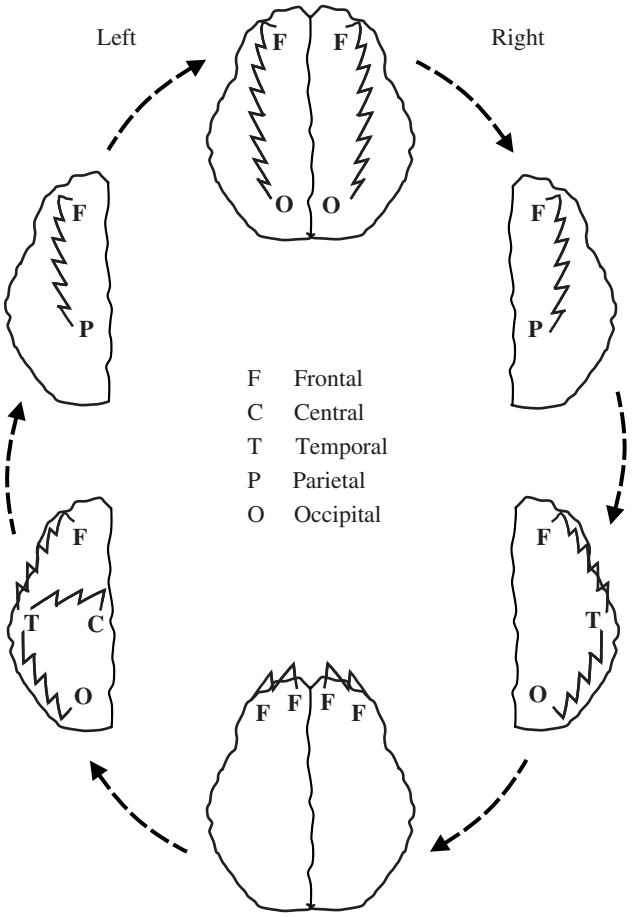

Figure 7.33 A cycle of growth of cortical connections for each level of skill development. *Note:* Jagged-line connections mark the leading edge of growth of coherence. Growth continues for each connection at other times as well. Connections between the middle and back of the left hemisphere are more prevalent than similar connections for the right hemisphere, and the temporal-central connection for the left hemisphere is shown as an example of that difference. *Sources:* From "Dynamic Growth Cycles of Brain and Cognitive Development" (pp. 263–279), by K. W. Fischer and S. P. Rose, in *Developmental Neuroimaging: Mapping the Development of Brain and Behavior,* R. Thatcher, G. R. Lyon, J. Rumsey, & N. Krasnegor (Eds.), 1996, New York: Academic Press; and "Cyclic Cortical Reorganization: Origins of Human Cognitive Development" (pp. 232–266), by R. W. Thatcher, in *Human Behavior and the Developing Brain,* G. Dawson & K. W. Fischer (Eds.), 1994, New York: Guilford Press.

and tools from nonlinear dynamics, biology, and cognitive science.

Explanation starts with people *in medias res,* and the structures of action, thought, and feeling are analyzed in the activities themselves, not in static logic, innate ideas, or internalized experiences. When a person acts, he or she functions on multiple developmental levels simultaneously, not just on a single level. As a person grows, his or her activities develop in many different shapes, not according to one or two basic patterns, as in linear change. Although the complexity of activities is great and their variability ranges widely, researchers can use powerful tools from dynamic systems and skill analysis to investigate the structures or organizations (patterns of components) and find the order in the variation.

The classic frameworks for analyzing structures have not acknowledged either the dynamics or the self-organizing properties of human action, feeling, and thought. They have relied on a static conception of structure as form, seeking simple "main effects" and "stabilities" instead of appreciating the power of analyzing variation. This static conception has reduced structures to one-dimensional forms with most of their components missing. It has reified psychological structures by treating them as logic, innate ideas, or sociocultural systems instead of placing them directly in the activities themselves. In its current guise, it forms the modern synthesis, in which nativist and empiricist positions are no longer in opposition but instead form a common framework based on Cartesian epistemology, reducing people to separate parts and analyzing them statically in separated nature and nurture.

Doing research within the dynamic structural framework leads to a different place. Analyzing the variability of human activities turns out to help illuminate the order within the variation; that is, designing research to analyze dynamics leads to new insights about the stabilities inside the variability. When development is analyzed as a constructive web instead of a linear ladder, clearly distinct pathways become evident for different people. For example, poor readers are not simply low on the ladder for development of reading, but they are developing their reading skills along more branched, less integrated pathways than normal readers. Abused children are not simply immature on the ladder for emotional stability and social reciprocity, but they have created distinct branched (often dissociated) pathways to cope with their abuse.

When multiple levels of skill are analyzed in each person, the debate about the existence of stages disappears. There is a common complexity scale for development and learning across domains, marked by discontinuous jumps at regular points in the scale, but it functions dynamically, not as a fixed ladder. Under optimal, highly supported conditions, people show jumps in performance

that act much like stages; but under ordinary, low-support conditions, the same people show no systematic stages, often progressing in smooth, monotonic growth. The complex shapes of growth curves under these various conditions provide important tools for analyzing relations among different components of human activity because the shapes can serve as clues for discovering such relations. Analysis of these shapes suggests relations between development of brain electrical activity and behavior, leading to new models of cycles of growth that relate brain activity to levels of skill development.

Recognition that individuals function at multiple simultaneous levels also allows the detection of strong microdevelopmental progressions reflecting people's construction of new skills and knowledge. It illuminates previously unrecognized mechanisms of transition such as co-occurrence of alternative strategies for approaching a task, repeated reconstruction of a skill to make it generalized, and construction of empty algebra-like shells to guide one's learning and facilitate building more complex skills. The common complexity scale in combination with growth models facilitates relating the short-term processes of microdevelopment to the long-term patterns of macrodevelopment.

When the collaborative nature of most activities is recognized and analyzed (instead of isolating people and studying them as separate "individuals"), important aspects of development become clarified. Processes of construction of skills can be straightforwardly detected in many situations because people interact with each other about their common activities with a task or problem. Many patterns of emotional development become clear because so much emotion arises from people's social relationships. Emotions such as shame and love are obviously social as well as biological, but even emotions such as fear, anger, sadness, and joy grow up in relationships and are defined by social scripts. Emotions act dynamically to shape or bias activity and development, and persistent, strong emotional experiences create distinctive developmental pathways such as richly textured shame concepts in China and elaborated negative self-in-relationship models in children who suffer abuse and trauma.

Scholars and researchers now have many new tools and concepts for analyzing the richness of human development, moving beyond Cartesian paradigms that reduce dynamic organization to static form and dichotomous analysis in nature versus nurture. Many examples are already in hand of how dynamic structural analysis helps illuminate phenomena that have been perplexing or that have gone undetected in prior paradigms. With the new dynamics, developmental scientists now have the possibility of capturing human nature in all its richness and variation instead of reducing people to one-dimensional stereotypes.
