CHAPTER 8

The Person in Context: A Holistic-Interactionistic Approach

DAVID MAGNUSSON and HÅKAN STATTIN

Since the birth of psychology as a scientific discipline, the central task has been formulated in various ways. Some of these formulations have greatly influenced both theory and empirical research by focusing on aspects of the functioning of the total human being. However, lack of consistency in the theoretical framework for what scientists claim is the same discipline that still exists and is a major cause of the fragmentation that characterizes research on psychological phenomena. More and more psychologists are becoming aware of the need for a general theoretical framework for designing, implementing, and interpreting studies of specific issues. This has been particularly evident in personality research (e.g., Cervone, 2004; Mischel, 2004). The aim of this chapter is to discuss this situation, identify its consequences by focusing on individual development, and suggest what can be done to promote further success in making developmental science a full member of the scientific family.

Focusing on that goal, the discussion in this chapter starts from the proposition that *the central task for scientific psychology is to contribute to an understanding and an explanation of why individuals think, feel, act, and react as they do in real life* (Magnusson, 1990). The discussion is based on the following propositions:

Proposition 1: The functioning and development of the individual is our main concern. However, an individual's current functioning and life-span development are not isolated from the environment in which he or she lives. A basic tenet for the presentation and discussion here is that the individual is an active, purposeful part of an integrated, complex, and dynamic person-environment (PE) system—the PE system. Consequently, it is not possible to understand how social systems function without knowledge of individual functioning, just as individual functioning and development cannot be understood without knowledge of the environment (e.g., Coleman, 1990). The fundamental implication for future psychological research is that we have to change the object of theoretical and empirical research from a context-free individual to a person who functions and develops as an active, intentional part of an integrated, complex PE system (e.g., Ryff, 1987).

Proposition 2: Within the PE system, the individual functions and develops as an integrated, indivisible whole. This circumstance has far-reaching implications for research on psychological phenomena.

Proposition 3: The proposed task requires a research strategy where results from single studies contribute to the synthesis of knowledge that is required for understanding why individuals think, feel, act, and react as they do in real life and how they develop in these respects.

Proposition 4: A basic requirement in such a research strategy is the application of a general theoretical model on individual functioning and development as a common framework for the design, implementation, and interpretation of studies on specific issues. This is characteristic of development in all scientific disciplines concerned with dynamic, complex processes.

These propositions are not new. They have been formulated before and are well known and widely accepted at the theoretical level. However, despite basic and far-reaching implications for theoretical and empirical research on developmental processes of individuals, their impact is limited in these respects. Our evaluation is that this circumstance is one cause of the fragmentation in what is normally designated developmental psychology. This chapter emphasizes the need for real consideration of the perspectives reflected in the propositions, in order to achieve real scientific progress in research on individual developmental phenomena.

The importance of an overriding, common theoretical frame of reference for scientific progress is demonstrated in the history of the natural sciences. In physics, the Newtonian model of the world served this purpose for a long time and formed the ground for the enormous success of research on the inanimate world. In the twentieth century, it was complemented by Einstein's relativity theory and by quantum theory; at present, theoretical physics is developing a general theory to overcome the incompatibility of the two: the string theory. For psychology, the theory of evolution presented by Darwin in 1859 as the framework for research on living organisms played a role closer to our current situation. An indication of the fundamental importance of a holistic frame of

This chapter is a revised version of D. Magnusson and H. Stattin (1998) "Person-Context Interaction Theories" published in the fifth edition of this *Handbook*. The chapter has been read and commented on by Lars R. Bergman, Jan Bergström, Michael Bohman, Magnus Kihlbom, Uno Lindberg, Ulf Lundberg, and Henry Montgomery. We are deeply grateful for their comments.

The work presented here was supported by grants from the Bank of Sweden Tercentenary Foundation, the Swedish Council for Social Research, and the Swedish Council for Planning and Coordination of Research.

reference for research in life sciences is the establishment of *Systems Biology*.

> Systems biology does not investigate individual genes or proteins one at a time, as has been the highly successful mode of biology for the last 30 years. Rather, it investigates the behavior and relationships of all of the elements in a particular biological system while it is functioning. (Ideker, Galitski, & Hood, 2001, p. 343)

In psychology, as a life science, a common frame of reference for the study of specific issues has the following main implications:

- Results of empirical studies on specific issues are necessary to build the synthesis of knowledge about the phenomena under investigation (e.g., Richters, 1997). The application of a general theoretical model implies, among other things, that results concerning specific aspects of the integrated individual acquire additional meaning compared to those without the common frame of reference. The whole is more than the sum of its parts. Others had seen before each specific aspect of nature that Darwin observed on his trip around South America. But it was not until Darwin systematized his observations and interpreted them in the general perspective of the holistic model of natural selection that they constituted the basis for the development of a general theoretical model of evolution, a model that could serve as the framework for the design, implementation, and interpretation of studies on specific issues. Accordingly, one of the most remarkable developments in the history of science was launched through Darwin's ingenious ability to systematize his observations into a general, holistic model (cf. Mayr, 2000a). As emphasized by scientists from very different perspectives, for further progress on the road to understanding and explaining how and why individuals think, feel, act, and react in real life, psychology is in the need of a general holistic framework. This need includes research on individual development.
- A basic requirement for scientific progress is communication between researchers investigating different but interdependent problems. A general theoretical framework offers a common conceptual space as a prerequisite for effective communication between researchers concerned with different issues at all levels of the phenomena involved in the processes under consideration. In natural sciences, a common theoretical framework allows astrophysicists to communicate with those concerned with problems at the atomic level, and vice versa. In his comments on scientific development, Montgomery (2004) notes that fragmentation results from a lack of coherent scientific models: "Language in science is in the midst of change and appears as dominated by two contradictory trends. Globalization of scientific English seems to promise greater international unity, while growth of field-specific jargon suggests communication diasphora" (p. 1333). To summarize: A general model for human functioning and development will help to overcome fragmentation in research by serving as a common theoretical framework for the specification of issues and the design and interpretation of empirical studies on specific phenomena and for effective communication among researchers on central issues.

THE ENVIRONMENT

In psychological research, the idea that individual functioning cannot be understood without considering the environment in which it occurs was explicitly expressed early on in Lewin's well-known formula $B = f(PE)$, when he focused on the individual's "life space" (Lewin, 1935, p. 11–12). However, the environment is a fuzzy concept with a variety of interpretations, and its application here calls for some specification. For a discussion of the environmental role in individual functioning and development, the environment can be ordered along the dimension of proximity to the individual's experiences. In the following discussion, three environmental positions along that dimension are distinguished: (1) the immediate situation, (2) the proximal environment, and (3) the distal environment.

An individual's current functioning always takes place in a situation with specific features. Individual functioning inevitably relates to specific situational conditions and cannot be understood in isolation from them. It is in momentary situations that we meet the world, form our conceptions of it, and develop our specific way of handling new situations. Individual experiences are fundamental for the developmental socialization process. Situations present—at different levels of specification—the information that we need to act adequately and they offer us the necessary feedback for building valid conceptions of the outer world. By assimilating new knowledge and experiences into existing

mental categories and by accommodating old categories and forming new ones, each individual develops an integrated system of mental structures involved in continuous interaction with the environment. On the basis of and within the limits of inherited dispositions, affective tones become bound to specific contents and actions, and strategies develop for coping with various kinds of environments and situations in a continuously ongoing learning process (Magnusson, 1981, p. 9). These formulations are linked to the analysis of current individual functioning across situations that is discussed later in the section titled: Individuality: The Developing Person.

This situation-bound process takes place in a variety of settings—at home, school, neighborhoods, clubs, or libraries, for example. Among other things, these settings offer opportunities for relationships with family members, peers, schoolmates, and other individuals. Together, these environmental elements with which the individual is or can be in direct contact, constitute what is discussed as the *proximal environment.* The proximal environment is to some extent individually unique, which is illustrated by research on the role of siblings in a later section.

Proximal environments are embedded in and dependent on the characteristic sociocultural and physical features of an environment at a more general level designated as the *distal environment.* The features of an individual's proximal environments are directly dependent on the features of the distal environment in which it is embedded.

Along the proximity dimension, the total PE system to which an individual belongs forms a hierarchic system in which immediate situations, proximal environments, and distal environments are integrated. The role of proximal and distal environments in the individual developmental PE interaction processes is discussed in the section titled: The Environment in the PE System.[1]

THE GOAL OF SCIENTIFIC PSYCHOLOGY

The goal of scientific work is to formulate the basic principles and specific mechanisms for how and why phenomena function as they do at various levels of complexity. This goal is as relevant to the study of human functioning and development as it is to the study of physics. The remarkable advances in the physical sciences, and the resulting rapid development of a highly technological society, have resulted in physics becoming the model for other scientific disciplines, including behavioral and social sciences. Unfortunately, other fields have sometimes adopted the goals and values espoused by physicists without considering whether the phenomena involved are congruent with the model that physics provides. For example, a central concept in the search for precise laws in the framework of the Newtonian mechanistic model of nature is "prediction." Ever since J. B. Watson (1913) defended psychology as a natural science by proposing that "prediction and control of behavior" are the goals of scientific psychology, accurate prediction has often been regarded as a main criterion for the validity of a scientific law in psychology. Fostered by the development and application of technically sophisticated statistical tools, prediction has also become a central goal for research on human ontogeny. The psychological importance of single variables or composites of variables in individual development is often measured by how well they predict later outcomes in statistical terms. The claim that prediction and control are central goals for developmental research continues to be espoused even in areas where it is not very appropriate.

Exact prediction of individual functioning and development as the ultimate goal for psychological research can be questioned for two interrelated reasons. The first has to do with individual functioning as integrated processes; the second concerns the laws that direct this type of processes.

One of the fundamental propositions behind modern models for dynamic complex processes is that these processes are guided by specific principles but tend to be unpredictable except under specific, restricted conditions (e.g., Kelso, 2001). Research on human functioning belongs to the "life sciences." The Nobel laureate Frances Crick (1988) discussed the kinds of laws sought in different disciplines and concluded that the phenomena that are studied in biological systems are such that the universally valid, strong laws that define physics are not applicable to biology. Mayr (1997), a leading biologist of the twentieth century, took the same position and concluded that biology needed to abandon the paradigm of classical physics to develop as a scientific discipline

[1] In this chapter, the concept "the physical environment" includes the biological components. In Western cultures, other individuals constitute the most important component. In other cultures, various forms of domestic and wild animals also contribute to form the integrated environment.

in its own right. As a life science, psychology has more to learn from biology than from physics.

In this perspective, the final criterion for success in our scientific endeavors is not how well we can predict individual behavior across different situations or over the life course, but how well we succeed in explaining and understanding the processes underlying individual functioning and development. The scientific goals for psychological research in general are then threefold:

1. To identify the factors operating in the integrated processes of human functioning and development. They may be mental, biological, and behavioral on the individual side and/or environmental components, depending on the nature of the process under investigation.
2. To identify the basic principles characterizing current functioning and developmental processes. This issue is discussed in a later section on individual development. Basic principles are general features that characterize developmental processes of all humans, independent of age, sex, and culture. For real scientific progress in research on individual development, these principles must be considered in specific theoretical and empirical research.
3. To identify the mechanisms by which operating factors work at the specific level of the individual in the framework of the PE system to fulfill their role in the integrated functioning of the individual (see methodologies and research strategies in a later section).

It should be emphasized that we take issue with prediction as the ultimate criterion for the scientific success of research on human functioning and developmental processes, not with prediction as a tool in a research design. The focus of the chapter is *individuality,* and a key concept in our discussion is *process.* Of course, prediction is a useful conceptual and methodological tool in an appropriate design for research on properly analyzed phenomena. The concept of prediction as a tool is also applicable in numerous practical situations to which psychological methods are being applied, for example, in personnel selection or decision making. In such situations, the certainty with which predictions are made, that is, the probability that certain events may occur, is of basic interest.[2]

[2] A problem with the concept of prediction in developmental research and in psychological research in general arises in discussions of empirical results by the use (or misuse) of the concept of prediction in two orthogonal meanings: (1) prediction of significant statistical relations, for example, between data for a predictor and data for a criterion; and (2) prediction of individual functioning. Significant correlation coefficients are very often discussed as if they could be interpreted as significant predictors of individual functioning. This is an unscientific misuse of statistics. It has been empirically demonstrated with solid data that even significant correlation coefficients of a size that are common in developmental research, cannot form the basis for that kind of conclusion (Magnusson, Andersson, & Törestad, 1993).

A THEORETICAL FRAMEWORK: THE HOLISTIC-INTERACTIONISTIC MODEL

Considering the central role of interaction in processes of living organisms, the general theoretical approach to the study of individual functioning and development comprises a holistic-interactionistic framework (Magnusson, 1995, 2001). Briefly, a modern holistic-interactionistic model emphasizes an approach to the individual and the PE system as organized wholes, functioning as totalities and characterized by the patterning of relevant aspects of structures and processes in the individual and in the environment. At all levels, the totality derives its characteristic features and properties from the functional, dynamic interaction of the elements involved, not from each isolated part's effect on the totality. Each component of the individual structures and processes that are operating, as well as each component of the environment, takes on meaning from its role in the total, integrated functioning of the individual (Magnusson, 1990). A striking example of this psychobiological process and its dependency on the characteristic context stimulation is the result of empirical research on olfaction presented by the Nobel laureates in medicine 2004, Richard Axel and Linda Buck (see, e.g., Buck and Axel, 1991). They showed that each specific scent is normally a mix of odorant molecules that activates a combination of different sensors—types of receptor cells that send their signal via the olfactory bulb to the cortex. The unique code that reaches the cortex makes us perceive a given odorant and assign meaning to it. Accordingly, the stimulating context must be structured and the biological system involved must be patterned in a unique way to make it possible for the individual to identify and give meaning to a certain odor.

It should be clear, and this is important for understanding its role in the research process, that the holistic-

interactionistic model is not an empty conceptual box: It has a substantive content of basic principles that characterize the processes of individual development in the same way that the basic principles of diversity and mutation do in the framework of natural selection. Basic principles in developmental processes are discussed in a later section.

PERSPECTIVES

An individual's thoughts, feelings, actions, and reactions can be the object of study from three complementary perspectives: synchronic, diachronic, and evolutionary. It should be recognized that the three perspectives are complementary, not contradictory. This chapter focuses on the diachronic perspective; that is, the developmental processes of individuals. The holistic-interactionistic perspective of individual functioning in a synchronic perspective was reviewed and discussed in Magnusson (1990) and Magnusson and Törestad (1993) and the interested reader is referred to those articles. In the following presentation, current functioning is included when it is appropriate. The evolutionary perspective is not considered here.

Research on psychological phenomena in a synchronic perspective is concerned with the processes of thoughts, feelings, actions, and reactions within the framework of existing mental, biological, and behavioral structures. Accordingly, "synchronic" models analyze and explain why individuals function based on their contemporaneous mental, behavioral, and biological states and independent of the developmental processes that may have led to the present state of affairs (e.g., most cognitive models). In contrast, "diachronic" models analyze current functioning in terms of the individual's developmental history. They are concerned with how relevant aspects of the individual and his or her environment have operated in the process leading to the current functioning.

Research on individual development refers to changes in mental, behavioral, and/or biological factors that are involved in the integrated processes of individual current functioning. In its most general form, development of an organism refers to any progressive or regressive change in size, shape, and/or function. Research on individual development is concerned with this process over the life span, from conception to death (Baltes, Lindenberger, and Staudinger, 1998; Cairns, 1998; Overton, 1998; Valsiner & Conolly, 2003, presented elaborated overviews and discussions of the concept of development, its theoretical, conceptual, and methodological implications).

THREE GENERAL APPROACHES TO PERSON-ENVIRONMENT RELATIONS

At a metatheoretical level, three general approaches to the study of person-environment relations in individual current functioning and development can be distinguished: (1) unidirectional causality, (2) classical interactionism, and (3) modern interactionism, here designated holistic interactionism. Each has its specific implications for theory building and for implementation and interpretation of empirical studies.

Unidirectional Person-Environment Models

The traditional view of the role of the environment in developmental processes has two interrelated characteristics. First, the individual and the environment are regarded, discussed, and treated as two separate entities. Second, the relation between them is characterized by unidirectional causality: The individual is the target of environmental influences. The view is reflected in theories and models at all levels of generality, from Marxist models for society to S-R (stimulus-response) models for very specific aspects of behavior studied in the mainstream of experimental psychology. Seemingly, very different theories adhere to this approach. According to classical psychoanalytical theory, the life course of an individual is under the unidirectional influence of the parents' treatment of the child during infancy. Watson (1930), in his discussion of individual development in a behaviorist perspective, gave the environment a decisive role in the processes of an individual development. Even in developmental theories that did not refer to a behaviorist or psychoanalytic view, the family was usually regarded as influencing the child in a unidirectional way during the socialization process from infancy through adolescence. The unidirectional approach is also manifested in research designs that employ concepts of prediction, independent and dependent variables, and predictors and criteria.

Adopting a psychometric variable approach in empirical research on the relation between environmental factors as independent variables and person characteristics as outcome variables has a long tradition. Good

examples are found in educational research on the role of the home background for individuals' educational and vocational career. In studies on the role of the environment for children and their socialization processes, the possible impact of the family has been a central topic. An example of this line of research was presented by Baumrind (1971). She distinguished between three groups of parental attitudes that influenced children's behavior: authoritative, authoritarian, and permissive. The influence of children's behavior on the parenting was not considered—child behavior was an output of parental practices.

Classical Interactionism

The central idea of classical interactionism is expressed in the formula $B = f(PE)$; that is, individual functioning is the result of the interplay of individual and environmental factors. This implies that interest focuses on the interface of person-environment relations. In contrast to the traditional unidirectional view, the classical interactionistic formulations emphasized that a characteristic of the relations is reciprocity (e.g., Endler & Magnusson, 1976).

Particularly during the 1970s and 1980s, the explicit formulations of a classical interactionisitic model exerted a twofold impact on personality research, besides having implications for planning, implementing, and interpreting developmental research. First, the issue of cross-situational consistency in individual current functioning became a central topic for theoretical debate (e.g., Magnusson & Endler, 1977; Mischel, 1973). Second, this debate accordingly led to an interest in theoretical taxonomies and empirical analyses of contextual characteristics (see Forgas & Van Heck, 1992; Magnusson, 1981).

In very general terms, classical interactionism has old roots. An early proponent of an interactionistic position was Wilhelm Stern (1935). He defined the arena for the reciprocal person-environment interaction as the person's "biosphere" or "personal world" (cf. Kreppner, 1992b). Baldwin had discussed ontogenetic and evolutionary development in such terms in the 1890s. And as suggested by Cairns and Cairns (1985), there is a direct line from Baldwin to Piaget, Kohlberg and others who have influenced various areas of developmental research. A major step forward in the application of an interactionistic view in empirical developmental research was the publication of two articles by Bell (1968, 1971), stressing the bidirectional relation between parents and their children. The reciprocity in mother-child relations was also stressed by Ainsworth (1983) in her discussion of attachment. This line of research has been followed up and summarized by Kerr and Stattin (2003).

Since the 1970s, most developmentalists have accepted the role of person-environment reciprocal interaction theoretically. Reciprocity in interpersonal relations has been a building block in many theoretical developmental models. Historically, from Bowlby (1952) onwards, developmentalists have employed terms that expressed the interdependent, reciprocal character of social interactions. However, while reciprocity was acknowledged in theory, the reciprocal nature of the concepts has often been lost in actual assessments. Leading developmental researchers have used different terms to identify this view.[3]

Holistic (Modern) Interactionism

According to a holistic-interactionistic perspective, psychological events reflect two interdependent levels of individual processes: (1) The continuously ongoing interaction processes between individual and environmental factors, and (2) the continuously ongoing processes among psychobiological and behavioral components in the individual. The view differs from classical interactionism in two respects. First, holistic interactionism emphasizes more strongly the holistic, dynamic character of individual functioning and of the total PE system, both in a current and developmental perspective. Second, it incorporates both biological

[3] As reported above, different concepts and formulations have been proposed and used for what is here designated "interaction" and "interactionism," including "transaction,""reciprocal determinism," "dialectic-contextualistic," "process-person," and "developmental dualism." Our reason for using the terms interaction and interactionism is that in all other life sciences these terms are well established as representing a fundamental aspect of the life processes of living organisms (e.g., Lindberg, 2000). In social ecology, the interaction concept is a fundamental one. In our view, it can only be harmful and detrimental to scientific progress in our own discipline, which is dependent on collaboration with neighboring sciences for successful scientific progress, if we continuously invent and apply new terms instead of adopting concepts that are already well established in disciplines with which we want to collaborate.

processes and manifest behavior into the model in a systematic, explicit way.

An essential aspect of a holistic-interactionistic model is that at all levels of the PE system, from the macro- to micro-level of cell systems, the operating components function and develop as integrated systems. Accordingly, the way integrated processes function and change is dependent on the interaction among all involved elements, vertically and horizontally, in the hierarchical organization of the organism. This proposition has decisive implications for effective methodology and strategy in research on human ontogeny (see the Methodological Implications section).

Holistic interactionism rests on five basic propositions:

1. The individual is an active, intentional part of a complex, dynamic PE system.
2. The individual functions and develops as a total, integrated organism.
3. Individual functioning in existing psychobiological structures, as well as developmental change, can best be described an integrated, complex, and dynamic processes.
4. Such processes are characterized by continuously ongoing interactions (including interdependence) among mental, behavioral and biological components of the individual and social, cultural, and physical components of the environment.
5. The environment functions and changes as a continuously ongoing process of interaction and interdependence among social, cultural, and physical factors.

The holistic-interactionistic model, summarized in the five propositions, has been fertilized from various sources at a rapidly increasing pace, largely as a result of scientific progress in neighboring life sciences (e.g., Magnusson, 1999a). Research on psychobiological and behavioral components of individual functioning and development have contributed to form a model that can serve as the framework for the design, implementation, and interpretation of empirical studies on specific issues. Modern models for dynamic processes, developed in natural sciences, have enriched the holistic-interactionistic framework, both theoretically and methodologically. Well-planned longitudinal studies have demonstrated the uniqueness of individual developmental processes. This has strengthened the notion of a holistic-interactionistic view as essential for understanding the mechanisms at work in the lifelong developmental processes of individuals.

An individual continuously encounters new situations implying new demands, threats, opportunities, and so on. In the process of interaction with the environment, the organism must maintain its integrity and the equilibrium of its internal regulations under varying conditions, even extremes. This adaptation process in each specific situation depends on mental, biological, and behavioral repertoire interaction of the individual, on the one hand, and the situational conditions, on the other.

An illustration of the interaction process in which psychobiological, behavioral and social factors are involved is seen when an individual interprets a situation—at work, during leisure time, and so on—as threatening or demanding. The cognitive act of interpreting the situation stimulates, via the hypothalamus and amygdala, the excretion of adrenaline and cortisol from the adrenal glands, which in turn triggers other physiological processes. The cognitive-physiological interplay is accompanied by emotional states of fear or anxiety and/or generally experienced arousal. Next, these emotions affect not only the individual's behavior toward and handling of the environment, but also his or her interpretation and expectations of sequences of changes in the situational conditions and, thereby, his or her physiological reactions during the next stage of the process.

The example illustrates how psychobiological components of the individual and components of the situation are involved in a continuous loop. The way this process goes on is contingent on, among other things, the environment as it is perceived and given meaning by the individual. The outcomes of such situation-individual encounters set the stage for subsequent actions and reactions to psychologically similar situations, as interpreted by the individual. The application of this perspective is illustrated in the discussion of stress research by Appley and Turnball (1986; e.g., Warburton, 1979, discussing physiological aspects on information processing and stress). In processes over time, this interaction involves the mental system (in its interpretation of certain types of situation), the physiological system, and the behavioral responses to such and similar situations.

Of particular interest in the holistic-interactionistic model is the role played by the individual's interpretation of what happens in the proximal environment and expectations about possible outcomes of his or her own actions. The appraisal of external information guides thoughts and actions and evokes physiological systems

that influence psychological events, thoughts, feelings, emotions, and actions. The individual's interpretation and appraisal of stimuli and events in the environment form an essential element in theorizing and empirical research on coping and adaptation (e.g., Smith & Lazarus, 1990).

Elements of a holistic-interactionistic model for individual development have been presented for some time. Influential forerunners of this view were Kuo (1967) and Schneirla (1966). Those who have contributed to the formulations of the holistic view include Cairns (1979, 1996), Gottlieb (1991, 1996), Lerner (1984, 1990), Magnusson and Allen (1983a, 1983b), and Sameroff (1989), among others. Brooks-Gunn and Paikoff (1992) argued for an integrated approach to the study of the socialization process, an approach that takes into account biological, affective, cognitive, and social factors. The bio-ecological model presented by Bronfenbrenner and Ceci (1994) is basically in line with the tenets of holistic interactionism. An application of the modern/holistic-interactionistic view in a specific field is found in Thelen's (1995) presentation of a new synthesis of motor development. Karli's (1996) presentation of an integrated, holistic bio-psychosocial approach to the development of aggressive behavior is in keeping with holistic interactionism. The same is true of Susman's (1993) discussion of the developmental processes underlying conduct disorder. Recently, Li (2003) and Baltes and Smith (2004) discussed the main features of a holistic-interactionistic view as a biocultural model.

The necessity—for a proper understanding of developmental processes—of considering the interplay of psychobiological, behavioral and social factors in a holistic-interactionistic framework is illustrated by examples from the Individual Development and Adapation (IDA) longitudinal study of Swedish children (Magnusson, 1988; Magnusson, Stattin, & Allen, 1985; Stattin & Magnusson, 1990). A complete cohort of boys and girls in a community in Sweden was followed from the age of 10. At the average age of 14.5 for girls, quite strong correlations existed between the age of menarche and data for aspects of norm-breaking behavior, school adjustment, and parent and teacher relations. For example, girls maturing very early reported much greater alcohol use than later-maturing girls. They also reported more strained parent and teacher relations and adjusted less well to school. Interpreted in a cross-sectional perspective, this result indicated that a group of girls at risk for antisocial development had been identified.

However, when the same girls were followed up at the age of 26 to 27, no systematic relation was found between age of menarche and drinking. On the other hand, very early biological maturation did have consequences for education, family, children, and job status. The girls who matured very early had more children and had completed less education than average or late maturing girls. These effects could not be attributed to early maturation only; rather, they were the net result of a web of interrelated factors, linked to biological maturation during adolescence: self-perception, self-evaluation, and, above all, the social characteristics of close friends. Girls with an early biological development perceived themselves in mid-adolescence as psychologically more mature than age-mates and associated more with chronologically older peers and boy friends (cf. Galambos, Kolaric, Sears, and Maggs, 1999). Briefly, they encountered a much more advanced social life, including what is regarded as norm-breaking behavior, than their later maturing age-mates (e.g., Caspi, Lynam, Moffitt, & Silva, 1993).

An essential point is that the onset of sexual maturity alone does not account for the observed short- and long-term consequences. Early biological maturation provided predisposing conditions for the integrated process involving individual mental and behavioral components, and social components in the environment. The current functioning of the girls during adolescent transition and its implications for their life history are dependent, among other things, on a combination of (a) early biological maturation, (b) easy access to older associates in the proximal environment, and (c) the dominant norms and rules in the proximal and distal environments.

Comments

Two comments are pertinent:

1. At a general level, the three approaches to PE relations reflect a historical development, in essential respects dependent on the scientific progress in other life sciences, including medicine. For example, in 1943 Clark Hull in a much-cited article in *Psychological Review* concluded that available knowledge about internal individual processes was too limited to serve as the basis for scientific analysis of them and sug-

gested that for the time being psychological research had to be restricted to the study of "molar behavior." As an effect of the rapid progress in human biology, Roger Russell in an APA presidential address in 1969, suggested, with reference to Clark Hull: "The situation is now different and is changing so rapidly that the psychologist is hard pressed to keep abreast of even those major developments in other biological sciences that are most relevant to his area of primary competences" (Russell, 1970, p. 211). Similarly, contemporary developments in the field of cognition, including information processing, learning, and memory, paved the way for the formulation of the holistic-interactionistic model.

2. What has been described here as three approaches to the study of PE relations reflects a characteristic feature of normal scientific development. Although none of them define an approach with very strict boundaries, either historically or contemporaneously, all three approaches still exist and are useful for different purposes, depending on the aim of the study and the characteristics of the phenomena under investigation. Individual contributors preceded the introduction of the holistic-interactionistic approach, more or less explicitly.

   The present distinction between the three approaches is not intended to be a comprehensive discussion of approaches to research on PE relations; it serves our purpose of proposing the holistic-interactionistic perspective as a necessary complement to the earlier models, as the basis for a general model of the functioning and development of the individual in the environment.

THE PERSON AS THE ORGANIZING PRINCIPLE FOR SCIENTIFIC INQUIRY

As we emphasized earlier, the individual functions and develops as an active, intentional part of an integrated PE system. This implies that the central issue for psychological theoretical and empirical research is not how the person and the environment interact as two separate parts of equal importance. It is how individuals, consciously and subconsciously, handle and adept to current situational conditions and how they develop over the life course in this respect. A basic proposition for the analysis is that individual development is not *determined* by but *dependent* on the environment.

The Person as an Active Agent in the Person-Environment System

The view of the individual as active and purposeful is not new. The dynamic conception of the mind and mental processes as activities, rather than as an organ receiving and processing information, was advocated by *the act psychologists* in Europe such as Brentano (1874/1924) and Stumpf (1883). In the United States, James (1890) was a proponent of the same view. The intentional nature of the individual's way of functioning, that formed a central element in Brentano's view, was also stressed by Tolman (1951) in his focus on purposive behavior. More recently, the individual as an active, purposeful agent has been emphasized in action theory (e.g., Brandtstädter, Chapter 10, this *Handbook,* this volume).

The Mediating Mental System

The view of the individual as the active, purposeful agent in the person-environment interaction process implies that a guiding principle in the individual's inner life and in his or her dealings with the external world resides in the functioning of the integrated mental system, including self-perception, perception of others, and worldviews, organized in schemata and plans. This proposition is reflected in the proposals to conceptualize personality as a goal-directed, adaptive open system (e.g., Allport, 1961; Hettema, 1979; Schwartz, 1987).

The mental system, based on brain activity, serves as a leading edge for adaptation in individual development in that it mobilizes neurobiological and physiological modifications. By selecting and interpreting information from the external world and transforming the information into internal and external activities, the mental system permits the organism to shape its effective environment and provides a rapid and reversible strategy whereby the organism can adapt to changing environments (e.g., Lerner, 1990; Nelson, 1999b).

Brain research has emphasized the role of the amygdala in mental processes. In a discussion of empirical studies on social phobia, Stein, Goldin, Sareen, Eyler Zorilla, and Brown (2002; see also Blumberg et al., 2003, for a discussion of the amygdala in adolescents with bipolar disorder) concluded:

> New leads for understanding the etiological substrates for social phobia have come from the basic and cognitive neurosciences. These studies have focused attention on the role of the amygdala and its rich networks of connections with other cortical and subcortical regions in the mediation of fear and anxiety. . . . Of particular relevance to social phobia, the amygdala is also thought to play an important role in the circuitry of social intelligence. Humans with bilateral amygdala damage are unable to make accurate social judgments of others. (p. 1027)

A central role for the view presented here is played by research on sensory perception and the functioning of the brain in the interpretation of information from the external world (e.g., Jeeves, 2004). In contrast to the mainstream traditional position, input into sensory processes is regarded as information that is interpreted and integrated by the brain and used in coping with internal and external problems rather than merely as stimulation of the sensory organs. The sensory organs function more as sensory systems than as independent sensory structures and the brain as a whole works as a pattern recognizer rather than as a device for measuring absolute magnitudes (e.g., Boncinelli, 2001; Tononi & Edelman, 1998). Vision, for example, is an active process of the brain, not a passive, reactive process (e.g., Popper & Eccles, 1977; Roland, 1993).

Subconscious Processes

A central concept in some psychodynamic models of the individual has been that of subconscious processes. The debate on this issue has been stimulated in recent decades by the growing interest in and understanding of the parallel processes of controlled (conscious, attended to, and thus subject to critical analysis) versus automatic (out of attentional focus and awareness) information processing (e.g., Kihlstrom, 1990; Öhman, 2002). One of the most important elements of subconscious processes is *expectation* in two interdependent respects: (1) expected outcomes of own activities in the present situation, and (2) general expectations about the environment in which the situation is embedded.

The role of subconscious processing of environmental information in the individual's adaptation to varying conditions was suggested by Sells (1966) in his analysis of feedback mechanisms in the adaptation process. Greenwald and Banaji (1995) discussed the role of subconscious processes in social cognition. It has also been suggested that unrecognized cognitive dysfunctions interfere with the socialization process (Buikhuisen, 1982), inhibit social adaptation, and promote delinquency in juveniles (Buikhuisen, 1987). Understanding the continuously ongoing processing of signals impinging on the senses out-of-awareness imparts new significance to the perceptual-cognitive system without necessarily referring to psychoanalytical concepts; at the same time, it reduces the central role earlier ascribed to conscious functioning.

Values, Valuations, and Norms

A central, sometimes decisive role in the mediating, mental processes that guide a person's purposeful dealing with the environment is played by the basic values, beliefs, norms, goals, and motives that are relevant for the particular issue under consideration (e.g., Eccles & Wigfield, 2002). In their discussion of the feedback processes underlying goal-directed action of an individual, Carver and Scheier (1998) stated: "Though not constituting the *whole* of the feedback loop, a goal is *essential* to the feedback loop" (p. 4).

The value structure underlies and influences the short- and long-term goals that direct an individual's thoughts and actions in current situations (Pervin, 1983). Max Weber, in his analysis of Protestantism and capitalism, made the implicit assumption that the individual's purposive, goal-directed activity is shaped by underlying values and preferences (e.g., Coleman, 1990). The history of politics and religion is full of illustrations of the strong impact of values and valuations on the functioning of individuals, organizations, and societies, reflected in attitudes, traditions, and conflicts. An elaborate model for how personal and social values, through attitudes and subjective norms, affect behavioral intentions and actions in a current perspective was presented in Fishbein and Ajzen's theory of reasoned action (Ajzen & Fishbein, 1980).

Values and valuations have a strong position in the integrated mediating system, both in guiding daily interests and activities, and in the organism's processes of maintaining continuity and stability in the individual's way of dealing with the environment. In a longitudinal study, Stattin and Kerr (2002) examined two types of value orientation in adolescents: "self-centered" (referring to concern primarily for one's own needs and enjoyment) and "other-centered" values (referring to concern for others' well-being and the common good).

Data for each of these groups showed coherent but different sets of correlations to various aspects of the adolescent life situations. More than 20 years after the first observation, other-focused values, relative to self-focused values, in adulthood were related to (a) stronger interest in other people, preference for being together with others, and a need to affiliate with other people or higher sociability; (b) more attached, than detached, interpersonal style; and (c) more warm and caring partner relations and a better family climate.

Overall, values and valuations can be seen to have a co-coordinating role, underlying functioning and development in diverse domains with implications for the life situation later on. This does not mean that values have a unidirectional impact on behavior. Values as well as cognitions, emotions, norms, and attitudes are part of the individual acting as a whole. At the same time, they are an effect of experiences and socialization, on the one hand, and influence the selection and interpretation of information from the external environment, on the other. For developmental research, the role of values and valuations in the socialization process and the role of various agents in the transfer of values and norms to youngsters should be highly central issues (Costanzo, 1991). This topic was addressed by Stattin, Janson, Klackenberg-Larsson, and Magnusson (1995), when concerned with how parents' punishment practices were reflected in their children's behaviors after they became parents.

Self-Consciousness, Self-Perceptions, and Self-Evaluations

In the processes of the individual's inner world as well as in his or her dealings with the environment self-consciousness—including self-perceptions and self-evaluations—is an important aspect of the mental system. James (1890) devoted a whole chapter to this issue (e.g., Epstein, 1990). In addition, in *The Wonder of Being Human: Our Mind and Our Brain,* the Nobel laureate John Eccles and Donald Robinson (1985) used the term "self-conscious mind" for what they saw as the highest mental experiences and discussed the emergence of self-consciousness and analyzed it as a central element in the brain-mind processes.

An expanding body of research has demonstrated that the ability of individuals to adjust to and cope with their environment depends on their beliefs and trust in their capacities, as was empirically demonstrated in a longitudinal study of females' educational careers (Gustafson & Magnusson, 1991). What matters are individuals' internal representations of situation-outcome contingencies and the mental representations of their roles as active participants in exercising control (e.g., Bandura, 1997). Children's experiences of handling their environment, of perceived control and predictability, have consequences for their view of themselves as (a) competent or noncompetent or as confident or non-confident in their abilities, (b) for their motivation to cope with demands of particular situations, and (c) for mobilization of behavioral and emotional resources. Harter (1990) described the prototype of the child with high self-esteem as the child who is confident, curious, takes initiatives, tolerates frustrations, and adjusts to environmental changes.

The development of the individual's self-perception, self-evaluation, and self-respect forms a main element in the process of learning and experience through which he or she gains the ability to exert predictive and active control over the environment (Bandura, 1977; Brandtstädter, 1993; Harter, 1983). The issue of personality and self in a developmental perspective is dealt with comprehensively by Baltes, Lindenberger, and Staudinger (Chapter 11, this *Handbook,* this volume). Pulkkinen and Rönkä (1994) empirically investigated the relation between self-identity in personal control over development and future life orientation and the role of school achievement, school success, and socioeconomic status in the home for these developmental aspects. In an article on the interaction between the self and the environment, Karli (2000) analyzed the interconnected brain regions that are involved in the socially adaptive functions of affect and emotion.

During developmental transitions, a central role is played by self-definitions in relation to formal and informal environmental age-graded developmental norms and expectations. Recent studies have convincingly shown that teenagers are well aware of whether they are "early," "on time," or "late" with respect to behaviors, such as formal age-prescribed behaviors and other less formal behaviors, connected with periods of transition; for example, time to be in at evening, bedtime, spending money, choosing clothes, and so on (e.g., Brooks-Gunn & Petersen, 1983). Stattin and Magnusson (1990) found that the definition of oneself as "early" among mid-adolescent girls tended to be associated with perceiving oneself as popular among boys, having more advanced drinking habits, more norm-breaking behaviors, but also

more school adjustment problems, and more psychosomatic and depressive reactions. Studies in Norway and Germany (Alsaker, 1995; Silbereisen & Kracke, 1997) have also demonstrated that self-definitions of oneself as being early maturing go hand-in-hand with engaging in more socially advanced behaviors in adolescence.

In his studies of illiterate inhabitants of isolated villages in Uzbekistan, Luria (1976) empirically demonstrated the basic role of culture in the development of individual self-perceptions. Brooks-Gunn and Paikoff (1992) dealt with this issue in their integrated approach to an analysis of what they designated "self-feelings" during the adolescent transition period.

Language and Language Acquisition

A crucial factor in processes of individual functioning and development is language and language acquisition. In a current perspective, access to a functional language plays a fundamental role for internal processes such as thinking and abstraction, as well as for behavior, for example in social contexts, regardless of cultural context, age, and level of intelligence. Access to a functioning language is central for the individual's interpretation of meaning in the environment. Language acquisition in the development of thinking was a central issue for Piaget (1964). In his empirical study of isolated and illiterate Uzbekistanis, Luria (1976) observed the link between access to linguistic ability and abstract thinking. The main topic of *Science* in February 2004 "Evolution of Language" is an indication of the current interest in this area from a broader scientific perspective. Recent research on individual language and language acquisition was summarized by Tomasello (1999; see also Lundberg, 2006).

Emotions

Everyday experiences show the importance of affective tones attached to inner life and external activities, with effects on our own behaviors and the behaviors of others. Scientists have recognized this in discussions of the human nature since ancient times. Darwin (1872) devoted a book to this issue, *The Expression of Emotions in Man and Animals* and William James in *Principles* (1890) discussed emotions and their relations to biological processes. From this perspective it is noteworthy, how empirical research on emotions was underestimated in the postwar period until the final decades of the twentieth century. A central role in the revival of research on emotions has been played by the work that has been presented, in the tradition of William James, on the connection between emotions and brain functioning. Research by Damasio (2003), LeDoux (1996), and others, has increased our knowledge of the role of feelings and emotions in the functioning and development of the mental, mediating system and their bases in brain processes. There is a growing interest in the role of emotions in decision making (see, e.g., Schwartz, 2000).

In an overview of research on emotional development during infancy and childhood, Thompson (2001) made a distinction between the structural perspective, in which emotions are analyzed by discrete states, and a functionalist perspective, questioning that emotions can be properly discussed as a package of elements. With reference to the latter view, he suggested what, in principle, is a holistic approach to the study of emotions and feelings in a developmental perspective:

> In this regard, what defines an emotion is not a network of internal subjective, physiological, and other components, but rather the constellation of a person's goals, appraisals, action tendencies, and other capacities in relation to environmental incentives, obstacles, and opportunities. (Thompson, 2001, p. 73–83)

Similarly, Forgas (2002) argued for a "multiprocess theory" when he discussed the role of affects in interpersonal processes. Tracy and Robins (2004) indicate the growing awareness of the integrated nature of individual mental life, focusing on self-conscious emotions, such as shame and pride, in contrast to "basic emotions," such as sadness and joy (cf. Damasio's, 2003, distinction between feelings and emotions).

Motivation

One of the most important concepts in individual functioning and development is that of motivation, closely connected with goals, values, emotions, and actions. Motivation is a fundamental issue for understanding human functioning and development: In everyday life, it is easy to recognize motivated individuals. Since the first centuries A.D., motivation has been a central topic in models of learning and education. A renewed interest has been demonstrated in several ways: For example, in modern action theory it has become a central topic, and there was a recent issue of *European Psychologist* focused on motivation and learning in different contexts (see Järvelä & Volet, 2004). Another issue of the same journal was devoted to the central issue of motivation and affect in self-regulation of behavior (Efklides,

2005). With reference to its role in delinquency, McCord (1997) suggested what she designated a construct theory of motivation.

Development of the Mediating Mental System

The way an individual's integrated mental system functions in a specific situation is the result of previous developmental processes of experiences and maturation. These processes take place within the limits of his or her constitutional dispositions in a continuous process of interaction with the physical, social, and cultural environment. The individual develops, in close interaction with environmental characteristics, an integrated cognitive, emotional system by assimilating new knowledge and experience into existing structures and accommodating old structures and forming new ones. Accordingly, the development of the brain is a fundamental topic for the discussion of appropriate models of individual functioning and development. "Neural circuits must be assembled with great precision in order to transmit and process information correctly" (Pasquale, 2000).

As a result of the PE interaction process, the characteristics of the mediating system in a person, and of its way of functioning (the specific cognitive structures that are built up, the specific contents of the structures, the affective tones bound to the structured contents, and the coping strategies), will depend on the environment encountered by the individual in the developmental process. The basic role of cultural factors in the establishment and use of an effective mediating system was empirically demonstrated by Luria (1976) in collaboration with Vygotsky. He showed how illiterate people living in isolated villages developed a mediating system and a language that hampered their ability to interpret the environment in abstract terms and to express self-perceptions and perceptions of others. Examples of the necessity of human contacts in the acquisition of language and other aspects of the socialization process are found in the documented cases of children who grow up without contact with other humans (McCrone, 1993). Altogether, these examples support the conclusion that while the human being is born with great biological (genetic and constitutional) potentials, the nature of the individual's functioning during all stages of the life course is dependent on his or her experiences, gained from the position in the integrated PE system.[4]

[4] An evolutionary perspective on the development of human speech was presented by Holden (2004).

The cultural dependency of mental processes was empirically illustrated by Irvine (1969): The concept of intelligence as defined in Western cultures had to be revised before intelligence tests could be used for comparing mental abilities in different ethnic groups (see also R. J. Sternberg, 2004). The experiences reported by Alistair Heron, the first professor of psychology in Africa in the 1960s, demonstrated that cultural factors are also important for sensory perception. He found that traditional culture-free tests did not function well in the contemporary African culture because these tests used figures in which angular corners played an important role, while boys and girls in traditional African villages lived in an environment in which everything was rounded. Ironically, when the "culture-free" tests were adapted to the environmental characteristic of the children's upbringing, the results were compatible with findings in Western cultures (personal communication to the first author).

To the extent that environments in which we are reared are similar, the main characteristics of our world conceptions have common characteristics. When the environments differ markedly, as between cultures, the total mediating system and the resulting interpretation of the environment also differs. In a series of cross-cultural studies of anxiety-provoking situations, systematic differences were found for children and youngsters in this respect (Törestad, Olah, & Magnusson, 1989). To the extent that interpretations of the outer world guide behavior, cross-cultural differences in actual behavior can be understood even in situations that are objectively similar. Valsiner and Lawrence (1996) analyzed the issue of individual development in cultural contexts, emphasizing the importance of making interacting person-culture systems the object of analysis (see also the discussion of development in the perspective of cultural psychology; Schweder et al., 1998).

Even children reared in the same family may not have identical physical and social environments. The proximal environments experienced by early and late born children may differ radically, due to the order of the children, differences in family relationships, and changes in the family's socioeconomic conditions (e.g., Dunn & Plomin, 1990). These circumstances contribute to inter-individual differences in conceptions of the outer world, and thus to differences in the interpretation of single situations, even among children who have grown up in the same proximal environment.

Comments

Cautions are advocated when components of the mediating system are the target of theoretical and empirical analyses. The foregoing discussion of various facets of the mental system uses a number of concepts, some of which reflect hypothetical constructs such as values, goals, norms, attitudes, and self-perceptions. When using such concepts it is easy to fall into the trap of reification, to forget that these constructs are only abstractions covering different aspects of an organism that functions as an organized whole. Perceptions, cognitions, emotions, values, norms, and attitudes are components of the same integrated process.

There are empirical studies to support the old idea that knowledge is acquired, not innate (Locke, 1690). In addition, the brain we are born with has properties that offer both potentials and restrictions for developmental processes. What becomes of a newly born fetus over the lifetime is the result of a continuous interaction process involving person-bound factors as well as factors in the proximal and distal environments. In this section, we have drawn attention to basic aspects of the functioning and development of individual mental life. To understand the functioning of an individual's mind and its role in the functioning and development of the integrated individual, all these aspects must be incorporated in a general model. (From different perspectives, an enormous number of theoretical and empirical studies have reported on what has been briefly reviewed here. Neither the space available nor our competence permits an exhaustive treatment of the field. The references given here do not do justice to all the relevant reports. They should be regarded as suggestions for further reading. Harré & Gillett, 1990, among others, provided an overview of the main topics discussed here.)

Behavior in a Holistic-Interactionistic Model

In the unidirectional models of individual functioning, behavior is usually regarded as just an outcome. A holistic-interactionistic model, however, views behavior in all its manifestations, including verbal and motor behavior, as playing an essential role in the current person-situation interaction, as well as in the processes of individual development.

As previously illustrated, if an individual interprets a situation as demanding or threatening, the individual's manifest behavior is an element of a continuously ongoing interaction process. It also serves to change the nature of the total PE interaction process in two interrelated respects. First, activities serve an important function for the individual, for example, by changing the situational conditions to satisfy personal short- and long-term needs and to avoid negative mental or biological experiences. Second, by his or her own behavior, a child contributes to his or her own social environment; by adapting to other individuals' behavior, the child develops and maintains effective social relations (Cairns, 1986a).

It should be observed that individual behavior in a specific situation with its specific characteristics is not solely dependent on the individuals' latent dispositions as reflected in trait measures. The behavior in a specific situation is a function of both individual mental and biological dispositions and the situational characteristics; it is a matter of mutual causation. A person with a strong latent disposition for alcohol will not become an alcoholic if the proximal environment does not offer access to alcohol. Similarly, it is only under specific environmental conditions that an aggressive person commits violent crimes. This is one reason why prediction of individual behavior in new situations is often not possible.

Biological Factors in the Person-Environment Interaction Processes

The incorporation of biological factors into the model for the functioning and development of an individual provides one of the basic new propositions in a modern/holistic-interactionistic model. For the following discussion it is necessary to clarify the distinction between "biological" and "inherited" aspects of individual functioning and development. When a specific behavior is empirically found to be related to some biological component of individuals, it tends to be misinterpreted as genetically determined. Biological functioning at a certain stage of development is more than the effect of genes. A developmental analysis is required to determine how a person's constitutional, biochemical, genetic, and experiential factors are interwoven.

In 1883, when Wundt advocated psychology as an independent scientific discipline, he emphasized the biological basis of psychological phenomena (Wundt, 1948). William James (1890), in *Principles of Psychology* devoted two chapters to a discussion of the brain and brain activity before dealing with his main topic, the mind. And in 1899, Angell and Thompson discussed the relation between organic processes and consciousness. Later,

in his presentation of functional psychology, Angell (1907) stressed the need for the integration of biological factors in the model of individual functioning. During the last decades of the twentieth century, Eysenck (1990) was an influential advocate of the biological bases for personality factors. Previously, Lehrman (1970), Schneirla (1957), and Tobach and Schneirla (1968) all discussed the role of biological factors in developmental processes. As emphasized by Lerner (1983), the interaction process between an individual and the environment can be described as an active adaptation process. In this adaptation process, biological factors, in constant interaction with mental components and behavior, play a central role. For example, Selye (1976) discussed the adaptive role of the adrenal cortex, which produces corticosteroids such as cortisol through release of ACTH from the anterior pituitary gland in response to stress. The relation of thoughts, emotions, feelings, and behavior to biological processes has been elucidated in recent empirical research (e.g., Damasio, 1999; LeDoux, 1996). Experiments on captive monkeys by McGuire and his coworkers showed how social factors, such as the status of the leader in the group and his interpretation of the behavior of other group members, affect his level of serotonin and 5-HIAA, which are important regulators of individual mood (Raleigh, McGuire, Brammer, & Yuwiler, 1984). In research on free-ranging baboons, Sapolsky (1990) demonstrated how strongly social and biological factors interact and how the feedback mechanisms of the cortisol system can be blocked in low-status animals (see also Sapolsky, 2005). The role of biological factors in adolescence was discussed by Petersen and Taylor (1980). Further reasons for considering biological factors in research on personality development were summarized by Susman (1998). How concepts from biological theory have been assigned a role in the continuity of social behavior was critically assessed by Cairns and Hood (1983) and discussed by Earls and Carlson (1995).

Contributions from developmental psychobiology have substantially increased our understanding of the role of biological factors in individual development processes (e.g., Kagan, 2003; Segalowitz & Schmidt, 2003). In the interaction processes, biological components of individual functioning are also influenced by environmental factors. For example, the contextual role in developmental processes is already evident in the prenatal period (e.g., Huizink, Mulder, & Buitelaar, 2004). And M. K. McClintock (1971), studying the influence of social factors on biological functioning, found that in the course of a study year, the menstrual cycle in female students who shared dormitory rooms had been synchronized; in many cases, they coincided totally before the end of the school year. Discussing the role of practice in forming individual behavior, Ericsson, Krampe, and Tesch-Römer (1993) argued that practice diminishes the role of biological factors, which are usually regarded as fixed.

Biology and Antisocial Behavior

Antisocial behavior is an aspect of individual functioning for which a systematic and often replicated relation to physiological activity/reactivity has been demonstrated. Research on neurotransmitters, hormones (e.g., testosterone, cortisol, and adrenalin) and pulse rate as components in adolescent development was summarized by Ortiz and Raine (2004) and Raine (2002). In these studies a positive, sometimes strong correlation has been found between antisocial behavior and low physiological activity/reactivity as reflected in low adrenaline excretion. In our longitudinal study IDA for boys at the age of 12 and 13, significant, negative correlation was found between data for aggressiveness and data for hyperactivity, on the one hand, and data for adrenaline excretion in the urine sampled in two different situations at school, on the other. Later, when criminal records were obtained for these males through the age of 30, a strong, significant relation was found between data for persistent criminal activity and data for relatively low adrenaline production in the situations at school (Magnusson, af Klinteberg, & Stattin, 1993).

It is noteworthy that persistent offenders as a group have been found to have more transmitter substance dysfunctions than do control groups of nonoffenders (Alm et al., 1994; Belfrage, Lidberg, & Oreland, 1992; Moffitt et al., 1997; Raine, 1997). In an earlier section, research showed the role of the brain, particularly the amygdala, in eliciting physiological activities as a basis for adequate mental and behavioral responses to fear and threat. It has been suggested that malfunctioning of the amygdala could be involved in inadequate violent behavior in such situations (e.g., Magnusson, 1996a).

Biology and Well-Being

Empirical research on the role of biological factors in individual development has been focused on antisocial behavior. Recently, empirical research has demonstrated the existence of a complementary biological system, connected with well-being, calm and positive

social interactions—the calm-connection system (Uvnäs-Moberg, 1998a, 1998b; Uvnäs-Moberg, Arn, & Magnusson, 2005). The corresponding physiological pattern consists of muscle relaxation and lowered levels of cortisol and cardiovascular activity as well as enhanced activity in the gastro-intestinal tract promoting digestion and anabolism. The vagal, parasympathetic nervous system is activated and the hypothalamo-pituitary axis and the sympatho-adreno-medullary system are shut down. At the central level, hypothalamus oxytocin plays an important integrative role.

From the holistic-interactionistic perspective, the introduction of the calm-connection system fills a vacant space in the model of the integrated psychobiological system. It complements and balances the fight-flight system—introduced by Cannon (1914) and further developed by Selye (1976)—which has played a central role in research on stress and antisocial behavior. As an integrated part of the functioning of the total organism, the concept of the calm-connection system enriches the theoretical basis for empirical research in the recently developed "positive development" area (see Aspinwall & Staudinger, 2003). As argued by Magnusson and Mahoney (2003), successful research in that area requires a holistic-interactionistic frame of reference to enable the formulation of the necessary synthesis of knowledge.

The brain plays a central role in the integration and coordination of the fight-flight and stress system, on the one hand, and the calm-connection system, on the other. During infancy, the brain is particularly open to and dependent on stimulation from the social and physical environment. Under optimal conditions, the brain develops so that adequate positive and negative emotions are attached to the information offered by the environments as well as to conscious and subconscious mental activities and behavior.

Comments

The brief overview of the role of biological components shows the importance of considering such components in theorizing and empirical research in integrated developmental processes. Two characteristics of the biological tradition in psychological research are noteworthy. First, for example, despite Angell's (1907) incorporation of biological factors into what might be seen primarily as a holistic view of individual functioning, biological factors have not been consistently integrated into psychological models. Rather, they have mostly formed an independent line of research with little impact on developmental research. Second, to the extent that biological factors have been studied empirically, their role in individual functioning has most often been seen as causal; a reductionistic view has dominated. Exceptions can be found in the work of Bronfenbrenner and Crouter (1983), Cairns (1979), and Lerner (1984) and in the presentations by psycho-biologists such as Kalverboer and Hopkins (1983) and Levine (1982). Dawson, Ashman, and Carver (2000) summarized research on the role of upbringing conditions and the long-term effects in brain development, and Glaser (2000) reviewed research on the role of child abuse and neglect for brain development. Also, an overview of research on biology in individual development was presented by Gottlieb, Wahlsten, and Lickliter (1998).

The Nature-Nurture Issue: Hereditary and Environmental Factors in Individual Development

The relative role of hereditary and environmental factors, both in current functioning and in individual development, has been a topic of debate since ancient times (e.g., Garcia Coll, Bearer, & Lerner, 2004; Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume). This issue is relevant to the focus of this chapter. Ongoing debate has been dominated by references to estimates of the relative magnitudes of group-level variance attributable to genetic versus environmental factors. The limits of this approach were underlined already by Anastasi (1958) and a number of followers (e.g., Cairns, 1979; Dodge, 1990; Medawar, 1984).

An important step toward understanding the role of genes in developmental processes was the discovery of DNA and the genetic code in the 1960s. This discovery opened new windows for mapping the individual genome structure and for research on the mechanisms by which genetic factors operate. The interpretation of recent research along this line has led to the introduction of theoretical models that emphasize the composite function of genetic and environmental factors in the developmental processes of individuals.

The present state of the nature-nurture debate was recently summarized by Lickliter and Honeycutt (2003a, 2003b):

> As a result, a number of psychologists continue to take for granted that behavior is somehow determined by more fundamental or primary processes that occur at the ge-

> netic level. This unidirectional, bottom-up view of the causes of behavior overlooks much of the conceptual and empirical content of contemporary biology, which shows that genetic factors are always part and parcel of the individual organism's developmental system. No single element or level in the system necessarily has causal primacy or privilege, and the functional significance of genes or any other influence on behavior development can be understood only in relation to the developmental system of which they are a part. (Lickliter & Honeycutt, 2003a, p. 830; see also, Gottlieb, 2000; Rutter, 2004)

The onset and course of certain developmental sequences may be determined genetically to the extent that they are common to all individuals. However, even such developmental sequences as the onset of the menstrual cycle and the regulation of growth in height are to some extent modifiable by environmental factors (Tanner, 1981). That there is a hereditary predisposition for a certain type of behavior does not mean that it cannot be changed by environmental intervention (Angoff, 1988). The individual phenotype develops within the framework offered by the genotype along with the environment, a process that starts at conception and goes on throughout the life span. On the stage set by inherited factors, many different dramas are possible (Waddington, 1962).

Accordingly, in most respects, individual development takes place in a process of maturation and experience in interaction with the environment, on the basis of and within the limits set by inherited factors. Kagan (1992), who argued for a hereditary component in temperament, emphasized how the environment modifies this influence. Cairns (1996), in a 20-year evaluation of the roles of heredity and environment in individual differences in aggression, concluded that the differences in mice obtained by selective breeding over 30 generations show strong environmental specificity. The aggressive behaviors in descendant lines can be modified by environmental social conditions to such an extent that the inherited differences are eliminated. In well-planned longitudinal studies of newborns, Meyer-Probst, Röesler, and Teichmann (1983) demonstrated that favorable social conditions acted as protective factors for later social development among children identified at birth as biologically at risk. With reference to the results of a training program for animals and humans, Schrott (1997) concluded that:

> environmental stimulation has been found to increase brain weight (especially forebrain), cortical thickness, the number of glial cells, the glia to neuron ratio, neuronal cell body and nucleus size, and to alter synaptic profiles by increasing dendritic branching, dendritic spine density and the number of discontinuous synapses. (p. 45)

A general model was previously discussed for the interplay of mental, biological, behavioral, and situational components involved in current functioning of an individual. In this model, the individual's interpretation of environmental events leads to activation of the sympathetic nervous system and excretion of stress hormones such as adrenaline and cortisol. Under normal conditions the process is an adaptive response, with no detrimental consequences for the individual. However, when persistent stress leads to overproduction of such hormones, they can override genetic regulation and may cause harm rather than protection (see Lundberg, 2005).

Biological Age: A Marker of Maturation Rate

As illustrated in the empirical study in IDA, described earlier, the rate of maturation is a powerful operating component influencing a girl's dealing with the environment and the environment's reaction to the girl. Effects of the rate of maturation have also been observed in studies of boys (Andersson, Bergman, & Magnusson, 1989).

Traditionally, individual development has been expressed in chronological age; that is to say that an individual's level of development is represented by the time the earth has circled around the sun since he or she was born. That is the one thing that all individuals with the same birthday have in common. It is a distressing fact that most studies on puberty and adolescence still neglect this observation even though alternative bases for the study of individual differences in developmental rate have been called for for decades (e.g., Baltes, 1979; Horn & Donaldson, 1976; Thomae, 1979; Wohlwill, 1973).

The existence of strong interindividual differences in growth rate may have profound consequences, not only for individual differences in various aspects of functioning, but also with respect to the way the environment reacts to the individual. Differences in developmental timing are thereby related to individuals' social relations, as well as to their capacity to meet environmental demands and to use environmental opportunities effectively. However, to control for biological age rather than chronological age when designing empirical studies is only a remedy under specified conditions. Biological and chronological factors are nested; the expression of

individual differences in growth rate for central factors in developmental processes is sometimes counteracted by societal influences, which are bound to chronological age: for example, compulsory school education, compulsory military service in some countries, and the compulsory age for retirement.

Personality Consistency: A Matter of Person-Environment Interaction

A core issue in discussions of PE relations is personality consistency. A series of empirical studies using a strict experimental design, both with children and with adults as participants in natural situations, investigated the cross-situational stability of manifest, current behavior using ratings based on systematic observations (Magnusson, Gerzén, & Nyman, 1968; Magnusson & Heffler, 1969). The studies yielded two important results. First, observations of individuals over situations with no variation in situational conditions showed a high cross-situational stability in ratings of manifest behavior. However, observations over situations when situational conditions were varied systematically with respect to members of the group and the group task revealed extremely low cross-situational stability of individual behavior. Second, in successive observations of the same participants in a number of situations, varied with respect to situational conditions, the agreement between independent raters of the participants' behavior increased successively to a reasonably high level. The conclusion was that a person's individuality is reflected in his or her unique way of handling situational conditions, reflected in partly unique patterns of manifest behavior across situations (Magnusson, 1980).

These results, obtained under strict experimental conditions, have fundamental methodological implications both for the study of the stability of personality characteristics and for the study of stability and consistency of developmental processes. In both cases, the choice between situation-bound state data and latent trait data will have decisive consequences for the outcome of an empirical study. Interpretations of observations of individuals in specific situations must always consider situational conditions under which the data were obtained and refer to; for example, when data refer to a laboratory study, to a natural experiment, or to systematized observations without an experimental design. The choice between state and trait data also has basic consequences for empirical studies of developmental issues. For example, measurements of the developmental stability of a certain behavior will, among other things, depend on the degree of similarity with respect to the situational conditions under which the original base data and the follow-up data were collected.

A study of relevance for the discussion of stability and continuity in developmental processes was recently reported by Li et al. (2004). Using a sample of participants with an age of 8 to 89 years, they tested the differentiation-dedifferentiation hypothesis about structures of intelligence across the life span and drew the following conclusion: "These results indicate more compressed functional organization of intellectual abilities and cognitive processes in childhood and old age than in adulthood. In particular, these findings support the dynamic differentiation-dedifferentiation view of intellectual development across the life span" (pp. 161–162). This study is an important complement to earlier studies showing changes in cortical organization during childhood (e.g., Johnson, 2001) and aging. Among other things, these studies lead to two interrelated conclusions of basic importance in designing empirical studies on developmental processes. First, the content of a specific hypothetical construct or a biological component used in cognitive models changes its character and role in the dynamic processes of brain functioning across ages. Second, its significance in actual functioning of the individual is not linear across time.

In development, both individuals and their environments change as integrated totalities. The individual changes as a result of biological maturation and cognitive-emotional experiences gained in the interaction with the environment and the individual's environment changes as a consequence of societal changes at different levels, and of the individual's direct and indirect actions in and on it (e.g., choosing a new job or moving to a new environment). The simultaneous changes of the person and his or her environment also alter the nature of the interaction processes. In the long run, such a change may be radical, partly as a result of the interaction process itself (e.g., Lerner, 1991). For example, the nature of the interactive process in a family changes across time. The interaction between a child and its family is not the same as that child's interaction with his or her family in puberty, middle age, or retirement. The interaction process thus precipitates development (see the discussion of transformation as a basic principle in development).

The formulations of modern models for complex, dynamic processes have enriched research on developmental processes. However, the total organismic system and its subsystems of psychobiological and behavioral factors have properties that imply that they are less chaotic than the processes studied in meteorology in which chaos theory was first developed; the individual is intentional and an active part in the ongoing person-environment interaction process. Each psychobiological system functions and develops in a process in which two forces balance each other: On the one hand, maturation and experiences work for change, and, on the other, the principle of resistance to change. In the face of environmental challenges, physiological systems maintain a dynamic balance. Referring to stability through change in such systems, the concept of homeostasis has been replaced by that of "allostasis" (McEwen, 1998). Each biological system defends itself against inappropriate causes of change, which might lead to malfunction or destruction of the system. For example, in the normal functioning and development of the brain, a number of events, which might have led to a detrimental butterfly effect, are ignored, and only those that contribute to effective current functioning and to the development of functional new structures are accepted. Buffering mechanisms of this kind serve a fundamental role in the survival of all living organisms, including the human being (Hartman, Garvik, and Hartwell, 2001; Magnusson, 2003).

The importance of social factors for cognitive developmental processes was discussed and emphasized by Baltes and Staudinger (1996a). The Baltes and Staudinger (1996b) volume presents a broad overview of the role of different social factors in various aspects of developmental processes, extending the analyses to include an evolutionary and a cross-cultural perspective. The extent to which individual development is affected by environmental factors in the processes varies for different elements. On the one hand, in sexual development there are some features, such as gonadal structures and functioning, that are strongly regulated by biological factors. On the other hand, other aspects of individual functioning, such as choice of peers and type of sexual relations, may be wide open to experiential influences (Cairns & Cairns, 1994) and to societal normative factors for the appropriate age for initiating opposite-sex relations (Maccoby, 1990). One factor that influences the extent to which the socialization process of an individual, from infancy through childhood and adolescence, shows high stability is the degree of ecological constancy in the upbringing environment (Magnusson & Endler, 1977).

In summary, each change in the process of human ontogeny is understandable in the light of the individual's previous life history and the environmental influences operating at the time of the change. At each phase in the life course of an individual, the present state is the child of the past and the parent of the future. This tenet holds even for changes that are so abrupt that they seem to break a stable direction of development. For example, changes that have been characterized as "turning points," sometimes appear as a result of "chance events" or "significant events." In this perspective, the question of whether individual development is characterized by continuity or discontinuity is a matter of developmental processes, not of specific aspects in individual functioning, which is the focus that has dominated the debate (see e.g., Horowitz, 1989). Interesting aspects of this issue include the significant events that cause abrupt changes in processes, the conditions under which they appear, their possible long-term effects on the life course, and the relation of these aspects to age levels, and gender differences.

Continuity as a characteristic of individual functioning and development, underlying both change and stability, has been discussed for centuries:

> What remains is the formidable task of disentangling causal status among the variables in the developmental sequence, including the transactions that turn genetic chemistry into behavioral individuality and the ways in which social context and social relationships are implicated in both stability and change. (Hartup & van Lieshout, 1995, p. 681)

Continuity in individual development processes does not imply that changes are necessarily predictable. This circumstance does not preclude a scientific analysis of the process, as demonstrated in the research stimulated by chaos theory. Let us only refer to Scriven (1959), who in his discussion about prediction and explanation in evolutionary theory countered the view that high predictability of single events is a prerequisite for real scientific explanation: "Satisfactory explanation of the past is possible even when prediction of the future is impossible" (p. 477).

Individuality: The Developing Person

Basic properties of the organism at any stage of the life process are the result of a coherent process that starts at

conception and extends from the prenatal period onward. Patterns of psychobiological components are established during fetal and infant life (e.g., Nelson, 1999a; Stern, 2001). The early organization of individual capabilities—particularly the organization of the brain as the central organ for interpretation and appraisal of external information, for attaching emotions and values to this information, and for activating biological autonomic, endocrine, and muscular systems—forms the platform for developmental processes and has consequences for the life course of the individual. During the establishment of the mediating system in early infancy, the brain is particularly open for and dependent on organized, patterned stimulation from the proximal environment.

The functioning of the organism displays an inherent plasticity that makes it possible to overcome early deficits stemming from the individual, the environment, or the individual-environment interactions (see, e.g., Garraghty, Churchill, & Banks, 1998). In a recent article, Li (2003) discussed a bio-cultural dynamic model of developmental plasticity. The presentation of indications that the brain is particularly open to change during the early adolescent period (Spear, 2000) is of critical interest in research on puberty and adolescence. The brain continues to produce new nerve cells in adulthood (e.g., Kempermann & Gage, 1999).

The concern of psychology, in theory and empirical research, is the individual. In a lecture at the Swedish Academy of Sciences in 2002, the Nobel laureate Ralph Greenspan emphatically underlined the individuality of living organisms. The same view was expressed by Mayr (1997):

> The most impressive aspect of the living world is its diversity. No two individuals in sexually reproducing populations are the same nor are any two populations, species, or higher taxa. Wherever one looks in nature, one finds uniqueness. (p. 124)

Greenspan ended his talk by emphasizing that the challenge now is to find appropriate ways of analyzing the specific nature of individual organismic processes. These statements are equally valid for the human being.

The hypothesis of personality crystallization may help to shed light on the issue of developmental individuality (Magnusson & Mahoney, 2003). According to the hypothesis, the developmental process of individuals whose systems organization differ at a certain point in time—as a result of different constitutional factors, maturation, and environmental experiences—will take partly different directions in the next step. Each step forms the basis for future developmental alternatives and more stable "types" will eventually emerge over time. If this view is correct, it should show up in clearer homogenization within categories of individuals and more clear differentiation between categories of individuals over time. Empirical support for this hypothesis was presented by Bergman and Magnusson (1997) in the longitudinal IDA program. They observed that each of a number of problem behaviors—aggressiveness, motor restlessness, concentration difficulties, low school motivation, and poor peer relations—was equally frequent among the boys at the ages of 10 and 13. Between these ages, however, the distribution of problem behaviors had changed. The proportions of boys whose frequency of problem behaviors was high and low, respectively, both increased at the age of 13. Consequently, the proportion with mild indicators of problem behaviors had diminished.

Comments

The presentation and discussion in this section leads to two conclusions with fundamental implications for empirical research on individual, developmental processes. First, the target of analysis is the individual as an integrated element in a sociocultural environment with its specific norms, rules, attitudes, values, and valuations. Accordingly, these characteristics should be taken into account in the appropriate way when designing and interpreting studies on specific issues. Second, if the researcher wants to generalize about developmental processes across cultures, a careful theoretical and, in some cases, empirical, cultural, and cross-cultural analysis is required.

THE ENVIRONMENT IN THE PERSON-ENVIRONMENT SYSTEM

An individual's way of thinking, feeling, acting, and reacting develops in a process of close interaction with the physical and sociocultural environment. It is therefore pertinent to enumerate certain basic environmental properties that are relevant to understanding the processes involved in individual development. The aim is not to give a comprehensive presentation of research on environmental factors in the functioning and develop-

ment of the integrated PE system. It is rather to draw attention to environmental aspects that should be considered when designing, implementing, and interpreting empirical studies on specific developmental problems. For a fuller conceptual treatment of the role of environmental factors in developmental processes, the reader is referred to Bronfenbrenner and Morris (1998) and Schweder et al. (1998).

The Concept of Context

A key concept in models for individual current functioning and development is that of context. The total, integrated, and organized PE system, of which the individual forms a part, consists of a hierarchical system of elements, from the cellular level of the individual to the macrolevel of environments (Hinde, 1996; Lerner, 1978; Riegel, 1975). In actual operation, the role and functioning of each element depends on its context of other, simultaneously working components, horizontally and vertically. The development and functioning of a cell depends on the functioning and development of surrounding cells with which it communicates; that is, it depends on an influx of information from surrounding cells (Damasio & Damasio, 1996; Edelman, 1987). The development and functioning of the cardiovascular system is dependent on how other bodily systems, for example, the immune system, develop and function. An individual's socialization process depends on the functioning and development of other individuals with which he or she associates. The way an element of a certain culture functions, such as the proximal environment of the individual, is dependent on how other, related elements function.

The total PE system is hierarchically organized with respect to structures as well as to accompanying processes (Koestler, 1978, used the concept "holarcy" to denote this characteristic feature of a system). Each level of the system is simultaneously a totality in relation to lower levels and a subsystem in relation to higher levels. Systems at different levels are mutually interdependent. The functioning and development of the proximal sociocultural system, of which the individual is a part, depends on the characteristic features of the society and culture (e.g., Bateson, 1996; Hinde, 1996). In sociology, Coleman (1990) presented a comprehensive theory of the functioning of the individual and the environment and the interactive characters of this process. This section is restricted to identifying and discussing some aspects of the external environment with which the individual must deal and interact.

The Environment in Developmental Research

At the theoretical level, researchers in the area of personality have long emphasized that individual behavior cannot be understood and explained in isolation from the situational conditions under which it occurs. The importance of the situational conditions for behavior was observed by Reinhardt (1937): "reliability of predictions as to future behavior . . . depends not upon the constancy of individual purpose alone . . . but also upon the continuance or occurrence of the same type of situation" (p. 492). The view was strongly emphasized by Brunswik (1952), when he suggested that psychology be defined as the science of organism-environment relationships. Historically, the role of sociocultural factors in the developmental process of an individual had already been discussed in 1777 by Tetens. A strong proponent of considering environmental factors in individual development was W. Stern (1927, 1935), who emphasized the role of the environment as a "proximal space." Similarly, the concept of "proximal development" was central in Vygotsky's (1978) theory of cognitive and language development. Barker's (1965) analyses of settings, as well as Bronfenbrenner's (1989) analyses of levels of environmental factors, yielded new and substantial content to the topic. In his discussion of individual development in a life-span perspective, Baltes (1976) emphasized the role of environmental factors referring to what he designated dualistic-dialectic paradigms (e.g., Riegel, 1976).

The fact that psychology has not developed a language of environments to the same extent that it has acquired a language of behavior and personality is particularly indicative when one considers the role that environmental theories have played in neighboring disciplines that are also concerned with the functioning and development of organisms at the individual level. For ethnologists, it has always been natural to refer to environmental factors (e.g., perceived territories) in explanatory models of animal behavior (see Schweder et al., 1998). From their various perspectives, anthropologists and sociologists have also made essential contributions—often overlooked and neglected in the theoretical debate in psychology—to the discussion about the role of factors for human behavior. In the 1920s, the sociologist William I. Thomas (1927, 1928) discussed many of the issues that

are in focus today. He noted the distinction between actual and perceived environments and situations and discussed the problems connected with defining and demarcating a situation; he also stressed the developmental role of the situations an individual encounters and argued that environmental conditions must be incorporated into models of actual behavior.

Conceptual and Empirical Analyses of Environments

A scientific analysis of person-environment interaction processes presupposes a systematized descriptive analysis of the environment at different levels (Schneirla, 1957; Sells, 1963). A first attempt at an analysis of situations and situational conditions was presented by Rotter (1955), who discussed what he termed "the psychological situation"; that is, the situation as it is interpreted and assigned meaning by the individual. In a related theme, the role of the situation as the temporary frame for individual behavior was the focus of the discussion in a volume edited by Magnusson (1981). In his discussion of environment and behavior Pervin (1978) included an analysis of stimuli, situations, and settings. An overview of theory and empirical research on situations was presented by Forgas and Van Heck (1992).

Actual and Perceived Environments

An old distinction is that of the environment "as it is" and the environment "as it is perceived," construed, and represented in the minds of individuals. Here the two aspects are discussed as actual versus perceived environments. Knowledge about the organization and function of the environment in both these perspectives is needed for a proper analysis of person-environment interaction processes. It is assumed that the main function of the environment in these processes is the environment as it is perceived and interpreted by the individual. However, individual perceptions and interpretations of the external world are formed and function with reference to the organization and function of environment "as it is," the actual sociocultural and physical environment.

The Actual Social-Cultural Environment

Current individual functioning and individual development are dependent on the sociocultural environment at all levels of generalization, from rules and customs at the level of cultures to the habits, norms, and rules that are specific to the proximal environment.

For a long time, child research treated the social environment in rather gross, general terms. During the final decades of the twentieth century, however, research was extended to more specific aspects of the environment, for example, infant-mother attachment (e.g., Ainsworth, 1983), the particular situation for each child in the family setting (Dunn & Plomin, 1990), the family as environment (Maccoby & Jacklin, 1983), and the environment in child rearing interactions (Radke-Yarrow & Kuczynski, 1983).

The character of the social environment is of central concern in clinical work. In this connection, there has been criticism of the context-free type of classifications of mental disorders that are common in psychiatric practice. Emde (1994), reviewing discussions about diagnostic classifications in early childhood stated that: "current diagnostic classification schemes for this age group were inadequate because of limited coverage and because such schemes did not pay sufficient attention to individuals in context" (p. 72).

The Actual Physical Environment

The importance of the amount and diversity of physical environmental stimulation has been discussed theoretically and demonstrated empirically. White (1959) emphasized the role of the child's interaction with the inanimate environment in his discussion of competence as an important factor in motivation. J. McV. Hunt (1961, 1966) underscored the importance of the physical patterning of stimulation when he discussed the development of intelligence and intrinsic motivation. In his analysis of cognitive development, Piaget (1964) stated: "Experience of objects, of physical reality is obviously a basic factor in the development of cognitive structures" (p. 178). The research by Hubel and Wiesel (1970) demonstrated the crucial role of patterned stimulation for the proper development of the perceptual system. The arrangement of the physical environment, as well as the variety of stimulation and information it offers, has implications for the development of sensory perception, as well as for cognitive development.

The Environment as a Source of Information and a Source of Stimulation

The impact of external factors comes primarily through individuals' processing of information offered

by the environment. The perceptual-cognitive-emotional process of selecting and interpreting relevant information from the environment is largely affected by prior learning and experiences of similar past events, as underscored in adaptation-level models (e.g., Schneirla's, 1957, discussion of "trace effects"). Prior exposure has generated cognitive schemata, attitudes, and more or less habitual ways of handling, coping with, and securing control of the environment (Thompson, 1981).

Experiences are interpreted in the current frame of reference. Helson's (1964) "adaptation level" theory couches this process as an influence from earlier, repeated experiences of stimuli of a similar kind, present background factors, and residual memories of cognitions, emotions, and actions associated with previously experienced situations that are now recurring. Or, in the words of the Nobel laureate Aron Klug: "One doesn't see with one's eyes, one sees with the whole fruit of one's previous experience" (Fensham & Marton, 1991). Krupat (1974) also subscribed to similar notions about human functioning when he stated that: "prior experiences with danger (as well as confidence in one's own ability) act to decrease the subject's sense of vulnerability" (p. 736). Repeated exposure to the same type of environmental event has a variety of effects. It might, for example, lead to a decreased strength of reactivity (Magnusson & Törestad, 1992), to a more positive attitude with "mere exposure effect" (Moreland & Zajonc, 1982), or to substituting the original quality of reaction with its opposite "opponent process" (Landy, 1978; Solomon & Corbit, 1974). Accordingly, individual differences in preceding person-environment interactions and the functioning of the individuals' mental systems, lead to individual differences in the interpretation of the stimuli and events of a current situation. Such individual differences account for the partly unique way in which individuals cope with situational conditions.

The concept of the environment as a source of stimulation is best illustrated in experimental psychology. An essential tenet of the experimental tradition is that the stimulus is defined in objective terms. This assumes that the impact of a certain contextual factor is general and has the same meaning and the same stimulus value to all individuals (e.g., Fechner's reasoning about the objective character of physical stimuli).

Learning theories, which are of interest for our discussion, emphasize the role of the environment as a source of information. For example, in Bolles' (1972) specification of laws of learning, the environment as a basis for learning how to handle the external world effectively provides two types of information; two contingencies in the surrounding world are learned. First, children learn to see linkages between certain external conditions and their outcomes (situation-outcome contingencies). Second, they learn that certain actions they take will lead to predictable outcomes (behavior-outcome contingencies). These learned contingencies render the environment both predictable and malleable. Seligman's (1975) theory of learned helplessness implies that the link between individuals' actions and the information they receive about the impact of these actions on the environment has been distorted, with detrimental consequences for individuals' mental life. If the learned helplessness state is generalized and persistent, individuals consider the environment impervious to their influence.

Optimal Environments

Related to the discussion of the environment as a source of stimulation is the issue of optimal stimulation, which involves two topics: preference (the preferred level of stimulation) and enhancement (the developmentally optimal level of stimulation; Wachs, 1977).

Much of the research on the role of environmental stimulation seems to assume a monotonic relation between the amount of diversity in external stimulation and optimal development (Wohlwill, 1973). However, there is enough empirical evidence to suggest that there is an optimal level of stimulation with respect to both preference and enhancement. Both too little or too much stimulation results in less satisfaction and less adequate development than occurs with intermediate stimulation (see Schneirla's, 1959, theory of biphasic approach-withdrawal processes). Empirical research on stress, for example, shows that either too high or too low demands on activity lead to physiological and psychological stress reactions.

What constitutes optimal environmental conditions varies between individuals, across age for a given individual, and between the sexes (e.g., Csikszentmihalyi, 1993). The optimal level of stimulation also varies with each individual's adaptation level, based on earlier experiences, learning, and maturation. This can be particularly critical at certain ages such as when the organism is prepared for and responsive to stimulation that will not have the same effect at other stages of development

(e.g., the concept of readiness). Hubel and Wiesel (1970) demonstrated the crucial role of optimal stimulation in a critical phase of development, studying the first period of life for the development of the ocular system in kittens.

The human organism has an inbuilt drive to order and organize external information. Two characteristic features of the environment facilitate this: consistent patterning and influenceability. The first requirement is that the environment is physically and socially organized in a consistent way. Such conditions facilitate the individual's striving to assign meaning to his or her proximal environment and make valid predictions about the external world as a basis for its own actions. The patterning and regularity of external information is particularly important during early infancy when the brain develops and is organized so that it links appropriate emotional reactions to what the child sees and does (e.g., Lagercrantz, Aperia, Ritzen, & Rydelius, 1997). Radke-Yarrow and Kuczynski (1983) addressed the role of caregivers in structuring the child's social environment to facilitate the socialization processes.

The second criterion for optimal environments is that they can be influenced by the individual's action and that this can be done in a predictable way; the individual must be able to exert active control of his or her environment. This criterion is a prerequisite for developing self-identity, self-efficacy, cognitive and social competence, and feelings of control.

Formative and Eliciting Events

Related to the distinction between models for current individual functioning and models for individual development is the difference between "formative" (developmental) and "triggering" (current) events (e.g., Spring & Coons, 1982). Formative life events influence the predisposition for a certain behavior, including antisocial behavior and the vulnerability to disorders. Thus, they affect development by increasing or decreasing the probability for later behaviors and disorders (e.g., Brown, Harris, & Peto, 1973). Triggering events may elicit a certain behavior or a schizophrenic episode without necessarily increasing or decreasing the probability for later behaviors and episodes.

Where triggering events are interchangeable because their effects are typically channeled through nonspecific routes, like stress in the case of physical and mental disorders, formative events may be more specific and noninterchangeable. From an interactionistic view, formative events would be active in development by shaping individuals' readiness to cope with particular situations. Triggering events occur only in the contemporary perspective; for example, access to alcohol on a specific occasion may release an act of alcohol abuse, while lack of alcohol may prevent alcohol abuse even in a person with a disposition for it.

Significant Events

There are individual differences in both the magnitude and type of environmental influences on the developmental process. Of particular interest is the occurrence of single events that have a profound impact on the life course of an individual. Although some of these events appear to occur randomly, their role in an individual's developmental process is dependent on the individual's readiness for a certain type of action or reaction, such as marriage or a new job, together with an opportunity offered by the environment (e.g., Bandura's, 1982, discussion of "chance events"). In other cases, a significant event may be the result of deliberate action by the individual himself/herself or by individuals whose actions influence others. Sometimes the effect is not visible immediately, but grows slowly and eventually has decisive effects on the individual's life in a manner that is typical of the so-called butterfly effect in chaos theory. Originally, attention was drawn to this characteristic of dynamic systems by Poincaré (1946):

> A very small cause, which escapes us, determines a considerable effect we cannot help seeing, and then we say that the effect is due to chance. . . . If we could know exactly the laws of nature and the situation of the universe at the initial instant, we should be able to predict the situation of this same universe at a subsequent instant. . . . But it is not always the case; it may happen that slight differences in the initial conditions produce very great differences in the final phenomena; a slight error in the former would make an enormous error in the latter. Prediction becomes impossible, and we have the fortuitous phenomenon.

Many of the processes that exert decisive effects on the life course of individuals have this characteristic. For example, buying a new house in a given area with specific features in neighbors, job opportunities, schools, and cultural and leisure-time activities, may have decisive effects on the future life course of all family members, not least of all the children. In other

cases, the effect is more direct and leads to what has been discussed as "turning points" (Pickles & Rutter, 1991). Often, the necessary condition for a significant event to have this dramatic effect is that the individual is in a state of disequilibrium at the time of its occurrence, and the event serves to restore the balance of the total system and give new direction to the life course (Magnusson, 1988, p. 33). Under such conditions, significant events in individual life cycles serve the same function as "bifurcations," addressed by catastrophe theory, in the physical environment.

Proximal Dynamic Person-Environment Systems

For current functioning as well as for developmental processes, the most significant environmental role is played by the part of the environment that an individual confronts directly. Discussing of environmental factors, W. Stern (1935) labeled this proximal environment personaler Nahraum" (Kreppner, 1992a, 1992b). Of particular importance for current functioning and development is the other individuals with whom the child interacts directly (e.g., Patterson & Moore, 1978). Peterson (1979) analyzed the role of person-to-person interaction and McClintock (1983) discussed how interactionistic analyses of social relationships contribute to theoretical and empirical progress.

Scholars are paying increased attention to the interpretation, understanding, and explanation of development as interactions between the socializing environment and the individual. At the same time, there is growing concern with the role of the distal sociocultural environment, which forms the framework for the families and peer groups. Certain models emphasize the commonality among behaviors in diverse contexts (Jessor & Jessor, 1977). Others are more apt to consider the match between environmental impacts and opportunities and the person's needs and characteristics (e.g., D. E. Hunt, 1975; Lerner & Lerner, 1987). Then there are those that entail a systematic study of the patterning of individual functioning in different contexts (Magnusson, 1988), while others are more process oriented, examining the interplay between the socializing agents and the individual person (e.g., Bell, 1968).

In this perspective, two social systems in which a child functions and develops are of particular importance: the family and peer network. Each system is complex and dynamic, and family and peer relations characteristically are involved in reciprocal, functional interaction.

The Family as the Environment in the Socialization Process

It is primarily in the frame of the home environment that we seek to understand a child's development. In a comprehensive study in the IDA program of children rejected by their peers at school, interviews with the parents revealed a systematic relation between these children and family characteristics in three respects: home atmosphere, parents' experience of their roles as workers and up-bringers, and relations between parents (Magnusson, Dunér, & Zetterblom, 1975). Socialization research has traditionally focused on the general structure of the home environment, cohesion, parental guidance and rule setting, the ways parents set up a predictive environment for the child, regulations concerning autonomy and responsibility in the family, parental encouragement and support, the parents as role models, family routines and communication, the involvement of children in family decisions, planning and organization, and so on. The issue of decisional autonomy in well-functioning families is seen as a developmental task for adolescents. In this process, Baumrind's (1989) differentiation between authoritative and authoritarian disciplinary styles and counterpoise of parental control and emotional support has gained widespread recognition. So has Olson's differentiation between cohesion and adaptability in families (Olson et al., 1983).

Reciprocity in Relations and Levels of Analysis

The family offers the best illustrations of the inseparability of a person and his or her context. The realization that parent-child relations are a bidirectional process, to be examined from an interactive viewpoint, is perhaps the single most outstanding feature of present-day research on family processes (e.g., Bell, 1968, 1971; Kerr & Stattin, 2003). Each member is an active, integrated part of the family system and contributes to his or her social context. In her historical overview of the socialization of children, Maccoby (1992) underscored that in recent decades two major changes had occurred in family research. The first was a movement from parents as the cultural transmitters (the top-down view or a main effects model) to a more interactive view of parent-child processes. The second was a profound understanding of

and preoccupation with the complex mechanisms involved in parenting: moderating and mediating factors, multiple determination, and interaction processes. Recently, Maccoby (2003) again emphasized the bidirectional view on research:

> Nowadays, most students of family dynamics adopt a much more nuanced view of influence among family members. They see it as a set of reciprocal processes unfolding over time, with each family member adapting to the overall configurations of family roles and functions, as well as to each other family member individually. (p. 193)

As summarized and discussed by Kreppner and Lerner (1989), there is also a stronger emphasis on transgenerational issues, orientations toward both psychologization and sociologization of family processes, the start of a more deepened understanding of the role of factors for similarities and differences in socialization of individual children in families, and stronger realization of the close dependence of socialization on the particular historical time.

Both macro- and micro-oriented research is needed to obtain a fuller understanding of within-family processes. The exchange of behaviors and emotions between parents and children in specific situations analyzed at the micro level may not necessarily be reflected in analyses conducted at a more molar level. The study by Dowdney and Pickles (1991) on mother's and child's expression of negative affect in disciplinary situations illustrates this. The children were found to respond to the immediate behavior of their mothers in specific situations, whereas the mothers reacted to child behaviors maintained over episodes.

Besides examining relations between family members as dyads, triads, and tetrads (von Eye & Kreppner, 1989), there is a need to define the family system from the viewpoints both of all members of the family (Olson et al., 1983) and of the total family itself as an object of research. The view of the family as a self-organizing entity and a functional whole has been highlighted in family system models (Belsky, 1981; Hinde, 1992; Minuchin, 1985). However, although socialization research today has come far in understanding family processes, few attempts have been made to examine family life (attitudes and behaviors) simultaneously from multiple perspectives: those of the father, the mother, and the children.

Families and the Time Dimension

Issues of parenting, parental attitudes, rules, and disciplinary practices are substantial. But isolated from other characteristics of the family and from changes in constellations, structures, and interaction patterns occurring in the family, they tend to be handled as static entities, as stable characteristics of the parents or the family as a whole. Rather, parenting is characterized by both stability and change. Over the years, parents' behaviors and attitudes change with the developmental level of the child, and can vary between children in the same family. Neither do changes on the part of parents occur in isolation from what is going on in the rest of the family; the overall family process changes over time. For example, Stattin and Klackenberg (1992) examined the relationship between childhood and adolescence for specific patterns of discordant within-family relations (with mother-child, father-child, and mother-father discord as the constituent factor).

Family in Context

In addition to an increasing emphasis on bidirectionality and complexity, there is today a stronger articulation of the contextual embeddedness of socialization (Lerner, 1989; Oliveri & Reiss, 1987). The child's functioning and development in day care, school, and the peer group are linked to the family. One of many such studies is Steinberg's (1987) study on latchkey children and their peer orientation. Moreover, parenting occurs in and is a reflection of the family itself, its economic situation, the availability and quality of day care and school, neighborhood influences, other institutional organizations and social networks, and the wider social and cultural context. How parents react to their children in everyday life is linked with their other experiences. For example, Greenberger, O'Neil, and Nagel (1994) reported substantial associations, as well as complex interactions, between aspects of the parents' work conditions and their parenting.

Peers

An extensive body of literature indicates that peer relations constitute the interpersonal environment in which much new behavior emerges among children and adolescents. Peer relationships and friendships are particularly interesting for adolescents (e.g., Berndt, 1982; Cairns & Cairns, 1994). With respect to the role of peers in the developmental processes, three themes for

research on peer relations can be distinguished: (1) individual behavior associated with peer relations, (2) the characteristics and the functioning of the peer group for individual behavior, and (3) the contextual embeddedness of the peer group.

Individual Behavior Dependency of Peer Association

The first theme focuses on the individual and the peer group and is of interest only insofar as it yields information about the individual. During the 1970s and 1980s, hundreds of studies were conducted on individuals' peer status (i.e., popular versus unpopular; neglected, controversial, and rejected children) and associated characteristics such as peer interaction, coping and problem solving, social skills and competence, school adjustment and achievement, different aspects of personality, emotions, loneliness, and prosocial and agonistic behavior (e.g., Coie, Dodge, & Coppotelli, 1982; Coie & Kupersmidt, 1983). In a developmental perspective, data for social-skill problems and low peer status of children and adolescents were statistically related to data for adjustment problems later in life such as school dropout, delinquency, and mental health problems (e.g., Cowen, Pederson, Babigian, Izzo, & Trost, 1973; Kohlberg, LaCross, & Ricks, 1972). This line of research was to a large degree a psychometric and sociometric approach, and reflected in the main a unidirectional view of causality.

Characteristics and Functioning of the Peer Group

The object of interest in the second line of research is the functioning of the peer group and its psychosocial processes. Bronfenbrenner (1943) made an essential point that is in line with the general view of this chapter:

> Social development applies not only to the individual but to the social organization of which he is a part. Variations occur not only in the social status of a particular person within the group, but also in the structure of the group itself—that is, in the frequency, strength, pattern, and the basis of the inter-relationships which bind the group together and give it distinctive character. (p. 363)

In this tradition, the reciprocity in friendships has been examined (Gershman & Hayes, 1983), and similarities between the individual and his or her friends in sociodemographic variables, attitudes and behaviors have been investigated (D. B. Kandel, 1978).

In contrast to the traditional sociometric and psychometric approach, a process-oriented approach was adopted by Cairns and Cairns (1994) in their longitudinal research program, as well as implemented in the theoretical framework of this chapter. Based on data collected on an individual basis over the whole adolescent period for a large sample, almost without attrition, they were able to study in depth and in process terms the dynamics of peer relations and the role of these relations for the developmental processes of individuals during adolescence (Neckerman, 1992). A program with the same goal, of depicting "action in," was the Berlin Youth Longitudinal Study. Among other things, empirical studies in that program (see Silbereisen & Noack, 1988) revealed the dual quality of many adolescent behaviors in both compromising momentary or future psychosocial health and being tools in the pursuit of satisfying the individual's personal and social goals.

Seen in the life-course perspective, a central question is how peer characteristics come into the picture of changing behaviors. Studies from the IDA program, reported by Magnusson et al. (1985) and Stattin and Magnusson (1990), verified how social behaviors, in both a short- and long-term perspective, are systematically linked with characteristics of the peers with whom one associates in early adolescence. For further empirical research, the interesting observation is that it is relationship to peers outside the classroom that matters most, a finding that restricts the generalizability of findings obtained by studying relations to classmates. Studies from the same program have documented that association with nonconventional peers together with low educational motivation in adolescence, is an antecedent factor in the background to an adult homemaking orientation rather than a career orientation among females (Gustafson, Stattin, & Magnusson, 1992).

The wealth of studies on peer relations has been more informative about relationships between peer status and behavior, and the social and personal characterization of the individual relative to the group, than about how the peer climate reinforces individual behavior, what characterize the peer group and its stabilization, group processes, and how behavior develops in the peer group (Hartup, 1996). One line of research has contributed new information on how delinquency escalates in friendship groups. In videotaped experimental settings, Dishion and colleagues (Dishion, McCord, & Poulin, 1999) examined how rule-breaking talk develops when boys speak and respond to each other's comments; the authors

have labeled this "deviancy training," meaning there was contingent positive reactions to discussing rule-breaking topics (e.g., Kiesner, Kerr, & Stattin, 2004).

The Contextual Embeddedness of the Peer Group

Of particular interest for a discussion of peer relations and peer group functioning is the role of the sociocultural proximal and distal environments as the framework for the emergence, structure, and functioning of peer groups. The role of sociocultural factors is illustrated by the formation and functioning of peer groups with respect to the emergence of criminal youth gangs. Emler and McNamara (1996) argued that research on adolescence tends to underestimate the degree to which the amount of time spent with peers and the extensiveness and activities of the peer group are tied to the institutional participations of adolescents.

Distal Environments

Family and peers are not the only socializing influences on children and adolescents. Proximal environments are embedded in economic, social, and cultural systems of a higher order. The specific nature of these distal systems in a particular society determines the opportunities and restrictions for the functioning and development of proximal environments, such as the family and peer groups, as well as the opportunities and restrictions for the functioning and development of individuals. A great deal of research has been focused on the broader sociocultural influences, as represented in the community, the neighborhood, at school, and in leisure-time settings (e.g., Lerner, 1995). For example, whether or not pubertal maturation affects girls' social adjustment has been found to be dependent on the school setting (Caspi, 1995), neighborhood conditions (Ge, Broady, Conger, Simons, & Murry, 2002), and characteristics of the community (Dick, Rose, Viken, & Kaprio, 2000).

Social and Economic Conditions

The best-known example of how distal economic and social factors and changes in these respects affect individual behavior is the seminal work by Elder and coworkers using data from the longitudinal studies at the Institute of Human Development at Berkeley, California (see, e.g., Elder, 1998). A series of studies systematically mapped the impact on family cohesion, parenting, and child behavior of the economic crisis during the depression in the early 1930s. One of the findings is that the "economic pressure" of severe income loss mainly affected the husbands (Elder, Van Nguyen, & Caspi, 1985). The increased arbitrary discipline of fathers, elicited by income loss, then affected problem behavior of the boys. A longitudinal study of how hard times, economic crisis, and value changes in Albania have affected family relations and child behavior, was reported by Kloep (1995). The psychosocial timetable may be heavily influenced by the broader macro social conditions and institutions, as demonstrated by Silbereisen (1995) in a series of studies with respect to vocational choice, when he compared adolescents raised in the former East and West Germany.

Formal and Informal Societal Regulations

To a varying extent, opportunities and restrictions for the functioning and development of individuals and of proximal environments are determined by formal, societal rules. Some are bound to chronological age such as entering and ending compulsory education, joining the army, or age of retirement. Some are nationally regulated, while others may be locally determined. The extent to which legal norms exist varies across countries and societies. The socialization process is also dependent on and influenced by informal societal norms and rules such as the rules for dating in the traditional U.S. culture or for female dress in fundamentalist Muslim countries. Informal rules for individual behavior may be general and even hold across societies; others are more specific and bound to certain groups (e.g., religious sects) or temporary trends (the hippie movement of the 1960s and 1970s). To some extent they are normative, for example being based on chronological age, and to some extent they are more individual, and bound to, for example, intellectual competence or membership of a certain class. Even the societal regulations that are informal may create implicit, sometimes very strong elements of expectations in the individual's sociocultural setting. In that sense, they are forceful in regulating individual behavior, particularly during puberty and adolescence.

The Environment as a Changing Stage for Individual Functioning and Development

The environment provides a frame of reference for ongoing individual behavior, a stage on which a wide range of behaviors can be manifested. As such, changes that are influential in developmental processes take place in both the proximal and the distal environment (e.g., Sameroff,

Peck, & Eccles, 2004). Components in the individual that are involved in maturation and experiences in the course of individual development are nested with environmental factors that change over time.

The developmental timetable for the settings surrounding peer relations illustrates how person and environmental factors are engaged in an interactive process of change. In childhood, peer interaction occurs in the near neighborhood, in nursery school, and later at school. In adolescence, leisure time activities change from adult-led, organized activities in early adolescence (e.g., sport clubs), to more adult-like, commercial activities (pubs, clubs, and discos) in later adolescence (e.g., Hendry, Shucksmith, & Glendinning, 1995). The kind of proximal environments an individual encounters in this developmental process is dependent on the nature of distal social, economic, and cultural factors and the families and individual's choices of environments (as long as they have options) and actions.

In a long-term perspective, the distal environment undergoes change. The changes, such as those described above, lead to changes in the proximal environments of individuals (Elder, 1996). Compare, for example, conditions today with those only 50 years ago with respect to travel, communication, exchange of information, and industrial production. Ideological and political movements influence and alter educational opportunities and systems as well as societal norms, rules, roles, and values. Urbanization, almost throughout the world, has not only meant that more people grow up and live in urban areas but also that the economic, social and cultural character of urban areas has changed, sometimes drastically. One implication of these changes is that a person growing up and staying in the same local environment may die in a distal environment that differs greatly from the one in which he or she was born. Moreover, different generations are born in and live in different environments, with different norms, values, resources, and demands. It follows that valid generalizations are difficult to make across generations and across cultures about what are the dominant factors and the operating mechanisms in individual developmental processes.

Individual-Environment Synchronization

To maintain a developmental perspective, we need to understand both the formal and the informal societal influence on behaviors, norms, and roles in child and adolescent development (Ryff, 1987). The infrastructure of formal and informal regulations tends to form a social timetable of demands and opportunities for the individual; a timetable that is sometimes strongly age graded (Caspi, 1987). Despite the wealth of specific options, a country's broader institutional infrastructure and legal system are often similar for the majority, spelling out normative social roles and norms at different ages. This is not to say that children and adolescents have only one route to follow. On the contrary, one of the central problems in individual development lies in the synchronization of the individual's mental, biological and behavioral capacities with the demands, opportunities, and restrictions of the proximal and distal environments. The diversity of possible life paths may generate stress and insecurity among young people. What can be considered a favorable pathway toward adulthood in a society depends on the culture's "implicit theory of success" (Klaczynski, 1990; Ogbu, 1981). It also depends on local variations in the ecology. For example, a rural environment typically offers less educational and occupational opportunities, and adolescents' and their parents' educational aspirations tend to be lower than in more urban milieus (Sarigiani, Wilson, Petersen, & Vicary, 1990).

It can be argued that much of young people's thinking about the future (occupation, education, family and marriage, and material standards) and about themselves is linked with formal contextual and age-dependent changes (Nurmi, 1991, 2002). Rather than being strictly related to cognitive development or due to an unfolding of cumulative earlier experiences, thoughts about oneself (identity and self-concept) and one's future (plans, decisions concerning the future, wishes, and fantasies), and the restructuring of these self-views and worldviews are likely to depend on the chronological age for formal transitions, particularly in education. Entering the gymnasium or not in Sweden, just like entering college or not in the United States, has a major consequence for future work roles (e.g., Petersen, 1993). Accordingly, the unfolding structure of the educational system in a given society can provide much of the incentives for change in adolescence and for decisions that have effects on the adult roles of parent, spouse, and worker (e.g., Klaczynski, 1990). It has also been argued that what may be seen as a general trend (e.g., declines in educational motivation in early adolescence) and interpreted as a consequence of characteristics of the developmental period in question, may actually be a reflection of specific changes in the school environment in mid-adolescence, which are at odds with individual aspirations (Eccles et al., 1993). With a shared timetable for youngsters in a

given society, cross-cultural data are needed to discern the governing role of such social regulation in development (Thelen, 1981).

Genetic research has introduced the concept of "sensitive" periods when the organism is more open to learning experiences than at other times. Analogously, the age for changes in educational tracks, opportunities to engage in more mature forms of behaviors (such as public dances, movies), and other environmental changes may be seen as "critical" windows when contextual influences provoke a restructuring of one's life, both prospectively and contemporaneously.

One aspect of the synchronization process is the timing of the individual's decisions with respect to certain central aspects of social life. As mentioned, the choice of academic trajectory is of importance for the expected adult social life course. Finishing school early is associated with different timetables for future family planning, marriage, occupation, and attainment of material goods than finishing school late (Gustafson & Magnusson, 1991). The same is true of decisions to leave home early or late (Stattin & Magnusson, 1995). Gustafson, Stattin, and Magnusson (1989) showed that girls who started to date boys early tended to be oriented to homemaking rather than to a career in early adulthood. In summary, how children and adolescents use the available opportunities in the sociocultural environment, the age at which they make transitions, and how they define themselves in age-graded norms in society, can have profound consequences for their adjustment contemporaneously and for their future life track. To some extent, individual behavior is organized by the broader sociocultural arrangements as, through its institutions and age requirements on behavior, society shapes the direction of and sets the milestones for individual behavior. But individuals also organize their own development within the opportunities and restrictions offered by the environment, and by their own actions, young people select some types of developing environments at the expense of others, and through these means contribute to shape their unique development.

A Cross-Cultural Perspective

Cultural factors affect individual behavior through organizational-institutional arrangements in the proximal settings in everyday life. The question of how the cultural context influences individual behavior sets a central task for cultural and cross-cultural research. Such studies in recent decades have documented the existence of similarities and dissimilarities between cultural settings; however, one of the major problems in such research on child development is still to link variations in individual functioning in physical and social settings to the specific cultural elements in each cultural group (Harkness, 1992). Cross-cultural comparisons are not just a matter of comparing countries and speculating about differences that empirical studies have documented. They are about understanding similarities and differences in the different conditions within these countries. Cross-cultural comparisons are particularly needed to examine whether the setting mechanisms behind behavior are similar across cultures, whether the mediators of behavioral, family, and peer processes are similar or different, and whether the same factors operate as moderating conditions for psychological functioning in the same way across cultures.

In their study of changes in self-feelings during the transition toward adolescence, Brooks-Gunn and Paikoff (1992) emphasized the limitations of work on that issue when it comes to generalization across cultures. Stattin and Magnusson (1990) suggested that the specific short- and long-term consequences of the rate of sexual maturation, obtained for Swedish girls, might be different in cultures with other social norms, rules, and role expectations for teenage girls. More specifically, in a society that promotes contacts between teenagers of different ages, and particularly engaging in heterosexual relations, the connection between early pubertal maturation and problem behavior would be stronger than in a society based on chronological age-stratified contacts between adolescents and more limited heterosexual relations. The hypothesis that distal cultural factors influence the character of the adolescent transition process was examined by Stattin, Kerr, Johansson, and Ruiselova (in press). The study was carried out at the same time in central Sweden and in eastern Slovakia. The tradition for young girls in that part of Slovakia does not promote girls' association with older boys or males and is more conservative about early sexual relations relative to the situation for Swedish adolescents. Stattin et al. found empirical support for the idea that under these conditions differences in menarche age did not have the same relation to current behavior as in Sweden. For Swedish girls, early pubertal development was an

instigation condition for heterosexual relations, and the early-developed girls were more norm violative than the later developed. This was not true for Slovakian girls. Overall, these findings are in agreement with the idea that sociocultural factors influences the association between pubertal timing and social behavior. Within a culture, similar processes may operate. Caspi and Moffitt (1991), in a study for a sample of New Zealand girls, found the same early maturation deviance but only if the girls' school was coeducational. Presumably the opportunities for association with older, working boys were greater in the coeducational setting than in all-girl schools.

Summary

This section summarizes and refers to a number of empirical studies on specific aspects of environments and their significance for individual development. Taken together, they demonstrate the broad range of proximal and distal aspects of the environment that are involved in individuals' current functioning and in the developmental processes that should be considered in a general model for these processes.

For a proper interpretation of the empirical studies we have referred to, it should be observed that individuals' adaptation to and handling of environmental conditions is a complex, dynamic process that needs a general, overriding theoretical framework in the final analyses of individual developmental processes. With few exceptions, the studies reported here have dealt with one or a few environmental components at a time at the group level, applying unidirectional models for PE relations. This approach has contributed to the identification of possible working environmental factors in the developmental processes. Empirical research has seldom dealt with the process of interaction in which environmental conditions operate at the individual level. The implications for theorizing about developmental processes are dealt with in a later section on measurement models.

One of the major challenges for further progress in research on the role of environmental factors in developmental processes is to develop and apply strategies and measurement tools that are appropriate for studying this issue at the level of the individual. This is an exceedingly difficult task but that cannot be a reason for not attempting it.

BASIC PRINCIPLES OF THE HOLISTIC-INTERACTIONISTIC MODEL

As we emphasized in the introduction, the holistic-interactionistic model is not an empty conceptual box; it contains fundamental principles that are characteristic features of the processes of individual development. Further scientific progress in research in this field presupposes consideration of these principles in the design, implementation, and interpretation of studies on specific aspects of developmental processes, independent of sex, age, and culture. In this section, we propose and discuss a number of what we regard as basic principles.

The Holistic Principle: From Variables to Individuals

The term "variable" is one of the most misused concepts in psychological research. Misunderstanding is sometimes due to the concept being used in two distinctly different senses: as a psychological concept reflecting a certain aspect of individual functioning, say intelligence or aggressiveness, and as a statistical concept, referring to the measurement level of data. It may be worth reviewing the original definition of a variable in mathematics: "a quantity that may assume any value or set of values." In psychology, the meaning has been extended to "a factor, in individuals and/or in the context that may vary across individuals." One of the misuses of the variable concept is associated with the common tendency to reify psychological phenomena as hypothetical constructs (e.g., Bergman & Magnusson, 1990). Hypothetical constructs are basically inferential in nature; they reflect aspects of the integrated, dynamic functioning of the individual but do not exist as separate structural units. An individual can function in an intelligent, dependent, or helpless way, but intelligence, dependence, and helplessness do not exist per se. Hypothetical constructs at the measurement level are usually referred to as "latent variables." Borsboom, Mellenbergh, and van Heerden (2003) recently examined the theoretical status of latent variables as used in modern test theory and argued that the application of such models requires "a realistic ontology of latent variables." This demand is not restricted to the study of latent variables in the application of test theory. It is equally valid when the concept of latent variables is

used in other measurements of situations involving hypothetical variables.

The integrated, holistic nature of developmental processes implies, among other things, that they go on and develop as irreducible wholes and cannot be decomposed into or understood as independent components. The holistic view of processes in nature has old roots. A formulation by Carl von Linné is appropriate here: "such a relation exists between all parts, that if just one disappeared, the whole would not last" (Broberg, 1978, p. 29). It is also a main proposition in modern models for complex dynamic processes. Accordingly, the whole picture conveys information that extends beyond what is contained in the separate parts. "The doctrine of epigenesis" is defined as: "Behavior, whether social or unsocial, is appropriately viewed in terms of an organized system and its explanation requires a holistic analysis" (Cairns, 1979, p. 325).

The uniqueness of an individual's life processes imply that a single component does not necessarily have the same psychological significance in the developmental processes for all individuals, independent of other, simultaneously working components of individual functioning. In the IDA longitudinal study, Magnusson and Bergman (1990) observed that data for aggressiveness in childhood was significantly related to data for adult criminality for males. Further analyses supported the hypothesis that the significant correlation between early aggressiveness and adult criminality was largely accounted for by males who as children had shown a combination of aggressiveness, motor restlessness, lack of concentration, poor peer relations, and other problem behaviors. When this multiproblem group of males was excluded from the sample, data for early aggressiveness no longer predicted data for adult criminality. In the same way, divorce in the family does not affect children independent of other aspects of family life and family relations. It is detrimental when it appears together with other risk factors (Stattin & Magnusson, 1996). The same holds for other aspects of upbringing conditions such as criminality, alcohol problems, and unemployment in the family.

The holistic principle holds for all systems, regardless of the level at which they operate. It holds at the cellular level, at the level of subsystems such as the coronary system, the immune system, the cardiovascular system, the cognitive system, and the behavioral system, as well as at the level of the individual as a total system. It also holds for the environment and its subsystems, such as the peer system among youngsters, as well as for the total PE system. Discussing the role of culture in human development, Wills (1993) stated: "It is primarily the elaborateness of culture, rather than any of its specific features, that has driven the evolution of the brain" (p. 42). Arguing for a holistic approach, Barrien Moore (2000), chairman of The International Geosphere-Biosphere Program (IGBP) concluded in a discussion about the challenges for future research on earth's life support system:

> [F]irst, the Earth functions as a system, with properties and behavior that are characteristic of the system as a whole. . . . Understanding components of the Earth System is critically important, but is insufficient on its own to understand the functioning of the Earth Systems as a whole. (p. 1)

In general terms, a holistic approach to individual functioning has been discussed for some time (e.g., Allport, 1937; Lewin, 1935; Russell, 1970; Sroufe, 1979). Mischel (2004) presented an overview of the historical development of this approach in personality research and of the present state of the art. In developmental research, a holistic view was advocated by a number of authors (Cairns, 1979; Emde, 1994; Ford, 1987; Lerner, 1984, 1990; Magnusson 1988; Sameroff, 1983; Wapner & Kaplan, 1983; Wolff, 1981). The implication of this view was expressed by Husén (1989), in discussing the challenges for the future of educational research: "we are now facing a paradigm shift from the overgeneralizations and abstractions of the Cartesian philosophy of man and Newtonian mechanics to a celebration of the individual and the unique" (p. 357).

Implications

Although proximal and distal environmental factors are involved in the developmental processes of an individual, not one of these factors acquires its significance in the process per se, only by the role it plays in the totality. In the mind of the person, each aspect constitutes an element in an integrated process and its significance and importance are to some extent unique for the individual. The same applies to each component in the functioning of the mind in current situations and in developmental processes. Accordingly, consideration of the holistic principle is essential for real scientific understanding of

both current behavior and developmental processes of the individual.

The holistic principle has fundamental consequences for the choice and application of appropriate methodologies and research strategies in empirical research on specific aspects of human functioning, both in a current and in a developmental perspective. A central implication is that the total process, which is the focus of interest in a particular study, cannot be finally understood by investigating single aspects isolated from other simultaneously operating components. For example, if we only think of single cells, we will not understand the functioning of the systems in which they work (e.g., Levi-Montalcini, 1988).

Neither the functioning of the individual nor developmental changes can be understood by summing results from studies of single aspects, a point that Allport made forcefully in 1924. As a consequence, the traditional variable-oriented approach needs to be complemented with a *person approach,* which considers a holistic-interactionistic framework (e.g., Magnusson, 2003).

Adoption of the holistic principle does not imply that specific mental, behavioral, and biological aspects of individual functioning and development should not be the object of empirical research. The warnings by Mayr (1976) with respect to biology are equally applicable to psychology: "The past history of biology has shown that progress is equally inhibited by an anti-intellectual holism and a purely atomistic reductionism" (p. 72). There is no real contradiction between a holistic approach to theoretical analyses and empirical investigations of specific mechanisms that are operating, in the processes underlying why an individual thinks, feels, acts, and reacts as he or she does (e.g., McCall, 1981). The formulation of the theory of evolution by Darwin in 1859 did not obstruct theorizing and empirical research on specific issues in life sciences. On the contrary, acceptance and application of the basic principles of natural selection in the theory of evolution laid the foundation for real scientific progress in research on living organisms.

Transformation, Emergence, and Novelty in Structures and Processes

Some theorizing and empirical research seems to assume implicitly that individual development is a matter of adding new elements to the existing ones in a process of accumulation or acquiring more of the same. Rather, individual development is a continuous process of restructuring, at the subsystem as well as the whole system level, within the boundaries set by psychobiological and environmental constraints:

> Throughout development, the child or animal refines properties of its expression, combines previously isolated properties together into new packages, and opens up new windows of receptivity to its world while closing other windows on the way to establishing a unique individuality. (Fentress, 1989, p. 35)

A change in one aspect affects related parts of the subsystem and sometimes the whole organism. Mayr (1997) emphasized the concept of emergence as one of the two major pillars of a holistic view on living organisms: "that in a structured system, new properties emerge at higher levels of interaction which could not have been predicted from a knowledge of the lower-level components" (p. 19). At a more general level, the restructuring of structures and processes at the individual level is embedded in and part of the restructuring of the total PE system.[5]

Accordingly, individual development implies continuous reorganization of existing patterns of structures and processes and creation of new ones. Sometimes totally novel behaviors appear. Research from the longitudinal program at Chapel Hill is illustrative (Cairns, Cairns, Neckerman., Fergusson, & Gariépy, 1989). In late childhood, girls develop new techniques of aggressive expression, including the ability to ostracize and ridicule peers in such a way that the target is unaware of who is attacking her. Females employ this strategy with increasing frequency in late adolescence. Boys, on the other hand, are more characterized by the developmental continuation of confrontational techniques that leave them open to direct and violent reprisals. What on the surface seems to be the same behavior for all individuals at various age levels may differ in its psychological significance for different individuals of the same age and for the same individual over time. This consequence of the

[5] In the life-span perspective, novelty implies both growth and decline in structures and processes, as emphasized by Baltes (1987).

principle of novelty in the holistic, integrated developmental process of an individual is often ignored in traditional developmental research.

Functional Interaction

Much of the debate on individual functioning in the framework of classical interactionism has been based on empirical studies that investigated person-environment interactions across individuals in statistical terms at the group level, using traditional experimental designs. In contrast, a fundamental characteristic of the processes of all living organisms at all levels is functional interaction among operating factors at the individual level (Miller, 1978; von Bertalanffy, 1968). Components of open systems do not function in isolation, and usually do not function interdependently in a linear manner within individuals. The processes are much more complex, particularly when mental, biological, and behavioral components are involved in joint operations.

Functional interaction is a characteristic of the developmental process of an individual in the life-span perspective; from the interaction that takes place between single cells in the early development of the fetus (e.g., Edelman, 1989; O'Leary, 1996) to the individual's interplay with his or her environment across the life span. The building blocks of all biological organs are the cells. Behind individual development as an organized, functional totality from a single cell lies the process of interaction among cells. Each cell develops, functions, and dies as a result of cell-cell interaction in which information is received from and sent to neighboring cells. The application of techniques from molecular biology and biophysics to unicellular model systems and nowadays even to transgenic organisms has opened up new avenues to an understanding of the mechanisms that regulate the growth, division, and development of new forms of cells and cell structures. In biological sciences, interaction is a central concept in models for the functioning and development of all living organisms, as emphasized by Mayr (2000b). In the annual report for 1998/1999 from the Swedish Council for Research in Natural Sciences, a central chapter was devoted to discussing the fundamental role of interaction in biological processes from cellular protein to brain level (Lindberg, 2000).[6]

Reciprocity and Interdependence

As pointed out earlier, a strong assumption in traditional, variable-oriented psychological research concerns unidirectional causality. Unidirectional influences on individual functioning with temporary and long-term developmental consequences obviously exist. For example, the outdoor temperature unidirectionally affects the individual's choice of clothes and in some respects his or her behavior. Interestingly, there are empirical studies that indicate that some aspects of an individual's development are related to the season of birth (e.g., Kihlbom & Johansson, 2004). To a varying extent across proximal and distal environments, individual lives take place and develop within boundaries set by existing norms, rules, and regulations.

Nevertheless, a primary feature in dynamic complex processes is the dynamic interaction of operating factors. Reciprocity and interdependence are features of the processes at all levels of individual functioning and of the PE system: They are a feature of the relationship between cells and their context in the womb during pregnancy, the way psychobiological components are integrated within the individual, the way in which individuals relate in the socialization process, and the way an individual relates to the environment (Bell, 1971; Caspi, 1987). In classical interactionism, person-person interaction was seen as a good illustration of the principle. Reciprocity among operating factors contributes to developmental change in the functioning of the total system:

> The basic principle underlying reciprocal influences in development arising from parent-offspring interaction is that of a moving bidirectional system in which the responses of each participant serve not only as the stimuli for the other but also change as a result of the stimuli exchanges, leading to the possibility of extended response on the part of the other. (Bell, 1971, p. 822)

As emphasized in a modern interactionistic view, functional interaction is also a fundamental principle in psychobiological processes within the individual. In a

[6] An example of the misunderstanding of the role of statistics is the demand that the existence of dynamic interaction in developmental processes should be proved by statistical models for the study of interaction in data sets. Functional interaction as a characteristic of developmental processes should be distinguished from statistical interaction models as tools in the treatment of data. In principle, they have only the word interaction in common (Magnusson, 2001).

discussion of the immune system, Maier and Watkins (2000) concluded:

> The brain and the immune system form a bidirectional communication network in which the immune system operates as a sense organ to provide the brain with information about infection and injury, thereby allowing the brain to coordinate a defense. Activated immune cells release proteins called cytokines, which signal the brain by both blood and neural routes. Information that reaches the brain across this sensory channel produces large changes in neural activity, behavior, mood, and cognitive functioning. Appreciation of the functioning of this network may illuminate poorly understood aspects of stress, depression, and intraindividual variability in behavior, mood, and cognition. (pp. 98–112)

Nonlinearity

As stated previously, much psychological research is focused on the statistical relations among variables at the group level. The most frequently used methods assume (a) that the relation among the variables is linear across individuals, and (b) that the relation obtained across individuals holds for the relation among factors operating within an individual.

Our concern here is linearity versus nonlinearity in the interrelations among components operating at the individual level. Nonlinearity, more often than linearity, is a characteristic of individual processes. The principle implies, for example, that the effect of hormone A on the dependent hormone B is not necessarily linear; the relation may assume very different functions. The same holds true for the interplay of a single individual with his or her environment. For example, individuals' psychological and physiological stress reactions to increasing stimulation from the environment are often nonlinear. The inverted U-relation found between performance as well as psychological and physiological stress reactions for individuals, on the one hand, and the strength of the demand from the environment, on the other, is one example. The nonlinear function for the relation between two operating person-bound factors or the relation between the individual and his or her environment may differ among individuals.

Causality in Functional Interaction

Understanding an individual's way of functioning and developing includes a discussion about causal mechanisms. These mechanisms are of special concern when discussing models of the processes by which individuals develop. Understanding causal mechanisms is also a prerequisite for effective intervention. The discussion here is related to the distinctions made in an earlier section titled: Three General Approaches to Person-Environment Relations.

At a metatheoretical level it is possible to distinguish three main causal models of relevance for the discussion here: the mentalistic, the biological, and the environmentalistic model (Magnusson, 1990). The main distinction concerns the focus each approach employs with regard to interpreting the main factors presumed to guide individual functioning and development. Few scholars are likely to identify themselves explicitly as representatives of either category. However, we argue that the models exist and affect what researchers actually do and discuss.

The mentalistic model emphasizes mental factors as the central ones for understanding why individuals function and develop as they do. The focus of interest in theorizing and empirical analyses is on intrapsychic processes of perceptions, thoughts, emotions, values, goals, plans, and conflicts.

In the *biological model,* an individual's thoughts, feelings, actions, and reactions are assumed to be determined basically by his or her biological equipment and its way of functioning. Primary determining factors are assumed to be found in the brain, the physiological system, and the autonomic nervous system. When biological models of individual development are applied, the major determining guiding factors are genetic and maturational. In its extreme version, this model implies that individual differences in the course of development have their roots in genes, while environmental and mental factors play a minor role.

The environmentalistic model locates the main causal factors for individual functioning and development in the environment. It is reflected in theories and models at all levels of generality for environmental factors: macro social theories, theories about the role of the "sick family" and S-R models for specific individual variables, are a few examples. The environmentalistic model has been very influential in developmental research.

In much traditional research, a common characteristic of the three general models is their assumption of unidirectional causality; mental factors are the main causes of behavior, and biological factors and environmental

factors, respectively, are implicitly assumed to be the basic determinants of mental activities and behavior.

In theoretical and empirical research, each of the metatheoretical approaches to understanding basic causal mechanisms has had and still has a strong, sometimes dominant impact. They have also had far-reaching implications for how societal issues have been discussed and handled, as well as for psychological application, for example, in discussions of appropriate treatment of mental illnesses. Their existence reflects a fragmentation of the field into subdisciplines in content, concepts, research strategy, and methodology and diversifies research into specialties with little or no contact across domains. Nothing is wrong with each of the three explanatory models themselves. The problem arises when each of them is assumed, mostly implicitly and without discussion, to be sufficient or at least the most important for psychology as a scientific discipline. This has hampered real progress in both research and application.

Perceptual, cognitive-emotional, biological, and behavioral components of an individual's functioning, and the perceived and interpreted aspects of the environment, are involved in a continuous loop of functional interaction in a current situation. Individual functioning as well as developmental processes are multidetermined and function and develop in a complex and dynamic way. From this perspective, Gottlieb (2003) discussed developmental causality in terms of "co-action."

This perspective implies that the concepts of independent and dependent variables and of predictors and criteria lose the absolute meaning they have in traditional research assuming unidirectional causality. What may function as a criterion or dependent variable in statistical analyses at a certain stage of a process, may at the next stage serve as a predictor or independent variable.

Temporality

Another central concept in a holistic-interactionistic model is that of process. A "process" can be characterized as a continuous flow of interrelated, interdependent events. This definition introduces time as a fundamental element in any model for individual functioning and development. In modern models of dynamic processes, a central concept is motion. Further, key aspects of biological processes are rhythm and periodicity (Weiner, 1989). Faulconer and Williams (1985), drawing on Heidegger, emphasized the importance of annexing temporality in our endeavors to understand individual functioning. Without the principle of temporality, the fundamental dynamic aspect of the processes of current functioning and development is ignored (e.g., Dixon & Lerner, 1988). The earlier referenced study by Li et al. (2004) shows how cognitive structure varies across ages in a nonlinear way and empirically demonstrates the importance of considering the temporal aspect of central individual processes in life-span research.

The temporal perspective varies with the character of the system under consideration. Individual differences in biological age among girls had consequences for current behavior during puberty and early adolescence but also for the further lifestyle in unexpected ways. Processes in systems at a lower level are generally characterized by shorter time perspectives than processes at a higher level. Cairns and Cairns (1985) made a distinction between short-term interactions in the perspective of seconds and minutes and developmental interactions in the perspective of months and years. They proposed that social learning processes, which are central for short-term, current adaptations, may be reversed or overwhelmed in the long-term by slower-acting maturational, biosocial processes (see also Riegel, 1975, in his presentation of a dialectical theory of development).

The pace at which structures and processes in the individual change as a result of maturation and experiences varies with the nature of the systems, especially the level of subsystems (see the discussion by Lerner, Skinner, & Sorell, 1980, about "nonequivalent temporal metric"). The anatomical structure of the fetus changes, as a result of cell-context interaction, much faster than the individual changes during adolescence. P. W. Sternberg (2004) pointed to a characteristic feature of cell development that should be considered in research on the development of biological mechanisms at the basic level, by stating:

> The amazing precision with which different cell types find their correct location in developing tissues has fascinated biologists for decades. Models of cell fate patterning during development emphasize the contrast between spatial gradients of developmental signals that act at long range and cell-to-cell signaling events that act locally. (p. 637)

Since systems at various levels are embedded in each other and components are involved in a dynamic interaction, the temporal perspective does not apply to only one subsystem at a time. Rather, the coordination and synchronization of system components with different time scales is critical.

Implications

To understand them, transformation processes must be followed over time. Short-term processes can be followed, observed, and studied by applying an experimental design. For long-term processes (e.g., pubertal change), the most frequent approach is systematized observation over time: a longitudinal study. Only by following girls up to adult age could the relevance of the teenage behavior in life course be traced in our study of biological age.

A fundamental circumstance with decisive consequences for empirical research is the existence of sometimes very strong interindividual differences with respect to the pace of developmental transformation processes. The study of individual differences in biological maturation among teenage girls, referred to above, demonstrates the inadequacy of cross-sectional studies on long-term developmental processes. Overwhelming numbers of empirical studies on adolescence have been and are being performed with reference to data from samples of a certain chronological age. The effect is to introduce an irrelevant and, with respect to size, unknown part of the total variance in sample data. Studying problems among girls at that age using a cross-sectional design, without considering the interindividual differences in the psychobiological timing of pubertal processes, may lead to erroneous conclusions and to negative consequences for the girls if the results are used as a basis for interventions.

Organization

The holistic-interactionistic model does not imply that developmental processes are random. A fundamental basis for the scientific analysis of individual development is the proposition that processes are guided by basic principles and specific mechanisms in structures that are organized and function as patterns of operating factors at all levels of the individual. Organs and components of organs constitute functional units of the total, integrated organism. Principles and mechanisms in the orderly organization serve to maintain integration and stability both of current functioning and of developmental change.

The orderly organization of behavior in a developmental perspective was emphasized and discussed by Fentress (1989). An interesting question is whether the differences between early development and aging are essentially a discontinuity in organizational directionality toward more as opposed to less organization (Baltes & Graf, 1996).

One basic, well-documented principle in the development of biological systems is their ability for self-organization, a characteristic of open systems, which refers to a transformation process by which new structures and patterns emerge (see Kelso, 2001, for an overview, and Barton, 1994, for a discussion of self-organization in developmental processes). From the beginning of fetal development, self-organization is a guiding principle. "Finality in the living world thus originates from the idea of organism, because the parts have to produce each other, because they have to associate to form the whole, because, as Kant said, living beings must be 'self-organized' " (Jacob, 1976, p. 89).

Within subsystems, the operating components organize themselves to maximize the functioning of each subsystem with respect to its purpose in the total system, as higher level subsystems organize themselves to fulfill their role in the totality. Self-organization is a fundamental principle in living cells (e.g., Hess and Mikhailov, 1994). This principle is found in the development and functioning of the brain, the coronary system, and the immune system.

> The strength and indeed the very preservation of nascent connections between neurons appear to depend on patterns of neural activity in the developing nervous system and these patterns of activity vary among individuals—at best they are only statistically regular—so that detailed wiring of each individual's brain is distinct. (Stryker, 1994, p. 1244)

The principle can also be applied to the development and functioning of the sensory and cognitive systems and to manifest behavior (see M. Carlson, Earls, & Todd, 1988).

Individual Differences

Two aspects of self-organization are pertinent for the discussion here. First, individuals differ in the way in which operational factors are organized and function within subsystems, which, in turn, also differ in organization and function. These organizations can be described as patterns of operating components within subsystems and as patterns of functioning subsystems. Weiner (1989) suggested that even the oscillations produced by the natural pacemakers of the heart, the stomach, and the brain are patterned.

In psychology, the idea of patterning is not new. Galton (1869) concluded that some people are more intelligent than others and each person's pattern of intellectual abilities is unique. A common way of presenting analyses of individual differences with respect to intellectual resources is in profiles representing patterns. Based on their own children's diaries, pioneers of child psychology such as Preyer (1908), Shinn (1900), and W. Stern (1914) described and discussed individual differences in developmental changes of patterns. Patterning of individual characteristics was also reflected in longitudinal research on child development in the period of 1930 to 1950 (see Thomae, 1979).

Second, the number of ways in which operating factors in a certain subsystem can be organized in patterns and the number of ways in which subsystems can be organized for the whole organism is restricted (e.g., Gangestad & Snyder, 1985, who argued for the existence of distinct personality types, with reference to shared sources of influence). Only a limited number of states are functional for each subsystem and for the totality (e.g., Bergman & Magnusson, 1991; Sapolsky, 1994). In the multidimensional space, individuals with similar patterns of working components form "dense points" (see the discussion about the crystallization hypothesis).

Complementary to the assumption of "dense points" in the multidimensional space is the assumption of "white spots," patterns of working components at a certain level that, for psychological and/or biological reasons, cannot occur (see Bergman, 1988b; Bergman & Magnusson, 1997). The identification of white spots, and of extreme and deviant developmental paths, might be as important as the study of dense points for understanding developmental processes in general (e.g., Caprara & Zimbardo, 1996; Kagan, Snidman, & Arcus, 1998).

Patterning as a basic characteristic of subsystem functioning can be illustrated with objective data from biological research. Studying cardiovascular responses in a stressful situation, Gramer and Huber (1994) found that the subjects could be assigned to one of three groups on the basis of their distinct pattern of values for systolic blood pressure, diastolic blood pressure, and heart rate as shown in Figure 8.1. A similar study on cardiovascular responses was reported by Mills et al. (1994).

The data presented by Gramer and Huber represent a momentary picture of individual functioning in terms of patterns. How individuals can be grouped on the basis of their distinctly different biological processes has been demonstrated, among others, by Packer, Medina, Yushak, and Meller (1983), who studied the haemodynamic effects of Captopril in patients with severe heart problems. Together, these results reflect a basic principle underlying individual differences in development: at all levels of organization, individual development is manifested in patterns of operating factors.

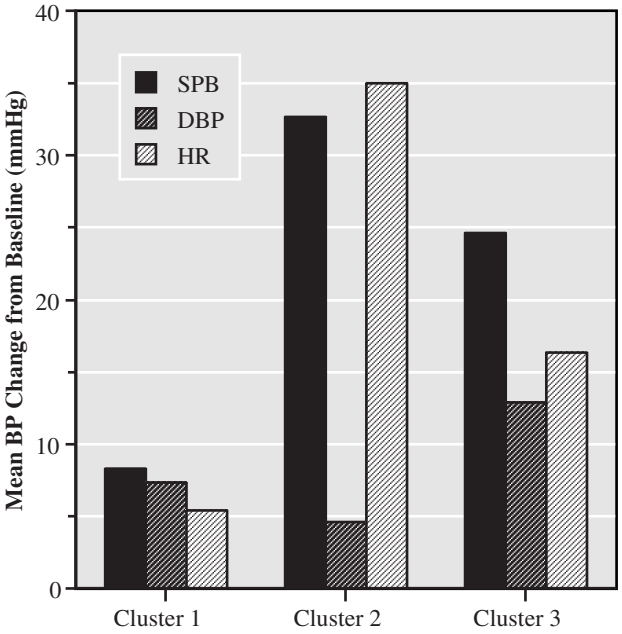

Figure 8.1 Magnitude of SBP, DBP, and HR reactivity in cardiovascular response clusters during speech preparation. *Source:* From "Individual Variability in Task-Specific Cardiovascular Response Patterns during Psychological Challenge" by M. Gramer and H. P. Huber, 1994, *German Journal of Psychology, 18,* pp. 1–17.

Organization of the Environment and the Person-Environment System

Organization is also a fundamental characteristic of the external environment, in all its manifestations. Both the physical and the sociocultural environment are structured and organized. The study of the nature of societal institutions and their organization by age, gender, and social class is fundamental to life-course sociology (see Elder, 1998). Of particular interest is the organization of the environment in how it is perceived and interpreted by the individual, through the eye of the beholder. As developing, evolving individuals, we strive for coherence in the world and of ourselves in the world. Particularly salient to the discussion about person-environment interactions is the individual's inborn striving for mental organization of the social environments, in families, peer relations, and other social networks (e.g., Kelvin, 1969). The organization of the environment as it is perceived

and interpreted by the individual in organized patterns and structures is a necessary condition for the individual's ability to deal effectively with and assign meaning to the enormous amount of information that is available at each moment of the person-environment interaction process, and for the individual to use the information for adequate and effective actions. One of the most important tasks for a child's caretaker is to act in a way that helps the child to develop valid and trustful mental organizations of the social world (Costanzo, 1991; Trevarthen & Aitken, 2001, p. 30).

Integration of Processes: Synthesis

At all levels of the dynamic, complex processes, the functioning parts are coordinated in their operations so as to serve the goal of the system to which they belong. This principle holds for parts of subsystems at all levels as well as for the coordination of subsystems in the functioning of the totality. Integration is the principle behind the fact that the total is not only more but something else than the sum of its parts.

Summary

This section has been devoted to the discussion of basic principles that hold for the developmental processes of all individuals. These principles must be considered in theoretical and empirical research on specific aspects of developmental processes. Of course, the principles discussed here are not to be regarded as a final complete list of basic principles, with respect to either number or content. Further theoretical and empirical analyses will certainly modify the list, as with normal scientific development in any area. Our aim here is to emphasize that without consideration of these basic principles, the results of statistical analyses may be statistically significant, but still run the risk of being irrelevant as a basis for understanding the individual processes.

THEORETICAL AND METHODOLOGICAL IMPLICATIONS

A characteristic feature of scientific progress in empirical sciences is increasing specialization. When specialization in a subfield of the natural sciences has reached a certain level, it becomes apparent that further progress lies in integration with what has been achieved in neighboring disciplines. In the introduction, we drew attention to the role of the theory of evolution for scientific progress in biological sciences. In general, the most important steps forward in natural sciences have been taken by integration at the interfaces of what were earlier conspicuously different disciplines; for example, at the interface of physics and chemistry and later at the interface of biology, chemistry, and physics. The earlier unambiguous and clear boundaries between subdisciplines changed to new disciplines, as scientific progress toward a better understanding of the physical and biological world required general models of nature.

We have briefly referred to what is the rule in natural sciences, including biology, to emphasize the fundamental role played by an overriding general theoretical framework for progress in those disciplines: The same holds for psychology as a scientific discipline. A general theoretical framework, a general model of the individual and society, is sorely needed for further, real progress in research on human ontogeny. The holistic-interactionistic model for individual development is suggested to meet that need.

The basic principles of the holistic-interactionistic model—the holistic principle, transformation with emergence and novelty, functional interaction, temporality, organization, and synthesis—have decisive consequences for the planning, implementation, and interpretation of empirical studies when the task is to contribute to the understanding of developmental processes. Now, that this perspective is increasingly accepted theoretically, the scientific challenge is to take its consequences seriously in empirical research.

To dispel a common misunderstanding and criticism, let us emphasize again that a holistic, integrated model for individual functioning and development does not imply that the entire system of an individual must be studied in every research endeavor. The acceptance of a common model of nature in natural sciences has never meant that the whole universe should be investigated in every study of specific problems.

Toward a Developmental Science

A consequence of the view advocated here is that for a full understanding and explanation of the developmental processes of individuals, knowledge from what is traditionally incorporated in developmental psychology is not enough. We need contributions from the interface of a number of traditional scientific disciplines: developmental biology, cognitive sciences, developmental psychology, physiology, endocrinology, neuropsychology,

social psychology, sociology, anthropology, and neighboring disciplines. The total space of phenomena involved in the process of lifelong individual development forms a clearly defined and delimited domain for scientific discovery. This domain constitutes a scientific discipline of its own, developmental science (Cairns, 2000; Magnusson, 1999b, 2000; Magnusson & Cairns, 1996). The contributions by excellent scientists—representing different aspects of individual development, from the fetal period to aging and from the cellular level to the interdependence of biology and culture—at a Nobel symposium under the auspices of the Royal Swedish Academy of Sciences in 1994, conspicuously attested to the underlying principles and the need for the establishment of Developmental Science (Magnusson, 1996b). The organization of research on individual development in the interface of well-established disciplines is in line with the growing urge for cross-disciplinary collaboration (e.g., Kafatos & Elsner, 2004). The proposition that research on individual development constitutes a field of research with its special demands on theory, methodology, and research strategy, does not mean that psychology loses its identity as a scientific discipline. Physics, chemistry, and biology did not lose their special merits as a result of the new developments at their interfaces. Contributing essential knowledge to developmental science instead strengthens psychology as an active partner in the mainstream of scientific progress.

Methodological Implications: Looking for Mechanisms

At an early stage, we proposed three main tasks for psychological research; the third was to identify the *mechanisms* that guide the operation of working factors in individual functioning and developmental processes. This goal requires the application of methodological tools that are explicitly linked to the character of the relevant phenomena and considering the basic principles of developmental processes.

The formulation of holistic interactionism draws attention to some earlier methodological issues of developmental research and raises some new ones. If the basic principles of the holistic-interactionistic model are taken seriously, there are specific implications for planning, implementing, and interpreting empirical studies.

Nature of Phenomena: Levels of Analysis

The nature of the structures and processes involved at different levels of the integrated person-environment system varies. The fundamental consequence is that it is not possible to collapse one level into another in empirical research (e.g., Novikoff, 1945). A necessary condition for any proper interpretation of empirical data is that the researcher is aware of and makes explicit the level of the phenomena at which the problem is located and formulated. For example, analyses of trait data have theoretical consequences that differ from those which apply in analyses of state data for the same latent variable.

Accordingly, the starting point for planning empirical research on a specific topic is a careful, systematic analysis based on observation of the phenomena at the appropriate level (Cairns, 1986b; Magnusson, 1992). If this requirement is not met, even sophisticated analyses of the data will yield not only trivial but sometimes misleading results. The starting point for the analysis is always a question, which may be motivated by theoretical considerations, by results from experimentally designed studies, and/or by direct observations in natural settings of the phenomenon under investigation.

Tools in the Acquisition of Information: Methods for Data Collection

It follows from the foregoing discussion that a particular methodology cannot be applied regardless of the level and character of the structures about which a research problem has been formulated. There is no single scientific method that can be used for effective research on all types of problems. An individual's life course is a highly idiosyncratic process. As long as our aim is to contribute to the synthesis of knowledge about individual developmental processes, in the final analysis they must be analyzed with reference to their holistic character. Given the very large number of elements at all levels of the individual's integrated developmental processes, this proposition poses a real challenge for the development and application of appropriate tools for the acquisition of information.[7]

[7] Psychological subfields are sometimes defined through methods. An example is "experimental psychology," which has been and often still is regarded as the most prestigious area of psychological research. Cronbach (1954) in a frequently cited article separated two psychological disciplines with reference to methods: experimental and correlational psychology, respectively (cf. Cronbach, 1975). We claim that there is a single, integrated space of phenomena that is the target of scientific analysis of psychological phenomena.

In empirical research, the classical method for observation and acquisition of information is the experimental design. Experimental designs are also important tools in a study concerned with current or developmental processes. Such designs are indispensable and particularly useful for the study of short-term transformation processes, such as during the fetal period of life, and of brain development at the cellular level as an effect of external information, for instance, in brain research on learning (e.g., E. R. Kandel & Schwartz, 1982). O'Connor (2003) emphasized the advantages of natural experiments in research on early experiences. This research strategy is an important tool both in experimental research on short-term processes and in studies on developmental processes over longer periods (e.g., Cairns, 1986a; Cairns & Rodkin, 1998).

The focus of this chapter is on individual development as a dynamic process of change across the life span. The basic principles that characterize the target of analysis restrict the application of the classical experimental design in empirical studies on basic developmental issues. The main reasons for this conclusion are the individuality of the processes and the individual differences in the way the basic principles of developmental processes function simultaneously. In this situation, systematized observation becomes an indispensable complementary tool. The history of science is full of illustrations to support this proposition. Charles Darwin's theory of evolution was based on his systematization of careful observations. Johannes Kepler's ingenious trio of laws for the earth's movement around the sun stemmed from Tycho Brahe's careful and systematic observations of the movement of the planets. Carl von Linnaeus's system for the categorization of plants was likewise the result of systematic observations, as was Fleming's discovery of penicillin. These contributions are only examples of all those that have formed the necessary conditions for further theoretical progress in their respective disciplines.

The basic principles of developmental processes lead to the conclusion that progress in research on working mechanisms requires further development and application of appropriate methods for systematic observation and description under controlled conditions. Sometimes nature offers conditions for systematized observation. An illustration of how knowledge can be obtained by observations that use variation in natural conditions for the study of basic psychological phenomena is Luria's (1976) study of language, self-perceptions, perceptions of others, and perceptions of the world. Studies of monozygotic and dizygotic twins, reared together or apart, offer another illustration (e.g., Bohman, Cloninger, Sigvardsson, & von Knorring, 1982; Haugaard & Hazan, 2003). In research on evolution, descriptive analyses based on systematic observation in varying forms plays a fundamental role. The same is the case in longitudinal research, aiming at understanding individual development as a life-span process, characterized by the basic principles summarized earlier.

Our understanding of individual and environmental functioning and of the functioning of the total PE system—currently and developmentally—would also gain from extending the arsenal of methods to include qualitative methods, frequently and successfully applied in ethnographic research (e.g., Schweder et al., 1998). An applicable complement is the narrative approach in which individual life stories are analyzed (e.g., Sarbin, 1986; Singer, Slovak, Frierson, & York, 1998). Fiese et al. (1999) used a narrative approach in their studies of various aspects of family life. An illustration of the fruitfulness of this approach was presented by Manturzewska (1990) in her studies of the life-span development of professional musicians. With reference to Tomkins' (1979) "script theory," R. Carlson (1988) advocated the usefulness of psychobiographical inquiry in several areas of personality research development. The comprehensive interview data collected by Cairns and Cairns (1994) in their longitudinal study of adolescence yielded information that could not have been obtained in other ways.

Generalization

A characteristic of much empirical psychological research is its ethnocentrism. Research on the upbringing environment, which is normally associated with transition behaviors and the timing of developmental events, has mostly been done in Western European countries, Australia and New Zealand, and the United States. Although cultural and cross-cultural research has provided valuable information about other cultures, our knowledge about whether these correlates are similar in countries elsewhere is still limited. Even where such broader comparisons have been made, this has often been done with instruments developed and

validated on individuals in Western countries. This state of affairs raises the basic question about generalization of empirical results obtained for the functioning and development of different aspects of the total PE system at different levels (e.g., Baltes, Reese, & Nesselroade, 1988). How far are results obtained in one environmental context valid in others? The importance of this question has been conspicuously demonstrated in research on the role of individual differences in biological maturation and its long-term consequences. Empirical studies on this issue indicate the danger of generalizing results on developmental processes obtained in one cultural setting to other cultural settings, as a basis for general conclusions about the human nature.

Generalization of results from studies on specific issues is a goal of scientific research. In the tradition of experimental psychology, replicability has been regarded as the main criterion of the validity of results. Unsophisticated use of this rule has sometimes, for example, had the consequence that differences in results from studies on a specific issue in different cultures have been interpreted as errors. This motivates some comments.

In the search for possible operating factors and for mechanisms underlying the simultaneous operation of these factors, the basic principles of developmental processes have four main implications for the generalization of results.

First, results concerning possible operating factors in the developmental processes should not be generalized across age levels without careful consideration of the phenomena being studied.

Second, results cannot be generalized from one level of analysis to another, either with operating factors or working mechanisms. The interpretation of much empirical research assumes that relations between operating components in the individual and/or in the PE system, studied at group level, can be generalized to hold for the relations between the components in developmental processes at the individual level. This tradition still dominates the field, despite a serious debate about the lack of theoretical and empirical support (e.g., Bergman, 1998; Ford & Lerner, 1992; Magnusson, 1998; Nesselroade & Featherman, 1991). The incorrectness of the assumption was demonstrated recently by Molenaar, Huizenga, and Nesselroade (2002), using simulation procedure; they showed that in the extreme case, significant relations between operating components, studied at group level, did not hold for any individual (see also von Eye & Bergman, 2003). Borkenau and Ostendorf (1998) came to the same result with empirical studies on individuals.

Third, results cannot be generalized from group means to individuals. Lewin (1931) strongly argued for this proposition. For example, representative sample means for a specific performance at a certain age are sometimes used as reference points for the evaluation of performance by individuals or groups of individuals. However, any parent can observe that their child does not necessarily follow the age curves presented in developmental research. Using group means as a basis for conclusions about the complex, dynamic processes of the individual will inevitably conceal important mechanisms. Kagan, Snidman, and Arcus (1998) discussed and emphasized, with reference to empirical studies of children, the value of studying statistically extreme groups.

Fourth, results concerning possible operating factors in one cultural context cannot be generalized to others without careful considerations. Neither can results concerning the role of specific components operating in one generation be generalized to another generation independent of the nature of the structures and processes under study.

An example of cross-national differences, important to consider in generalization of results on individual development, is a series of studies on how German, Russian, and American children's beliefs about their ability relate to school performance. In general, few cross-national differences were found with respect to children's views of what factors are important for performance. However, American children systematically reported stronger beliefs that they could influence these factors and their performance. Despite this, considerably lower belief-school grade correlations were obtained for the American than European children (Little, Oettingen, Stetsenko, & Baltes, 1995; Oettingen, Little, Lindenberger, & Baltes, 1994). Silbereisen and coworkers have compared youngsters raised in the former East Germany with similar groups in West Germany with respect to correlates and background conditions of transition behaviors. Their analyses revealed that many correlates in the East were quite different from those of the West, while youngsters raised in West Germany were often similar to those found in U.S. studies. One illustration is the timing of leaving home (Silbereisen, Meschke, & Schwartz, 1996).

There are also differences in these respects between children from different Western countries. For example, the dating system has not existed in Western Europe to the same extent as in the United States, and that could mean, for example, that the impact of pubertal development might have quite different implications. The role of biological maturation during early adolescence supports this proposal. In some areas, the differences in sociocultural environments between the United States and Western European countries might be so great that it is hard to generalize about adolescents and young adults from one culture to the other. For example, the ecology of some big U.S. cities, with their ethnic compositions, physical structure, and demographic characteristics, is seldom found in Europe. Because the types of criminality, existence of gangs closely tied to certain neighborhoods, and so on, are heavily associated with the urban ecology, studies of violence and gang criminality in the United States do not readily apply to European communities (Shannon, 1988). Even within the United States, the proximal environment for a child or an adolescent in a small Midwest town may be radically different from that in New York or Los Angeles.

These examples demonstrate that what can be generalized about individual current functioning and the developmental processes from one culture to another are not results concerning the general role and relative importance of single operating factors (see, e.g., Baltes, 1979). Rather, what can be generalized are the mechanisms in the person-environment system working at the level of the individual. Necessarily, empirical research with that goal needs the theoretical framework that is provided by a general model for the human being in the environment. It is worth recognizing that differences in individual functioning and development, related to differences in social and cultural environments, contain important information that is valuable in the search for such mechanisms.

Of course, the issue of generalization also concerns the area of intervention and prevention. For example, preventive strategies that have proved effective for U.S. preschool children are not necessarily so when implemented in other cultures, among other things because the preschool infrastructure, the basic content, and the organizational structures of activities for children, differ markedly between countries.

Measurement Models

Methods are tools for analyzing data to understand the processes operating within given psychobiological structures and involved in developmental change. The development of sometimes sophisticated statistical tools has helped to strengthen empirical developmental research. However, for a correct application of statistical methods it is crucial to recognize that they are tools for analysis of data in the same way as axes, knives, and razors are tools for cutting. Tools are never good or bad in themselves. The appropriateness of a particular statistical method for a particular study depends on how effectively it contributes to a correct answer to the problem. The degree of statistical sophistication can never be a criterion of the scientific value of an empirical study.

Traditionally, statistics are most often applied in the following strategy framework:

$$\text{Problem} \rightarrow \text{data} \rightarrow \text{statistics}$$

No statistical tool has a value on its own in the research process, it is only when a statistical tool matches the character of the phenomena, that is, when it is linked to an analysis of the phenomena under investigation, that it can contribute scientifically solid answers to relevant questions. The claim here is that adequate application of any statistical method presupposes a research strategy that includes a measurement model linking the statistics to the problem; that is, the following general schemata:

$$\text{Problem} \rightarrow \text{measurement model} \rightarrow \text{data} \rightarrow \text{statistics}$$

Two basic complementary measurement models (MMs), with specific implications for the data to be used and the relevant statistical tools, were proposed by Magnusson (1998, 2003). The fundamental difference between both MMs lies in the way in which the psychological significance of a single datum—representing a response to a stimulus, a response to a test or questionnaire item, a rating of observed behavior, and so on—is derived. The theoretical framework for the conceptual distinction between both measurement models is expressed in what has been designated the variable approach and the person approach, respectively.

Measurement Model 1

According to measurement model 1 (MM1), *a single datum for individual A on a latent dimension k derives its psychological significance from its position on that dimension in relation to positions for other individuals, B, C, D, and so on* as shown in Figure 8.2a.

MM1 is the measurement model for what has been designated the *variable approach*. In general, empirical developmental research is dominated by the application of MM1. This is the case for most of the studies on the role of environmental conditions in the developmental processes of individuals, which we referenced earlier. The approach also dominates empirical studies on relationships among person-bound variables. The focus is on a single variable or a combination of variables, their interrelations (R-R and S-R relations), and their relations to a specific criterion. The problems are formulated in terms of variables and the results are interpreted and generalizations made in such terms. Commonly used statistical models include comparisons between means and other location parameters, correlation and regression analyses, factor analysis, structural equation modeling, contingency tables, and the original version of LISREL. An abundant arsenal of statistical tools is available and applied in these analyses (see, e.g., Bergman, Magnusson, & El-Khouri, 2003).

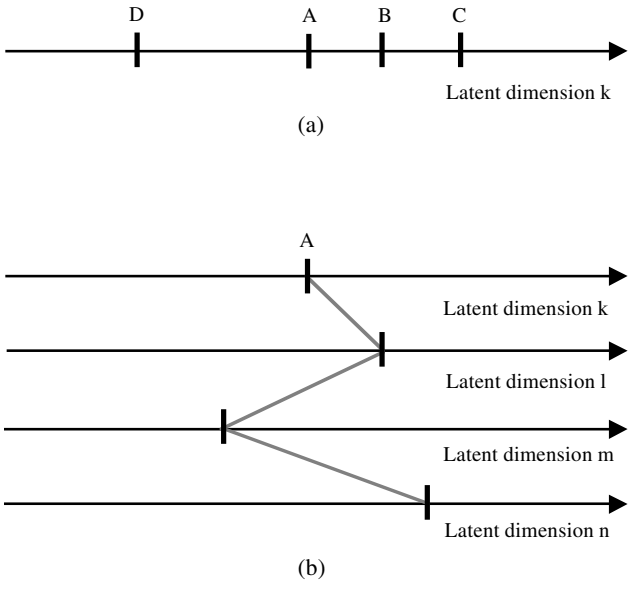

Figure 8.2 (a) Measurement model 1: The variable approach. (b) Measurement model 2: The person approach.

Two comments are pertinent for the discussion of the appropriateness of MM1 as the link between data and psychological phenomena.

1. Most of the statistics applied in these analyses are based on the assumptions of normal distributions of data for single variables and of linearity and homoscedasticity in the relation between variables (see Miccery, 1989, for a critical discussion of the assumption about normality). Reference is seldom made to a psychological model for developmental processes before these tools are applied. Classical test theory provides a good example (e.g., Magnusson, 1967).
2. Statistics applying MM1 yield answers to questions about variables at group level. The implication of the fact that generalizations are made in these terms, not in terms of individuals, was previously considered.

The most frequently applied statistics in research on individual development are linear regression models in the framework of MM1. In studies of developmental processes, the proper application of linear statistical models in that framework presupposes that the following interrelated assumptions are met (see Magnusson, 1998, p. 48).

1. Individuals can be compared on a nomothetic, continuous dimension in a meaningful way.
2. Individuals differ only quantitatively, not qualitatively, along the dimension for a certain variable.
3. Relationships between variables and their way of functioning in the totality of an individual are the same for all individuals. For example, using a multiple regression equation, each variable has the same weight for all individuals and reflects what is characteristic for the average individual.
4. The interrelations among variables studied in nomothetic analyses can be used to make inferences about how the variables function within individuals.

   In analyses of developmental issues, for example in analyses of the problem of stability and change in a developmental perspective, a fifth assumption should be valid.
5. The psychological significance and meaning of positions on the nomothetic scale should be the same quantitatively and qualitatively across ages.

These assumptions should be observed for the correct application of linear models in MM1. Two interrelated features of data matrices for individual variables are involved.

The first has to do with the existence of statistical colinearity at the data level, reflected in sometimes very high functional interrelations among the large number of operating components involved in most developmental processes (e.g., Darlington, 1968). At the individual level, the variables in the data analyses cover different aspects of the functioning of one and the same organism as a totality. Thus, it is not surprising that data pertaining to one latent variable also contains information about other, simultaneously operating latent variables in the process. The high correlations often found in data at group level, for example, among various aspects of manifest behavior such as aggression and motor restlessness, reflect the fact that they largely overlap with respect to content at the individual level. Therefore, studies of data for single variables will, sometimes greatly, overestimate the unique contribution of single components to the process of developmental change, as well as the unique role of specific aspects of the environment in these processes. The strength of this effect was empirically illustrated by Magnusson, Andersson, and Törestad (1993) in a study of the developmental background of adult alcohol problems. This effect is most often overlooked because frequently the role of only one or a few variables is studied and reported, independent of each other.

The second feature is the existence of statistical interactions among operating variables (e.g., Hinde & Dennis, 1986). To a certain extent, statistical interactions can be handled in, for example, structural modeling, but these possibilities are limited. As shown by Bergman (1988a), in spite of the existence of interactions in data, variable oriented linear analyses do not always consider these interactions when the model is tested against the correlation matrix.

From a historical point of view it is interesting to note that Baltes already in 1979, with reference to reviews of life-span developmental research, emphasized the inappropriateness of "one-factor" and unidimensional conceptions of development and concluded: "On the contrary, German writers have espoused a position that includes multidimensionality, multidirectionality, and discontinuity as key factors of any theory of human development through the life span" (p. 263). However, on the whole empirical research did not draw the necessary consequences of this important theoretical insight, namely that another measurement model than M1 is needed.

Measurement Model 2

According to measurement model 2 (MM2), *a single datum for individual A on a latent dimension k derives its psychological significance from its position in a configuration of data for the same individual, representing his or her positions on the latent dimensions k, l, m, n, and so on.* These latent dimensions are assumed to represent simultaneously working components in the system under investigation as shown in Figure 8.2b. MM2 is a logical consequence of the analysis of main characteristics of developmental processes in earlier sections; that is, it fits the characteristic features of the individual holistic developmental processes. Accordingly, MM2 is the appropriate measurement model for the choice of statistics in the final analyses of developmental processes at the level of the individual. An implication of MM2 is that statistics yield information about the individual, and generalizations refer to individuals.

The MM2 is the measurement model for what has been designated *the person approach*. Figure 8.3 illustrates the fundamental proposition that the same position for different individuals (A, E, and F) on a certain latent dimension may differ entirely in its significance in the integrated psychological, biological, and behavioral functioning of the three individuals. For example, the same level of aggressiveness in

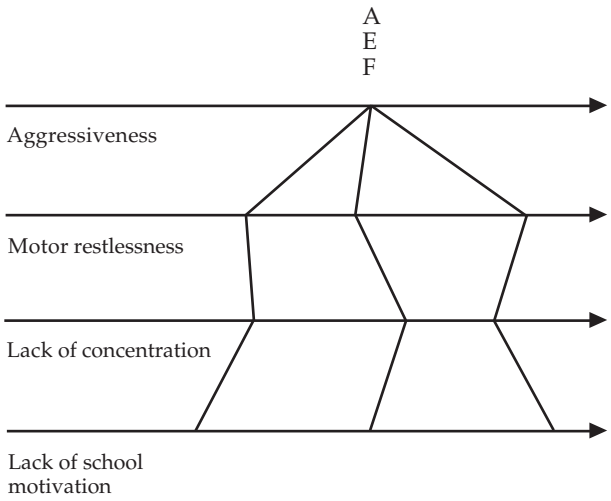

Figure 8.3 Fictitious profiles for three individuals (A, E, and F) based on data for four problem behaviors.

individuals A, E, and F has a different psychological significance in the individual patterns of other problem behaviors, including motor restlessness, lack of concentration, and lack of school motivation. The observation of high fever is an important indicator of illness. However, it is only when it has been assessed together with data for other, simultaneously working factors in the patient that it can lead to a final choice among possible diagnoses, a choice that can form the basis for relevant treatment. The importance of these illustrations follows as a consequence of the basic principles of developmental processes and was empirically demonstrated in a number of studies in our research group and elsewhere.

MM2 is applied for two main purposes:

1. The identification of groups of individuals who function in a similar way at the organism level and in a different way compared to other individuals at the same level. In data, individuals are categorized on the basis of individual profiles across relevant variables.
2. The analysis of short- and long-term developmental processes in terms of patterns. Models for dynamic, complex processes, derived from natural sciences, have contributed to the development and application of methods and models with consideration of the specific character of individual processes (Bergman, 2002).

Pattern Analysis of Individuals

In other scientific disciplines concerned with dynamic complex processes, such as ecology, meteorology, biology, and chemistry, pattern analysis has become an important methodological tool. In developmental psychology, it has been applied in a steadily increasing number of studies.

Two interrelated issues require special consideration in a proper pattern analysis of individuals. First, data should refer to the same level of individual functioning. Second, scaling of individual data included in the pattern analysis demands careful analysis of the nature of the variables because the scales of the different variables must be comparable. Rarely in psychology is this true without the application of special scaling procedures to the raw data. This scaling can be of different types, the most frequent solution being that the variables are standardized to make the scores in the different variables comparable and to ensure that a variable with a very large standard deviation does not dominate the pattern analysis. However, this is a medicine with side effects because it may be important to retain differences in variation between variables. Sometimes this can be achieved approximately, for instance by using quasi-absolute scaling. This issue was dealt with in detail by Bergman, Magnusson, and El-Khouri (2003, pp. 38–42).

With reference to different theoretical models of the phenomena being investigated, a number of methods for pattern analysis have been presented and applied: cluster analytical techniques (Bergman, 2002; Bock, 1987; Manly, 1994), Q-sort technique (Block, 1971; Ozer, 1993), latent profile analysis (LPA; Gibson, 1959), configural frequency analysis (CFA; Lienert & zur Oeveste, 1985), latent transition analysis (Collins & Wugalter, 1992), log-linear modeling (Bishop, Feinberg, & Holland, 1975), and multivariate P-technique factor analysis (Cattell, Cattell, & Rhymer, 1947; Nesselroade & Ford, 1987). (See also, Cronbach & Gleser, 1953, who discussed four cases for profile similarity.) Overviews and discussions of models were presented by Bergman et al. (2003) and von Eye and Bergman (2003).

For the study of developmental issues, the approach has primarily been applied in studies linking patterns observed at different ages. Relatively few attempts have been made to develop and apply methods for the empirical analyses of dynamic, developmental processes in patterns. For further progress in research on human ontogeny, an important challenge lies in the development and application of such methodological tools.

Individuality and Generalization

The emphasis on individuality naturally raises the problem of generalization to individuals from the cluster profiles. Two comments are pertinent.

1. All individuals referred to a certain cluster do not show exactly the same configurations of working components, reflected in the patterning of empirical data for that cluster (e.g., Bergman, 1988b). An implication of this is that empirical results of grouping individuals on patterns of data for relevant components can be used for the identification of general mechanisms in the functional processes of individuals belonging to the specific clusters, and for the study of inter-cluster differences. They cannot, however, except under very specific conditions, be used

for prediction, either of a single individual's behavior in a specific situation, or of the life course of a certain individual. In both cases, the actual outcome is dependent not only on the individual's mental, behavioral, and biological dispositions, which define his or her belongingness to one of the clusters, but also on the specific proximal and distal environmental conditions under which he or she lives and develops (see the discussion of plasticity).

2. Clusters in a super space for a system at a certain level do not imply a static view, classifying all individuals once and for all as types, in the classical sense, of the concept. The boundaries of many clusters are fuzzy and permeable. Some individuals' specific profiles do not belong to a specific cluster; all individuals cannot unambiguously be referred to one or the other of the main clusters (see Bergman, 1988b). Also, due to specific individual developmental paths, an individual may move from one cluster to another. Changes may result from changing psychobiological conditions (e.g., severe illness, progressive mental disease, and strong life events), changing environmental conditions, or a combination of the two.

Pattern Analysis of Environments and Person-Environment Systems

As emphasized earlier, the circumstance that both the physical and the sociocultural environments are structured and organized is a prerequisite for the individual's experiencing of them as meaningful and for the individual's purposeful actions. It is important to note that the psychological significance of a certain environmental aspect lies in the contribution it makes to a working, integrated pattern of such factors.

This view leads to the same conclusions for environments as for persons. Studies of single aspects of the environment, taken out of context, do not form the basis for understanding the role of the environment in the processes of individual functioning. Accordingly, the application of MM2 has a place in the study of environment in the patterns of components that are relevant for the problem under consideration. An example is the study of female life careers, reported by Gustafson and Magnusson (1991) from the IDA program, in which the females' home background was described using patterns of relevant factors: father's and mother's education, parents' income, parents' evaluation of the girl's capacity for higher education, and parents' evaluation of higher education. The patterning of these environmental components turned out to have significance for the future life career of the daughters.

MM2 has a particular role in the study of children's environments at times when the organism is particularly open to environmental influence during infancy and early puberty. Because the individual and his or her environment, at the highest level of generalization, function as an inseparable system, the appropriate theoretical and empirical analysis should include analyses about patterns of person and environmental components, assessed simultaneously. For instance, Cairns et al. (1989) included both individual variables (e.g., cognition, aggression) and environmental variables (e.g., socioeconomic status) in constructing developmental patterns related to early school dropout. The application of MM2 is also of particular interest in the newly established area of positive development.

Comments

The relation between both MMs is orthogonal; there is no contradiction between them. Both are useful tools in developmental research, depending on the specific purpose.

The measurement task is distinctly different in the two approaches. In MM1, the task is to locate individuals on the latent dimension(s), and the appropriate measurement technique is the one that discriminates along the whole range of possible individual positions. In MM2, the task is to assign individuals (or environments and PE systems) to categories at the appropriate level, and the measurement problem is to maximize cutting scores on the borders of each category or class.

Statistics

A consequence of the formulation of theoretical models for complex, dynamic processes in natural sciences has been the development of statistical methods for the study of such processes. One line is the revival of nonlinear mathematics and methods for the study of patterns. For further scientific progress in research on individual development, it is important to take advantage of this development. If adequately applied, the new methodologies have important implications for theory building and empirical research on the dynamic, complex processes of individual development. An overview and discussion of

statistical tools in a person approach was presented by Bergman et al. (2003). There is a growing interest in and application of models and methods in this direction in developmental research (e.g., Bergman & El-Khouri, 1999, 2001; Molenaar, Boomsma, & Dolan, 1991; Nagin & Tremblay, 2001; Nesselroade & Molenaar, 2003; Nesselroade & Schmidt McCollam, 2000; Vallacher & Nowak, 1994; Valsiner, Chapter 4, this *Handbook,* this volume; van Geert, 1998; von Eye & Bergman, 2003). This development is of interest for two reasons: it has demonstrated the implications for empirical research of a holistic view of integrated, holistic processes, and it has stimulated the development of methodological tools (see, e.g., Lewis, 2000). At the same time, modern models for dynamic, complex processes, for example chaos theory, must be applied with caution. In contrast to the conditions under which chaos theory was originally found to be a valuable tool, an important working factor in individual current functioning, and accordingly also in developmental processes, is the individual's intentional active role—consciously and subconsciously—in the PE system.

RESEARCH STRATEGY

The foregoing sections have outlined a number of implications for successful research strategies in psychological research in general and in developmental research in particular. Instead of repeating them, attention is drawn to a few consequences, which ensure naturally from the perspective developed in this chapter.

A Multivariate Approach

When our concern is the functioning and development of a system—at the subsystem level, at the level of the total person, at the group level, or at the level of the PE system—the emphasis on multiple causation and the interdependency of operating factors at each level has as the consequence that the analysis should include a broad range of components, which have been identified as essential for the understanding of the processes at the appropriate level. This follows from the definition of a developmental science.

A Longitudinal Design

Two interrelated elements form the basis for the conclusion that longitudinal research on individual development is essential for understanding and explaining mechanisms in developmental processes over the life span: (1) the basic principles of transformation (with emergence and novelty), interaction, temporality, organization, and synchronization, and (2) the uniqueness of how these principles characterize individual developmental processes. Inherent in the nature of developmental processes is the requirement that they be studied in a temporal perspective (e.g., Sameroff & MacKenzie, 2003). Longitudinal research enables the researcher to study mechanisms in the developmental processes in a way that is not possible in cross-sectional research. The fundamental basis for this proposition is that it is not single variables but the integrated individual that develops and is identifiable over time (Magnusson, 1993). If a historian tried to understand the historical process behind the outbreak of World War II by drawing a sample of newspapers from different European countries on a certain day in June 1939, transforming the news into data and performing a multidimensional analysis of the data matrix, no one would take him seriously. But isn't that what we do by using cross-sectional group data as a basis for conclusions about developmental processes?

The only way to understand processes is to follow them over time. The period for following the individual varies with the process that is being investigated. A study on brain development during the first weeks of life and infancy requires frequent observation for a limited time. Frequent observations during shorter periods of time may also yield deeper understanding of factors associated with changes in motivation, adjustment and performance in the transition from day care to school, during the very 1st year of school, or in the transition from school to work as demonstrated by Nurmi and his coworkers (see, e.g., Nurmi, Salmela-Aro, & Koivisto, 2002).The same may be the appropriate approach during other periods of rapid, dramatic change, for example, during the beginning of menopausal changes or some aspects of aging (see, e.g., Nilsson et al., 2004). Understanding these processes requires frequent observations of individuals for a relatively limited period of time. A manageable way to handle this time-consuming procedure could be to make the observations on a small sample of individuals in close collaboration with each of them or their caretakers. An investigation of the individual implications of pubertal development for the further life course necessarily needs a period of observation that extends across adolescence until adult life. As empha-

sized before, totally wrong and clinically disastrous implications can follow from unduly brief observation of pubertal development. This was unambiguously demonstrated in the Stockholm IDA program. For further analyses and discussions about the role of biological maturation in developmental processes, it is of interest to note that when the females in the IDA program participated at the age of 43, no significant relations were found between physical and mental health at that age and menarche age (El-Khouri & Mellner, 2004).

Longitudinal research has a long tradition. The arguments for this approach were formulated forcefully by many developmental researchers (e.g., McCall, 1977), and the merits and pitfalls were also carefully analyzed (e.g., Baltes, Cornelius, & Nesselroade, 1979; Schaie & Baltes, 1975). For various reasons, it took a long time for the merits of longitudinal research to be sufficiently appreciated so that strong research programs were launched. In recent decades, however, there has been a growing awareness of the necessity to conduct such research. A manifestation of this trend is that the first scientific network established by the European Science Foundation in the mid 1980s was the European Network on Longitudinal Research on Individual Development.[8]

An inventory, administered by Schneider and Edelstein (1990) in the framework of the network, identified about 500 ongoing longitudinal research projects in Europe concerned with psychosocial and psychobiological development. Recently, an overview of longitudinal research programs in the United States was presented by Phelps, Furstenberg, and Colby (2002).

Comment

Individual development, in its most general form, can be defined as any progressive or regressive change in size, shape, and/or function. This definition has two interrelated consequences. First, what constitutes longitudinal is not only time but whether changes occur in the structures or process(es) being studied. Second, the appropriate method for systematic observation of change—laboratory experiments, natural experiments, systematic, descriptive analyses of phenomena over longer periods of time, narrative reports, and so on—varies with the nature of the process(es) being studied and the conditions under which observations can be made.

Cultural and Cross-Cultural Research

We have drawn attention earlier to the extreme ethnocentric view that is reflected in planning, implementing, and interpreting psychological research, including developmental research, in Western countries (see, e.g., Graham, 1992). Both in theory and practice, the Western human being is often regarded as the norm and the behavior of human beings from other cultures as deviant. This is expressed in many ways. One implication of the view on individual functioning and development as dependent on and related to the nature and functioning of the environment is the need for systematic cultural and cross-cultural research. The role of the environment is not restricted to stimuli and events in the immediate situation. As we have argued, each specific event is embedded in social and cultural systems at different levels and is interpreted by the individual in the specific framework of these systems. Results of studies of differences in the developmental processes among children being raised in different cultures contribute essential knowledge, both with respect to the factors operating in the individual and in the environment, and with respect to the mechanisms by which these factors operate. The enormous importance of cultural research for our generalizations about "human nature" was demonstrated in the research reported by Luria (1976) on illiterate and isolated humans. Today, further information has accumulated about the variation in parenting in different cultures (Harkness & Super, 2002).

Multidisciplinary Collaboration

Understanding and explaining individual functioning and development presupposes knowledge of the role of psychobiological components of the individual and of environmental factors involved in the PE system. As argued in the earlier discussion of developmental science, this implies the need of knowledge from research at the interface of a number of neighboring disciplines. Shanahan, Valsiner, and Gottlieb (1997) presented an interesting analysis of developmental concepts across

[8] In a series of workshops, topics of central interest for understanding and explaining individual development were discussed and presented in eight volumes (Baltes & Baltes, 1990; de Ribaupierre, 1989; Kalverboer, Hopkins, & Geuze, 1993; Magnusson & Bergman, 1990; Magnusson, Bergman, Rudinger, & Törestad, 1991; Magnusson & Casaer, 1993; Rutter, 1988; Rutter & Casaer, 1991).

disciplines. Such knowledge comes as the result of collaboration between researchers in the traditional field of psychology, and also between researchers from psychology and those from other disciplines concerned. A prerequisite for such collaboration and for real scientific progress is the formulation of and reference to a general, common model of the individual and society. Systematic, well-planned collaboration in the field of developmental science with reference to such a common model has strong potentialities. In an editorial in Science, Leshner (2004) concluded, among other things, after the American Association for the Advancement of Science (AAAS) annual conference on Science at the Leading Edge: "We are learning another important lesson: that no field stands alone. Progress in any one domain is absolutely dependent on progress in many other disciplines" (p. 429). This conclusion is equally valid for research on individual developmental processes.

Prevention, Treatment, and Intervention

Research on the mental and sociocultural structures and processes operating in individual life courses constitutes a central scientific concern in its own right. However, the societal implications are also important, in as much as knowledge about the positive and negative aspects of human development can be used to promote healthy and prevent harmful development. The holistic-interactionistic model has important implications for the knowledge that is needed for effective intervention and treatment in societal policy, manifested in the formation of agencies, programs and other initiatives.

Empirical studies indicate that the existence of single individual problems and/or single problems in the social environment during childhood and adolescence have only a limited negative influence on the future adjustment of individuals. An increased risk for later maladjustment problems appears in individuals for whom problem behaviors accumulate during late childhood and adolescence and/or in social settings characterized by a broad range of risk factors (e.g., L. N. Robins, 1966; Stattin & Klackenberg, 1992). Adjustment problems of different kinds tend to gravitate toward a limited number of individuals, and this group is responsible for a large portion of adjustment problems manifested in early drug and alcohol abuse, criminality, bullying, and so on (Stattin & Magnusson, 1996).

In spite of these well-known circumstances, discussions of and research on these types of problems are often focused on a certain variable (e.g., aggressiveness), or a certain problem (e.g., alcohol abuse), applying a specific perspective (e.g., a sociological, psychological, or criminological perspective). In this situation, intervention programs are often implemented in isolated environments, concentrated on a single problem, and focused on a special age group with reference to a single perspective. Often the prophylactic actions and treatment programs are temporary "projects," not anchored in an overriding, long-term strategy based on available scientific knowledge and experiences from a broad range of expertise among those involved in the applied field. Different actors and agencies are active in the same area, often in parallel but sometimes in competition; that is, without coordination and collaboration.

Empirical research indicates that negative aspects of the development process of individuals tend to go together. For example, Magnusson (1988) reported from the IDA program that 52% of those who were registered for criminal activities during the ages of 18 to 23 were also registered for alcohol abuse and/or psychiatric care. Of those who were registered for alcohol abuse, 77% were also registered for criminal activity and/or psychiatric care. The corresponding figure for those with psychiatric records was 58%. More than a matter of, for example, alcohol problems or violence, it is a matter of general lifestyles. The broader range of adjustment problems during adolescence cannot be isolated from the earlier development process and social context. The implications for societal organization of prevention and treatment of asocial and antisocial behaviors are obvious.

The holistic-interactionistic model for individual development implies that the total person-environment system must be considered, not single problems of individual functioning and single risk factors in the social context, in the organization and implementation of societal programs for intervention and treatment. Long-term programs and strategies must be worked out based on knowledge from all relevant fields of developmental science, and planned and implemented in close collaboration among professionals representing multiple agencies, programs, and initiatives, which must be integrated so that the breadth of the individual person-environment system is adequately engaged.

CONCLUSION

As a background to some conclusions, some of the conspicuous tendencies in theoretical and empirical research on individual functioning and development can be briefly summarized:

1. To the extent that empirical studies refer to theory, hypothesis testing is done with reference to piecemeal theories holding for the subarea(s) to which the issue under consideration belongs; there is a lack of reference to an integrated, overriding theoretical framework (e.g., Löfgren, 2004).
2. Problems are investigated and the results discussed in statistical terms as if statistical significance were synonymous with psychological significance. This often applies, for example, in discussions of causal models and causal relations. The tradition has been fostered by the development of sophisticated data analytic methods.
3. The study of personality and individual development is defined as the study of interindividual differences (e.g., Block, 2003). Results of studying individual differences at group level sometimes form the basis for conclusions about functioning at the individual level.
4. Theoretical and empirical research is very ethnocentric. It is often implicitly assumed that results of studies performed in Western cultures can be used as basis for conclusions about human nature.

Each of these approaches has its merits and has contributed essential knowledge in some subfields in which it is appropriately applied. Each of them also has its limitations, which become particularly clear when the purpose of studies is to contribute to understanding individual developmental processes. A number of prominent scientists have emphasized the hampering effect of the fragmentation of psychology on scientific progress, as reflected in the points summarized above (e.g., Sanford, 1965). Lately, Rom Harré (2000) gave the following evaluation in an article in *Science:*

> It has been about thirty years since the first rumblings of discontent with the state of academic psychology began to be heard. Then, as now, dissident voices were more audible in Europe than in the United States. It is a remarkable feature of mainstream academic psychology that, alone among the sciences, it should be almost wholly immune to critical appraisal as an enterprise. Methods that have long been shown to be ineffective or worse are still used on a routine basis by hundreds, perhaps thousands of people. Conceptual muddles long exposed to view are evident in almost every issue of standard psychological journals. This is a curious state of affairs. New pathways and more realistic paradigms of research have been proposed, demonstrated, and ignored. . . . The natural sciences have achieved their enormous success by the adoption of schemata through which the indeterminate world around us can be made to disclose some of its features. (p. 1303)

We have noted in several connections here promising trends toward integration of subareas, for example, at the interface of cognition and brain research, brain research and emotions, self-consciousness and emotions, and so on. Further scientific progress in research on individual development, in line with what happens in other life sciences, requires that the full consequences of integration in the framework of a general model of the person in the environment are accepted and applied.

We have analyzed and discussed individual development as an integrated, dynamic, complex process going on in the framework of an integrated PE system and have pointed to precise and important implications for empirical research. The holistic-interactionistic model has formed the general theoretical framework for the discussion of the functioning and development of the individual in that setting and for the identification of basic principles in developmental processes.

As we have emphasized earlier, the holistic-interactionistic model is not another vague concept that sometimes appears in discussions of psychological issues and occasionally becomes popular. The scientific application of the modern holistic-interactionistic model requires consideration of the basic principles of which the most conspicuous have been discussed here: the holistic principle, transformation, interaction, temporality, organization, synthesis, and—a most central principle—individuality.

The proposition that the holistic-interactionistic model and the ensuring basic principles can serve as the general theoretical framework for empirical research on developmental processes needs two comments:

1. The formulations of the model and its consequences have to be seen as open for modification, based on further experiences gained from its application. Evolutionary theory is not the same today as it was 150 years ago; it has been modified by reformulations

and extensions (Goodwin, 1994). This is an example of the normal development of science.

2. The adoption of a holistic-interactionistic general frame of reference for the study of specific phenomena is in line with general trend in scientific disciplines concerned with dynamic, complex processes, including life sciences. The claim for a common theoretical framework for the study of individual development is part of a broader scientific zeitgeist. A growing understanding of the need for a general model of the individual as an active, intentional part of his or her PE system is expressed (e.g., Li, 2003).

A holistic-interactionistic general frame of reference for the design, implementation and interpretation of empirical studies on specific developmental issues does not mean that everything achieved hitherto has been wrong and without important results. The holistic-interactionistic model is not a substitute for, but includes and is a complement to, the existing approaches as an example of the progress of normal science. To make real progress in future theorizing and empirical research, the challenging task is to see the theoretical, methodological, and research strategy implications and take them seriously.

Mayr (1997) in his analysis of the history of biology concluded that the remarkable success during the twentieth century could not have been achieved if biology had not left the paradigm of physics and developed its own theoretical ground or a methodology that fits the nature of the biological processes. We need an overriding theoretical framework as a prerequisite for building the synthesis of knowledge about why individuals think, feel, act, and react as they do in real life and how they develop in these respects. Our goal in this chapter has been to summarize the motives for a holistic-interactionistic model to play that role. However we choose to designate it, the time has come for a general model. We need it in the formulation of the problems to be investigated, in the choice of appropriate data and measurement models, and in the interpretation of the results, it we want to keep up with progress in other life sciences.

The Mind: Worldviews and Self-Perceptions

The building blocks of all societies and cultures are individuals. To use a metaphor, individuals are the cells of a society. In that role the individual is an active, intentional participant in a dynamic, complex interaction process with the environment. This perspective leads to some comments.

The integrated mind, involving perceptions, cognitions, self-perceptions, emotions, and values, forms the mental frame of reference for an individual's conscious and subconscious sense of meaning in observations of the external world and of her or his own role. Thus, the mental life of an individual plays the decisive role for that individual's inner life, relations to other people, interpreting what happens, expectations about what might happen in the proximal and distal environments, and the goals and directions of internal and external activities.

At each stage, the way individual mental life is structured and functions is dependent on the individual's interaction with the environment during earlier life phases. A consequence is that no two individuals have the same worldview and self-perceptions. The integrated common environmental frame of reference for attitudes, beliefs, and behaviors, dominating the proximal and distal environment of an individual, plays a central role in the development of his/her worldview.

For many individuals on the globe, religious beliefs with political consequences dominate and guide mental processes and manifest activities to an extent that is often forgotten in scientific psychology. Religious and political beliefs that are shared by all members of a proximal group, a society, or a culture form not only a strong basis for unity, solidarity, and harmony but also cause conflicts with individuals, groups, and cultures with other beliefs. Armstrong (2000) presented an illustrative historical overview of this in her book *The Battle for God.*

Religious beliefs and other aspects of worldviews have an enormously strong role in history as well as in the present world. For most people, world views organize their lives and their use of resources for participation in personal, religious, social, cultural, and political activities. The roots of both solidarity and conflicts at all levels, from individuals to societies, are in the minds of the people and their religious and political leaders. With respect to these circumstances, understanding the functioning of the integrated minds of individuals should be one of the most central tasks for scientific psychology. We must recognize that science can never answer existential questions, such as what is the meaning of life, or present a final solution to the question of which belief has the strongest scientific ground. What we can do, to the benefit of all societies in the long run,

is to contribute to a synthesis of knowledge about the role and consequences of worldviews for individuals, groups, and societies. This task implies, among other things, a challenge for basic research about the individual in the environment from the perspective proposed in this chapter. To meet that challenge with solid scientific work, we need a general model of the individual and society.

CHAPTER 9

The Developing Person: An Experiential Perspective

KEVIN RATHUNDE and MIHALY CSIKSZENTMIHALYI

AN EXPERIENTIAL PERSPECTIVE ON HUMAN DEVELOPMENT

Human development is viewed through an experiential lens in this chapter. Experiential or phenomenological perspectives are underutilized in developmental thought, despite the fact that they can reveal much about the process of development. In particular, optimal experience and its regulation can help explain why some individuals are able to maintain cognitive flexibility throughout life and are better able to navigate a path of lifelong learning. A better understanding of these person-level processes can also shed light on the characteristics of social contexts that positively affect experience and, therefore, the course of development.

Phenomenological analyses tend to be descriptive and not focused on the developmental process. There are also numerous methodological and theoretical difficulties involved in studying subjective experience (Giorgi, 1985). For these reasons, many researchers have not considered an experiential approach feasible for exploring developmental questions. However, what a person feels and reports during an activity is one of the few ways of discovering how efficiently an individual focuses energy and attention at the moment. And understanding the use of attention is one of the most valuable levels of analysis for exploring the development of a person, especially as it relates to the acquisition of psychic resources, or education broadly defined.

Adopting an experiential perspective in no way implies taking the person out of context. Nor does it suggest that individual processes are more important than biological or cultural ones. Although receiving a privileged interpretive position in this chapter, studying subjective experience is compatible with many contemporary theories of human development. Like these, we assume that a person can actively affect the course of development, but that development emerges from the

interrelations of biological, psychological, and sociocultural forces (Lerner, Chapter 1, this *Handbook,* this volume). To avoid any misunderstanding on these points, it is useful to begin the chapter by briefly articulating a few of our assumptions about experience and the developing person and suggesting how these assumptions fit with other contemporary theories.

An Experiential Turn: Putting the Study of Experience in Historical Context

There are many difficult and provocative questions implicit in the study of experience and its ramifications for the scientific study of the person. What is the nature of experience and consciousness? Can first-person, subjective data be reconciled with objective, third-person techniques? Are the data reliable or hopelessly biased? How does a phenomenological method challenge the traditional assumptions of experimental science? What is the best method for systematically exploring subjective experience? None of these questions are dealt with at length in this chapter, although our position on some of them becomes clear while exploring other topics (for a discussion of these methodological and epistemological issues, see Chalmers, 1995; Rathunde, 2001c; Taylor & Wozniak, 1996; Varela, Thompson, & Rosch, 1991). Nevertheless, it is useful to take time to put the study of experience in historical context.

William James did much to establish the relevance of subjective experience for psychology. James's interest in experience and its relation to optimal functioning were unique for his time. He initiated what might be considered an experiential turn in U.S. psychology that laid the foundation for current work in a number of related areas. For example, one of his most important achievements was linking immediate experience and relatively permanent mental structures. "Only those items which I notice shape my mind," he said, "without selective interest, experience is an utter chaos" (James, 1890, p. 402). This statement signals James's inclusive and holistic view of consciousness and his attempt to understand how immediate interests and emotions affected the ongoing stream of thought. His stream-of-thought metaphor highlighted the crucial importance of understanding the moment-to-moment use of attention as a foundation for understanding many other outcomes, such as lifelong learning, and even genius.

The experiential turn initiated by James resulted from his interests in the stream of experiencing and the human being as an experiencing agent (Taylor & Wozniak, 1996). This underlying focus distinguished his work and integrated his many areas of inquiry. Other psychologists writing at the time tended to remove outcomes and behaviors from the stream of experience, reify them, and set them off as objective facts in contrast to a murky subjective realm. James's epistemological approach of radical empiricism (Taylor & Wozniak, 1996) did not operate in this dualistic fashion. He understood the constant interplay of subjective and objective content in the stream of thought; what was taken to be objective at one point in time was subjective at another, and vice versa.

James's (1902) research on exceptional mental states and transcendent/religious experiences was also important for the foundation of an experiential perspective and for topics that are discussed later in this chapter (e.g., deeply engaging or "optimal experiences"). Unlike many other psychologists, James did not discount such experiences because he believed they could be a primary source of energy that stimulated optimal human functioning. In a presidential address entitled "The Energies of Men" that was delivered before the American Philosophical Association at Columbia University in 1906 (James, 1917, pp. 40–57), James considered why some individuals "live at their maximum of energy." He posed two questions: (1) What were the limits of human energy, and (2) how could this energy be stimulated and released, so it could be put to optimal use? He noted that these questions sounded commonplace, but added: "As a methodological program of scientific inquiry, I doubt whether they have ever seriously been taken up. If answered fully, almost the whole of mental science and the science of conduct would find a place under them" (p. 44).

Another key thinker in the experiential turn of American psychology was John Dewey. If James set the focus on the use of attention and energy, Dewey applied such a perspective most consistently to the developing person, especially in regards to education and lifelong learning (Rathunde, 2001c).

That Dewey was a phenomenological thinker is undeniable. Like James, his methodological approach shunned dualistic and positivistic approaches. Kestenbaum (1977) notes, "For his entire philosophic career, Dewey in one way or another was brought back to this realization that subject and object, self and world, cannot be specified independently of each other. His conception of organic interaction, and later his conception of

transaction, were attempts to capture the reciprocal implication of self and world in every experienced situation" (p. 1). There is a phenomenological sense to all of Dewey's thought because meanings must be "had" before they could be "known" in reflection and knowledge. Ideas were not simply generalizations based on objectively observed facts, nor were they images or copies of external objects; instead, they were functional in that they helped to organize the world rather than replicate it. Dewey conceived ideas as tools for transforming the uneasiness of experienced problems. Rational processes, therefore, could suggest a solution to a problem and a goal, but if the goal became an end in itself and was disconnected from the stream of experience, it corrupted energy, attention, and development.

This basic postulate of Dewey is key to understanding one of the most important points in this chapter: Intrinsic motivation provides an invaluable and continually renewable source of energy for development. Intrinsic motivation, as conceptualized here, is not another instance of dichotomizing inner and outer as is sometimes the case with intrinsic versus extrinsic motivation debates. Rather, intrinsic motivation can be thought of as the energy that results when momentary involvement and goals are not artificially or forcefully divorced from one another. Dewey often relied on dialectical terminology (e.g., synthesis-analysis, concrete-abstract, and subjective-objective) to illustrate the healthy interrelation or tension of such motivated thinking (Dewey, 1933). He often described a rhythm between complementary opposites such that one pole emphasized a mode of immediate participation or a feeling of being wrapped up in an activity, and the other pole corresponded to a distancing from momentary involvement to assess the directionality of the learning process. Such a contrast in consciousness furnished essential feedback allowing spontaneous involvement to stay on track toward a valued goal (see also Kolb, 1984; Rathunde, 1996, 2001a).

The part of the dialectic that is overlooked by many psychologists is immediate experience. Much of the seminal work of phenomenologists such as Husserl (1960) and Merleau-Ponty (1962), in contrast, has focused on this prereflective experiencing that is embedded in the stream of consciousness and, therefore, difficult to describe. If such immediacy is not considered in relation to consciously pursued goals, it is very difficult to understand the motivational forces behind them. Dewey understood this, as did James. It was the primary reason that Dewey devoted so much time to understanding the relation of education and experience (1938). He believed that education must not ignore the importance of momentary, unfolding experience. That is why Dewey stressed the interplay of thinking and doing in the classroom; rationality was a problem-solving tool best used in coordination with action. In contrast, traditional educational approaches—still predominant today—often promote a decontextualized, fact-based approach to knowledge that is not sensitive to the quality of students' ongoing experience. We return to this theme later in the chapter when attempting to understand the role of social contexts in promoting optimal experience.

A key point in this chapter is that optimal experiences, or states of highly focused and intense engagement, reveal the times when—in James's words—a person "lives at their maximum of energy." The developmental importance of such times lies in the momentum they make available for growth. Western and Eastern thought and literature are full of allusions to extraordinary states of experience that can serve as turning points on one's life path. James, for example, approached optimal experience in terms of mysticism and religion. Whereas, for Dewey (1934/1980), aesthetic experiences served as the primary example of intensified states of experience that revealed the optimal use of energy. "Dewey considered aesthetic experience as a realization of the possibilities of ordinary, common, nonaesthetic experience" (Kestenbaum, 1977, p. 9). Aesthetic experiences could reveal a great deal about human potential and the ideal conditions for learning.

In contemporary psychology, Abraham Maslow (1968) was instrumental in highlighting how such "peak" experiences were related to optimal growth in self-actualizing individuals. Maslow—like Dewey and James before him—grounded his thought in a philosophy that challenged traditional scientific approaches. Maslow's grounding came from the tradition of existentialism as well as phenomenology. Self-actualizing individuals were on a path of lifelong learning; as one might expect, they reported more peak experiences than individuals who were stuck in lower phases of growth. Peak experiences could occur in any domain of life, but Maslow tended to view them, like James, as rare, transcendent moments that could have life-changing consequences.

The approach in the present chapter continues the turn toward experience. However, one important difference is to view optimal experiences, hereafter also referred to as *flow experiences* (Csikszentmihalyi, 1975,

1990), as more widely available and integrated with daily life. Flow can accompany a life event of singular importance, but it can also occur in the context of seemingly ordinary daily activities. The research on flow that has emerged over that last 30 years introduces a distinct focus on daily life and development, especially the development of a person's skills in creative and educational endeavors. Another difference from past approaches is in the nature of the empirical research that has been conducted. In addition to the use of first person, narrative accounts that have historically been used in research on optimal experience, one of the distinguishing features of research on flow has been the use of the Experience Sampling Method (ESM). The ESM uses electronic paging devices (e.g., programmed watches) to randomly signal study participants and prompt them to record their immediate experience and thoughts. Such a method of "systematic phenomenology" blends qualitative and quantitative information in a unique way and is currently used in a wide variety of research fields (Hektner & Schmidt, in press). Findings from several ESM studies are used in the chapter to illustrate how an experiential approach can shed light on the developing person.

The Developing Person in Context

The great extent to which human development is embedded in biosocial and cultural contexts, an insight that has increasingly taken hold in developmental thought over the past several decades, is a fundamental component of phenomenological thinking (Brandtstädter, Chapter 10; Bronfenbrenner & Morris, Chapter 14; Elder & Shanahan, Chapter 12; Lerner, Chapter 1; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume; Nakamura & Csikszentmihlayi, 2003). Phenomenologists emphasize how much is taken-for-granted and not explicitly conscious in a person's experience: Again, much of life is "had" or given in immediate experience before it is "known" in conscious thought (Damasio, 1994). Merleau-Ponty emphasized the omnipresent influence of the body on perception. Dewey noted the pervasive influence of social contexts reflected in the preobjective habits that informed a person's life (Kestenbaum, 1977). The perspective in this chapter is that with increasing age and wisdom, a person can wield significant self-regulative control over their attention, experience, and growth. However, before discussing a person's capacity to actively influence their own development, it is important to make clear the high degree to which a person's attention is rooted in their physical and social circumstances.

Each community develops an image of what constitutes a "good" person and what qualities and skills are important to develop to be a valued member of a group. For example, the traditional Hindu view is that a person is not an individual, but a position in a network of social relations (Marriott, 1976). A physical specimen of *Homo sapiens* is not a person, unless he or she belongs to a group, and fulfills the responsibilities thereof. The classical Chinese view and the understanding of the native tribes living along the Amazon River are not that different (Lévi-Strauss, 1967). In most cultures, the individual in its physicality is no better than any other animal. It takes the transforming power of culture and society to turn the animal into a person.

Different cultures use different techniques for making sure that children acquire the knowledge, behavior, and emotions that will enable them to function appropriately as adults. This process of socialization is often informal, enforced by the constant pressure of public opinion. But most cultures evolve formal mechanisms of socialization, often reinforced by complex rituals and ceremonies. India provides some of the clearest examples of this process. The classical Hindu culture has taken great pains to make sure that from infancy to old age its members conform to appropriate ideals of behavior. "The Hindu person is produced consciously and deliberately during a series of collective events. These events are *samskaras,* life cycle rituals that are fundamental and compulsory in the life of a Hindu" (Hart, 1992, p. 1). Samskaras help to shape children and adolescents by giving them new "rules of conduct" for each successive step in life (Pandey 1969, p. 32). As the Indian psychoanalyst Sadhir Kakar (1978) wrote half facetiously, "Samskaras mean 'the right rite at the right time.' . . . The conceptualization of the human life cycle unfolding in a series of stages, with each stage having its unique 'tasks' and the need for an orderly progression through the stages, is an established part of traditional Indian thought . . . one of the major thrusts of these rituals is the gradual integration of the child into society, with the samskaras, as it were, beating time to a measured movement that takes the child away from the original mother-infant symbiosis into the full-fledged membership of his community" (pp. 204–205).

Rites of passage certify that a child or young adult is ready to enter the next stage of personhood, until he or

she grows old and has played every possible role that is available in the community. In some cultures, a man or woman is not considered a full-fledged person until their first grandchild is born. Being a grandparent means, among other things that: (a) one is fertile, and therefore endowed with sacred power; (b) one is successful, because only reasonably wealthy parents can find spouses for their children; and (c) one is wise or at least experienced, having lived this long (LeVine, 1980). Only when these qualities are finally achieved is a person finally complete.

In Western societies, transitions to higher levels of personhood are no longer well marked, except in terms of educational progress, where various graduation ceremonies punctuate one's academic career. Religious progress, marked by such ceremonies as the Jewish bar mitzvah and the Catholic sacrament of confirmation, are bare vestiges of the importance that the spiritual formation of personhood had in the Judeo-Christian tradition. But even though we no longer have clearly marked transition points to higher levels of personhood, we do expect, in our society also, different qualities from people at different stages of life.

So while we lack communal rites to celebrate a person's passage from one stage to another, developmental psychologists recognize the importance of such transitions in their descriptions of the life cycle. For instance, Eric Erikson (1950) focuses on the sequence of psychosocial tasks we must confront: Forming an identity in adolescence, developing intimacy in young adulthood, achieving generativity in middle age, and finally bringing together one's past life into a meaningful narrative at the stage of integrity in old age (see also Vaillant, 1993). Robert Havighurst (1953) shifted the emphasis more on social role demands, and developed a model of life transitions based on changing expectations related to age—for example, the student, the worker, the parent. More recently, Levinson (1980) and Bee (1992) proposed similar models. Developmental theories usually do not make the claim that these tasks are always resolved, or even that the person is necessarily aware of them. But unless they are successfully resolved, the person's psychological adaptation is likely to be impaired. Common to these models is the assumption that individuals who deviate from normative developmental stages without good reason run the risk of compromising their chances for full personhood.

Stressing the ways in which a person is socially constructed and embedded in their social contexts seems to imply a passive and relativistic position. It may suggest that the criteria of personhood are more or less arbitrary, the *result* of chance historical developments in different places and times. It may also suggest that most aspects of life are "unconscious" and not subject to a person's active influence. However, we do not believe these statements to be true. The understanding of how a person develops may vary a great deal across times and places, and social practices may place powerful constraints on paths to becoming a person. However, adopting an experiential perspective highlights core aspects of human nature that—if nurtured and allowed to flourish—provide opportunities to exert influence on the course of development.

Human Nature and Optimal Arousal

One key aspect of human nature that is similar across cultures is the need for optimal arousal. Decades of research on "approach/withdrawal" theory (Tobach & Schneirla, 1968) and "optimal arousal" theory (Apter, 1989; Berlyne, 1960; Hebb, 1955) illustrate that there are common human responses evoked by a person's arousal level, and these responses start in early infancy (Turkewitz, Gardner, & Lewkowicz, 1984). Optimal arousal is genetically based and transcultural. It has presumably emerged during the evolution of humankind because it is adaptive and has been useful in assisting human development, especially in negotiating a person-environment fit that is effective and rewarding.

On one end of the arousal continuum are experiences such as anxiety and fear, which have obvious implications for safety and survival. Such high arousal conditions elicit responses that attempt to reduce arousal to manageable levels (e.g., withdrawal). On the other end of the spectrum are low arousal conditions, such as boredom, that elicit a less obvious but equally important response—attempts to increase arousal (e.g., approach, exploration, play). The focus in this chapter is primarily on the optimal arousal of flow, the axis of this arousal continuum. Because all experiences are situated in contexts, the exact nature of anxiety, boredom, and flow will differ with respect to specific content. In other words, cultures have different symbolic domains, and because they organize information differently, there are many differences in what activities are likely to produce flow, and what specific steps constitute the most effective path to it. However, numerous, cross-cultural studies of flow (Csikszentmihalyi, 1975, 1990; Nakamura &

Csikszentmihalyi, 2002) suggest that there is a remarkable consistency in the experiential process and the phenomenological state.

To understand the developing person from an experiential perspective, one could start from other common human experiences besides flow. However, there are certain advantages in focusing on optimal arousal, especially when a primary goal is to understand the developing person. Anxiety ignites a conservative response (e.g., caution, consolidation of a position); it motivates because of the need to protect things that are thought to be essential, such as one's life, family, or beliefs. Conditions of low arousal, like boredom, spark an opposite movement. Such experiences can motivate exploration and can have a liberating or diversifying effect on a person's attention. Both of these aversive states, of course, do not always prompt responses that "solve" a problem in a way that promotes growth and leads to optimal arousal. The highly anxious person may fail to take risks that truly solve a problem and may opt, instead, for a short-term solution that manages stress (e.g., accepting the safety of the status quo). And to the extent that boredom turns into contentment or a desire for distraction and entertainment, it can also stall meaningful growth. In this case, the developmental impasse is due to a weakened focus of attention and a foolish waste of energy.

The experience of flow occupies a unique place on this experiential continuum and represents a healthy solution to the problems of boredom and anxiety. When it is unfolding, flow manifests an optimal combination of order and novelty; it represents the coordinated operation of stabilizing and broadening uses of attention (Fredrickson, 1998). In terms of the flow model (described in more detail later in the chapter), this combination is represented by the constructs of skill and challenge: Flow occurs more often when a person's skills and challenges are similarly strong and potent. In such conditions, skills are being transformed by the new challenges a person engages, and challenges are being transformed by the application and expansion of skills. Flow is a more difficult way forward as a solution to boredom and anxiety than the short-term solutions of distraction or retreat. The flow experience, therefore, provides a valuable window for viewing the developing person because of its status as a complex experience, or one that lies at the very "edge" of stability and change (Waldrop, 1992). This combination leads to that distinctive phenomenological state wherein one feels a sense of being in control, but in circumstances one has never faced before. It is in this sense that we think of flow as a full or optimal experience.

The absence of flow also reveals much about the developing person. As with other dialectical models, such as Piaget's (1962) model of assimilation and accommodation, the balance between skills and challenges is thought to be in flux and always changing. To resolve a high arousal condition (i.e., high challenge and low skill) in a way that promotes growth over the long run, a person needs to raise skills and thereby increase a sense of order and emerging control. However, when arousal is reduced in the short-term by disregarding a challenge or holding ever more tightly to the skills already possessed, flow will not occur. Conversely, a healthy solution to boredom (low challenge and high skill) occurs when a person challenges their existing skills and thereby initiates an emerging sense of change and expansion. The short-term solution of finding a distraction, or some form of quick entertainment, may take the sting out of feeling bored, but it will not result in flow. In the long run, such "solutions" are a waste of valuable resources of attention that could be invested in growth-oriented activities. Dewey referred to these unhealthy outcomes as drudgery and fooling, respectively (Dewey, 1913).

The experiential dialectic described here is presumably genetically based and a part of human nature. From a physiological perspective, the human organism is born trying to maintain optimal arousal. Attempts to avoid too much or too little stimulation are apparent from the first moments of life. Therefore, these corrective responses do not depend on the environment for their origination. For example, infants learn through a process of habituation and recovery (Caron & Caron, 1968; Cohen & Younger, 1983). When a novel stimulus is introduced, infants will pay attention until they habituate to the new sight; then, building on the newly formed habit, they will pay attention again when a novel stimulus is introduced. If overstimulated, infants will avert their eyes from a person or object, thereby decelerating their heartbeat and reducing arousal.

Different cultural domains result in thousands of manifestations of optimal arousal and flow. However, the underlying need for optimal arousal, a basic organizing principle of human life, helps to explain the underlying dynamics of these manifestations. We think it helps to explain why works of art with a combination of order and novelty are the most preferred (Arnheim, 1971), why the most performed and loved pieces of music are ones that introduce novelty in a context of familiarity

(Simonton, 1984), and why family conversations that allow for connection and separation of family members are experienced as more enjoyable and interesting (Hauser, 1991; Rathunde, 1997). Each of these situations holds greater potential for optimal arousal because they allow for the intersection of ordering and novelty producing uses of attention. Such situations, therefore, more often result in flow and are intrinsically rewarding.

Instigating One's Own Development: The Potential Self-Regulation of Experience

A major goal in presenting this perspective is to describe the dynamics of optimal experience in enough detail to allow some insight about the potential self-regulation of development. Experience has an important role to play because development unfolds in time and is an emergent phenomenon; moment-to-moment experience, therefore, lies at the very center of this unfolding and provides a holistic level of integration between biology, person, and the cultural environment.

Contemporary theories assessing the significance of biology for human development have moved beyond bottom-up reductionism and have embraced systems views that assert a bidirectional influence between genes and the environment (e.g., Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume). Such approaches suggest that genetic instructions are responsive to the developing organism's external environment, including sensory events and internal neural events. Although systems models acknowledge the importance of psychological phenomena, they are largely focused on observable behavior and not subjective experience as defined in this chapter. Because it is now widely acknowledged that genes, in themselves, do not lead directly to phenotypic traits, an experiential perspective on the developing person would propose that experiences such as flow or interest enter into the bidirectional communications betweens levels in a psychobiological systems view (Gottlieb et al., Chapter 5, this *Handbook,* this volume). This suggestion is consistent with Schneirla's (1959, 1965) observation that the effect of an environmental stimulus depends on the organism's state of arousal and experiential history.

Even if one were to adopt a reductionist view—still common in developmental psychology—that asserts a more fundamental role for genetic activity in producing behavior, an experiential perspective would still be useful for understanding how individuals could maximize their potential given their biological predisposition. The idea of reaction range suggests that there is a constrained set of phenotypes possible for each genotype (Gottesman, 1963). For instance, a person with a genotype that predisposes to introversion is not going to be as outgoing as an extrovert. However, if such a person put himself or herself in the position to have many positive social experiences, it would maximize their orientation toward social engagement. An experiential perspective would emphasize how opportunities for flow in communication and interaction could maximize the range of outgoingness that a particular genotype "allows." A systems view of the same interrelationships would, in theory, provide an even greater role for experience to affect a personality outcome.

Cultural determinism, like biological reductionism, is also being abandoned by most social scientists in favor of systems models that account for the bidirectional influence between persons and social contexts (Lerner, 2002). Again, moment-to-moment experience lies at the heart of emergent person-environment interactions and, therefore, provides a potential leverage point for affecting development and the course of socialization.

Experiential perspectives on the reciprocal influence of person and context have been around for many years, although they have not been organized around a construct of optimal experience. In the first part of the twentieth century, for example, the so-called Chicago school of symbolic interaction (e.g., ideas influenced by George Herbert Mead, William I. Thomas, and Charles H. Cooley) had a strong phenomenological orientation. Thomas and Znaniecki's (1927) *The Polish Peasant in Europe and America* was considered the classic study of the time and a precursor to later attempts to develop a phenomenological alternative to reductionist social science approaches. Symbolic interactionists, through concepts such as Thomas's "definition of the situation," showed how the person-context relationship could not be understood apart from subjective experience and interpretation.

Adding flow as an organizing construct to a phenomenological perspective can further specify how a person is an active influence and not just a passive receptacle of cultural information. Investments of attention are strongly influenced by the subjective quality of experience. Rewarding experiences like flow, for example, attract attention and can affect the selection of biocultural information (Inghilleri, 1999; Massimini & Delle Fave, 2000). In other words, over long periods of time, information and domains that provide opportunities

for flow experience can shape culture through the selection of memes. Similar to biological transmission, the differential transmission of memes in cultural interaction has an eventual impact on the evolution of the culture. To the extent that the self-regulation of optimal experience is possible, individuals can play a conscious role in the way a culture changes.

A person is subject to the socialization forces of a culture, but he or she is capable of initiating change because the opposite is also true: Social practices must accommodate human nature and its parameters for optimal experience. Just as the eye works best by avoiding the extremes of too little or too much illumination, socialization processes will be rejected when they do not provide opportunities for sustaining optimal arousal through transforming anxiety and/or boredom (i.e., by building new skills or finding meaningful challenges, respectively). When social practices consistently result in aversive experiences, or offer only short-term solutions to such experiences, they will not be replicated or endorsed by future generations. Individual actors—through their own self-regulatory actions—will be compelled to change them.

Rigid social practices, for example, authoritarian regimes or unchanging traditional cultures, might survive for a time due to threat of violence, the pressure of public opinion, or the safety and familiarity they provide to a people facing anxiety-provoking threats. However, if such contexts do not provide individuals with opportunities to transform the challenges faced, experience is likely to alternate between anxiety and the deadening of the human spirit resulting from the inflexible "solutions." With time, the quality of life in such contexts works to undermine the stagnant system. Many modern societies face the opposite dilemma: The absence of an external threat and the relative comfort of life have resulted in socialization practices that are geared toward entertainment and distraction rather than growth. Such permissive systems protect the right for self-indulgence, but they provide few opportunities to really challenge the existing order that provides the basis of comfort. Personal experience in such a society can become increasingly frivolous and meaningless. Therefore, pressure for change results from trying to escape the aversive cycle of "solving" the problem of boredom with endless new distractions.

Anxiety that is not effectively resolved through the growth of new skills (i.e., finding a new sense of order) is often resolved by a retreat to the status quo; boredom that is not ameliorated with meaningful challenges is often "treated" with temporary distractions. Both of these undesirable outcomes, if multiplied over time, can result in unhealthy developmental trajectories for societies and the people in them. However, such conditions will not hold in the long run because they waste valuable resources of attention and do allow a person to organize and reorganize experience in increasingly more complex ways. In these aversive social conditions, therefore, the organismic imperative to seek optimal arousal will instigate change. At first, change may come from a "creative minority" of individuals who see a better way forward (Toynbee, 1987). Eventually, however, if a society is to flourish, the forces of stability and change in a society must work in a complementary way, with each used to refashion the other. Simonton's (1984) research on creativity provides some empirical support for this suggestion. Periods of great human achievement and progress often coincide with historical periods where social integration and differentiation were both present, but one did not dominate the other. Later in the chapter a similar reasoning is applied to two important contexts of socialization—schools and families.

Ideal Outcomes of Adult Development: The Role of Psychological Complexity

If optimal experiences like flow indeed signal that the person-environment fit and the developmental process are on a positive trajectory, then one of the most promising areas of research using an experiential perspective is to explore a person's capacity for the self-regulation of optimal experience. To the extent that the dynamics of optimal experience are better understood, it becomes possible to consider how such regulation might unfold. We propose the construct of psychological complexity to refer to an individual's flexible negotiation of experience. Psychological complexity is the self-regulative capacity to move toward optimal experiences by negotiating a self-environment fit that is integrated and differentiated, or a fit that achieves an optimally arousing balance of order and novelty.

Psychological complexity, or more simply—complexity, refers to habitual dispositions that actively respond to aversive experiential conditions: when anxiety indicates disorder in the self-environment relationship, creating order through a higher level of integration becomes a conscious goal; when faced with boredom, seeking change through differentiation becomes the aim. In other words, a person with psychological complexity responds to new challenges with skill-building

attempts, rather than a retreat to familiar methods that alleviate anxiety without transforming the problem that creates it. When facing the opposite experiential impasse, such a person responds to conditions of monotonous ease and comfort by finding a challenge that focuses attention in a transformative direction. Such a change is more than a shortcut to stimulation; it embraces what Piaget would refer to as disequilibrium in the self-environment relationship as a way toward higher development (Piaget, 1962).

Attempts by infants to maintain optimal arousal suggest the early foundations of psychological complexity, and adult interference with these regulation efforts, we believe, creates the first obstacles to the development of complexity as a psychological disposition. However, the notion of psychological complexity is meant to describe mature patterns of self-regulation that are more likely to result with age and experience; our use of the construct here refers to highly developed habits of response that are based in practice and experience. Therefore, the strategy adopted in this chapter is to illustrate how complexity unfolds through the life cycle, beginning with its potential manifestations in later life.

By starting at the end of the life span, and working our way back to childhood, it is easier to recognize patterns that are more likely to result in positive adult regulation and development. Of course, there is still much disagreement about the nature of continuities in development throughout the life span, and even about whether any childhood conditions will lawfully relate to adult conditions. We try not to address such questions, which are amply dealt with in other sections of this volume. Suffice it to say that if perspectives that view the developing person as both active producers and products of their ontogeny are correct, then knowing the desirable endpoints of ontogeny makes it easier to understand how actions earlier in life may enhance the prospects of optimal developmental outcomes.

Despite differences in content across various cultural contexts, across domains of activity, and across points in the life course, and despite the inevitable differences in what will be recognized as constituting "development" and "optimal functioning," we believe it is possible to say something affirmative about optimal adult development. One fruitful direction, we believe, is to look beyond outward appearances and focus on how—within any system—optimal functioning involves the need for integration and differentiation in the self-environment relationship. Psychological complexity can be manifested in many different ways, but there is an underlying similarity in the ups and downs of arousal and the process of negotiating optimal experience. It is reasonable to believe that a person with psychological complexity will more often enjoy the full engagement of attention and optimal arousal that it implies, and will have, therefore, a greater capacity to actualize their potential.

There are compelling reasons to take a position on optimal patterns of development, despite the ambiguity and risk involved. Bruner (1986) has argued that developmental psychologists cannot just *describe,* but must also *prescribe* optimal ways of developing. If not, they abdicate their role in the construction of the public meanings that societies depend on for self-regulation. When such metatheories about the "good man" and the "good society" are explicitly delineated, they not only add to the public dialogue, they also provide a selective principle for determining the nature and direction of developmental research. Rogers (1969) said much the same thing in defense of his conception of the optimal person; he challenged others: "If my concept of the fully functioning person is abhorrent to you . . . then give your definition of the person . . . and publish it for all to see. We need many such definitions so that there can be a really significant modern dialogue as to what constitutes our optimum, our ideal citizen" (p. 296). More recently, Seligman and Csikszentmihalyi (2000) have suggested the same by urging more research be devoted to understanding positive developmental outcomes.

Starting with the fully developed person also allows us to draw from a recent study of creativity in later life in which we describe in detail the mature self-regulation and complexity that potentially characterizes later life. Because physical maturational changes culminate in adolescence, and the periods of middle and late adulthood often are marked by declines in some physical and cognitive skills, theorists have struggled to conceptualize whether adults are in fact "developing," declining, or simply changing (Pearlin, 1982). Our perspective on this debate is similar to Baltes and Smith's (1990) "weak" developmental hypothesis about the possibility of adult development culminating in wisdom. This hypothesis states that increasing age does not necessarily result in wisdom, and that on average older adults may not demonstrate more wisdom than younger ones, but because wisdom is conceptualized as an expertise that requires cumulative practice, and because increasing age provides for more experience and time for such practice, notable outcomes of wisdom will be disproportionately seen in older adults. Likewise, notable manifestations of psychological complexity are more likely to occur in

adulthood, although less developed forms of self-regulation occur at all stages of the life course.

A second reason for starting at the end of the life cycle, therefore, is to facilitate our search for the beginnings of mature self-regulation and complexity in the periods of infancy, childhood, and adolescence. If one first articulates a clearer picture of desirable adult developmental outcomes, then it is easier to search the literature on early developmental periods and, it is hoped, find the connections that link certain patterns in childhood with desirable adult outcomes. We explore in particular the link between psychological complexity and the neotenous development of human children that provides for extended periods of exploration and play (Gould, 1977).

Few would disagree that the ideal outcome for adult development is someone who is fit in body and mind, curious and interested in life, pursuing a vocation with vigor, close to family and friends, helpful and involved in the community, and concerned with making sense of the world. However, different cultures would undoubtedly fill in a different set of outcomes for each of these categories of adult success. Instead of suggesting specific criteria for optimal development, we propose to look through an experiential lens at similarities in the process of regulating experience. Attempts to negotiate optimal experience, and sustain it using the dialectic of integration and differentiation, may look different depending on the symbolic domain under observation, but the dynamics involved are the same and have their basis in optimal arousal and human nature. One of the main tasks in this chapter, therefore, is to explore the self-regulatory skill of turning neutral or adverse everyday situations into engaging experiences.

Before turning to specific examples of psychological complexity, more is said in the next section about optimal experience, complexity, and development. After providing examples of complexity in adulthood, the remaining sections address its antecedents in child and adolescent development. An emphasis is placed on the foundations of complexity in family and school environments.

OPTIMAL EXPERIENCE THEORY

What are the similarities in the process of negotiating optimal experience? How is optimal experience or flow sustained using the dialectic of integration and differentiation? These are some of the questions taken up next. To locate our answers squarely in classical developmental theory, we first explore the notions of optimal experience and psychological complexity in terms made familiar by the early developmental literature, starting with the Piagetian perspective.

A Phenomenological Extension of Piaget

A number of familiar concepts from Piaget's theory are helpful for providing a preliminary understanding of how optimal experience and complexity are related. For instance, *equilibration* expresses a fundamental insight of Piaget: that development is an evolutionary process that exists "between" subject and object. While some theorists before him explained development from the side of the subject (e.g., through a priori structures, rationalism, or other nativist ideas), and others explained it from the side of the environment (e.g., association, positivism, or other nurture perspectives), Piaget tried to solve the riddle of development with an interactionist, open-systems model. Some may find this statement at odds with the too common interpretation of Piaget as a static stage theorist; this misunderstanding, however, arises from his multiple uses of the term *equilibrium.* For instance, it was sometimes used to refer to moment-to-moment adjustments of assimilation and accommodation, sometimes to the temporary accomplishments of the stages, and sometimes to the ideal endpoint of formal operations. It is at the first level of moment-to-moment interactions that Piaget is most clear concerning development as an ongoing relationship between self and environment: assimilation and accommodation are in constant search for equilibrium or balance. Acting in the world continually introduces disequilibrium that must be corrected. It is at also at this level, therefore, that an experiential interpretation of Piaget is best accomplished.

Despite the fact that maturationists and environmentalists both claim a part of his vision, the theory is more accurately understood as derived from an open-systems model of evolutionary biology: "It [Piaget's theory] does not place an energy system within us so much as it places us in a single energy system of all living things. Its primary attention, then, is not to shifts and changes in an internal equilibrium, but to an equilibrium in the world, between the progressively individuated self and the bigger life field, an interaction sculpted by both and constitutive of reality itself" (Kegan, 1982, p. 43). Thus, equilibrium describes the state of the open system such that the self and environment are related in a way

that is differentiated and integrated; to our way of thinking, *such equilibrium would signal optimal arousal.* Assimilation and accommodation are two facets of a unitary and dynamic evolutionary process and must be understood together: As an organism differentiates, it moves, so to speak, through assimilation toward accommodation (i.e., from structure toward change). This movement calls for a reverse movement through accommodation toward assimilation (i.e., from change to structure) that integrates the organism with the environment in a new way.

By describing development in such general systems terms that focus on the relationship between self and environment, some thorny conceptual dichotomies become less troublesome (e.g., nature/nurture), and the person can be seen less as the result of the relational process (i.e., the more traditional interpretation), and more as the *process* of organizing information and creating meaning itself. A new burden, however, is then placed on the theorist, namely, to describe and measure the transitory state of equilibrium. There are at least two basic ways to address this problem: from the "inside," emphasizing how the self experiences the relational process; and from the "outside," looking at practical consequences. An experiential approach would adopt the former approach. However, Kegan (1982) noted that Piaget took the latter course, viewing the assimilation/accommodation process descriptively from the outside; he focused on the successes in problem solving associated with different stages of cognitive development. Consequently, the approach ignored the assimilation/accommodation process from the participatory angle of the self. Presumably, this is one reason why the theory is often faulted for failing to provide a sufficient look at the role of emotion and motivation in development (Sternberg, 1984). In fairness to Piaget, however, there were larger historical reasons that led many psychologists to ignore the internal reference. Aside from a few existential and phenomenological approaches, these participatory questions have seldom been raised in the field of developmental psychology; when they have, they often lacked theoretical and methodological rigor to allow intersubjective verification.

In summary, Piagetian theory is helpful for linking optimal experience and complexity to foundational ideas in the developmental literature, but for several reasons it does not suffice for the purposes of this chapter. The theory tells us little about how the relational process between self and environment is *experienced by the self,* thus it tells us little about what—in human terms—motivates development. Assimilation, accommodation, and equilibration, while important for locating the action of development in the relation between self and environment, are notoriously vague as concepts that can be measured and studied; they therefore have limited utility. If, however, a framework of internal reference is adopted, new research opportunities arise. For instance, if equilibrium indicates a complex relationship that is fully involving, then it becomes possible to look at development from a perspective that emphasizes full involvement as a measurable criterion of the self-environment negotiation process. Much can be learned about this process, we believe, by adopting a phenomenological perspective that focuses on the experience of self-environment relations. For instance, what does a complex relationship feel like? How can relationships that are too one-sided—too integrated or too differentiated—be recognized phenomenologically?

Piaget suggested answers to the earlier questions in concepts such as *functional pleasure* and in brief references to intrinsic motivation. Unfortunately, he never developed these ideas in much detail. For instance, Piaget observed that infants laughed at their own power, tried to make interesting sights last, and manifested enjoyment (i.e., functional pleasure) when acting competently. Such observations were short-lived and limited to the early sensorimotor stages, however, as he turned his attention to the external manifestations of successful problem solving associated with higher stages of cognitive development. In so doing, a fruitful course of investigation was abandoned, one that might have added significant insights about the search for equilibration, and the enjoyment and intrinsic motivation associated with it.

The claim here is that moments of self-environment equilibrium are experienced by the self as optimally rewarding. To the extent that Piaget was correct in asserting that the search for equilibration energized human development, it is accurate to say that development is also motivated by the search for optimal experience. It is through monitoring such experiences that we can learn to recognize when relationships are complex and when they are too differentiated or too integrated (i.e., having overemphasized either accommodation or assimilation, respectively). And to the extent that the person is defined less as a static entity and more as a relational process, then a theory of optimal experience becomes an important link to a fuller understanding of the developing person.

Other Perspectives on Self-Environment Equilibrium

It is worth mentioning a few other early proponents of the view that development is motivated by a search for self-environment equilibrium, and that such equilibrium is linked with optimal experience and the full development of the person. Although many thinkers could be mentioned here, going as far back as Aristotle (MacIntyre, 1984), we have selected three more recent authors whose insights are relevant: Friedrich Nietzsche, Abraham Maslow, and Carl Rogers. Their views are linked through an idea they shared: *love of fate.* All three believed that love of fate was *the* mark of the fully developed person, whether that person was called "overman" by Nietzsche, "self-actualizing" by Maslow, or "fully functioning" by Rogers (1969); and all of them depicted the love of fate as a deeply rewarding synchrony between self and environment.

What does it mean to love one's fate? For Nietzsche, it meant the affirmation of life through a full acceptance of its circumstances. Despite hardship or obstacle, or perhaps more accurately, because of them, one would not wish for one's life to unfold in any other way. This is so because the process of overcoming obstacles provides the opportunities through which the person is created. *Amor fati,* or love of fate, is a central concept in Nietzsche's philosophy: "My formula for greatness in a human being is amor fati: that one wants nothing to be different, not forward, not backward, not in all eternity. . . . Not merely bear what is necessary . . . but love it" (1968, p. 714). The fully alive person (i.e., the *over* man) is not content with just surviving and adapting, but is intent on transcending himself or herself. Such experiences of transcendence provided his deepest motivation: "I want to learn more and more to see as beautiful what is necessary in things; then I shall be one of those who make things beautiful" (1974, p. 223).

Maslow's (1971) studies of self-actualization and peak experiences led him to a similar conclusion. The healthy person is not motivated just by deficits, simple endurance in life, or by the survival of self or offspring, but also by growth. Based on his observations and interviews with individuals he considered to be self-actualizing, including creative artists and scientists, he concluded that the processes of growth were often rewarded with fulfilling peak experiences. These experiences coincided with a synchronous relationship between self and environment; he referred to this synchrony as a balance of "inner requiredness" with "outer requiredness," or "I want" with "I must." Especially true of self-actualizing persons, during such experiences "one freely, happily, and wholeheartedly embraces one's determinants. One chooses and wills one's fate" (p. 325).

Rogers (1969) endorsed a very similar perspective. He comments about the fully functioning person: "He wills or chooses to follow the course of action which is the most economical vector in relation to all the internal and external stimuli because it is that behavior which will be the most deeply satisfying" (p. 294). As a result, he continues, "The fully functioning person . . . not only experiences, but utilizes, the most absolute freedom when he spontaneously, freely, and voluntarily chooses and wills that which is absolutely determined" (p. 295). Thus, as with Nietzsche and Maslow, a love of fate corresponds to an inner-outer synchrony that evokes a deeply rewarding experience. And like both of the other thinkers, Rogers (1959) believed that the person was not satisfied with mere survival, but was instead motivated to expand and grow: "The inherent tendency of the organism is to develop all its capacities in ways which serve to maintain or enhance the organism. It involves not only what Maslow terms 'deficiency needs' . . . [but also] expansions in terms of growth. . . . Life processes do not merely tend to preserve life, but transcend the momentary status quo of the organism, expanding itself continually and imposing its autonomous determination upon an ever-increasing realm of events" (p. 196).

Love of fate reveals a relational synchrony of self with environment; as such, it is the mark of distinction of the developing person. It is deeply rewarding because it coincides with the most "economical vector" between inner and outer stimuli.[1] Most important, it is an experience that confirms, manifests, and accompanies what the organism wants most: to develop and to grow. Such complex relationships maximize being through the differentiation and integration of the person, which allows the fullest expression of life and energy. In Piagetian terms, to grow means that a new equilibrium has been

[1] It is worth pointing out again that when the person is defined relationally, as in this chapter, it can be misleading to fall into the familiar use of the terms *subject* versus *object, inner* versus *outer,* and so on. This terminology tends to isolate the person from the world, which is not our intention. On the contrary, it is more consistent with our perspective to say that the "location" of the person is neither inner nor outer, or, perhaps better, is both at once.

attained, one that is "higher" in the sense of being more synchronous with reality (i.e., as formal operations are more attuned to reality than concrete operations). What these thinkers add to Piaget's perspective is more about the internal reference, and the intrinsically motivating character of moments of growth.

The Optimal Experience of Flow

Flow theory continues in this tradition of thought and further defines in experiential terms such moments of synchrony and growth. A flow experience (Csikszentmihalyi, 1975, 1990, 1993; Nakamura & Csikszentmihalyi, 2002) describes a prototypical experience of an intrinsically motivated self-environment fit. Flow is a deeply involving and enjoyable experience that has been described by a variety of different respondents, in a variety of cultures, in strikingly similar ways (Csikszentmihalyi & Csikszentmihalyi, 1988). Athletes refer to it as being "in the zone," poets as being visited by the muse.

In flow, a person is fully concentrated on the task at hand. There is a feeling that action and awareness merge in a single beam of focused consciousness. In flow, it is very clear what needs to be done from one moment to the next; goals are clearly ordered and sequenced. One also knows immediately how well one is doing: Feedback is unambiguous. The tennis player knows whether the ball was hit well, the violinist hears whether the note just played was right or wrong. In flow, a person loses self-consciousness; the vulnerable ego disappears. In George Herbert Mead's terms, there is only "I" without a "me" to worry about. The sense of time becomes distorted to fit the experience; hours seem to pass by in minutes. When these dimensions of experience are present, one is willing to do what makes these feelings possible for their own sake, without expecting extrinsic rewards. The poet enjoys the experience of writing, the bond trader enjoys beating the market, and both will continue doing these things because they are enjoyable—even in the absence of the rewards of fame and wealth.

Finally, and most important, flow begins to be experienced when there is a fit between the *skills* of the self and the *challenges* afforded by the environment. For example, we cannot enjoy a tennis game if our opponent is either much better or much worse than we are; only a game with a well-matched opponent is likely to be enjoyable. We don't enjoy reading a novel in which plot and characters are too difficult to visualize, nor one that is too obvious and predictable; we enjoy instead the text that fits our imaginative powers. It is this aspect of enjoyment that is most relevant to the relational synchrony that lies at the heart of optimal personhood.

The experience of flow marks an achieved balance of arousal-increasing and arousal-decreasing processes. The flow model describes this balance in terms of the fit between perceived challenges and skills: An activity wherein challenges predominate increases arousal; an activity wherein skills predominate reduces arousal. Thus, a synchrony of challenges and skills permits a state of deep involvement, while the pitfalls of either over- or underarousal (i.e., anxiety or boredom) are avoided. In this sense, flow seems to represent the subjective dimension of that "goodness of fit" between temperament and environment that underlies several developmental perspectives (e.g., Lerner & Lerner, 1987; Thomas & Chess, 1977).

In fact, it could be argued that flow is likely to be experienced when an individual is fully functioning relative to the developmental opportunities that a given stage provides. For instance, in terms of the Eriksonian stages, an infant at the first stage whose only opportunity for action is feeding itself and whose only skill is to suck milk will be in flow when at the nipple. As the opportunities for action in the physical and social environment grow, so must the child's abilities to act increase if the child is to continue to experience enjoyment. Therefore, one would expect the challenges provided by the tasks of identity, intimacy, generativity, and integrity to present further, more complex opportunities for flow.

Anxiety and boredom are aversive phenomenological states that result from a disequilibrium in the momentary fit between skills and challenges or self and environment. When challenges are too high relative to skills, the asynchronous relationship leads to anxiety because one feels overwhelmed, out of control, threatened by a loss of integrity and order. In contrast, when skills are too high for the given challenges, the fit between self and environment is too easy and comfortable, resulting in the loss of novelty and therefore a decrease in the sense of focus and urgency.

The balance of skills and challenges can be described further in Piagetian terms. An assimilative mode indicates the existence of an organized, preexisting structure of information. That structure makes the processing of new information more automatic because it can be organized by the existing structure. The idea of "skills"

suggests an analogous process; a skill is a practiced response, one that is habitual and automatic. A skilled pianist, therefore, primarily relies on an assimilative mode when reading an easy piece of music. On the other hand, if the challenge of reading the score moves beyond the skills of the pianist, an accommodative mode comes into play. Accommodation is a more effortful response to novelty (Block, 1982). In attentional terms, accommodation uses more voluntary, controlled, or linear processes, rather than immediate, automatic, or global processes, as does assimilation (Schneider & Shiffrin, 1977). To say that a flow experience is more likely when skills and challenges are in balance is to say that flow is more likely when assimilation and accommodation are in equilibrium and immediate and voluntary uses of attention work in concert to intensify concentration. Rathunde (1993, 2001a) has also described this coming together of immediate and voluntary modes of attention as undivided interest, a synonym for flow that implies something about the underlying attentional dynamics (see also Rathunde & Csikszentmihalyi, 1993).

Piaget (1962, see pp. 147–150) recognized that when assimilation dominates accommodation the fit between self and environment is too rigid and one-sided. In an *overassimilative* mode, the self habitually perceives the environment subject to its own preconceptions, and consequently one might say that objectivity is diminished (Kegan, 1982). Overassimilation is equivalent to an imbalance of skills over challenges, and it feels like boredom. When bored, one is too "subjective," too habitual, and closed to new opportunities for action. Conversely, when accommodation dominates assimilation, or when novelty overwhelms the processing capacity of a preexisting structure, the self is unhinged and oriented outside of itself; it is so decentered toward the uncertainty in the environment that the possibility for feelings of relatedness, connection, and meaning are diminished. *Overaccommodation* is equivalent to the imbalance of challenges over skills, and it is experienced as anxiety. When anxious, one feels at the mercy of environmental circumstances that are beyond one's control and thus blinded by the excessive stimulation to ways of making sense of the situation.

When skills and challenges are in equilibrium, action is fully centered on the relationship between self and environment. The skilled pianist who performs a challenging score is drawn into a more involving relationship. The automaticity of existing skills provides confidence, structure, integrity, and a foundation from which the new material can be reached; yet, the reach is not easy, and the novelty of the score demands careful attention. It is just such a combination that requires full attention—resources brought to bear through habits of "chunking" the information, and resources mustered through effort. And this full attention is experienced as a feeling of flow, of being caught up in a single energy system that unites self and environment. Motivation to continue the activity becomes intrinsic—not in the mistaken sense of "in" the self, but rather "in" the self-environment relationship.

Yet another way to look at the full involvement of flow is in the combination of positive affect and heightened concentration. Some activities may evoke positive affect, but will soon be experienced as frivolous if they lack focus and the need for concentration. Alternatively, some activities begin with intense concentration, but are soon experienced as oppressive and alienating because they are devoid of pleasant feelings. Dewey (1913) has called the former experiences "fooling" and the latter "drudgery." In contrast, he described optimal experiences as affectively and cognitively engaging, providing both a sense of playfulness and spontaneity, as well as a corresponding seriousness and focus on goals. For some individuals, work is drudgery because serious concentration is not accompanied by positive emotion, and leisure is fooling because good moods cannot be sustained due to a lack of focus. For other, more fortunate people, work and leisure are both thoroughly enjoyed, and in fact indistinguishable; they provide for undivided interest, and each is a type of "serious play" (e.g., Rathunde, 1993, 1995).

The implications of an affective-cognitive synchrony for the quality of experience can also be described using the psychoanalytic constructs of *primary* and *secondary process* thinking. These two processes are often dichotomized in an either/or fashion. Primary process is identified with the pleasure principle and with dreams, myth, emotional thinking, fantasy, poetic feeling, and so on. Secondary process, in contrast, is identified with the reality principle and thus with reason, logic, science, intellect, abstract thought, and so on. A severe split between these two processes is tantamount to pathology. In Freudian terms, relatively uninhibited primary process thought suggests the dominance of the id over and against the ego and superego, whereas the dominance of secondary thought processes is suggestive of the repressive control of the superego over and above the ego and id. A healthy ego, at least to a greater extent than an un-

healthy one, is able to synchronize id and superego or primary and secondary process thought therefore achieving greater self-regulation, freedom, and health. Several psychoanalytic thinkers have also associated such a synchrony with creativity (Jung, 1946; Kris, 1952). The implication is that healthy ego development is presumably related to the ability to regulate arousal and negotiate optimal experience.

Finally, that optimal experiences synchronize affective and cognitive modes is supported by the descriptions of flow, peak experiences, and the emergent experiences of fully functioning persons. Respondents describe flow as an enjoyable merging of action and awareness in that actions follow each other spontaneously and unselfconsciously, yet there remains an intense and careful monitoring of feedback in relation to one's goals. Maslow (1971) has commented about peak experiences: "We have found that peak experience contains two components—an emotional one of ecstasy and an intellectual one of illumination. Both need to be present simultaneously" (p. 184). Finally, and in a similar vein, Rogers (1969) described the fully functioning person as both a *participant* and an *observer* of an emergent experience: "The sensation is that of floating with a complex stream of experience, with the fascinating possibility of trying to comprehend its everchanging complexity" (p. 285). Thus, in all of these descriptions there is a component of automatic and controlled attention, a component of primary process thinking that is immediate, and an aspect of secondary process thinking that is monitoring the environment. Such combinations of information, like the contrasts of dark and light in a painting, are what makes such experiences remarkable and interesting.

Flow and Development

Just as we cannot step in the same river twice, we cannot enjoy the same activity with the same intensity more than once. To continue providing optimal experiences, flow activities must constantly be *re-created.* It is this fact that makes the flow model a developmental model. As Piaget also observed, disequilibrium between the processes of assimilation and accommodation is inevitable and needs to be continually addressed. In our phenomenological perspective, disequilibrium is signaled by boredom and anxiety—two inevitable life experiences. In the simplest terms, one transforms boredom by finding challenges and overcomes anxiety

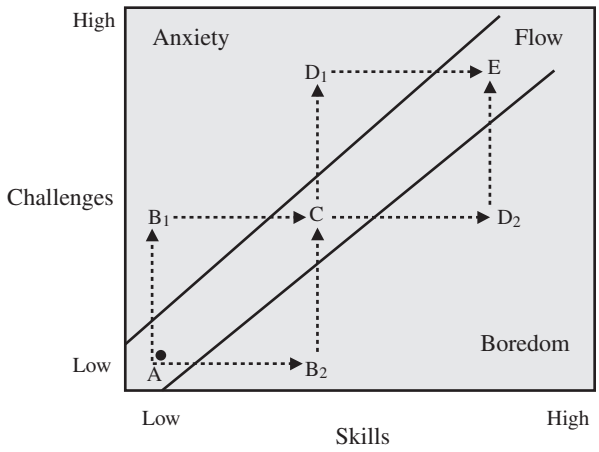

Figure 9.1 The dynamics of flow. A, C, and E are enjoyable states of equilibrium of increasing complexity. B_1 and D_1 are states of anxiety that require learning new skills for a person to return to flow. B_2 and D_2 are states of boredom that require new challenges for a return to flow.

by building skills. It is through this perpetual dialectical process that development proceeds; and it proceeds in the direction of greater complexity because optimal experiences cannot be recaptured through a regression of skills and challenges, but only through their progression (Csikszentmihalyi, 1990; Csikszentmihalyi & Rathunde, 1993).[2]

Figure 9.1 shows how the raising of skills and challenges has been depicted in previous discussions of the flow model. To reenter the "flow channel" from states of boredom or anxiety, challenges and skills must be raised appropriately. In other words, flow can proceed from boredom or from anxiety. Once "inside" the experience, there are common features to flow, but seen in the broader context of before and after, the experiences are quite different. For instance, the transition from boredom is a process of *finding* something novel enough that it tests one's skills. Boredom, in a healthy personality, initiates a process of searching for a meaningful challenge, not just a diversion; as interest and curiosity draw the self out of its shell, boredom wanes, and experience becomes more intrinsically rewarding. In contrast, the

[2] Our focus here remains on immediate subjective experience, but it is possible to adopt other time frames and perceive the same dialectical tension. In other words, one may overcome the anxiety of an entire week, month, or year by finding a way to build new skills. As mentioned earlier, the same is true of equilibrium; that is, it can refer to immediate experience or stages that characterize larger periods of time.

transformation of anxiety is more like *solving* a problem. A positive response to anxiety does not shrink back to a position of safety; rather, it initiates a process that tries to resolve a dilemma. With increasing success and a growing sense of resolution, order, or closure, anxiety dissipates, and the quality of experience improves.

Similar to the movement away from boredom, the movement from assimilation toward accommodation involves problem finding in the sense of pushing the limits of an existing information structure. When assimilation is joined by an emergent sense of accommodation, but not overwhelmed by it, experience is optimal. For instance, an individual who has just learned to ski discovers new challenges by testing the limits of his or her skills on new hills; these challenges, if not overwhelming, intensify the skier's experience because they evoke greater concentration and require quicker adjustment. When, however, it becomes clear that a particular challenge is beyond reach, the skier feels out of control and anxiety sets in. In this instance, accommodation that moves toward assimilation is a problem-solving process that rebuilds a new structure. Perhaps the skier needed to learn a more effective way to turn to control the speed of descent; as the first clumsy actions become more practiced and second nature, anxiety lessens, attention is withdrawn from the self-consciousness of "forced" turns, and, at least until the new turns become too automatic, the experience of skiing is again exhilarating.

Apter (1989) has referred to such changes as arousal *reversals.* In his reversal theory, he calls the former problem-finding mode *paratelic* and describes it as an arousal-increasing mode wherein attention is focused on the here and now, and more on means as opposed to ends. In contrast, the latter problem-solving mode is referred to as *telic.* In this mode, attention is more focused on the goals of an activity, there is a future-time orientation, and the activity moves toward reducing arousal. In everyday language, the paratelic mode is more spontaneous, fun, and playful; the telic mode is more serious and worklike. The rewards of a paratelic mode are those resulting from the movement from boredom to optimal arousal; in contrast, a telic mode finds optimal rewards by moving from anxiety back to optimal arousal. Consistent with the perspective here, optimal experience is simultaneously paratelic and telic.

Psychological Complexity and Development

What qualities facilitate optimal experiences and the trajectories of growth that have been outlined earlier? Such a question is not intended to change the relational focus in favor of more traditional psychological conceptions of personality traits or characteristics. However, to discuss the person often requires a way of speaking about qualities or characteristics "as if" they were contained in the person. Despite the pitfalls of such language, the qualities discussed can still be thought of in relational terms; and to the extent that they are depicted as relatively stable "traits" of persons, they can also be conceived as stable ways of relating to the environment.

Bronfenbrenner (1992; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume) has recently discussed such personal attributes in terms of their relational potentials and collectively refers to them as *developmentally instigative characteristics.* Such characteristics have two features. The first refers to qualities that encourage or discourage certain reactions from the environment; for instance, a baby acts as a stimulus to others by being either fussy or happy, and calls forth certain corresponding reactions. A more important developmental influence and, according to Bronfenbrenner, one that is much ignored and in need of study by developmentalists is *developmentally structuring characteristics* that involve an active, selective orientation toward the environment. About such instigative attributes he comments: "When they are manifested over time in particular settings, [they] tend to evoke complementary patterns of continuing developmental feedback, creating more complex developmental trajectories that exhibit continuity through time. The result is a person-specific repertoire of evolving . . . dispositions that continues to be distinguishable over the life course, and hence constitutes what we recognize over the years as the person's individual personality" (1992, pp. 219–220).

There are several examples of developmentally instigative qualities explored in the literature that are relevant to optimal experience. For instance, Block (1982) has discussed how ego resiliency is related to the ability to move through the dialectic of assimilation and accommodation. When novelty overwhelms a particular schema, accommodation is needed to restore psychic equilibrium. However, the movement through assimilation to accommodation may, at first, prolong and intensify an anxious state until progress is made toward reorganizing the structure. If a person is unable to muster the effort needed to push through anxiety, he or she may persist with failed assimilative efforts (i.e., perseveration, fixation), or might selectively ignore the challenge. An ego-resilient person is better able to keep

the two modes in equilibrium and therefore avoid the particular dangers of overassimilation and overaccommodation by being flexible in changing life conditions. Such a person is capable of spontaneity under conditions of overassimilation, and capable of self-direction and organization under conditions of overaccommodation (Block, 1982; Block & Block, 1980).

Bandura's (1977) concept of *self-efficacy* also suggests a relational quality that is relevant for the dialectic of optimal experience. For instance, persons with high self-efficacy *slightly overestimate* their ability to master challenges. This "distortion" has the effect of inducing persons to select challenges that are slightly beyond their current capacities. In other words, it induces the confidence to take a risk. Because the selected challenge is not unrealistic, however, the person is able to master it, thus reinforcing and strengthening the feeling of self-efficacy. The same could be said about the positive feedback loop that coincides with high self-esteem. After experiencing flow, self-esteem increases, and people who experience flow more often (i.e., who spend more time in high-challenge, high-skill situations) report higher levels of self-esteem (Adlai-Gail, 1994; Wells, 1988).

Ford and Lerner's (1992) description of the competent person as possessing *flexible* self-regulation is also relevant here: "A competent person can modify effectively his or her own behavior and/or the features of the social situation in which he or she is engaged. . . . People can, for instance, change their topic of conversation if they find they are boring or upsetting others; or if they are bored or upset by what is being said, they can turn the topic of conversation round to more pleasant topics, or terminate it. . . . Such competency—such efficient self-regulation—is an instance of how one may act as a producer of their own development" (p. 85).

Such a competent or flexible person is, of course, not free from the biological and environmental constraints that bind everyone else. We are all limited by particular inherited and learned characteristics, and most settings impose social and physical demands that cannot be ignored. Nevertheless, it is possible to negotiate a *goodness of fit* with the setting. According to Ford and Lerner (1992), flexible persons are better able to (a) evaluate the challenges facing them and their abilities or skills to respond; (b) select and gain access to those contexts where there is a high probability of a good fit, and avoid those contexts where there is not; and, as in the earlier example of a conversation; and (c) either change themselves to find a better fit (e.g., change their own pattern of response in a conversation—or accommodate) or try to change the context itself (e.g., try to alter others' topics of conversation—or assimilate). A competency in self-regulation thus allows us to be more active shapers of our development.

Far from reducing an ecological and interactionist perspective to the side of personality, these observations about self-regulation reinforce the notion that the self-environment relationship is the primary factor in development. Instigative or structuring qualities, though, set in motion *interaction styles* that are sustained by the accumulation of their own consequences. Results from certain actions instigated by the individual produce a stream of feedback that sustains the trajectory of growth. It is not that the person remains the same in every environment; rather, it is that there is *consistency in the way that a person varies behavior as a function of the environment.* Developmentally instigative characteristics produce a continuity in the way behavior is changed. In this chapter, we are especially interested in the continuity of response that directs the person toward self-environment equilibrium and optimal experience.

An example of how such consistency in change might operate is helpful. In overly challenging situations, a person might recognize that arousal reduction and skill building are the appropriate course of action; in times of boredom, the person might seek to increase arousal by seeking higher challenges. Such a person, who at one moment manifests a conservative attitude of perseverance and at another, a confidence aligned with taking risks, might seem to the outside observer to be inconsistent, contradictory, and at the mercy of environmental influences. On the contrary, from the internal reference of subjective experience, such flexibility or complexity of response displays consistency. Only then is a person capable of making choices that move predictably in the direction of optimal experience.

In this chapter, and in previous work (Csikszentmihalyi, 1996; Csikszentmihalyi & Rathunde, 1993; Csikszentmihalyi, Rathunde, & Whalen, 1993), persons that exhibit such active-interactive orientations have been referred to as being *psychologically complex,* or more simply being complex. A complex person has *the self-regulative capacity to move toward optimal experiences by negotiating a better fit or synchrony of self with environment.* Traditional conceptions of personality that claim a stability of response, regardless of environmental circumstances, have been shown to be lacking (Barker, 1950; Mischel, 1968). We do not dispute the fact that the social and physical demands of different

contexts evoke different behaviors. Traditional conceptions of personality, however, fail to look for *consistency within the change,* or the consistency in the ways that a person varies his or her behavior as a function of the setting (for further discussion of this point, see Cairns & Hood, 1983; Sroufe, 1979).

Physical scientists describing complex systems are also aware of this phenomenon of consistency in change; they call it emergent self-organization (e.g., Prigogine, 1980). Waldrop (1992) comments:

> Self-organizing systems are adaptive, in that they don't just passively respond to events the way a rock might roll around in an earthquake. They actively try to turn whatever happens to their advantage. . . . Complex systems have somehow acquired the ability to bring order and chaos into a special balance. This balance point—often called *the edge of chaos*—is where the components of a system never quite lock into place, and yet never quite dissolve into turbulence, either. The edge of chaos is where life has enough stability to sustain itself and enough creativity to deserve the name of life. . . . The edge of chaos is the constantly shifting battle zone between stagnation and anarchy, the one place where a complex system can be spontaneous, adaptive, and alive. (pp. 11–12)

Although these words were written to describe the beauty of fractals—the patterned turbulence of rivers, weather, and other natural phenomena—they apply equally to psychological systems. This edge of chaos (and conversely, the "edge of order") has been described here as equilibrium, balance, and synchrony. Optimal development also involves such a predictable unpredictability, and an unpredictable predictability. Note the similarities between the following passage from Rogers's (1969) description of the fully functioning person, and the earlier description of complex physical systems:

> It should therefore be clear that this person will seem to himself to be dependable but not specifically predictable. If he is entering a new situation with an authority figure, for example, he cannot predict what his behavior will be. It is contingent on the behavior of this authority figure, and his own immediate reactions, desires, and so on. He can feel confident that he will behave appropriately, but he has no knowledge in advance of what he will do. . . . It is the maladjusted person whose behavior can be specifically predicted, and some loss of predictability should be evident in every increase in openness to experience and existential living. In the maladjusted person, behavior is predictable because it is rigidly patterned. If such a person has learned a pattern of hostile reaction to authority . . . and if because of this he denies or distorts any experience which should supply contradictory evidence, *then* his behavior is specifically predictable. . . . I am suggesting that as the individual approaches the optimum of complete functioning his behavior, though always lawful and determined, becomes more difficult to predict. (pp. 292–293)

The behavior is lawful, according to Rogers, because the fully functioning person will attempt to select the best path toward growth and the synchrony of inner and outer demands. But this choice, in any given situation, cannot be known in advance, and that is why it is misleading to think of the person in anything but relational terms. Our concept of psychological complexity tries to avoid static definitions by viewing the person in terms of the dialectical process of integrating and differentiating self and environment. As Kegan (1982) observes, the person is "an ever progressive motion engaged in giving itself a new form." Here, in contrast to traditional approaches that see the person as a result of this process, the focus is placed not on what a person does, but the doing that a person is. Such an approach distinguishes the person from "self" (i.e., a more psychological, subject-oriented perspective) and from "role" (i.e., a more sociological, object-based perspective). It also facilitates the recognition of similarities in the experiential process that underlies unique instances of self-regulation across the life course. We turn now to examples of such self-regulation.

EXAMPLES OF COMPLEXITY IN LATER LIFE

The optimal developmental outcomes described in the previous section are predicated on the achievement of psychological complexity. Complexity describes dialectical polarities in the person that enable him or her to continually negotiate, and renegotiate, an optimally rewarding self-environment fit. On the most general level, these polarities involve structure *breaking* and *building* and problem *finding* and *solving*. A person with such potentialities is presumably better able to "instigate" development by flexibly working at the edges of order and novelty, without letting one or the other dominate. In other words, they can negotiate a self-environment fit that is integrated and differentiated or that attains an optimally arousing balance of order and novelty.

The terms structure breaking and problem finding characterize the move away from boredom because they provide what is needed to raise arousal and increase stimulation; structure building and problem solving describe the process of reducing arousal, a movement back to order that is needed when experiencing anxiety. An enjoyable and deeply involving conversation, for example, requires participants to express differing points of view; it also requires the coordination of such views for common understandings. When a conversation drags, a person with psychological complexity would presumably find a "problem" by working to stir things up, perhaps by expressing an opinion, offering new information, playing devil's advocate, and so on. If a conversation is losing its continuity, and participants are expressing widely divergent points of view, such a person would work to build bridges and shared understandings. The particular qualities that represent complexity would depend on the particular domain of activity, but in general it can be stated that structure-breaking/problem-finding phases start from an implicit sense of order that coincides with a push to take a risk, test a limit, be open to new challenges, and seek the edge of chaos. Conversely, a structure-building/problem-solving phase begins from a taken-for-granted sense of diversity or novelty, which coincides with a determination to find closure, be diligent, and patiently seek the edge of order.

To get a better sense of the phenomenology of the process, it is also useful to select another example and use the constructs of skill and challenge to consider how attention must be used during problem finding versus solving. Suppose that we are trying to understand how a student maintains optimal arousal while putting together a research paper for a history assignment. The need for problem finding starts from an implicit sense of order. Perhaps, the student has a good understanding of the topic at hand; he or she has read the assigned book, taken notes in class, and his or her high skills in the situation are more than adequate to complete the assignment. However, it may not be very interesting to do so. In terms of attention, having high skills means that the student does not have to expend much effort; understanding the topic is relatively automatic. Therefore, to convert boredom to optimal arousal and deeper involvement while doing the assignment, the challenge is to differentiate his or her understanding of the topic; it is to find new information and ideas that put his or her skills to the test. If the student takes the challenge seriously, such a situation sets up a good opportunity for flow: *His or her high skills provide a context of integration and "free" voluntary or selective attention to work on the challenge to differentiate.* At some point during this process, the intensity of his or her involvement should trigger a flow experience.

Conversely, problem solving begins from a context of differentiation. Let's say that the student became really involved in searching for new information and was enjoying the process. He or she gathered a variety of new sources, jotted down a number of new ideas, and worked for days on the challenge of differentiating her original understanding. Now, however, boredom with writing an easy paper is no longer his or her problem. The ground has shifted and he or she feels anxious when considering the task ahead; the challenge has become the need to integrate all the new information. In terms of attention, the same dynamics apply, but the focus is reversed. Now, the student's skills allow him or her to recognize multiple dimensions of the historical topic under study. The student does not have to expend much effort to consider all the different facets that he or she has become aware of over the past few days of research. If he or she takes this new challenge seriously, the situation also sets up a good opportunity for flow: His or her skills provide a context of differentiation that frees up voluntary or selective attention to work on the challenge of integration.

The key point in both cases is that automatic and voluntary modes work together to intensify the present moment. In the problem-finding situation (i.e., transforming boredom), voluntary effort was doing the work of differentiation and finding novelty, and immediate attention was providing a sense of integration and order (i.e., the students original grasp of the assignment). In the problem-solving scenario (i.e., transforming anxiety), voluntary effort was used to do the work of finding new connections that could order the new information (e.g., finding a new theme or thesis for the paper), while immediate attention provided a kaleidoscope of new facts. In both cases, skills (automatic attention) and challenges (voluntary attention) must work in a complementary fashion to negotiate optimal arousal. Flow occurs when both are engaged and deepening the intensity of the present moment beyond what either mode could accomplish on its own.

We turn now to illustrate more concretely how some individuals in later life manifest complexity. While there are a number of dialectical models of adult thinking that are conceptually similar to our notion of complexity, there is still a need for more specificity in regard to how

these dialectical thought processes are *actually manifested* by real persons. Recently, we had the opportunity to gather information relevant to this underexplored issue from a pool of interviews collected at the University of Chicago about creativity in later life (Csikszentmihalyi, 1996; Nakaumura & Csikszentmihalyi, 2003). The 100 respondents in this study were individuals who were successful on the cultural stage (13 had been awarded Nobel prizes, and the rest had achieved comparable renown), but their lives can be used as examples of success in a broader sense, as modeling optimal developmental trajectories. In the interviews, they talked about many factors related to their impressive accomplishments, but more important, their words gave excellent descriptions of how complexity is enacted in actual life situations. We draw from these interviews to make more concrete the theoretical ideas that have been presented thus far. These examples of later-life complexity, in turn, set the stage for a discussion of some connections that can be made to current developmental research.

Individuals who have been recognized for their eminent creativity may seem inappropriate for illustrating complexity. Creativity is often identified with one part of the developmental dialectic we have described, namely, the part associated with breaking structures and finding problems. It is true that creativity is most often identified with such differentiating responses; but that is probably because many creativity studies have set out to measure creativity in this way. However, creativity, which is sustained over a great length of time and results in eminent achievement, is not something that rests on divergent thinking alone; convergent, integrative thinking is equally important.

A few perspectives on creativity have recognized a bipolar psychological process that is characterized by the coordination of an affective immediacy and cognitive detachment to drive the integration and differentiation process.[3] For instance, Getzels (1975) has commented: "Despite the self-evident need for strenuous effort . . . creative thinking entails, at least in some degree, surrender to freely rising playfulness" (p. 332). Einstein's account of his creative process suggested a similar duality (Hadamard, 1954, p. 142): a phase of "associative" play and a more "laborious" phase requiring logical coherence. Gardner (1993, 1998) has recently suggested that a playful, childlike quality survives alongside the mature intellect of seminal creators (see also Simonton, 1984). Barron (1969) described creativity as a synchrony of immediacy and detachment in a chapter entitled "Cycles of Innocence and Experience." The title is drawn from the poetry of William Blake and contrasts "prelogical" thought that is concrete, spontaneous, and free of abstraction (i.e., innocence) with thought that utilizes "reason" and therefore has a logical structure (i.e., experience).

Why is creativity associated with both immediacy and detachment? Our model suggests that both uses of attention are needed to move toward the subjective rewards of structure breaking and structure building. Creativity is not just about what is gained by playfulness and spontaneity that is free from abstraction; it is also about what is gained from the voluntary and directed control of attention that takes effort. Each use of attention creates the conditions of the other; and both must work together to integrate and differentiate information. Barron's (1969) description of creativity said much the same thing, without the emphasis on subjective experience, "In the creative process there is an incessant dialectic and an essential tension between two seemingly opposed dispositional tendencies: the tendency toward structuring and integration and the tendency toward disruption of structure and diffusion. . . . The task is to avoid sacrificing one possibility to the other. We must be able to use discipline to gain greater freedom . . . tolerate diffusion, and even occasionally invite it, in order to achieve a more complex integration" (pp. 177–179).

Dimensions of Complexity

Next, we illustrate psychological complexity and optimal development by concentrating on seven polar dimensions. This number is arbitrary and could be expanded or reduced depending on the number of examples under discussion. These polarities, we believe, reveal the capacity for finding optimal experience through a process of differentiation and integration.

A central polarity that surfaced in the University of Chicago study of creativity[4] was the combination of

[3] Although the focus here, as in much of the chapter, is on psychological processes, creativity cannot be reduced to this level.

[4] Quotations not otherwise attributed are taken from interviews the authors and other members of the University of Chicago research team collected in the course of a project entitled Creativity in Later Life, sponsored by the Spencer Foundation (Csikszentmihalyi, 1996).

agency and *communion,* that is, the drive toward both independence and interdependence (Bakan, 1966). This is often seen as an "androgynous" trait, in that it combines elements traditionally associated with both males and females. Why has androgyny been linked to positive developmental outcomes (Baumrind, 1989), as well as to eminent achievement (Spence & Helmreich, 1978)? Our perspective suggests that both characteristics play a role in negotiating optimal experience through structure changing and building; therefore, persons with a predominance of either attribute (i.e., a highly sex-typed individual) are at a disadvantage, at least in domains of activity where these qualities are especially important for competent performance.

One such domain is interpersonal relations or, more concretely, the act of communicating. Skills of communication are essential for playing one's role on the cultural stage, no matter what that role is. It is equally central to business management (Leavitt, Pondy, & Boje, 1989), the emotional well-being of families (Larson & Richards, 1994), and political leadership (Gardner, 1995; Kouzes & Posner, 1995).

For instance, students who cannot speak their mind to a teacher (agency) or listen to what that teacher has to say (communion) will not get the most out of the relationship, neither will the teacher. The teacher or student, therefore, who is capable of agency and communion in interpersonal communication—"speaking" as an individual and "listening" in a posture of openness to the other—would presumably be at an advantage for learning from such communication and for experiencing optimal rewards in the process. Charles Cooley (1961), though not discussing androgyny or optimal experience, said much the same thing about the optimally healthy person. After suggesting that males were, in general, less socially impressible and more inclined to an aggressive, solitary frame of mind than females, he commented: "So long as a character is open and capable of growth it retains . . . impressibility, which is not weakness unless it swamps the assimilating and organizing faculty. I know men whose character is proof of stable and aggressive character who have an almost feminine sensitiveness regarding their seeming to others. Indeed, if one sees a man whose attitude toward others is always assertive, never receptive, he may be confident that man will never go far, because he will never learn much. In character, as in every phase of life, health requires a just union of stability with plasticity" (p. 828).

In our interviews with persons who had successfully negotiated adult roles, the combination of agency and communion was often evident. For instance, the path-breaking historian John Hope Franklin told about a memorable teaching experience that involved taking a graduate seminar to North Carolina to study the Reconstruction period. The class was exploring the idea advanced by a book claiming that segregation, and the Jim Crow laws of the 1880 to 1890s, were relatively new and therefore not "sanctified by age." When asking one of the students how he was progressing, Franklin recalled:

> His eyes were just sparkling. . . . He had found practices, as well as laws, segregating blacks and whites from much earlier. . . . And so he was saying that [the author's] thesis was collapsing. That was an overstatement to be sure. He was overly enthusiastic, but he was excited, and I got excited about a finding like that . . . of course, [the author] had made some exceptions . . . and this [the student's findings] fell, in part, in the excepted category. But it doesn't detract from the fact that he was excited. And I was excited because he was excited, you see?

In the anecdote, Franklin reveals subtle and complex social skills. He listens to his student with an attitude of acceptance and shared enthusiasm, without, for the moment, judging or correcting his student's overly enthusiastic response. By being unobtrusive, receptive, and patient—in other words, by manifesting some of the key qualities of communion—Franklin was facilitating his student's agency and joyful discovery. Although aware that the student was overly enthusiastic, and somewhat in error about the facts, Franklin decided that the joyful moment was better left alone because the student would need to draw on that excitement to complete the hard work that lay ahead. Franklin continued:

> Those students who will do the long haul are always willing to put the time and attention to the solution that the problem requires; one has to continue to be patient. . . . And that means that the student can't fudge or cheat or stretch his materials. He's got to stick with what the findings are. In my teaching I always give examples of that sort of thing among reputable historians. Not that I'm trying to debunk or anything like that, but I will point to a passage of widely and highly respected work and indicate to them just the way in which this particular historian misrepresented, and in some instances, prevaricated about the facts. I go back and show them what the facts were. Those are things I think are important.

Thus, the student's excitement stands, for the moment, but it will not stand in the way of the facts. Eventually, through more assertive episodes of instruction, Franklin demands that students coordinate their affectively charged insights with the careful work that distinguishes the scholar. In this way, Franklin balances communion and agency: Sometimes he listens to students to support their individuality, but at other times he speaks from a position of authority so that students must adopt a mode of communion and listen to him. Given his complex teaching style, it is not surprising that Franklin said of his over 50 years of teaching that it is "the thing that I like most of all."[5]

A second polarity that emerged from the interviews involved the productive tension in work between *passionate investment* and *detached objectivity.* One of the best examples of this combination emerged from an interview with another leading historian, Natalie Davis. Her awareness of this dialectical tension in her working style was unusually clear:

> Well, there're two different things—they overlap. One is this intense interest in finding out what was going on in the past. . . . I like to take mysteries to solve and I'm just very, very intrigued. . . . There is a kind of a rush of affect about it that I think is even more than curiosity. . . . I often say that I love what I'm doing and I love to write. . . . It's the curiosity part that pushes me to think about ways of finding out about something that I thought, or previous people thought, or people could not find out about, or ways of looking at a subject in ways that had never been looked at before. That's what keeps me running back and forth to the library and just thinking and thinking and thinking.

Equally as important as affect, however, is a mode of *detachment* that allows the person to make sure that the enthusiasm fits reality:

> It is very important to find a way to be detached from what you write . . . to let you work out the criticism. You can't be so identified with your work that you can't accept criticism and response. . . . The side of me that is more . . . detached tries to let the situation that I'm writing about, and its complexities . . . just be. The danger of too much affect is not only that the self gets too involved in it where we can't take criticism . . . but also that there's too much restructuring of the people around your own investment.

When asked about how these modes fit together, she elaborated:

> It is not as difficult now to be of several minds when I'm writing something: the side that's absolutely carried away, floating along with the project, and the side that's also detached and looking at myself. . . . They fit together. I don't feel it's one phase or the other. . . . It's immense curiosity in the beginning . . . you find all this stuff and then you begin to shape it. . . . The movement between identification, affect on one end, and detachment on the other, it has always got to be. And I feel this is present from the beginning, this kind of vacillation . . . the positioning of myself with different vantage points.

These passages provide a compelling illustration of complexity in action. Davis's passion and curiosity invite differentiation and save her work from tedium and rigidity; her detachment, in contrast, begins the process of criticism and the shaping of the multiple pieces into an organization that is not characterized by premature closure. In Davis's words, moments of synchrony between these two modes achieve a *multiple vision,* or being of "two minds" at once. Having these two vantage points prevents the work from being either conventional or idiosyncratic and allows it to develop and to grow.

A third polarity is related to the previous one, and can be described as the combination of *divergent* and *convergent* thinking. Convergent thinking involves the ability to find commonalities in varied information; it is a rational, problem-solving orientation representative of the intelligence that is often measured by IQ tests. Convergent thinkers have, so to speak, internalized the social mind; their thoughts usually can be predicted from knowing what others have thought. In contrast, divergent thinking is oriented toward individuality and problem finding. It involves fluency, or the ability to generate many ideas, explore multiple perspectives, make unusual associations, and so on (Guil-

[5] We have more to say later in the chapter about this interpersonal dynamic, and about how qualities such as agency and communion in children may be nurtured in family interaction. For instance, a mother's communion has often acted as a buffer for the father's agency, and vice versa. This traditional, sex-typed alliance is but one "solution" for creating a family context that spares children the fate of growing up in a home that overemphasizes one or the other quality and thus forces children into *one pattern of response.* We return to this observation when considering how early experience in the family may have consequences for attaining complexity in later life. For now, we point out that parents with androgynous parenting styles have reported *more enjoyment in parenting* (Lamb, 1982).

ford, 1967; Runco, 1991). This ability has been thought to be synonymous with creative thinking.

Divergent thinking, however, is not much use without convergent thinking as a counterbalance, and vice versa. This point came across in the remarks of another eminent scholar, the historian William McNeill. He described the starting point for his work as a process that led to "finding one's bent." Once an idea appeared in his mind, he found that it would spontaneously "crop up" in many different contexts, including some where he did not expect to find it. At some point in this divergent, differentiating process, however, a more convergent frame of mind was needed to gauge how the idea fit with reality. The later mode helped to bring closure and required more meticulous work, self-criticism, and intellectual integrity. The following quotation discusses this coordination of divergence (openness) and convergence (closure):

> I've looked at myself and my colleagues and thought about what it is that makes some people able to get things done, write books, write articles, complete tasks, and someone else of equal intelligence, perhaps of superior intelligence, never quite gets things done—he wastes time, he throws his time away, deadlines go past and still he isn't done. I think the most important discrimination involves two things. One is the capacity to focus attention—called attention span in small children—which varies enormously. There are people who are always looking for an interruption and run off like that [snaps fingers] given the possible chance. You have to have tunnel vision. . . . The other thing is that you can handle the hypercriticism. . . . I know some of my colleagues who had extremely powerful and original minds, but who looked at what they had written and always said "it's not good enough." That is hypercriticism and they're really frozen by their own critical capacity. There is a nice balance—surely you want to be critical of what you've done, rewrite it, think it through carefully, not splash it on to a page and say that's it. But too much criticism can be self-destructive, and too much openness can be self-destructive. You have to have a balance, a certain openness up to a certain point, and then get it done, and be willing when it comes time to do it, to say, . . . "I'm going to lock on this task now, it's time to do it." . . . [It is] closing things off at the right time, and not letting your critical faculty get so acute, so sharp that you can't get anything done. Both extremes I've seen act destructively upon . . . achievement. . . . They can be obstructive, perhaps, not destructive, but obstructive. . . . I think if you just study people around you reflecting on those who do and those who don't accomplish things they want to, these are the two pitfalls [too open, or too closed] that I've become aware of, things that obstructed very competent minds from achieving that which they wished to do.

A fourth polarity is again related to the previous two. Similar to the polarities of attachment/detachment and divergent/convergent thinking is the coordination of *playfulness* and *discipline*. The sociologist David Reisman, for instance, succinctly described such a synthesis in his comment that he "wanted at the same time to be irresponsible and responsible." The sculptor Nina Holton articulated in more detail the need for a sense of play and work to permeate the creative process:

> Tell anybody you're a sculptor and they'll say "Oh, how exciting, how wonderful." And I tend to say "What's so wonderful?" I mean, it's like being a mason. Or being a carpenter, half the time. But they don't wish to hear that because they really only imagine the first part, the exciting part. But, as Kruschev once said, that doesn't fry pancakes, you see. That germ of an idea does not make a sculpture which stands up. It just sits there. So, the next stage, of course, is the hard work. Can you really translate it into a piece of sculpture? Or will it be a wild thing which only seemed exciting while you were sitting in the studio alone? Will it look like something? Can you actually do it physically? Can you, personally, do it physically? What do you have by way of materials? So, the second part is a lot of hard work. And sculpture is that, you see. It is the combination of wonderful wild ideas and then a lot of hard work.

A third instance of this polarity was expressed by Jacob Rabinow, one of the most prolific inventors in the world. When working on a project that required more discipline than playful intuition, he would use a mental "trick" to slow himself down:

> Yeah, there's a trick I pull for this. When I have a job to do like that, where you have to do something that takes a lot of effort, slowly, I pretend I'm in jail. Don't laugh. And if I'm in jail, time is of no consequence. In other words, if it takes a week to cut this, it'll take a week. What else have I got to do? I'm going to be here for 20 years. . . . See? This is a kind of mental trick. Because otherwise you say, "My God, it's not working," and then you make mistakes. But the other way, you say time is of absolutely no consequence. People start saying how much will it cost me in time? If I work with somebody else it's 50 bucks an hour, a hundred dollars an hour. Nonsense. You just forget everything except that it's got to be built. And I have no trouble doing this. I work fast, normally. But if something

> will take a day gluing and then next day I glue the other side—it'll take 2 days—it doesn't bother me at all.

A fifth polarity that is less obviously related to the preceding ones is the coordination of *extroversion* and *introversion.* It is not uncommon that particular individuals prefer to be either at the center of action or at a spot along the periphery that allows them to observe what is going on. Generally, people tend to be either on one or the other side of this dimension; in fact, whether one is extroverted or introverted is held to be one of the basic and most enduring traits of personality (Costa & McCrae, 1980; McCrae & Costa, 1984). Complex persons, alternatively, seem to enjoy both the company of other people or solitude, depending on the demands of the moment. The physicist and writer Freeman Dyson, for instance, pointed to the door of his office and said:

> Science is a very gregarious business. It is essentially the difference between having this door open and having it shut. When I am doing science I have the door open. I mean, that is kind of symbolic, but it is true. You want to be, all the time, talking with people. Up to a point you welcome being interrupted because it is only by interacting with other people that you get anything interesting done. It is essentially a communal enterprise. . . . There are new things happening all the time and you should keep abreast and you keep yourself aware of what is going on. You must be constantly talking. But, of course, writing is different. When I am writing I have the door shut, and even then too much sound comes through, so, very often when I am writing I go and hide in the library where nobody knows where I am. It is a solitary game. So, I suppose that is the main difference. But, then, afterwards, of course the feedback is very strong . . . and you get a tremendous enrichment of contacts as a result. Lots and lots of people write me letters simply because I have written books which address a general public, so I get into touch with a much wider circle of friends. So it's broadened my horizons very much. But that is only after the writing is finished and not while it is going on.

In this comment, contact with people—talking, listening—is identified with keeping abreast of new things and different points of view. While interaction is a process of letting in information, closing the door for solitude is a process of limiting information. The door, so to speak, acts as a boundary between self and other much as intellectual detachment creates "distance" from spontaneous action so that feedback can be integrated. Others have noted that social interaction is a dialectical process between forces driving people together and apart, and either excessive openness or closedness has detrimental effects on relationships and personal growth (Altman, 1975; Altman, Vinsel, & Brown, 1981). An excessive orientation toward extroversion or toward introversion reduces our flexibility to negotiate a rewarding self-environment fit; it makes us more predictable, less sensitive to the moment, and therefore less complex in response to the variable needs of the situation. The introvert may forfeit the opportunity to grow because of lack of stimulation, and the extrovert because he or she does not take time out to reflect on experience.

The following quote from Piaget (1952) fits well with Dyson's description of the dialectic of contact and solitude:

> It is true that I am sociable and like to teach or to take part in meetings of all kinds, but I feel a compelling need for solitude and contact with nature. After mornings spent with others, I begin each afternoon with a walk during which I quietly collect my thoughts and coordinate them, after which I return to the desk at my home in the country. . . . [I]t is this dissociation between myself as a social being and as a 'man of nature' (in whom Dionysian excitement ends in intellectual activity) which has enabled me to surmount a permanent fund of anxiety and transform it into a need for working. (p. 55)

A sixth polarity might be described in terms of the interconnection between periods of *energy* and *quietude.* As one might expect, many of those interviewed for the study worked long hours with great concentration and intensity; however, this did not mean that they were slavishly tied to their work. On the contrary, it was not uncommon to come away from interviews with the impression of persons who were unhurried and at peace with themselves. It is especially startling to hear people with a lifetime of exceptional accomplishments to their credit describe themselves as fundamentally lazy. Only a self-imposed daily discipline, they say, kept them from giving in to the lackadaisical side of their nature.

Several told stories that helped to explain these apparently contradictory traits, stories that portrayed a harmonious interweaving of activity and rest. For instance, the economist Kenneth Boulding described working in beautiful, natural settings by "writing" with a tape recorder while looking at a mountain stream. And there were numerous stories of intense periods of work interspersed with naps, walks, bike rides, gardening, chopping wood, and other diversions that had more than

a restorative relation to work. The important theme that emerged linking these diverse anecdotes was that the energy of these persons was not controlled entirely by external schedules. Rather, they instinctively knew when to focus their attention and when to relax it; several commented that they had "mastered their own time." They considered the rhythm of activity and idleness to be important for the success of their work, and they learned such strategies from trial and error. The Canadian novelist Robertson Davies gave the following entertaining example:

> Well, you know, that leads me to something which I think has been very important in my life, and it sounds foolish and rather trivial. But I've always insisted on having a nap after lunch, and I inherited this from my father. One time I said to him, "You know, you've done awfully well in the world. You came to Canada as an immigrant boy without anything and you have done very well. What do you attribute it to?" And he said, "Well, what drove me on to be my own boss was that the thing that I wanted most was to be able to have a nap every day after lunch." And I thought, "What an extraordinary impulse to drive a man on!" But it did, and he always had a twenty-minute sleep after lunch. And I'm the same. And I think it is very important. If you will not permit yourself to be driven and flogged through life, you'll probably enjoy it more.

Finally, complexity was manifested by attitudes toward work that were at once *iconoclastic* and *traditional,* oriented toward blazing new trails while preserving the integrity of their respective domains of action. Contrary to the modern prejudice that holds that old ideas are probably wrong, and that anything new must be better than whatever is old, these individuals understood that ideas and practices that have been passed down through the generations must have had some advantages or they would not have been preserved, whereas novelties have not yet stood the test of time.

Without question, a strong and independent ego characterized many of those we interviewed; yet so did humbleness and a clear awareness that in their work they "stood on the shoulders of giants," and that their achievements were made possible only by the tradition in which they were trained. Confidence often fed into an aggressive, iconoclastic disposition; for instance, the Nobel-prize winning economist George Stigler stated:

> I'd say one of the most common failures of able people is a lack of nerve. And they'll play safe games. They'll take whatever the literature's doing and add a little bit to it. . . . So there's a safe game to play. In innovation, you have to play a less safe game, if it's going to be interesting. It's not predictable that it'll go well.

But innovation for its own sake does not make sense, except in relation to the tradition of thought that provides the background against which novelty can be recognized. The artist Eva Zeisel produces ceramics that have been recognized by the Museum of Modern Art in New York as masterpieces of contemporary design, yet she feels rooted to the artistic folk tradition in which she grew up as a young girl in the early decades of the century. She shows a keen awareness of the interplay between innovation and tradition in the following excerpt:

> This idea to create something different is not my aim, and shouldn't be anybody's aim. Because, first of all, if you are a designer or a playful person in any of these crafts, you have to be able to function a long life, and you can't always try to be different. I mean different from different from different . . . to be different is a negative motive, and no creative thought or created thing grows out of a negative impulse. A negative impulse is always frustrating. And to be different means not like this and not like that. And the "not like"—that's why postmodernism, with the prefix of "post," couldn't work. No negative impulse can work, can produce any happy creation. Only a positive one.

Dialectical Thinking and Optimal Experience

The concepts of agency, passion, divergent thinking, playfulness, extroversion, iconoclasm, and energy share common features, as do communion, detachment, convergent thinking, discipline, introversion, tradition, and quietude. This, of course, is partly due to the selective focus that was brought to bear on the interviews; in other words, to some extent we found in the interviews what we were looking to find. But there must be more to these polarities; countless related ones have surfaced in many fields of study and in different religions, mythologies, and philosophies in the East and West. They are present in the Buddhist philosophy associating the optimal experience of Nirvana with the middle path between the so-called yang qualities of the male (e.g., dominance, activity, aggression) and the yin qualities of the female (e.g., passivity, receptivity, yielding; Kuo, 1976). Notions of dialectical opposition are also woven into the fabric of Western thought from early philosophers such as Anaximander and Heraclitus, through Aristotle and Plato, and continuing through Marx, Hegel, and others

(e.g., Adler, 1927; Rychlak, 1976). Such oppositions have also characterized some of the most prominent theories of human development, from Freud's notions of the ego mediating demands from the id and superego to Piaget's dialectical model that we discussed earlier in some detail (see also Lerner, 2002; Riegel, 1973).

The emergence of related dialectical themes from so many different time periods and cultures provides a compelling reason for theorists of human development to continue to puzzle over their meanings. Our interpretation of the polarities culled from the interviews emphasizes the phenomenological perspective that we have tried to develop in this chapter. It looks across all of the complementary pairs and asks: How is each related to the optimal experience associated with structure changing and building, and thus with moving beyond boredom and anxiety? We see commonalities among traits like passion, playfulness, extroversion, energy, and among the corresponding traits of detachment, discipline, introversion, and quietude. The former group tends to manifest a style of attention that is immediate and subjective; a style more associated with assimilative modes and a lack of separation between subject and object. The latter group suggests attention that is voluntary and objective, or a style that is more in line with accommodative modes. As we have argued, both uses of attention must work in a complementary fashion, sometimes working together to raise arousal and find a new challenge (i.e., differentiation), and sometimes working to lower arousal and build new skills (i.e., integration). In a context of playful exploration, for example, sometimes discipline must be used to recognize a new challenge and increase novelty; and sometimes it must be used to build new skills and increase order. Having both traits, therefore, provides a person with a self-regulative capacity to find and sustain optimal experience.

A phenomenological interpretation such as the one earlier cannot provide a comprehensive explanation for the existence of these various polarities, but it does provide an often-overlooked entry point for theorists and researchers who are interested in exploring dialectical themes. If one of the most important goals of development is a person's flexibility in adjusting to new situations (Kelly, 1955; Lerner, 1984), then the material from the interviews attests to potential for human flexibility in later life. But more important, it helps to explain how experience is optimized by avoiding the boredom of overly integrated states and the anxiety of overly differentiated ones. The polarities are instructive for understanding the process of finding challenges and building skills, and thus also for understanding the temporary equilibrium of challenges and skills that trigger flow experiences.

Why, for instance, has John Hope Franklin enjoyed teaching so much? How are the qualities of agency and communion related to his enjoyment of teaching? A phenomenological interpretation suggests that his complex teaching style was *self-correcting,* thus allowing him to avoid the negative experiences associated with being too receptive to students or too directive toward them. The former problem plagues those who try to accommodate every encounter with the other; it transforms interaction into an activity that is experienced as overwhelming, lacking in control, and thus inviting anxiety. Conversely, consistently ignoring the interests and points of view of others, never changing one's behavior in response to the encounter, makes interaction monotonous and boring.

Both extremes are avoided in Franklin's teaching style because he is capable, as the changing situation warrants, of shifting between the qualities of agency and communion. In the example cited earlier, he did not hesitate to be emphatic in response to his student's overly enthusiastic "discovery." He listened attentively to the student, letting him take the lead. Yet, based on knowledge gained through this episode, Franklin will be better able to find the right time to insist that the student check his facts. In this way, his agency as a teacher is supported by insights gained through communion. And the same can be stated in reverse: Franklin's responsiveness to his student was initially set up by taking his class to North Carolina and assigning the study of the Reconstruction period. In this way, the polarity of agency and communion helped to negotiate the most rewarding fit between teacher and student and presumably made this experience of teaching more enjoyable.

A similar reasoning would hold for the other polarities. The process of work (e.g., writing, research, sculpting) was presumably more rewarding for those who described various combinations of playfulness with discipline, passion with detachment, and so on, because of the greater flexibility in forging a self-environment fit. For instance, Davis's notion of observing immediacy (i.e., being of two minds at once) allowed her to recognize problems as they arose in the spontaneous course of working. Curiosity elicited a need for detachment to shape the material generated in this exploratory mode; this feedback from active engagement led to the discovery of problems that needed to be recognized and solved. Borrowing a phrase from the philosopher and theologian Paul Tillich (Gilkey, 1990), it might be said of Davis and

others who expressed similar dialectical themes that their *objectivity was based on intense subjectivity.* And the converse of this statement is likewise relevant: *their subjectivity was based on intense objectivity.* In other words, it was through recognizing and solving problems (e.g., through critical revision of written work, "tricking" themselves into more patient modes of work, closing the door for solitude) that they constructed the skills and sense of confidence that, in turn, supported modes of further exploration.

In summary, the polarities described earlier instigate a person's development while optimizing his or her experiences; each describes, albeit in different ways and in regard to different activities, a flexibility in negotiating a fit between self and environment (for further discussion of goodness-of-fit models see Lerner, 1984; Thomas & Chess, 1977).[6] One extreme of each polarity tends to describe the more unselfconscious process of assimilation (i.e., using existing schemas or skills to make processing more automatic and efficient), and the other half describes the more painstaking process of accommodation (i.e., using selective effort to change one's skills). A person who is able to coordinate both processes can (a) effectively counterbalance differentiation with integration, and vice versa; (b) avoid the loss of psychic energy associated with persistent boredom or anxiety; and (c) better direct and invest attention in optimally arousing and growth-enhancing activities.

Complexity and Wisdom

Of the roles available in the cultural repertoire for an older person, perhaps the one that best captures the optimal developmental outcome is the notion of *wisdom.* We now examine more closely what this concept entails and how it is related to the dynamics of complexity developed in the previous section.

Wisdom as a quality of the long-lived person in a community is a theme that repeatedly occurs in Eastern and Western cultures. Such persons are thought to have a special insight that enables them to make or advise the "best" course of action in a given set of circumstances. The transmission of this idea across countless generations and societies argues for its validity on evolutionary grounds. Just as biological information that helps survival is transmitted from one generation to the next, it is reasonable to believe that the cultural transmission of this concept, with its rich web of meaning, is important for similar reasons (Csikszentmihalyi & Nakamura, in press; Csikszentmihalyi & Rathunde, 1990).

There are many names by which a wise person is known: mentor, sage, counselor, elder, teacher, and so on. All of them connote one attribute that we believe is central: *an ability to select, or help others select, a course of action that is optimal for survival and growth, based on insight in regard to relevant life processes.* The wise person, in the broadest sense, is able to give good counsel about solving fundamental problems of living (Baltes & Smith, 1990). Such counsel, in both the East and the West, has historically been linked to reflection on life experiences; through reflecting on the successes and failures in a long life, the wise person develops a *meta-awareness of the process of the self-environment relationship* (Rathunde, 1995). A wise teacher, for instance, has been described as unobtrusive, discrete, and patient, qualities that facilitate the joyful self-discovery of younger individuals by allowing them to make mistakes that further their growth (Chinen, 1984; Clayton & Birren, 1980). Such decisions of noninterference (or interference) are based on a superior awareness of complex interpersonal processes, as apparently was the case with the historian John Hope Franklin's interaction with his student.

A central characteristic of wisdom, mentioned earlier, is the ability to transcend narrow, specialized thinking and to see events in their broader contexts. John Reed, former CEO of Citicorp and one of the most astute and successful captains of finance, describes his ways of approaching problems:

> I have always been a person who had to understand the context within which I operate. Some people are perfectly capable of coming in and saying, "Gee, the cars are going out with bent fenders, what do I have to do to get rid of that?" and they'll just figure out what machine is bending the fender. It'll never interest them who designed the car, who is going to own it, or any of the other externalities. I'm not that way at all. I'll work a problem, but in order for me to identify with it, I have to have a context. So I get curious: Who is going to drive the car? Why was it designed this way? Does the bending of the fender have to do with the design? That is the pattern of my thought process—I have always tried to put it into a context.

It is important to note that Reed does not claim that his holistic, contextualized approach makes him a more

[6] Lerner (1984), in addition, contains an in-depth, multidisciplinary look at human plasticity, its foundation in evolutionary processes, and the developmental importance of flexible self-regulation.

successful businessman; in fact, he provides examples of very effective CEOs whose tunnel vision expresses only convergent thinking. But he claims that personally he enjoys the more complex contextual approach and could not think otherwise. (Of course, to continue in his role, Reed had to satisfy the objective rules expected of a person in his position, and in fact, during the last 4 years of his tenure, the value of his company's stock appreciated by over 400%.)

Contemporary research on wisdom suggests useful standards for the process of optimal human development. Sternberg (1990) describes wisdom, in contrast to intelligence and creativity, in the following way: "The wise person seeks to understand the meaning and limitations of this [existing] knowledge. The intelligent person seeks to make optimal use of this knowledge. The creative person, though, wishes to be freed from this knowledge" (p. 153). Using the analogy of three branches of government, Sternberg associates wisdom with a *judicial* function of mental self-government, intelligence with an *executive* function, and creativity with a *legislative* function. Such a tripartite schema is consistent with what has been said thus far about complex systems. A creative/legislative response represents the movement toward differentiation, or the attempt to go beyond what is known and to generate novelty. An intelligent/executive response, in contrast, can be thought of as the movement toward integration, in that it seeks consistency based on establishing clear and predictable parameters for action. Finally, a wise/judicial response expresses a contextual evaluation of the process of knowing and therefore an understanding of the strengths and limitations of legislative/creative and executive/intelligent responses.

Attaining wisdom allows the person to combine these self-governing functions in a way that is optimal for development. A creative response may generate movement toward change, but for this reason it may not be useful in situations that call for decisive action. An intelligent response may reinforce consistency, but would be inadequate for generating new ideas. A wise response would reflect an awareness of how each function compensated for the limitations of the other: Intelligence would be rigid if not informed by creativity, and creativity would lead to chaos if not reined in by the focus of intelligence. In the final analysis, it is wisdom that takes into account specific self-environment circumstances, evaluates them in terms of process, and thus gains oversight as to when creative responses must give way to more intelligent ones, and vice versa. A wise response would therefore reflect what Rogers called the predictable unpredictability of the fully functioning person: whether a particular response (i.e., seeking change or stability) is appropriate may not be known in advance; yet, the action that best fits the situation at hand will reliably be chosen, and such actions may reflect either continuity or discontinuity (see also Lerner & Busch-Rossnagel, 1981). Thus, wisdom is yet another way to describe the flexibility of the complex person who finds the best path toward growth and optimal experience (Rathunde, 1995).

Recently, a number of researchers investigating adult development and *postformal cognition* have similarly depicted the flexibility and the dialectic performance of so-called wise persons (Brent & Watson, 1980; Clayton & Birren, 1980; Holliday & Chandler, 1986; Kramer, 1983; Labouvie-Vief, 1980, 1982; Pascual-Leone, 1990; Sinnott, 1984). Labouvie-Vief (1990), for instance, notes the dualities described by Piaget (e.g., assimilation and accommodation), by Freud (e.g., primary and secondary processes), by James (e.g., the spontaneous "I" and the conceptual "me"), and even by contemporary neuropsychologists who contrast two different anatomically and chemically based processing systems (Tucker & Williamson, 1984). She utilizes the historical distinction between *mythos* and *logos* to label these dual modes. Mythos signifies *a close identification of the self with the object of thought* (i.e., a mode of subjectivity where knower and known are indivisible); logos signifies the use of reason, or *the ability of thought to separate subject and object,* to logically analyze a relationship.

Labouvie-Vief (1990) conceives wisdom as *reconnecting* these two important ways of relating to the world. Traditionally, they are often set against each other and dichotomized. Thus, mythos has come to be identified with emotion, the body, subjectivity, and other so-called feminine characteristics; logos, in contrast, because of its correspondence to rational thought, the mind, objectivity, and so on, has been perceived as more masculine.[7] This is also the dichotomy that underlies the gender differentiation of children in our culture (Gilligan, 1982; Gilligan, Lyons, & Hanmer, 1990). If

[7] It is worth noting that this alignment of objectivity and subjectivity with masculine and feminine characteristics is best suited to instrumental domains, where it is men who have traditionally had to learn to accommodate to reality demands; this alignment would often be reversed in expressive, social activities, where women have had to assume more objectivity.

wisdom reconnects these modes by looking beyond their illusory polarization, then such a description comes close to the meaning of complexity.

Others have identified related polarities that are characteristic of wisdom. Meacham (1983) has described a balance of *mature faith* and *cautiousness;* Erikson, Erikson, and Kivnick (1986) discuss the same idea as the blending of *trust* and *skepticism.* Trust and faith allow one to engage activities wholeheartedly and with spontaneity that leads to new ideas and connections; skepticism and caution, in contrast, slow down this movement to integrate the emergent connections in a way that best cuts with the grain of reality. The dissociation of these qualities not only describes a condition that has negative consequences for individuals, it also sheds light on unwise practices in a larger social system. For instance, Tillich's project of synthesizing objectivity and subjectivity implied a cultural critique. He suggested that modern science, by overemphasizing the scientist's need to be detached to know the object (i.e., by ignoring the reverse fact that subjectivity provides the basis for objectivity), has primarily identified itself with the objective-detachment pole of the dialectic, resulting in the disassociation of technical knowledge from *human* concerns and interests. This, in turn, has resulted in the many current problems and dangers associated with the undirected use of technology.

Wisdom is a construct that depicts the fullest expression of what has been described here as psychological complexity. The wise person develops, to a greater extent than most, the capacity to move toward optimal experiences by understanding the dynamic relation of self and environment. This is perhaps why wisdom is often discussed in the context of states of transcendence or ecstasy. The wise person, presumably as the result of reflection on a long and rich life, understands the need for integration to avoid anxiety and disorder, and the need for differentiation to avoid boredom and stagnation. Because of their ability to coordinate subjective and objective modes (Labouvie-Vief, 1990, 1994), self-regulating the process of integration and differentiation becomes more feasible. Such persons are best prepared to turn any situation to their advantage by consistently moving toward synchrony, but in an unpredictable fashion that depends specifically on time, place, and context.

Descriptions of the wise person, like descriptions of any complex system, will of necessity be paradoxical, and are best expressed through dialectical notions that emphasize process, opposition, and interaction in specific circumstances. Thus, developmental research aimed at better understanding such instigative characteristics of persons will undoubtedly prove to be difficult. Nevertheless, productive research is already proceeding under the aegis of wisdom as a potential adult outcome (e.g., Baltes & Smith, 1990). A phenomenological interpretation of wisdom may add to this growing body of work. In addition to empirical studies, more hermeneutic studies of wisdom in various cultures and historical periods would also be useful.

In summary, this section attempted to illustrate more concretely some of the characteristics of psychological complexity, namely, qualities enabling a harmonious dialectic between differentiation and integration. Characteristics that make it possible to take an active role in creating one's environment and furthering development comprise only a part, perhaps only a small part, of the vast array of biological and cultural influences on the development of the person. Nevertheless, they comprise the part that is most human in human development. The capacity for lifelong learning and the relative lack of "hardwired" responses to the environment are perhaps *the* distinguishing characteristics of humans. Lerner (1984) reached the same conclusion, arguing that what is optimally developed in development is the style or self-regulative capacity to adapt to unforeseen contextual conditions (i.e., changing self to fit context or context to fit self). Although such instigative characteristics are probably related to genetic predispositions (e.g., aspects of temperament may influence modal levels of openness/withdrawal, ability to focus attention, and so on; see Thomas & Chess, 1977), they are also influenced by contexts of socialization, especially the family. Thus, a better understanding of how such characteristics may emerge through child development is a question central to understanding the development of the person.

THE FOUNDATIONS OF COMPLEXITY IN CHILD DEVELOPMENT

Having sketched our ideas about adult complexity in theoretical terms and through examples of desirable outcomes, we turn our attention to examining how the foundations of complexity might be established in child development. Although it is impossible to trace with precision the evolution of the outcomes we have discussed, or support a strong causal position on the link between early experience and these outcomes, the assumption

here is that the previous discussion will make it easier to identify processes in the early years that facilitate the full development of the person. Many of the presumed connections await further research and verification. To limit the focus of the discussion, we make three additional assumptions:

1. If complex outcomes are manifested by dialectical polarities, then contexts that socialize such outcomes will presumably have a dialectical character.
2. Of the many relationships that are important for child development, two undoubtedly are crucial: the parent-child relationship and the teacher-student relationship. We therefore limit our discussion to these two interactive contexts. Our discussion of parent-child interaction starts in adolescence and works its way back to early childhood and infancy. Our discussion of the school context is focused on the important transitional period of early adolescence, a time when mature patterns for self-regulation are beginning to form.
3. If there is a plausible link in the ontogenetic development of complexity from birth to old age, then it is reasonable to assume that human beings are prepared by evolution to (potentially) develop in such a way. Thus, we conclude the chapter by exploring the thought that complexity is a goal of human development rooted in our evolutionary history.

Guided by these limiting assumptions, this section explores the possible relationship between children's socialization and complex outcomes in adulthood. The approach taken is exploratory, with two intentions: to develop further the experience-based theoretical perspective in this chapter and to stimulate future research on these and related issues.

The Importance of Social Context

How is a foundation for later-life complexity established in childhood? We agree with Bronfenbrenner (1992) that mature self-regulation is in large part the legacy of past social experience: "It is true that individuals often can and do modify, select, reconstruct, and even create their environments. But this capacity emerges only to the extent that the person has been *enabled* to engage in self-directed action as a joint function not only of his biological endowment but also of the environment in which he or she developed. There is no one without the other" (pp. 223–224). As to what type of environment is optimal: "Extremes either of disorganization or rigidity in structure or function represent danger signs for psychological growth, with some intermediate degree of system flexibility constituting the optimal condition for human development" (p. 241). We would add that such system flexibility is important for the possible emergence of optimal experience.

Following Piaget, most research that has explored the constructive nature of thought has not so valued interpersonal processes. Theoretical work on social cognition, for instance, has focused on how internal constructions—*developed independently of contact with other people*—affect the perception and therefore the dynamics of social interaction (Kahlbaugh, 1993). Many of these theories, in addition, do not incorporate the dialectical insights of Piaget (Kuhn, 1978). Thus, few attempts have been made to theorize how thought, in general, develops out of dialectical interactions between self and other. Even less common is any attempt to view these interactions in light of how they affect ongoing experience.

In part, as a result of the slow assimilation of the Russian perspective on development represented by the work of Luria and Vygotsky, a greater emphasis is currently being placed on how the person develops in a sociocultural context, and how higher mental functions are "internalized" from social interaction (Bruner, 1990; Mead, 1934; Rogoff, 1990; Stern, 1985; Wertsch, 1979, 1985, 1991). The time is ripe for approaches that *link dialectical developmental principles to social interaction.* Toward this end, the thought of James Mark Baldwin (1906, 1908, 1911) provides an important historical context (Kahlbaugh, 1993) and critical insights for our attempt to link phenomenology to social processes.

Baldwin's thought is relevant to the concerns in this chapter for several reasons. His theory of "development" (i.e., progress in constructing "platforms" of organization) is dialectical and rests on syntheses of dualistic oppositions. Much of what has been said earlier in regard to Piaget also applies to Baldwin: Development proceeds through the interplay of a conservative, assimilating function that fits information to preexisting structures and a change-oriented accommodation function that reconstructs the subject due to opposition encountered in environment (Broughton & Freeman-Moir, 1982).

More important for our purposes are three differences between Baldwin and Piaget. First, Baldwin was

more attuned to the importance of subjective rewards associated with successful adaptation; he believed positive experiences induced repetition, and repetition led to the formation of habits. As did his colleagues John Dewey and William James, Baldwin (1906) talked at great length about *interest* as the motivating force of attention (pp. 41–44). Thus, his insights are more in line with our goal of providing a phenomenological rendering of assimilative and accommodative processes.

A second crucial difference is the way Baldwin conceptualized optimal adult development. Piaget emphasized logical thought in his final stage of formal operations and the capacity to formulate rational hypotheses about relationships in the world. In his highest stage, hyperlogic, Baldwin emphasized *an aesthetic appreciation of the world that transcends dualities.* His descriptions of this stage resemble contemporary theories on postformal operations and wisdom (Basseches, 1980; Kramer, 1983), and our earlier comments on complexity in later life: "The intuition of reality reached in aesthetic contemplation preserves all the meaning of fact or truth except its externality to experience, and all that of use or worth except its subjectivity in experience; thus essentially removing from the constitution of the real the opposition of inner and outer, subject and object" (Baldwin, 1911, p. 256).

The most important difference between Baldwin's and Piaget's models has to do with the role of social processes. For Piaget, the quality of the social environment could affect the speed with which children develop through various stages, not the quality of the stage itself, and social processes became more important as children developed more mature forms of thought. Social processes were more integral to Baldwin's account of development. He recognized the greater novelty associated with social interaction, and therefore its more important role as a source of resistance that promotes growth: "Persons remain, even after each vital experience with them, still the unreduced; and the individual's mass of surging psychic tendencies and dispositions comes up again and yet again to the task of appropriating them in the molds of habit and recognized fact" (1906, p. 61). Thus, one reason Baldwin located the development of the person more centrally in social interaction was because such encounters were the source of continual challenge and novelty and therefore a powerful stimulus to development.

It was through interaction that the assimilating and accommodating functions were stretched to the highest degree, and *these functions were developed from birth in coordination with a primary caretaker.* Through *imitation,* for instance, a child accommodates the other; but imitation is never "pure" in the sense of a replication because actions are infused with private meaning, and what is learned is always in relation to subjective experience. Similarly, when appropriating a word, one makes it one's own by filling it with personal intention (Bakhtin, 1981). In this way, accommodation is "creative" and not passive mimicking. Through a process of *ejecting* the self, the child assimilates the other on its own terms; when contradictions arise, the self is reconstructed. Thus, the dynamics of development are much like Piaget's, but relations with a primary caretaker are seen as essential to the dialectical growth of the self, and social dependency becomes essential for development to occur (e.g., Tobach, 1981; Tobach & Schneirla, 1968).

Interaction with a more powerful person (in relation to the child) will encourage accommodation; interaction with a less powerful person will favor assimilation. A mother might be thought of as "less powerful" when she is reactive to the wants and desires of the infant; in other words, when *she* accommodates, the child assimilates. A mother is "more powerful" when the child must accommodate, perhaps by imitating actions, reacting to verbal or physical stimulation, adjusting to schedules of feeding, and so on. One can see in this general dynamic how the dialectical growth of the self might proceed in a positive direction through the mutual give and take of mother and child, or how habits of unsuccessful assimilation or accommodation might develop through relations with an overly active or a chronically passive mother.

The common terms *love* and *discipline*[8] represent parenting behaviors that encourage complexity: When a parent appropriately mixes love with discipline, a child develops successful habits of assimilation and accommodation, thus making the coordination of these modes, and optimal experiences, more likely to occur. Over time, children socialized in homes that balance love with discipline develop a superior capacity to *self-regulate* their attention and respond to the environment in ways that promote optimal experience and growth. In other words, they are more likely to manifest the

[8] Too often the word *discipline* is equated with punishment. The word is a derivation of the Latin discipulus, meaning pupil. This meaning reflects the idea that discipline is about *training the mind and character through experience.* Insofar as punishment furthers such training or instruction, its meaning is consistent with discipline.

development-instigating characteristics that are associated with complexity.

There is a variety of ways parents might provide children with a healthy combination of love and discipline. One strategy is what we now think of as the traditional nuclear family. Fathers and mothers have historically created a well-rounded system through a division of labor: Fathers play the role of disciplinarian and mothers that of nurturer (Parsons & Bales, 1955). The manifestations of such traditional sex-role divisions are apparent in parental styles of interaction. For instance, fathers, due to their active styles, are more often a source of stimulation, whereas mothers are a source of arousal modulation or comfort (Field, 1985). In general, fathers have been less sensitive to a child's perspective, and thus they have constituted a source of external challenge for the child; mothers have been more willing to subordinate their attention in support of their children's interests.[9] Although contemporary families maintain less rigid boundaries between parental roles, one still can observe strong vestiges of these historical patterns (Larson & Richards, 1994).

The traditional solution, however, is but one of many possible ones. One or both parents, or a single parent, can adopt an *androgynous* role as a nurturer and disciplinarian. Arguably, such a style holds distinct advantages for the well-timed delivery of love and discipline, and thus for achieving a more satisfying parent-child relationship (i.e., a mother would not have to rely on "Wait until your father gets home" to provide discipline, and a father would not have to use the refrain "Go ask your mother" when asked for support). It is not hard to imagine several other ways that love and discipline can be effectively combined. A nurturant family, for instance, may enroll the child in a school that is intellectually and physically rigorous. Or a child with accomplished and demanding parents may be accommodated by an attentive caregiver or by other members of the extended family. The point is not to argue for a particular family organization (although some arrangements may be advantageous); rather, the claim is that *children who develop strong habits of assimilation and accommodation in some proximal context of socialization* are more likely to develop a mature ability to self-regulate experience as adults.

[9] If reacting to a "more powerful" father is associated with learning habits of accommodation, then the increasing absence of father involvement in modern homes could help to explain the apparent decline of social integration in many communities.

Parent-Child Interaction and the Growth of Complexity

The earlier hypotheses are used next to explore and integrate various perspectives on parenting over the course of child development. In the following selective review, we attempt to link parental love and discipline, or *support* and *challenge,* to three stages of child development: adolescence, early childhood, and infancy.

Parenting in Adolescence

Does a family still influence adolescent development? Do the qualities of love and discipline still matter, and in the ways discussed earlier? Even if interactions with parents were related to habits of self-regulation, it could be argued that patterns established in childhood would be relatively "fixed" by the teenage years; in Vygotskian (1978) terms, the "intermental" would have already become the "intramental." Furthermore, adolescents encounter a much wider social circle than young children and fall under the sway of peer influence. They have also wider unsupervised exposure to symbolic media (e.g., television, books, music, and film), as well as the effects of schooling. Despite all of the previously mentioned influences, however, a great deal of research suggests that parental qualities like love and discipline (referred to by various names in the literature) are still important for adolescent development (Damon, 1983; Irwin, 1987; Maccoby & Martin, 1983).

Diana Baumrind (1987, 1989) has associated the combination of "responsiveness" and "demandingness" (i.e., authoritative parenting) with optimal competence in adolescence, operationally defined as the androgynous combination of *agency* and *communion.* Cooper and her colleagues (Cooper, Grotevant, & Condon, 1983) found that the combination of *connection* and *individuality* in family interaction (i.e., listening and coordinating views, and expressing individual options) was related to adolescents' identity achievement and role-taking skills. Both of these outcomes demonstrate effective differentiating and integrating processes that are associated with psychological complexity: Identity achievement requires a period of *crisis* (i.e., the exploration of alternatives) and *commitment* (i.e., firm decisions after considering the alternatives; Marcia, 1966); role taking requires considering others' perspectives, and then integrating one's own (Cooper et al., 1983). Finally, Stuart

Hauser's (1991) research has revealed how supportive (*affective enabling*) and challenging (*cognitive enabling*) "moves" in family conversations were related to higher adolescent ego development; it also seems that higher stages of ego development are increasingly dialectical in character (Kegan, 1982; Loevinger, 1966).

Our own research with families and adolescents is consistent with the earlier findings, although it emphasizes experiential outcome measures. For instance, talented adolescents who perceived their family contexts as *supportive* and *challenging* reported more optimal experience and interest in their daily lives, especially while doing school activities; parents perceived by their sons and daughters as supportive and challenging reported more satisfaction in their relationships with their children and in their own lives (Csikszentmihalyi et al., 1993; Rathunde, 1996). A follow-up study of a representative national cross-section of approximately 700 teenagers replicated these findings with a more diverse sample: After adjusting for the adolescents' gender, grade (6th through 12th), ethnic background (African American, Asian, Latino, Caucasian), and parental education, adolescents from supportive and challenging families reported more optimal experience and interest in school (Rathunde, 2001a).

Why is a supportive and challenging family context associated with positive experiential outcomes? As we have argued earlier, two basic modes of attention must work in close synchrony to negotiate optimal arousal, flow, and the growth of knowledge: a passive-immediate mode of attention and an active-voluntary one (James, 1890). In Piaget's terms, these modes correspond to assimilation and accommodation, respectively. Separating these two ways of engaging the world disrupts optimal experience and learning and can lead to fooling or drudgery (Dewey, 1913, 1938), two short-term "solutions" to under- or overarousal. A family context that is supportive and challenging facilitates the interconnection of both uses of attention and is, therefore, more likely to be associated with adolescents ability to find optimal experience. A family environment is challenging when parents expect adolescents to take on more mature responsibilities, learn new age-appropriate skills, take risks that lead toward greater individuation, and so on. Thus, a challenging context is one wherein adolescents acquire the training effect of discipline; they "practice" reorganizing their attention, recognizing the views of others, and formulating plans of action that accommodate progressively new expectations and goals. When a parent creates a supportive environment by taking care of everyday necessities, listening in a nonjudgmental way, allowing the adolescent to explore interests, and so on, an adolescent can engage the world in a way that is less self-conscious, less constrained by the demands of reality, and more attuned to his or her own subjectivity and imagination. This theoretical reasoning is consistent with other perspectives in the field that stress the benefits of some combination of love and discipline in the family, but it is derived from our experiential approach.

There has been some empirical confirmation for these assertions. For example, we used the ESM to operationalize these two modes of attention (i.e., immediate involvement and a voluntary focus on goals) and collected information from adolescents about the levels of support and challenge they received in their families. In both cross-sectional and longitudinal studies, and with students from a variety of socioeconomic status (SES) and ethnic backgrounds, results consistently showed: (a) a relationship between the perception of high family support and adolescents' immediate moods and energy, and (b) a significant link between the perception of family challenge and adolescents' selective attention to important goals. Furthermore, not only did adolescents from families that *combined* high support with high challenge report more flow and interest in their learning activities, they invested more time in them, and developed their skills to a higher degree (Csikszentmihalyi et al., 1993; Rathunde, 1996, 2001a). Our interpretation of these results suggests that a supportive and challenging family, because it allows flexibility in the assimilation and accommodation dialectic, makes it easier for adolescents to negotiate a good person-environment fit, and such a fit is more likely to result in optimal arousal and experience.

Repeated experience in such families is likely to result in the formation of self-regulative habits (i.e., preliminary signs of psychological complexity) that facilitate turning boredom and anxiety into flow. In contrast, the same studies showed that adolescents from high support/low challenge families (i.e., permissive environments) were more invested in passive leisure (e.g., television viewing) and other modes of "fooling," and adolescents from low support/high challenge families (i.e., more authoritarian environments) spent a great deal of time on important school activities, but reported negative moods and more "drudgery" while doing them. These family contexts, in contrast to ones that provide strong support and challenge, may be reinforcing patterns of regulation that will increasingly prevent, rather

than enhance optimal experience. Future studies are needed to explore these possibilities.

Parenting in Childhood

If adolescent experience is tied to conditions in the home, despite the greater influence of friends, school, and the media, it is likely that the quality of younger children's experience is *even more closely tied to conditions at home.* Barbara Rogoff's (1990) research is especially relevant to this issue. She has studied parents and children in a variety of cultural settings, using a Vygotskian perspective that emphasizes the development of mind through interpersonal interaction. The primary theoretical concept in her approach is the support-challenge combination of *guided participation:* "Guided participation involves adults or children challenging, constraining, and supporting children in the process of posing and solving problems—through material arrangements of children's activities and responsibilities as well as through interpersonal communication, with children observing and participating at a comfortable but slightly challenging level" (p. 18).

The basic processes of guided participation are universal. In all cultural settings, parents and children must *bridge* to a mutual interpretation of a situation that allows *intersubjectivity,* or a common focus of attention and shared presuppositions (Rogoff, Mistry, Göncü, & Mosier, 1993). Thus, all parents use some measure of support and challenge: support to bolster children's attempts to master skills, and challenge to move children toward higher levels of mastery. Support and challenge must be skillfully proportioned by adults to help children avoid situations that are over- or underchallenging. For instance, support might be manifested by simplifying the structure of a task by breaking it down into subgoals, verbally relating new tasks to old ones, carefully following a child's gaze and attention, helping a child avoid frustrating obstacles, and so on. But as a child grows more skilled, the level of challenge could be raised by asking questions that seek more information, releasing some responsibility to the child, *not* intervening when children can be successful on their own, and so on.

A parent must carefully observe a child's cues to effectively guide participation: "Interactional cues—the timing of turns, nonverbal cues, and what each partner says or does not say—are central to the achievement of a challenging and supportive structure for learning that adjusts to the learner's changes in understanding" (Rogoff, 1990, p. 104). A child might explicitly ask for more or less help, or signals could be implicit, involving a look, a gesture, listlessness, or gaze aversion. A number of studies reveal sensitive adjustment in action. For instance, effective tutors hypothesized what was the best level for intervention, and then modified their hypotheses based on students' reactions (Wood & Middleton, 1975). Mothers assisting 6- and 9-year-old children on a classification task began by giving redundant verbal and nonverbal information; as the session continued, however, their use of redundancy decreased and only reappeared when children showed difficulty or hesitation in solving problems (Rogoff & Gardner, 1984). Finally, similar moment-to-moment dynamics were evident even at the university level when experts tutored students in the fields of chemistry, physics, computer science, and mathematics (Fox, 1988a, 1988b).

The benefits of guided participation emerge from maintaining a child/learner in the *zone of proximal development* (i.e., where the child is challenged slightly beyond his or her skill level, yet is capable of mastering the challenge with the help of a more skilled partner; see Vygotsky, 1978). According to Rogoff, this zone represents a "dynamic region of sensitivity" where development occurs, and the skills of a culture are passed from one generation to the next. From a phenomenological perspective, we would add that a child's subjective experience within this zone is very close to the more optimal, intrinsically rewarding flow experience. In the zone of proximal development, challenges are slightly higher than skills, and the person experiences the slightly unpleasant state of *arousal,* which will change into flow if the person develops the next level of skills (Csikszentmihalyi & Rathunde, 1993). Our experiential perspective suggests that it is the attraction of flow that spurs the child to make these adjustments.

A number of studies confirm that guided participation is beneficial for children's development. For instance, it has been linked to infants' and toddlers' communicative competence (Hardy-Brown, Plomin, & DeFries, 1981; Olson, Bates, & Bayles, 1984), to improvement in children's seriation skills (Heber, 1981), and to greater exploration of novel objects by 3- to 7-year-olds (Henderson, 1984a, 1984b). Wood and Middleton (1975) found that when mothers tailored their instruction to their children's needs (i.e., guiding at a slightly challenging level, adjusting their instruction to children's successes), children performed more effectively on a task of building block pyramids. Interestingly, the number of interventions a mother made did not relate to performance; rather, it was the quality of the interventions that was effective.

While guided participation is a universal process, there are important variations across cultures in the goals that are valued and the means to their attainment: "A major cultural difference may lie to the extent to which adults adjust their activities to children as opposed to the extent to which children are responsible for adjusting to and making sense of the adult world" (Rogoff et al., 1993, p. 9). The former, *child-centered* pattern emphasizes parental accommodation to a child's level by joining the child in play, treating the child as a conversational peer, and so on. Such is the pattern described in the studies cited earlier, and it is the typical pattern manifested in middle-class families in the United States: "In the middle-class populations that have been studied, the bridge between adults' and children's points of view is often built from children's starting point, with adults building on children's perspectives by focusing on children's direction of attention and adjusting adult concepts to reach children's understanding" (Rogoff et al., 1993, p. 19).

When children are more embedded in the everyday lives and work environments of adults, they are responsible for accommodating to adults through observation and emulation. In this *adult-centered approach,* a child might be expected to speak when spoken to, reply to questions, or simply carry out directions, with adults providing helpful feedback in response to the child's efforts. This pattern has been observed in a variety of non-Western cultures such as in Kaluli, New Guinea, and Samoa, where children were expected to adapt to normal adult situations (e.g., caregivers modeled unsimplified utterances; Ochs & Schieffelin, 1984). It has also been observed in some African American communities where children were not encouraged to initiate dialogue with their elders and held their parents' attention longer when remaining silent (Ward, 1971), and in Eastern cultures, such as Japan, where parents stressed children's roles as apprentices to more experienced members of the community (Kojima, 1986).

The goal of parenting in Polynesia, according to Martini and Kirkpatrick (1992), is to turn children into *'enana motua,* or "parent persons." To achieve this goal, socialization revolves around teaching children how to become competent householders and establish and maintain familiar relations at home, away from home, and in the broader community—while maintaining autonomy in a dense network of binding relationships. This complex balance between group participation and autonomy is further reinforced by the culture, starting with peer interaction among children (Martini, 1994).

Rogoff and her colleagues (1993) argue that people from differing communities could benefit by synthesizing child-centered and adult-centered patterns of socialization. For instance, the child-centered approach in the West is thought to have benefits for developing the "discourse of schooling," whereas the adult-centered approach helps to develop children's observational skills. By encouraging skills of observation, the adult-centered approach might help Euro-American children to better coordinate their actions with others in a group; the child-centered approach, in turn, could help traditional communities, and some minority communities in the West, to access educational opportunities that open doors to Western institutions, which rely on assertive individuality.

Parenting in Infancy

A great deal of work on parenting in infancy helps to elaborate the theoretical dynamics under discussion. For instance, Field (1985, 1987) has suggested that whereas infants are born with genetic predispositions that make them differentially responsive to stimulation in the environment (e.g., Eysenck, 1973; Freedman, 1979; Izard, 1977), mothers who learn their infants' stimulation and arousal modulation needs, *and who match their behavior accordingly,* provide optimal contexts for the development of secure attachment and self-regulation (see also Lewis & Rosenblum, 1974). So a mother modulates her behavior to match her child's need for stimulation or comfort, thus helping the child to maintain an optimal level of arousal. Under normal circumstances, mothers and infants even achieve a synchrony in their behavioral and physiological rhythms (Brazelton, Koslowski, & Main, 1974; Field, 1985; Stern, 1974).

When a mother fails to stimulate or comfort a child in appropriate ways, the child may withdraw from interaction, show gaze aversion, negative affect, elevated heart rate, or other disturbances; such infants, when hospitalized and removed from under- or overstimulating environments, often show improvement (Field, 1987). However, if a mother *consistently* fails to develop a synchronous pattern that fits her child's needs, the child can experience behavioral and psychological disorganization, making him or her vulnerable to a number of later developmental problems. For instance, relationships have been reported between early interaction disturbances and school-age behavioral and emotional problems, including hyperactivity, limited attention span, and disturbed peer interaction

(Bakeman & Brown, 1980; Field, 1984; Sigman, Cohen, & Forsythe, 1981).

Some infants (e.g., a preterm or Down syndrome baby) may be "harder to read" in terms of their arousal needs, but parents typically adapt and do a better job than strangers. Interaction coaching studies have also shown that parents can learn to be more sensitive interactive partners. For instance, when asked to mimic their infant's responses, mothers become less active behaviorally and more attentive to their infant's cues; in contrast, when asked to keep their infant's attention, they are less sensitive to infant cues and more active behaviorally (Clark & Seifer, 1983; Field, 1977). The former coaching technique therefore enhances a child-centered approach to parenting, and the latter technique encourages an adult-centered approach.

Intersubjective perspectives are also at the front line of attachment research (Bretherton, 1987). Attachment theory suggests that infants and parents are genetically prepared for mutual negotiation and cooperative action (Bowlby, 1969; for contrasting perspectives see Gottlieb et al., Chapter 5; Thelan & Smith, Chapter 6, this *Handbook,* this volume; Trevarthen, 1979), and that even newborn infants are capable of experiencing a sense of emergent self-organization (Stern, 1985). What is particularly useful about attachment research is the abundant empirical and theoretical work that has addressed how early interactions affect later child development. Attachment researchers hypothesize that the quality of the early caregiver-infant interactions affects how children interpret their worlds through the development of a *working model* (see discussion later). Thus, basic styles of relating to the world are thought to be fundamentally connected to the interactive characteristics of early caregiver-infant interactions.

The term *attachment system* refers to a coherent behavioral-motivational system that is organized around a particular figure (or figures). Bowlby (1969) observed that the attachment system was *activated* by perceived danger and *deactivated* by safety. Bretherton (1987) contends that it is more helpful to think of the system as *continually active,* because this clarifies two distinct attachment phenomena: use of the caregiver as a safe base when there is perceived danger, and use of the caregiver as a launching point for exploration. Bretherton's conceptualization allows the attachment system to be seen on a continuum with other optimal arousal models discussed in this chapter. And like the other models discussed, the attachment system combines two "antithetical" human propensities: to seek continuity (comfort) in the face of overwhelming change, and change (stimulation) in the face of numbing continuity.

It is not surprising that a support/challenge combination is also recognized as the most effective way to parent infants. *Secure attachment* is associated with caregiving that is supportive when it needs to be, yet challenging in terms of encouraging exploration and autonomy.[10] Such a balance helps create the synchronous patterns associated with secure attachment (Isabella & Belsky, 1991), such as those observed in feeding situations, face-to-face interactions, responses to crying episodes, and many other types of interactive behaviors (Ainsworth & Bell, 1969; Bell & Ainsworth, 1972). Asynchronous patterns leaning toward over- or understimulation, alternatively, have been associated with insecure attachment patterns (Isabella & Belsky, 1991).

Because of the dependence of human infants on their caregivers, the latter have enormous influence on the patterning of intersubjective relations during the 1st year of life. Attachment theory suggests that from these relations children develop an internal working model of how the world works. Such a model serves a functional purpose: It represents reality as it is experienced and therefore allows the utilization of past experience to imagine alternatives and make decisions (Craik, 1943). In an evolutionary perspective, working models provide a survival advantage to the extent that they permit more insightful and adaptive behavior (Johnson-Laird, 1983). The adaptiveness of a model depends on its correspondence to the actual world (i.e., what is represented has to simulate relevant aspects of the environment); the more complex a working model is, the more flexible are an organism's potential responses.

Based on interactions with a caregiver, a child learns essential information about how self and other are related, and this information becomes a template for future interpretations. Distortions or disturbances in the interactive relationship result in distortions in processing information; because working models become automatic and habitual, these distortions can lead to relatively stable maladaptive patterns of development. Stern (1985) makes the provocative suggestion that when mothers consistently "overattune" or "under-

[10] The attachment literature typically describes optimal parenting in terms of a child-centered approach. This is underscored by the fact that most attachment researchers view maternal insensitivity as a mother's inability to *take the perspective of a child* (Ainsworth, 1983).

attune" to infant cues, they can *undermine infants' ability to evaluate their inner states.* From an experiential perspective, this result would seriously undermine later abilities to evaluate boredom and/or anxiety and respond in ways that promote flow experiences.

Also relevant from an experiential perspective are studies that show attachment patterns have carryover effects that influence children's *style* of engaging activities. For instance, secure attachment at 12 months predicted more adaptive communication in a problem-solving task too difficult for 2-year-olds to perform by themselves. Securely attached infants tried to solve the problem independently, but turned to the mother for help when they got stuck; mothers, in turn, comforted their children and helped them to focus on the task (Matas, Arend, & Sroufe, 1978). Thus, the style of engaging the task reflected the style of interaction in a securely attached dyad (i.e., exploration in a context of support). It is also noteworthy that securely attached toddlers displayed more enthusiasm and task enjoyment.

In summary, several perspectives on parenting in adolescence, childhood, and infancy converge around the idea that parental combinations of support and challenge create optimal contexts for child development. A deeper recognition of such continuities across parenting studies is an important step toward more integrative theories of child development. One of the most important areas to explore, we believe, is how the system flexibility created with combinations of support and challenge affect children's subjective experience and their emergent capacity to self-regulate arousal. Studies in each of these areas inform the phenomenological perspective in this chapter. Combinations of parental support and challenge were associated with adolescents' reports of flow experience in school (Rathunde, 1996, 2001a), children's engagement in the zone of proximal development (Rogoff, 1990), toddlers' enthusiastic task performance (Matas et al., 1978), and infants' optimal arousal (Field, 1987). Common to all the perspectives reviewed was an emphasis on children's development through intersubjective experience in the family; the historical roots of this perspective can be found in Baldwin (1906), Cooley (1902), Mead (1934), and Vygotsky (1962).

Teacher-Child Interaction and the Growth of Complexity

School contexts, like family contexts, play a fundamental role in socializing children and facilitating their development. If it is true that the flexibility of supportive and challenging families facilitates the interconnection of immediate and voluntary uses of attention and, therefore, children's ability to find optimal experience, then it is reasonable to assume that the same applies to school contexts. A challenging school environment would activate students' accommodative efforts (i.e., voluntary attention) to reorganize their thinking, acknowledge new points of view, formulate new plans, and so on. A supportive school environment would sustain students' assimilative habits (i.e., immediate attention) of exploring the world from their own point of view, using their imagination as a bridge to new experiences, and feeling comfortable and effective. Support and challenge in a school environment would therefore create a flexible social system with the ideal conditions for "full" attention or bidirectional attention that can maintain students' optimal arousal and facilitate the ongoing transformation of challenges and skills.

Education philosophies can be at odds concerning the value placed on these two different aspects of learning. For example, contemporary concerns about increasing student achievement (e.g., a back-to-basics orientations, increased emphasis on performance and standardized testing) tend to emphasize a student's need to accommodate others' points of view as represented by teachers and/or texts. Adults *present* challenges, and students are expected to work hard to integrate the new information. Such approaches place a high value on the use of what we have been calling voluntary attention, or modes that have traditionally been referred to as "objective," rational, or conceptual. William James referred to this knowing as "knowledge about" (Taylor & Wozniak, 1996). In contrast, and coinciding with a greater attentiveness to child development and a recognition of children's constructive powers, several education philosophies emerged in the twentieth century that placed a greater emphasis on students' intrinsic motivation to learn. These approaches emphasized learning from the inside out, so to speak, and are often connected with Dewey's progressive movement in education (Semel & Sadovnik, 1998). They place a higher value on what we have been calling immediate attention, or modes that have typically been described as more "subjective" or intuitive. Taylor and Wozniak (1996) note that James sometimes referred to this knowing as perceptual; experience was direct and immediate and "there is no separation of knower and known" (p. xvii). Teachers who place an emphasis here

would expect students to *discover* challenges that would lead them forward toward greater knowledge.

Our perspective, as is clear from the many examples of psychological complexity, is that both uses of attention are needed to transform the other. Following James and Dewey, both of whom recognized this dilemma, when one mode is disconnected from the other, the process of knowing breaks down with deleterious consequences. James (1904) commented, "Knowledge thus lives inside the tissue of experience. It is *made;* and made by relations that unroll themselves in time" (pp. 539–540). When separating out parts of experience with voluntary or selective attention, the tissue must remain intact and the parts of experience that are highlighted must find their place again in relation to the ongoing stream. In this way, James thought that knowledge was neither subjective nor objective, but when understood as a function or process, it was both at once. Likes James, Dewey had a mistrust of purely rational analyses. His progressive movement was a reaction against the "intellectualist fallacy" that equated the real exclusively with conscious knowledge "about" something (Kestenbaum, 1977). Unfortunately, Dewey's philosophy of experience was misunderstood or ignored on this point. He was often seen, as many others were who were associated with the progressive movement, as proposing an "easy," laissez-faire form of education that paid too much attention to children's interests. Dewey's philosophy rightly understood, however, mirrors James on the interconnection of subject and object and immediate and voluntary attention. This is clear, for instance, in Dewey's (1934/1980) description of a "complete" or aesthetic experience (i.e., the ideal model for ordinary experience): "Art celebrates with peculiar intensity the moments on which the past reinforces the present and in which the future is a quickening of what now is" (p. 18). Aesthetic experiences were an intensification of the basic rhythm of subjective and objective phases of thought, and this intensified rhythm is experienced as a powerful stream or flow of experience.

Schools, or individual teachers, that overemphasize either a teacher-directed, abstract/conceptual approach or a student-directed, concrete/intuitive approach can sometimes be effective, but only because the underemphasized component of attention operates regardless of the explicit philosophy of the school. In other words, the stated philosophy may reinforce and acknowledge one direction, but learning can only take place through the interrelation of immediate and voluntary modes. Therefore, the "missing" use of attention operates like an unannounced guest in the school: Teachers using outside-in approaches don't give enough credit to student imagination and intuition that meet teachers or textbooks halfway; teachers who believe in inside-out approaches may fail to acknowledge that rational and abstract thinking is a necessary component for maintaining enthusiastic student interest in a subject. Such one-sided approaches would be more effective if the educational philosophy recognized the dynamics of optimal arousal and the need for immediate and voluntary attention to work in concert to appropriately transform anxiety and/or boredom.

The biggest experiential problem created by teachers who always present challenges is that they inevitably introduce new information that fails to properly connect with the skill levels of students; they introduce a feeling of anxiety, therefore, that becomes difficult to turn into optimal arousal. For example, if students are presented with a challenge that lacks meaning for them, or overshoots their skills and capacity for mastery, they are unable to engage the challenges with the immediate confidence that a practiced and habituated set of skills would provide. In this situation, anxiety can only be "resolved" with drudgery; students go through the paces using the tools given to them and doing what they are told. Learning is compromised by a disruption in the stream of experience and the disconnection of immediate and voluntary uses of attention. Alternatively, the experiential impasse created by teachers who are always letting students discover challenges is that the challenges selected may not be sufficiently novel enough to propel a change in students' existing skills; the resulting feeling of boredom becomes difficult to shed and turn into optimal arousal. For example, student's may select "challenges" that do not move them out of immediacy and evoke effort and voluntary attention. In this equally negative learning environment, boredom is "overcome" with what Dewey called fooling; students distract themselves with unimportant diversions. Again, the stream of experience is disrupted due to the disconnection between concrete and abstract uses of attention; this disconnection, in turn, does not allow the accelerated rhythm of thought that is subjectively experienced as flowlike.

How school environments that lacked the right balance of support and challenge could tear the tissue of experience was illustrated by our study of talented teenagers (Csikszentmihalyi et al., 1993). One part of the study looked at student experience and talent devel-

opment in the arts (i.e., athletics, music, and visual arts) versus the sciences (i.e., mathematics and science). According to the students we interviewed, the former domain was often perceived as student-centered: Teachers were highly supportive and encouraged students to discover challenges, take initiative, be intrinsically motivated, and so on. In contrast, math and science classes were more often perceived as adult-centered: Teachers presented challenges, were not perceived as particularly caring or supportive, required student compliance, and instilled extrinsic motivation with an emphasis on grades and performance. The prevailing emphasis in the school context was related to specific impasses in student experience. For example, students in the arts showed an ESM pattern of fooling. They often felt a momentary sense of ease and enjoyment with respect to what they were doing in class when signaled by the pager (e.g., they reported above average moods and involvement at the moment); but they could not see how what they were doing was truly important (e.g., they reported below average relevance to their goals and future). In contrast, students in the science classes reported a drudgery pattern. When they were signaled, students reported that they could see how their activities were relevant; but they reported below average involvement at the moment. Those students who went on to develop their talents the farthest by the end of high school—*across all of the talent areas* —more often reported immediate engagement *and* a focus on important future goals (Rathunde, 1993, 1996, 2001a). Consistent with such full attention to their school tasks, they also reported more frequent flow experiences.

The earlier scenario is played out in many school contexts around the country each day. Our interpretation is that it results from one-sided philosophies that pit against each other the value of teacher versus student direction, challenge versus support, and conceptual versus intuitive thinking. Applying what we have learned about optimal experience to education leads us to believe that such dichotomies end up emphasizing voluntary effort at the expense of momentary involvement, or immediate involvement at the expense of voluntary effort. The former is more associated with authoritarian/rigid tendencies in the school environment (i.e., high challenge with low support) and the former with more permissive/disorganized school environments (i.e., low challenge and high support). Just as we argued with respect to family contexts, each of these particular imbalances of support and challenge reduce flexibility in the assimilation and accommodation dialectic, make it more difficult for students to negotiate a good person-environment fit, and by slowing down the ideal rhythm of mental activity they reduce the likelihood of experiencing flow. More important, repeated experience in environments that lack system flexibility (Bronfenbrenner, 1992), is likely to result in the formation of self-regulative habits that work against the development of psychological complexity and the ability to turn aversive experiences like boredom and anxiety into flow. A clearer recognition of these unfortunate but familiar patterns in many school environments would be an important step toward a more inclusive and experientially sensitive philosophy of education, one that was concerned about how characteristics of the school context affected the phenomenology of students and their emergent capacity to regulate their arousal.

Students' Quality of Experience in Middle School: A Comparison of Montessori and Traditional School Environments

The middle school transition is one of the key points during child development. It has been well documented that many young adolescents have difficulties with the transition to middle school (Carnegie Council on Adolescent Development, 1989; Eccles et al., 1993). One finding that is particularly relevant to this chapter is that there is a drop in students' intrinsic motivation to learn (Anderman, Maehr, & Midgley, 1999; Gottfried, 1985). As most teachers can attest, during the elementary grades many children are enthusiastic about learning. However, middle school too often brings a decline in motivation and the quality of school experience.

Eccles and her colleagues (1993) explain these declines by suggesting that the middle school transition can result in poor fit between an adolescent's developmental stage and the school environment. They cite several aspects of this growing mismatch: fragmented class content when young adolescents are capable of more sophisticated cognitive integration; more rigid, control-oriented teachers and environments when identity, choice, and autonomy are becoming more important in the lives of young people; and an emphasis on public evaluation and competition at a time when students are feeling self-conscious and "on stage." Adolescents are also more peer-oriented and at a stage crucial for the development of interpersonal skills; yet, many middle school teachers increasingly rely on top-down, lecture approaches that make it difficult for students to collaborate

during class time (Wentzel, 1998). Finally, at a time of stressful and rapid development change, when students need continued adult support, teacher-student relationships become more remote and impersonal (Feldlaufer, Midgley, & Eccles, 1988).

Our perspective is consistent with the studies discussed earlier; however, it shifts the emphasis to how middle school changes might affect students' experience and potential for optimal experience. Many middle schools make the mistake that some of the science classes made in our study of talent development. The balance of support *and* challenge is shifted in favor of the latter, leading to more rigid and authoritarian school environments. Learning becomes more adult-directed: Teachers present the challenges, increasingly stress grades and performance, and are not as interpersonally supportive. Such changes are initiated with the best of intentions. Academic achievement is highly valued in our culture, and the commonsense understanding of such achievement, especially in the technologically important domains of math and science, suggests that it is based on abstract and conceptual thought, not concrete and intuitive "feelings." Thus, as students' powers of abstraction and deductive reasoning grow with puberty (Piaget, 1962), teachers, school administrators, school boards, and state legislatures turn toward pedagogical methods that, at face value, seem to fit the task at hand. Unfortunately, these changes introduced in the school context are often self-defeating. As explained earlier, more authoritarian social contexts affect how immediate and voluntary modes of attention work in concert. From an experiential perspective, the changes introduced in middle school are likely to promote voluntary effort at the expense of immediate involvement, reduce flow because the interplay of these modes is impeded, and therefore reinforce a pattern of student drudgery. Although not focused on experiential outcomes, most of the research done to date on the middle school transition would be consistent with such an interpretation.

A more compatible environment for young adolescents, we believe, would be one that placed a greater importance on students' quality of experience and emergent capacity to regulate their arousal for the purposes of lifelong learning. Such an environment would place a high value on support and challenge to create a degree of system flexibility that enhanced the assimilation and accommodation dialectic and thereby the intensity of mental activity that would more often lead to flow. To explore these ideas, a recent study compared students' quality of experience in Montessori and traditional middle school classrooms (e.g., Rathunde, 2001b; Rathunde & Csikszentmihalyi, 2005a, 2005b). The Montessori educational philosophy, in theory, has many of the qualities just described that would enhance adolescent experience. Although it is mainly associated with thousands of schools worldwide that specialize in early childhood education, over the past several decades the approach has increasingly been incorporated into middle schools, both public and private.

The Montessori philosophy shares with optimal experience theory a phenomenological focus on states of deep concentration and intense engagement. This is illustrated by the origins of the method. Maria Montessori came to believe that children's spontaneous concentration revealed the essence of being human. What she had in mind when speaking about concentration was akin to flow. According to Standing's (1984) biography of Montessori, a key turning point in the development of her method occurred after observing a 3-year-old child who was so engaged with wooden cylinders that she could not easily be distracted. Montessori was impressed with children's powers of concentration and spoke of it often: "It has been revealed that children not only work seriously but they have great powers of concentration. . . . Action can absorb the whole attention and energy of a person. It valorizes all the psychic energies so that the child completely ignored all that is happening around him" (Montessori, 1946, pp. 83–84). Witnessing the episode with the wooden cylinders apparently evolved into the main theme of the Montessori method: creating a school environment that fostered deep engagement and concentration.

A second important way in which the Montessori educational model fits with optimal experience theory is the emphasis placed on lifelong learning, rather than short-term performance. Through her concept of "normalization," Montessori tried to capture the personality characteristics and flexibility of attention that would result in self-directed learning. Similar to the notion of psychological complexity, normalization would result in adaptability to the environment and the ability to negotiate a person-environment fit: "Adaption to the environment and efficient functioning—therein is the very essence of a useful education." A "normalized" child would be on the road to recurrent episodes of deep concentration, and this would put them in contact with the essential motivational forces of human nature that

would help sustain lifelong learning. Also similar to the concept of psychological complexity, normalization depended on uniting what she called two important streams of energy—body and mind—so that abstraction did not become an end in itself. Standing (1984) commented, "More than in any other system of education, her whole method is based on a deep understanding of the relationship between these two elements—mind and body" (p. 159). Montessori most often referred to the protective function of the mind-body connection in terms of thinking and acting. She (1976) commented, "It is essential for the child, in all periods of his life, to have the possibilities of activities carried out by himself in order to preserve the equilibrium between acting and thinking. . . . [otherwise] His thoughts could . . . have the tendency to lose themselves in abstraction by reasoning without end" (pp. 24–25).

A third important way in which the Montessori philosophy parallels our views on education relates to the context of optimal experience. The fundamental question asked about context is the same in both approaches: If one assumes that a key to the path of lifelong learning is recurrent states of intrinsically motivated concentration, *then how can adults prepare an environment for children that facilitates the occurrence of deep concentration and flow?* Montessori's (1989) answer to this question was conveyed in her notion of the *prepared environment,* which shares two important similarities with optimal experience theory. First, a prepared environment must have a balance of support and challenge, or in Montessori's terminology, a balance of freedom and discipline. Montessori understood that freedom of choice was a precondition for concentration; however, she never lost sight of the opposite and equal need for order, structure and discipline in the environment. She commented (quoted in Standing, 1984), "On this question of liberty . . . we must not be frightened if we find ourselves coming up against contradictions at every step. You must not imagine that liberty is something without rule or law" (p. 286). Second, because the environment is conceptualized from an experiential starting point, a teacher in the Montessori prepared environment pays special attention to a student's ongoing quality of experience. A priority is placed on finding activities that engage interest and fit with a student's developmental level, maintaining an orderly and aesthetically pleasing environment so as to eliminate unnecessary distractions, and working, often in an indirect way, to protect and enhance a child's focus and concentration (see also Rathunde, 2001b).

The study compared five Montessori schools and six traditional schools that were carefully matched in terms of SES and other important school and family variables. The main differences between the schools were their pedagogical approaches. The school contexts in five Montessori middle schools were more in line with the experiential perspective articulated here and the reforms suggested by many contemporary education researchers (e.g., Ames, 1992; Anderman et al., 1999). For example, they were imbued with a philosophy of intrinsic motivation, students had freedom to select projects and improvise on themes introduced by the teacher (e.g., students at all the schools had several hours per day for self-directed projects), students were given responsibility to make decisions that affected their classrooms and the school (e.g., purchasing supplies), achievement competition was diminished and grades were not mandatory, students were typically grouped based on shared interests rather than ability, a significant portion of daily time was unstructured and could be used for peer interaction and collaboration, and block scheduling at some of the schools allowed teachers to expand or contract contact time with students depending on what was happening at the moment in the classroom.

The ESM provided a systematic look at students' daily experiences. Results showed (Rathunde & Csikszentmihalyi, 2005a, 2005b) that the Montessori students reported higher affect, potency (i.e., feeling energetic), intrinsic motivation, and more flow experience while engaged in academic activities at school. When engaged in informal, nonacademic activities at school (e.g., eating lunch, socializing), the students in both school contexts reported similar experiences. The Montessori students also perceived their teachers as more supportive *and* better at maintaining order in the classroom (i.e., upholding discipline). Finally, the Montessori students spent more time doing self-directed individual projects, and they also more often perceived their classmates as friends and spent more time in collaborative work with them. The traditional middle school students spent more time in didactic educational settings (e.g., listening to a lecture, note taking, watching instructional videos).

One of the strongest findings in the study had to do with the connection between the use of immediate and voluntary attention. Recall that we expected the traditional middle schools to more closely resemble the

science classes in our study of talent development. Such teacher-directed environments that presented challenges, stressed grades, and lacked interpersonal support were hypothesized to emphasize voluntary effort at the expense of momentary involvement and thus lead to a pattern of drudgery at school. Our findings supported this expectation. When the students in the traditional middle schools responded to the ESM pager, they reported being able to see how their school activities were important to their goals, but they did not feel very involved at the moment with what they were doing. In contrast, the Montessori students reported much higher percentages of *undivided interest*—the simultaneous combination of felt involvement and perceived importance—while doing academic work.

Comparing educational contexts is a difficult enterprise that is full of empirical pitfalls. However, these initial studies show promise for conceptualizing school contexts from the point of view of student experience. Many public schools have drifted toward transmission models of top-down education and standards-based testing. The Montessori schools may have been able to avoid these trends because of a long-standing commitment to intrinsic motivation. Nevertheless, the principles of focusing on experience, creating the right balance of support and challenge, and so on, are not the province of any particular philosophy. The greater importance of these findings, therefore, should be seen in the context of the narrowing of perspective in the United States and other societies in the West that increasingly equate knowledge with a thin set of cognitive skills (Johnson, 1987; Lakoff & Johnson, 1999; Sternberg, 2001). To our way of thinking, such a narrowing makes it less likely that students will develop the habits of psychological complexity that, above all else, depend on the flexibility of attention and the integration of concrete and abstract ways of thinking.

Middle schools lie at a crossroads in adolescent development. It is a crucial developmental stage when mature abstract thought emerges with full force. Learning how to deal with these new cognitive powers make early adolescence a turning point when many things can go wrong; negative school experiences during this stage could affect the long-term educational path of young people (Anderman & Maehr, 1994; Csikszentmihalyi & Schneider, 2000; Eccles, Lord, & Midgley, 1991; Sternberg, 2001). Positive experiential habits formed in early adolescence, alternatively, can set the stage for adult habits of psychological complexity and future career success.

NEOTENY AND COMPLEXITY: THE EVOLUTIONARY LOGIC OF UNENDING CHILDHOOD

Are the recurring themes in this chapter—the phenomenology of assimilation and accommodation, the balancing of skills and challenges, the intersubjective dynamics of support and challenge, and so on—just instances of a selective ordering of information, or do they reflect something intrinsic to human nature? We believe that the connections made thus far between complexity in later life and its foundation in child development have a deeper meaning that can be discerned in an evolutionary framework. In keeping with the strategy of moving from maturity to earlier developmental periods, we take one final step "back," so to speak, to an evolutionary perspective on neoteny.

Neoteny refers to the retardation of development, especially that of the nervous system, such that infants are born relatively immature and must learn what they need to know to survive (Gould, 1977; Lerner, 1984). Compared to other primates, humans are considered neotenous because their rate of development from fetus to adulthood is unusually slow. In fact, adult humans even retain many of the physical traits of the human fetus, such as flat-facedness and minimum body hair (Bolk, 1926). Huxley (1942) and others (e.g., Montagu, 1989) have suggested that neoteny "drives off" of the developmental timescale traits that have been a part of our evolutionary past (e.g., the heavier eyebrow ridges and projecting jaws of adult apes, of Neandertaloids). More important than the physical characteristics, Lorenz (1971) maintained that the behavioral outcomes of neoteny—the retention of childlike traits such as curiosity, playfulness, and flexibility, to mention just a few—are far more important. He concluded that the defining characteristic of humans was nonspecialization, allowing an *unending state of development* and an ability to change in response to new environments.

In his book *Growing Young,* Ashley Montagu (1989) concurs with this perspective and sums it up in the following ironic phrase: "The goal of life is to die young—as late as possible" (p. 5). He argues that we are biologically prepared by evolution to "grow young," or to emphasize rather than minimize childlike traits as we mature. Although the importance of these ideas are known by a small group of social and natural scientists, Montagu asserts that the enormous ramifications of an *applied understanding of neoteny* have yet to be fully recognized. Such an understanding would explicitly recog-

nize and nurture childlike traits, leading to adjustments in parenting and teaching philosophies; it would also redefine society as a system designed to extend the neotenous traits of humankind.

The universal manifestation of attachment processes provides deeper insight into the evolutionary logic of neoteny. Attachment discloses the fact that heavy parental investments in caregiving have a genetic underpinning (Bowlby, 1969), and that human infants and their parents are biologically prepared for intersubjectivity (Papousek & Papousek, 1987). Thus, parents and infants come equipped with the necessary skills for dialectic negotiations and joint meaning-making: "Humans are born with a self-regulating strategy for getting knowledge by human negotiation and co-operative action. . . . Thus socialisation is as natural, innate or 'biological' for a human brain as breathing or walking" (Trevarthen, 1988, p. 39).

The concept of neoteny thus provides a unifying link among various parts of this chapter. First, it provides a rationale for the presumed goal of complexity in later life, the defining characteristic of which was unending development due to flexibility (see also Lerner, 1984). The lifelong learners we interviewed can thus be seen as examples of the neotenous promise of human evolution. Second, the concept provides a way to link the idea of complexity with our observations about child development in social interaction. The trade-off in having a plastic versus fixed path of development is the enormous dependence that human children have on their parents (Gould, 1977; Lewontin, 1981). This dependence is illustrated by comparisons to other primates; humans give birth at a later age, have fewer young with each gestation, have longer gestation periods, lactate longer, and have fewer children across their lifetime (Altmann, 1989; Johanson & Edey, 1981). The human fetus is also expelled from the womb "early" because the evolution of brain size made premature birth necessary to permit safe passage through the birth canal (Montagu, 1989). This almost total dependence of human infants on caregivers, and the genetic predisposition to form attachments, explain why "individual" development occurs in a social process.

How does this slow and steady "tortoise strategy" lead to adult complexity? And what about this strategy is connected to optimal experiences that we claim are so important for development? These final questions of the chapter are addressed by taking a closer look at the *opportunity for play* afforded by neotenous development. Of the many consequences resulting from this basic human predicament of prolonged dependence, we believe play says the most about human development. Neoteny provides infants with ample time to play in a relatively *unpressured* context; Bruner, Jolly, and Sylva (1976) add that play was favored by evolution as a pressure-free time during which adult skills could be imitated with successful solutions *that lead to pleasure.* The phenomenon of play thus contains the evolutionary logic of neoteny; a closer look at its character reveals the essential connection among parental protection, optimal experiences, and the growth of complexity.

The Syntelic Character of Play

Baldwin (1906) has analyzed the character of play in a way that links it to the highest levels of human development. He refers to play as *syntelic* to capture its unique confluence of subjective and objective, inner and outer, characteristics:

> Both the inner freedom and the outer semblance must be retained [in play]; the latter gives consistency, pattern, dramatic quality, all that is meant by "semblance"; the former give control, selective character, essential inwardness. (p. 114)
>
> The play object becomes not the inner or fancy object as such, nor yet the outer present object as such, *but both at once, what we are calling the semblant object,* itself the terminus of a sort of interest which later on develops into that called "syntelic." (p. 116)

Baldwin is suggesting in these comments that play opens up the opportunity for make-believe against a background of reality (i.e., real sense objects); both of these qualities—an essential inwardness and an outer semblance—must be present. If there is no reference in play to the external world, it becomes pure fancy, and it loses its interest and drama. Alternatively, if play is too reality dependent or compulsory, it again loses its interest, but for a totally different reason. Play must retain its character of self-illusion, what Baldwin calls a "don't-have-to feeling," that invests the object with personal meaning, inner determination, and a feeling of self-control; to a certain extent, this quality *tempers* the external control that would otherwise hold. Thus, Baldwin (1906) states, "Play is a mode of reconciliation and merging of two sorts of control. . . . For it provides for the relative isolation of the object and opens the way for its treatment by experimentation" (p. 119).[11]

[11] Analogously, one can think of the scientific process as syntelic, as an oscillation between theoretical (subjective) and empirical (objective) modes of "control."

It is the syntelic character of play that makes it crucially important and links it to higher forms of human thought. By allowing the oscillation between subjective and objective modes, Baldwin perceives a developmental link to the emergence of basic human dualisms (e.g., mind/body, self/other, truth/falsity) and the eventual *overcoming* of such dualisms with full development. The legacy of play can thus be seen in the syntelic character of Baldwin's highest form of thought: aesthetic contemplation. Like John Dewey's (1934/1980) comments on aesthetic experience, Baldwin's descriptions of aesthetic modes are remarkably close to contemporary perspectives on postformal thought processes, and to our remarks on flow experience: "In aesthetic experience the partial insights of intelligence and feeling are mutually conserved and supplemented" (1911, p. 279). His perspective, though, adds insight to the developmental history of such outcomes; in other words, play is germinal to the highest forms of human thought as its syntelic character is elaborated and reinstated on higher levels of organization.

The essential benefits of playing lie in the manipulation of information in a pressure-free context that is informed by external and internal determinants, but controlled by neither. Play can retreat from compulsion and the "have-to" state of mind, or escape from the irrelevance of a "don't-have-to" consciousness. Thus, play captures the same self-environment synchrony we described in flow experiences; in addition, the dynamics of both are similar. Berlyne (1960, 1966), for instance, viewed play as serving a stimulus-seeking function when the organism was bored and an arousal-decreasing function when the organism was anxious. Other theorists have emphasized the positives of one or the other function; for instance, Ellis (1973) viewed play as stimulus seeking, and Freud (1959), Vygotsky (1962), and Erikson (1977) thought of play primarily as a safe way to reduce tension by dealing with problems in a symbolic way.

Also, like flow, play results in the differentiation and integration of the self. When it is exploratory, it generates novelty (Fagen, 1976); when it is imitative (or repetitive), it builds habits (Piaget, 1966). Vandenberg (1981) likened these differentiating and integrating aspects of play to the functions of genetic mutation and DNA, respectively, in providing for biological diversity and continuity. Play may be no less important in providing for cultural diversity and continuity. A number of theories have drawn connections among play and human creativity, achievement, and flexibility (Bruner, 1972; Rubin, Fein, & Vandenberg, 1983; Sutton-Smith, 1976). One of the strongest statements on the importance of play is given by Huizinga (1955), who saw it in the roots of our cultural institutions.

In conclusion, neoteny is connected to play through the establishment of an optimally stimulating context that is free of survival pressure due to parental investments of energy. Groos (1901) notes from an evolutionary perspective that *this period of human immaturity exists precisely for the purpose of play,* and there is a correlation between the length of play and an organism's eventual complexity (see also Gould, 1977; Johanson & Edey, 1981; Lerner, 1984; Lewontin, 1981). When flow experiences are seen on a continuum with play (i.e., as play reinstated on adult levels of organization), Groos's formula can be extended to flow experiences; in other words, *to the extent that adults continue to have flow experiences, their lives reflect a neotenous pattern of unending development.* This observation is consistent with our earlier examples of complexity in later life: These individuals regulated their attention in ways that promoted flow experiences and maintained the ability to "play" in adulthood.[12]

Much can be learned about the development of the person by better understanding the social conditions that take advantage of a neotenous developmental pattern. Important clues about these conditions can be found in the attachment relationship between caregiver and infant. Unless otherwise plagued by problems of their own, parents are prepared by evolution to create a play space through adjustments of support and challenge that helps infants to regulate their arousal. It is not a coincidence, we believe, that optimal developmental outcomes in infancy, childhood, and adolescence are all associated with parental combinations of support and challenge; such combinations—to the extent that they create appropriate conditions for optimal experiences—are consistent with the evolutionary logic of neoteny. Thus, future studies that continue to uncover how families (or other contexts of socialization) facilitate optimal experiences and outcomes will inform the creation of social environments that are more consistent with our biological potentials.

Another area of research from which much can be learned about unending development is the study of suc-

[12] In Baldwin's terminology, to "play" in adulthood means having *aesthetic experiences* that allow the reconciliation of the various partial truths (e.g., feeling and intellect, inner and outer). Dewey (1934/1980) likewise thought that aesthetic experiences reconciled feeling and intellect.

cessful aging. The examples of complexity used in this chapter illustrate that it is worthwhile to ask lifelong learners how they were able to stay interested and involved. Much research, however, remains to be done. Do "protective" social conditions still play a role in facilitating optimal experiences in late adulthood? How much of this regulatory function is (or can be) taken over by individuals through the internalization of supportive and challenging conditions they have experienced in their lifetimes? While the focus in this chapter has been on the individual's responsibility for negotiating optimal experience, it is certain that social conditions remain important. For instance, many of those we interviewed had the benefit of tenured or emeritus positions on a faculty; many had extremely devoted spouses, and most seemed free from financial worries. Further studies of successful aging can shed light on how personal instigative qualities, and social conditions, work to maintain the promise of neoteny. To the extent that insights gained are linked to child development, including the earliest moments of parent-child interaction, developmental theory will benefit greatly.

CONCLUSIONS: THE ROLE OF EXPERIENCE IN DEVELOPMENT

Theories of development have tended to look at the individual as an organism propelled along the life course by external forces. From conception to death, individuals were seen as dependent variables who were a function of a host of independent variables: genetic programs, early environments and stimulations, social and cultural contexts. In opposition to such overly deterministic perspectives, recent approaches have emphasized the active, purposeful role of the individual in helping to shape his or her developmental trajectory (e.g., Brandtstädter, Chapter 10; Bronfenbrenner & Morris, Chapter 14; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume).

Our experiential perspective on the developing person fits in this latter approach. It recognizes the fact that human beings come into the world exceptionally immature and must depend on a supportive social context to develop their full potentialities. The social context, in turn, expects the growing individual to display certain minimum competencies before he or she can be accepted as a "person." In addition, each culture evolves expectations of optimal personhood that serve as the ideal goals of individual development. Despite the fact that how a person develops may vary greatly across time and place, adopting an experiential perspective highlights the basic human disposition to regulate arousal that begins with the first moments of life. Common to the many manifestations of personhood across cultures, therefore, is an experiential dialectic that attempts to maintain and cultivate optimal arousal. Psychological complexity is the name we have chosen to represent the mature ability to flexibly regulate arousal and optimal experience. A person with complexity has the capacity to move toward flow experience by negotiating a self-environment fit that is integrated and differentiated, or a fit that achieves an optimally arousing balance of order and novelty. It is reasonable to believe that such a person will more often enjoy the full engagement of attention and be living at what James (1917) called their "maximum of energy." Having such energy and attention at their disposal provides a greater capacity to actualize full potential.

What propels the development of flexible self-environment negotiation and complexity? Although the specific construct of complexity is not commonly used, many developmental theories address the conditions that favor the development of a person who has the capacity to instigate their own development. Many of these theories have been mentioned in this chapter. However, few of them look at the *proximal* causes for the emergence of self-regulation, or adopt a phenomenological approach that monitors the moment-to-moment uses of attention and feedback through experience that guides regulation and decisions to engage new challenges and develop new skills. In addition, few developmental theories focus on deeply involving states, like flow, that reveal all is well with arousal regulation and that development is on a positive track. We have tried in this chapter to conceptualize optimal development using such optimal experiences as a starting point.

So the central pragmatic question for development becomes: How do we help children learn to enjoy as many aspects of their lives as possible? How do we create contexts that will help children develop complexity? Our answer is based in the habits and dispositions that result from repeated experience in family and school contexts that are entrusted with the primary job of socializing children. A child who is overwhelmed by too many and too difficult opportunities, or who has learned to respond with apathy and indifference to an environment that lacks stimulation, might never learn to enjoy the active shaping of his or her experience. Alternatively, practice and repeated success in

environments that facilitate optimal arousal will develop the capacity for psychological complexity. We have argued that supportive and challenging family and school contexts help in this regard because they are sensitive to the balance of children's skills and challenges, and therefore to the interconnection of immediate and voluntary modes of attention that must work together to transform anxiety and/or boredom. Although this perspective is still being developed and is not yet based on extensive empirical examination, we have reported the results of several studies that hold promise for understanding how social contexts affect the interconnection of these two modes and therefore the likelihood of optimal experience.

If experiential considerations are ignored when attempting to understand positive self-regulation and development, we miss the fact that to become active agents in their own ontogeny, individuals have to *want* to develop. And they will want to do so only if they enjoy it. If they do not, development becomes alienating because the child as well as the adult learn and grow primarily for extrinsic reasons. The child will study to graduate from school, the adult will work to get a paycheck and be promoted, and both will endure their present conditions listlessly in anticipation of a more pleasant future. This is not a developmental trajectory that leads to complexity or a desirable old age. By contrast, development takes an intrinsically motivated course if a child feels fully engaged and fully present while learning and engaging new challenges. Habits developed in the successful regulation of optimal arousal are ones that form a solid basis for lifelong learning.

CHAPTER 10

Action Perspectives on Human Development

JOCHEN BRANDTSTÄDTER

THE RISE OF ACTION PERSPECTIVES IN DEVELOPMENTAL PSYCHOLOGY

Developmental psychology has elucidated the conditions and constraints of human ontogeny from a diversity of theoretical perspectives. However, it has not paid a great deal of attention to the individual's contribution to the creation of his or her own developmental history throughout the life span, although action perspectives are gaining momentum in developmental research and theorizing. Through action, and through experiencing the consequences of our actions, we construe representations of ourselves and of our material, social, and symbolic environments, and these representations guide and motivate activities, which shape and influence our behavior and personal development.

Action thus forms development, and development forms action: The individual is both the active producer and the product of his or her ontogeny. The central tenet of an action-theoretical perspective thus holds that human ontogeny, including adulthood and later life, cannot be understood adequately without paying heed to the self-reflective and self-regulative loops that link developmental changes to the ways in which individuals, by action and mentation, construe their personal development. This should not imply that individuals are the sole or omnipotent producer of their biography. Just like any

I am grateful to Richard M. Lerner, who provided thoughtful editorial comments on the entire manuscript, and to Werner Greve, who gave valuable comments on an earlier draft.

other type of activity, activities related to personal development are subject to cultural, sociohistorical, and physical constraints that lie partly or even completely outside one's span of control but decisively structure the range of behavioral and developmental options. Action-theoretical perspectives on development must therefore consider not only the activities through which individuals try to control their development over the life course, but also the nonpersonal or subpersonal forces that canalize such activities.

The idea that human individuals play an active part in shaping their development and aging has never been doubted seriously. Yet, at least until recently, no systematic effort has been made to frame this idea in an elaborated theoretical statement. Though actions have been recognized as formative elements of every individual life history, they have hardly figured as elements in developmental theories (Dannefer, 1989). Presumably, one reason for this neglect lies in the traditional preoccupation of developmental research with the formative periods from early childhood to adolescence. Activities of self-regulation and intentional self-development are related to personal goals, plans, and identity projects; such orientations typically become more differentiated and concrete in the transition to adulthood when developmental tasks of independence and autonomy gain importance. It is certainly no mere coincidence that early proponents of action-theoretical perspectives were simultaneously advocates of a life-span perspective in development; Charlotte Bühler (1933) is a prominent example. The neglect of action-theoretical perspectives may also reflect deeper epistemological and methodological reservations. The applicability of causal explanatory schemes to actions is a long-standing and still strongly contested controversy in philosophy of science, and a final consensus is not in sight (e.g., Brand, 1984; Lenk, 1978; Thalberg, 1977). Moreover, an action perspective that conceives of development as a process that is shaped and canalized by collective and personal action appears to be barely compatible with the search for deterministic laws and universal principles of development. These questions are discussed at more length later. It should be noted at this juncture, however, that notions of universality, ordered change, and determinism in human development have recently come under attack from various lines (e.g., Bruner, 1990a; Gergen, 1980). In the same measure, interest in action-theoretical perspectives has grown during the past decades (e.g., Brandtstädter, 1984a, 1984b, 2001; Brandtstädter & Lerner, 1999; Bruner, 1990b; Chapman, 1984; Crockett, 2002; Dannefer, 1984; Eckensberger & Meacham, 1984; J. Heckhausen, 1999; J. Heckhausen & Dweck, 1998; Lerner, 2002; Lerner & Busch-Rossnagel, 1981; Silbereisen, Eyferth, & Rudinger, 1987; Valsiner, 1989).

The actional stance seems to offer a vantage point for integrating developmental and cultural perspectives. In fact, the concepts of development, culture, and action are intrinsically related as illustrated by Figure 10.1. Development, as the result of personal and collective activity, is essentially a cultural product—this is the core of the argument advanced in the present chapter. Conversely, actions, and self-regulatory activities are dependent on developmental change; the goals, values, and beliefs that motivate and direct such activities change under the joint influence of ontogenetic and cultural-historical factors. Similar conceptual and functional links also relate the domains of action and culture. Cultures are the collective result of individual actions and decisions, even though the long-term and cumulative dynamics of cultural evolution and change generally are beyond the grasp of any single individual (Hayek, 1979). On the other hand, cultures form action-spaces (Boesch, 1980, 1991) that shape possibilities, outcomes, and meanings of actions, and cultural institutions constitute certain types of action, as I explain later. The mentioned relationships also imply a functional interdependence between culture and human ontogeny, which is mediated through constructive and selective action: Individuals shape their developmental ecology and thus regulate their own development; they construct a personal culture (Heidmets, 1985) that becomes a constitutive element of the larger cultural

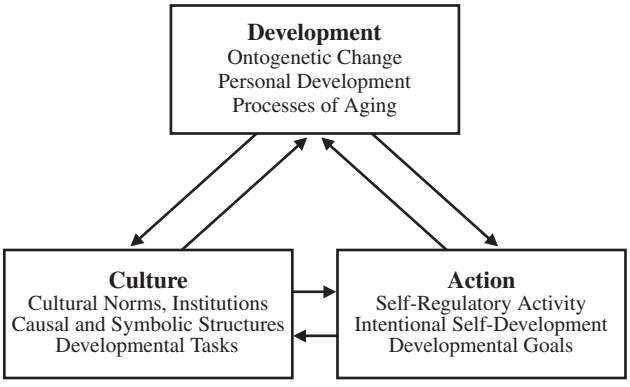

Figure 10.1 Development, culture, and action as interrelated spheres.

macrosystem. The cultural context, in turn, forms an arrangement of constraints and "affordances"—to use Gibson's (1977) terms—that canalizes and institutionalizes developmental pathways. This canalization is an essential requirement for the maintenance and self-perpetuation of the cultural system; conversely, human ontogeny in its physical, social, and psychological aspects is fundamentally dependent on the regulative and protective influences of the cultural context.

In the following sections, I focus on the multiple ways in which personal and collective actions, embedded in cultural and historical contexts, form, and are formed by, development over the life span.

Cultural Regulation of Development

The regulation and control of ontogenetic and age-graded change is integral to the processes by which cultures stabilize, reproduce, and reform themselves (e.g., Bourdieu & Passeron, 1977). Every cultural system has at its disposal a broad armamentarium of techniques, institutions, or rules to regulate development, and without such cultural proxies and scaffolds, human development would be virtually impossible. Neonates and young children vitally depend on persons who care for their physical and psychological development and who organize environmental contingencies in ways that enhance growth and fend off harmful influences. The regulation and institutionalization of development becomes increasingly salient in processes of education and socialization that define an arrangement of developmental tasks, affordances, and options across the life cycle. Like development itself, the canalization and control of development is a lifelong process. This process serves to transfer cultural values and problem solutions, and to inculcate attitudes, dispositions, and skills that are, or are considered to be, necessary for existence and coexistence in a cultural-historical context. The ontogenetic necessity of culture, however, is rooted more deeply in the biological constitution and the phylogenetic evolution of *Homo sapiens* (e.g., Tobach, 1981).

Among the evolutionary and biological predicaments that make possible, and at the same time enforce, the cultural contextualization of ontogeny is the great plasticity and openness of development. These features are already implied in the notion of culture, insofar as it connotes the cultivation and perfection of some object or process that is amenable to modification, particularly of life itself. As early as 1777, Johann Nicolas Tetens considered the "perfectibility" of human development as being premised on two basic conditions: the capability for reflexion and self-referential action (*innere Selbsttätigkeit*) and the modifiability of development:

> Among all fellow animate creatures, the human being is by far the most perfectible, the one that, at birth, has the largest potential for development . . .; the human being is the most flexible and versatile of all creatures, the one that can be modified with the greatest diversity, in accordance with the wide sphere of activity for which it is destined. (Tetens, 1777, p. 40; trans. J. B.)

The functional relationship between culture and ontogeny is captured even more cogently in the argument that cultural institutions—and the developmental and action potentials necessary for creating culture—compensate for the lack of specialized adaptive automatisms in the human organism. This idea can be traced back to the writings of Herder (1772); it has been taken up and elaborated in the anthropological system of Gehlen (1955/1988). As Gehlen pointedly puts it, the human individual is a "deficient being," who is characterized by a lack of physical specialization and of ties to a specific environment, and for whom culture has thus become a "second nature":

> Man is an acting being. In a narrower sense, he is also "undetermined"—he presents a challenge to himself. Actions are the expression of man's need to develop an attitude toward the outside world. To the extent that he presents a problem to himself, he must also develop an attitude toward himself and make something of himself . . . self-discipline, training, self-correction in order to achieve a certain state of being and maintain it are necessary to the survival of an "undetermined" being. (Gehlen, 1955/1988, pp. 24–25)

According to this stance, culture secures survival and development by providing an artificial arrangement of "outside-the-skin," compensatory means of adaptation (see also Geertz, 1973). The notion of humans as deficient beings, however, may be misleading as far as it equates lack of specialization with adaptive deficit. In fact, the lack of adaptive automatisms and instinctual regulations is more than offset by the remarkable ability of human agents to cope with adversity through creative and constructive action. To respond flexibly to the continuous and fluctuating adaptive challenges posed by a nonstationary environment, behavior must be organized

with sufficient latitude for variation and experience-based modification. The excessive growth of the cortical and neocortical areas of the central nervous system lends the requisite openness and variability to the cognitive and motivational control of behavior. Of particular mention here are capacities of abstraction, categorization, and representation, which enhance extraction of order and regularity from the flow of events and allow for a mental simulation of actions and effects. Human adaptive competencies are further boosted by language and communication. Language enables the transmission of knowledge, and provides the symbolic means for the social control of behavior, as well as for self-control and self-reinforcement (e.g., Luria, 1979; Zivin, 1979). The markedly prolonged period of physiological maturation and growth, the correspondingly long period of protection and care, and the emergence of family and group structures form a complex of mutually supportive evolutionary factors that make for both the vulnerability and the potential of human development (cf. Bruner, 1972; Gould, 1977; Lerner, 1984).

Culture and development thus form a functional synthesis that can be assessed adequately only when the mediating role of actions and self-related activities is considered. Cultures are aggregated systems of problem-solutions that have been developed during the process of cultural evolution; they offer solutions to adaptive problems that arise from the biological constitution of the human species, as well as to problems related to the maintenance and further evolution of the cultural system itself, and they also offer existential orientations that guide human actors in their search for meaning and purpose. Most important, cultures augment action resources and developmental options through compensatory strategies and "prosthetic devices" (Bruner, 1990b), thus enabling the developing subject to transcend constitutional limitations. These compensatory arrangements also comprise "psychological tools" (Vygotsky, 1960/1979), which are embodied in cultural conventions, institutions, and knowledge systems:

> Psychological tools are artificial formations. By their nature they are social, not organic or individual. They are directed toward the mastery or control of behavioral processes. . . . By being included in the process of behavior, the psychological tool alters the entire flow and structure of mental functions . . . just as a technical tool alters the process of a natural adaptation. (Vygotsky, 1960/1979, p. 137)

The commonplace formula which defines development as the joint or interactive product of genetic and environmental influences gives short shrift to the dynamic relationships that mediate development, action, and culture. Environment is "nature organized by organisms" (Lewontin, 1982, p. 160); likewise, developmental ecologies are "intentional worlds" (Shweder, 1990) that constrain and enable intentional self-development.

The semantic and symbolic content that essentially characterizes actions and cultural action spaces cannot be reduced to physical or physiological processes. Although the meaning of actions may be related to, and can partly be extracted from, the physical features of actions, intentional and physical aspects of action are not related in ways that would allow for reductive explanations (Dennett, 1987). This does not mean that an actional stance would necessitate discarding the "natural" bases and constraints of action. Natural and cultural aspects influence and pervade each other in the developmental process (Boesch, 1980; Brandtstädter, 1984a, 1984b; Dannefer & Perlmutter, 1990; Gibson, 1977), and I have already pointed to the interdependence between the cultural and phylogenetic bases of development. In developmental genetics, increasing recognition is being given to the fact that the genetic regulation of development is to a considerable extent mediated by behavioral systems (e.g., Gottlieb, 1992). Individuals choose and create their environments according to preferences and competencies that, as phenotypic dispositions, are linked to genotypic factors; such dispositions also influence the ways in which individuals respond to environmental influences to which they have exposed themselves selectively (e.g., the concept of "active genotype-environment covariation"; Scarr & McCartney, 1983; see also Plomin, 1986). Through their actions, individuals form, and continually transform, their phenotype and extend it into their personal culture and developmental history.

Personal Regulation of Developmental Processes

The cultural regulation of human ontogeny is closely intertwined with, and in part mediated by, processes of intentional self-development. The active subject is a constitutive and productive element of the cultural system, which is continually realized, maintained, and reformed through personal action. At the same time, individual action in its physical and symbolic aspects is inherently bound to the action space of a culture; it is

through transaction with the cultural context that individuals construe prospects of possible and desired developmental courses and acquire the knowledge and means to implement these prospects.

Culture, therefore, is not a system of forces that is intrinsically opposed to self-development, as alienation literature since Rousseau has maintained; rather, cultural contexts both constrain and enable self-regulatory processes. Cultural demands and affordances may be more or less congruent to and often conflict with the individual's developmental goals and potentials. The relational pattern of personal and contextual constraints of development is continually redefined and transformed in the course of cultural evolution and individual ontogeny. These changes, which occur in historical as well as in personal-biographical time, permanently induce conflicts and discrepancies in the transaction between the developing individual and the cultural ecology: Developmental tasks, role expectancies, or performance standards may overtax the individual's developmental resources; social opportunity structures may impede realization of personal goals and identity projects, and so on. As dialectic approaches have emphasized (e.g., Kesselring, 1981; Riegel, 1976), such discrepancies and conflicts are driving forces in cultural evolution as well as in the individual's development over the life span because they promote readjustments and new syntheses within the system in which they originate.

Individuals can respond to these adaptive problems in a variety of ways. They can adjust personal goals and projects to situational constraints and resources, or, conversely, attempt to modify external circumstances to suit personal interests and capabilities; they may try to evade or neutralize normative demands, or accommodate to them. Such adaptive activities generally aim at reducing discrepancies between factual or perceived courses of personal development and the person's normative conception of self and future development; they also serve to stabilize and maintain personal identity, thus displaying the functional characteristics of autopoietic processes through which living systems maintain and perpetuate themselves (e.g., Brandtstädter & Greve, 1994; for an explication of the concept of *autopoiesis,* see Maturana & Varela, 1980; Zélény, 1981).

These considerations support and illustrate the argument that processes of intentional self-development are integral to human ontogeny over the life span. However, one should be aware that these processes, like any human activity, involve elements beyond personal control. We organize our life and activities within a sociocultural matrix that structures and constrains personal action and development; our possibilities to alter these contextual constraints are limited. We even have limited influence on the "inner" context of our actions; in particular, we cannot deliberately change our own motives and beliefs (e.g., Brandtstädter, 2000; Gilbert, 1993). Action-theoretical stances here reach limits that have to be carefully fathomed. Finally, one should not discount the influence of accidental, uncontrollable events and "chance encounters" (Bandura, 1982a) in any individual life history, although, even here, some degree of control may be involved, as individuals may deliberately expose themselves to or actively seek risks or chances.

From the point of view of the acting subject, development over the life span appears as a blend of expected and unexpected, controlled and uncontrollable elements, or as a story of gain and loss, of success and failure (Baltes, 1987; Brandtstädter, 1984a). Efforts to keep this balance favorable are essential aspects of human activity. Individuals differ in the degree to which they feel able to alter the course of personal development, however, and such differences profoundly affect the emotional attitude toward self and personal future; feeling incapable of achieving desired developmental goals, or of becoming the person one wants to be, is largely coterminous with depression and loss of meaning in life.

Historical Notes

Action approaches to human development have a long history that can be traced back to antiquity. The idea that human beings make themselves is already expressed clearly in the philosophical work of Aristotle, who conceived of action as the process by which the person transforms self and life in accordance with ideals of rationality (Müller, 1982). In the Renaissance, self-formation and self-perfection flowered and even became a dominant form of life. The Renaissance ideal of *uomo universale,* of the individual who strives for self-perfection in all areas of development, resounds in the works of Shaftesbury, Herder, Schiller, and Goethe (Spranger, 1914); Tetens' notion concerning the "perfectibility" of human development, which was mentioned earlier, is still clearly influenced by this ideal. Giambattista Vico (1725/1948) even based his philosophy of history and culture on the argument that we can truly understand only what we ourselves have created (see also Bunge, 1979).

In early German psychology—especially in the philosophically oriented branch of "understanding" psychology (Dilthey, 1924; Spranger, 1914)—human development had always been conceived as a lifelong process of active self-development (Höhn, 1958). In Charlotte Bühler's conception of development during the life course (Bühler, 1933; Bühler & Marschak, 1969), the theoretical focus was on success and failure in concretizing and realizing life goals, the outlines of which emerge already in childhood and adolescence. However, early concepts of intentional self development were strongly loaded with connotations of freedom and spontaneity, and generally implied an anticausalist methodological stance. Such positions did not find fertile soil in a discipline that identified itself increasingly with the methodological ideals of the natural sciences (e.g., Cairns, 1983; Reinert, 1976).

In particular, it was the rise of behaviorism with its explicit antimentalist stance that impeded the broader reception and further development of action perspectives. This remains true despite the fact that it was the behaviorist program that promulgated an almost unlimited manipulability and modifiability of developmental processes (Bijou & Baer, 1961; B. F. Skinner, 1953; J. B. Watson, 1930). It was in the behaviorist framework, too, that the themes of self-control and self-regulation were first addressed systematically. From the behaviorist point of view, self-regulation boils down to a process by which individuals control their own behavior through manipulating stimuli and reinforcement contingencies: "When a man controls himself . . ., he is behaving. He controls himself precisely as he would control the behavior of anyone else—through the manipulation of variables of which behavior is a function" (B. F. Skinner, 1953, p. 228). A theoretical stance that rejects mentalistic terms such as personal goals, beliefs, or intentions as explanatory concepts, however, can hardly grasp those very issues that are of central interest to an action perspective; namely, the connection of personal development with the system of meanings, institutions, and norms that constitutes cultural contexts as well as personal activities in cultural settings.

In psychology, interest in these topics has been renewed by the so-called cognitive revolution of the 1950s and 1960s. The philosophical and epistemological critique of methodological behaviorism (e.g., Putnam, 1975) has further contributed to dispelling the skepticism that has surrounded the action concept. Today, action-theoretical approaches figure prominently in many domains of research. Moreover, the traditional dichotomies of explanation versus understanding, freedom versus determinism, or causalism versus intentionalism have lost much of their adversarial fervor; philosophical positions that plea for compatibility or, at least, peaceful coexistence between these stances have been advanced (e.g., Davidson, 1980; Dennett, 1987). The resurgence of cultural perspectives in psychology, and an increased theoretical concern with the cultural bases of behavior and development—Bruner even presages an impending "contextual revolution"—finds a natural ally in action-theoretical approaches:

> A cultural psychology, almost by definition, will not be preoccupied with "behavior" but with "action," its intentionally based counterpart, and more specifically, with *situated action*—action as situated in a cultural setting, and in the mutually interacting states of the participants. (Bruner, 1990a, p. 15)

THE CONCEPT OF ACTION

Unfortunately, or not, the attempt to explicate the concept of action cannot proceed from a single or unitary theoretical frame of reference. Action-theoretical formulations have been advanced in such diverse fields as psychology, sociology, anthropology, biology, philosophy, or economics; and even in these disciplines, concepts of action come in different shapes.

In the narrower domain of psychology, we can roughly distinguish between structural, motivational, control-system, and social-constructivist action theories.

Structural Theories of Action

This family of theories centers on the structural analysis of actions. There are different formats of structural analysis and it is not always possible to separate them clearly. One line of research has focused particularly on the formal structure of actions and of the cognitive operations underlying action; this approach is represented by the work of Piaget (e.g., 1970, 1976). Other approaches have centered more strongly on the componential analysis of specific activities and skills (e.g., Fischer, 1980; Mascolo, Fischer, & Neimeyer, 1999). Yet another variant of the structural approach is instantiated in the analysis of basic syntactic features that constitute

different types of actions, such as their actors, instruments, goals, objects, and further contextual elements (e.g., Aebli, 1980; Bruner, 1982; Fillmore, 1968; Schank & Abelson, 1977).

Motivational Theories of Action

Influential action-theoretical formulations have been advanced in motivational psychology, perhaps the most prominent being the expectancy-value models of action originating from the work of Tolman and Lewin (for overviews, see Feather, 1982; Krampen, 1987a). According to the basic explanatory scheme of this approach, actions are explained and predicted as a joint function of (a) personal expectations related to action-outcome contingencies, and (b) the subjective evaluation of expected consequences with regard to personal goals and standards. Different variants and extensions of this basic model have been proposed (e.g., Ajzen, 1988; Atkinson, 1970; Fishbein & Ajzen, 1975; H. Heckhausen, 1989; Vroom, 1964).

Control-System Theories of Action

In the tradition of G. A. Miller, Galanter, and Pribram (1960), this type of action-theoretical approach draws on cybernetic and systems-theoretical concepts. The basic analytic tool is the feedback cycle: Processes related to the transformation of goals into behavior and to the regulation of goal-related activity are described as hierarchically organized levels of discrepancy-reducing feedback loops (e.g., Carver & Scheier, 1981, 1998; Ford, 1987; Powers, 1973).

Social-Constructivist Concepts of Action: Activity Theory

A largely autochthonous strand of action research has emerged in the former USSR from the work of Vygotsky and his pupils (Leont'ev, 1978; Luria, 1979; Vygotsky, 1934/1986). Based on the tenets of dialectical materialism, this approach has a strong sociohistorical orientation. Goal-directed activity is seen as the mediator between external reality and individual consciousness; cognitive structures develop from the individual's interaction with cultural symbols as well as with material objects and tools, which, as objectified ideas and problem-solutions, organize thought and action (see also Cole, 1978; van der Veer & Valsiner, 1991; Wertsch, 1981).

This classification cannot claim to be exhaustive; there are no sharp boundaries between the theoretical clusters and there is a broader spectrum of research programs that, to various extents, borrow or integrate elements from the theoretical families described earlier. Such programs focus on, for example, social-cognitive aspects of action (e.g., Bandura, 1986, 1997), on cultural-symbolic perspectives (e.g., Boesch, 1980, 1991; Bruner, 1990a, 1990b; Valsiner, 1998), or on processes related to the formation and implementation of actions and action plans (e.g., Frese & Sabini, 1985; Gollwitzer & Bargh, 1996; Kuhl & Beckmann, 1985; von Cranach, 1982). Influential contributions to action theory have also been advanced in neighboring disciplines, particularly in sociology (e.g., Bourdieu, 1977; Parsons & Shils, 1962; Schütz, 1962) and in anthropology (e.g., Geertz, 1973; Gehlen, 1955/1988; Tyler, 1969). Last, analytical philosophy of action has contributed significantly to elucidating the action concept (for overviews, see, Brand, 1984; Care & Landesman, 1968; Moya, 1990). Some of the earlier-mentioned theoretical positions have been cast from the outset in a developmental framework or are framed as developmental theories; this is particularly true for structuralist and social-constructivist approaches. These approaches contribute important elements to a more comprehensive theoretical perspective of intentional self-development, which is outlined in later sections.

These introductory comments should make it clear that the different theories and research programs centering on the concept of action do not form a coherent system. Given the inherently cross-disciplinary nature of the action concept, the vision of a grand unifying action theory seems utopian. This compromises any effort to formulate consensual definitions. To elucidate the concept of action, I concentrate in the following on some general and rather uncontroversial elements that seem particularly relevant for conceptualizing the interdependencies between action and development.

Explicating Action: Conceptual Constituents

Is it possible to identify a set of essential and discriminative features that is common to all instances of actions, and that separates actions from other forms of behavior that would not count as actions? When speaking of acts, actions, or action-like activities, we obvi-

ously do not refer indiscriminately to any behavior but to behaviors that can and should be explained and predicted in a specific way. We seem to imply that the observed behavior has been chosen by the individual because of personal beliefs and values, and that it can be interpreted as serving some personal goal or as expressing personal attitudes and values. Accordingly, when accounting for actions, we try to show how they are linked with the actor's values, beliefs, attitudes, or competencies. When interpreting an observed behavior as an action or particular type of act, we suppose that the actor "could have done otherwise" (Chisholm, 1966), and that he or she was sufficiently free to refrain from the behavior (even nonbehaving sometimes can be considered as an action). Conversely, behavioral events that are beyond personal control seem not to qualify as actions; physiological reflexes, emotional reactions, and all forms of inadvertent or erroneous behavior (slips of attention, lapses of memory, and so on) are typical examples. These differentiations are also fundamental to moral and ethical evaluations; according to the conceptual rules inherent to moral discourse, standards of justice, rationality, or responsibility apply only to intentional and personally controlled behavior, not to nonintentional behavioral events (Austin, 1956).

There is no one-to-one correspondence between behaviors and actions; a given behavior, taken as an observable physical event, is often only one of several components that constitute an action (Thalberg, 1977). For example, an action of greeting can be instantiated through a multitude of physically different behaviors (i.e., through waving the hand, nodding the head, uttering a verbal formula); in turn, a given behavior such as waving the hand may instantiate such different actions as greeting, giving a signal, or chasing away a mosquito depending on the "inner" context (the individual's intentions, beliefs, and so on), situational specifics, as well as on the system of symbols, social norms, and conventions according to which certain behaviors in certain situations instantiate a specific action. To categorize a given behavior as a specific type of action thus generally involves an interpretative process that transcends the immediate observable givens; in this sense, actions may be conceived of as interpretative constructs (Lenk, 1981). Occasionally, a distinction is made between actions and acts in which the term *acts* is taken to denote the generic category or type of actions to which a given action belongs (e.g., Harré & Secord, 1972). Again, the same generic act can be instantiated through different actions, and the same action can instantiate different acts. To count as instantiations of some act or type of action, different actions must bear some structural semblance to one another: They have to possess those features that, according to conventions and conceptual rules, are constitutive for the respective act type. Parenthetically, this point is fundamental to the construction of developmental continuity and coherence, which often involves establishing structural or "homotypic" equivalence (Kagan, 1971) between phenomenally different behaviors at different ontogenetic levels.

In a first approximation, we may thus consider criteria such as intentionality, personal control, reflexivity, and (perceived) freedom of choice as defining actions (e.g., Groeben, 1986; T. Mischel, 1969). However, none of these criteria is without problems. Considering the criterion of intentionality, intended action outcomes often imply undesired or harmful side effects that are simply tolerated; people may be held morally and legally responsible for such condoned effects even when they did not focally intend them. There are also cases of reduced intentionality, for example, when someone doodles aimlessly on paper while making a phone call. The criterion of personal control has its complications as well. There are many nonintentional behaviors, such as physiological reflexes, that we can control in a technical sense; for example, we can deliberately induce sweating by exposing ourselves to higher temperatures. It does not follow that such physiological reflexes are actions (although the instrumental activities by which we brought about the response certainly are). It is also true that actions in any phase involve component processes that are not under personal control; we would have no control over our own behavior and development without the helping hand of mediating mechanisms that lie beyond our control. As already intimated, we even do not have full command over the internal context of our actions; thus, we are not at liberty to intend, wish, or believe whatever we want to believe, wish, or intend (e.g., Kunda, 1990; Lanz, 1987).

Within the confines of this chapter, I cannot dwell on the conceptual intricacies surrounding the notion of action (for a more detailed discussion, see, Greve, 1994; Moya, 1990). For the present purpose, the earlier considerations may be condensed in a working definition: *Actions may be conceptualized as behaviors that (a) can be predicted and explained with reference to intentional states (goals, values, beliefs, volitions); (b) are at least partly under personal control, and have been selected*

from alternative behavioral options; (c) are constituted and constrained by social rules and conventions or by the subject's representation of these contextual constraints; and (d) aim to transform situations in accordance with personal representations of desired future states.

This definition again underscores the intimate relation between action and personal development. Self-referential actions that are intentionally related to personal development, however, have additional properties that are delineated in later sections. Before addressing these issues, I attempt to give a more detailed account of how personal and social factors intertwine in the regulation of action.

Constraints of Action: Constitutive and Regulative Rules

Human action is related to rules in a twofold sense. In a first and familiar sense, actions and personal action spaces are *constrained* by rules; in a second and more fundamental sense, actions—or at least some actions—are *constituted* by rules. Following Searle (1969), one can differentiate between regulative and constitutive rules (the distinction can be traced back to Kant; see also Brandtstädter, 1984b; D'Andrade, 1984; M. J. Smith, 1982; Toulmin, 1974).

Regulative Rules

Personal action is regulated by a variety of cultural prescriptions and restrictions, and these can be more or less formal and explicit (laws, norms, customs, social expectations, etc.). Such rules delimit situationally defined zones and margins of action. The limits imposed by regulative rules, however, are not rigid; cultural laws, in contrast to natural laws, can be violated. Regulative rules, however, have "normative force" (Toulmin, 1969); they are linked to subsidiary social forces such as sanctions or patterns of reinforcement that tend to increase the frequency and probability of rule-conforming behavior. Regulative rules, whether they are externally imposed or "internalized" and integrated into the processes of self-regulation, generate regularities in patterns of action and development. For example, the developmental tasks or normative timetables which determine the proper scheduling of biographical events in social contexts (e.g., Chudacoff, 1989; Neugarten & Hagestad, 1976) define systems of regulative rules that institutionalize and synchronize individual life courses and thus impose order and regularity on development.

Constitutive Rules

When considering acts or action episodes such as marrying, formulating an excuse, promising something, or taking a penalty kick, it is evident that such actions are not simply regulated, but, in a stronger sense, are *constituted* by rules. Just as one can play chess only within the framework of chess rules, one can marry someone, give a promise, and so forth. Only according to specific semantic rules and social conventions that define, at least in outline, in which ways and under which contextual circumstances an action has to be performed to count as a valid instantiation of that particular act. Describing or understanding an action as an instance of a generic act presupposes familiarity with the corresponding constitutive rules (Winch, 1958). The rules that constitute particular acts are represented individually in scriptlike cognitive structures or schemas (Schank & Abelson, 1977). These scripts or schemas enable us to organize our activities according to socially shared meanings, and to extrapolate, anticipate, and coordinate courses of action in social settings.

Through constitutive rules, certain types of action are linked inseparably to cultural institutions. As D'Andrade (1984) has pointed out, changes in institutional contexts alter the range of possible actions, eventually creating radically new types of action:

> One consequence of constitutive rule systems is the enormous expansion of the behavioral repertoire of humans compared with the behavioral repertoire of other animals. For example, without the system of constitutive rules called football, the behaviors of scoring, blocking, passing, and so on would not exist. (p. 94)

Regulative and constitutive rules provide important vantage points for reconstructing developmental regularity and invariance from an action-theoretical point of view. The constitutive rule concept in particular offers a fresh perspective on the traditional theme of developmental universals; as I show later, the formal or conceptual rules that determine the structure of particular skills and competencies also impose order on the ontogenetic construction of the corresponding competencies.

The Polyvalence of Actions

The concept of polyvalence is related to the valence concept in Lewinian theory; it refers to the fact that one and the same action can serve different purposes and in-

tentions and correspondingly can have, and usually has, multiple meanings at both personal and public levels. For example, the person who quits smoking can do so for health reasons, to avoid social conflicts, for financial reasons, to demonstrate willpower, or for some combination of such reasons. Actions or action tendencies mostly result from a mixture of instrumental, symbolic, expressive, and aesthetic valences, which may sometimes conflict:

> Polyvalent means three things: first, actions, aiming at composite goals, are "over-determined"; second, they connote different areas of experience; and, third, they draw their justifications not simply from the concrete specific results they (tend to) achieve, but also from the subjective experiences implied, from personal fantasms, cultural rules and values. (Boesch, 1991, p. 363)

From the polyvalent (or polysemous) nature of actions, it follows that one and the same basic action can simultaneously instantiate a multitude of different acts. When Mr. Doe mows the lawn, he is cutting the grass, making noise, and exercising his muscles; by doing this, he is—depending on the given causal, social, and symbolic context—perhaps pleasing his neighbors, evading conflicts with his wife, showing a sense of responsibility, and so forth (Rommetveit, 1980). Some of these effects and implications may be intended, others may be simply tolerated or even remain unnoticed. To capture the multiplicity of levels on which a given action can be described, Goldman (1970) has coined the metaphor of an "act tree" whose branches are generated through causal mechanisms, conventions, or language rules. The ways in which actors construe the effects and implications of their own activities, and describe their actions, may differ from the interpretations of external observers. Such differences may give rise to social conflicts and identity problems, the solution of which often requires negotiation of consensual interpretations. Negotiating meanings is a basic strategy for establishing consensus and co-orientation between developing individuals who have to coordinate their actions and developmental goals in, for example, martital relationships or family systems (Berger, 1993; Brandtstädter, Krampen, & Heil, 1986). As is evident from these considerations, the meanings and motivating valences of actions, even of everyday activities, can be and often are ultimately rooted in global identity goals and life themes.

Different kinds of knowledge and expertise, and corresponding developmental steps, are is required for a differentiated representation of the meanings and effects of action: Knowledge about the causal structure of action spaces is required for gauging possible action-outcome contingencies whereas the construal of semantic or symbolic implications requires corresponding conceptual knowledge. The polyvalence of actional meanings also implies emotional polyvalence; when different interpretive schemes can be applied to a personal or observed action, different or "mixed" emotional evaluations may result. For example, an aggressive action may be coded as an act of self-assertion, as an infringement of moral norms, as a lapse of self-control, and may simultaneously invoke feelings of pride, guilt, or shame. The emergence of such mixed feelings appears to be an ontogenetic marker of the individual's developing ability to represent the causal and semantic implications of observed events and behaviors (Harter, 1986).

Self-control and intentional self-development crucially hinge on the construction and deconstruction of meanings and evaluative standards. Human actors can take an evaluative stance with respect to their own intentions, emotions, and actions; for example, we may experience feelings of pride or shame with regard to our own feelings. Such metaemotions or second-order evaluations are characteristic for a higher ontogenetic level of action regulation, a level on which moral principles, social norms, and personal representations of "ought selves" (Higgins, 1988) become integrated into the process of intentional self-development (see also Frankfurt, 1971). Again, ontogenetic requirements should be noted. The polyvalence of actions reflects the embedding of individual behavior into a hierarchy of contextual levels that—to borrow terms from Bronfenbrenner's (1979; Bronfenbrenner & Morris, 1998) model of developmental ecologies—extends from the encompassing macrosystem of cultural institutions, norms, and symbols through intermediate mesosystems down to the social and physical microsystems that constitute the proximal setting for the individual's activities. The representation of meanings proceeds ontogenetically in a sequence that corresponds to the increasing abstractness and complexity of the contextual levels in which actions are situated. Whereas early in development, the focus for evaluating one's actions is primarily on perceived and anticipated effects in the immediate or proximal environment (e.g., reactions of parents or peers), the evaluative scope widens on subsequent developmental stages so that more complex and abstract system perspectives become progressively influential in self-regulation (see

Eckensberger & Reinshagen, 1980; Edelstein & Keller, 1982; Harter, 1983; Selman, 1980).

The Context of Action

Psychological action explanations primarily center on the "inner" context of action: on the individual expectations, goals, beliefs, and so forth that determine the intentional structure of action. This explanatory focus, however, provides only a reduced, largely ahistorical, and adynamic picture of action that is of limited use for developmental theorizing. To appreciate how an individual's life history relates to the patterning of personal goals, projects, and actions across the life course, external contextual conditions must be taken into account. The blending of intended and unintended, expected and surprising outcomes that makes up any biography is essentially determined by the external context of action and its physical, material, and social constraints.

People generally have only limited insight into the contextual conditions of their behavior. The complexity of the causal and symbolic structures that generate meanings and effects of action generally exceeds the representational capacities of the individual actor; unintended and unexpected effects are intrinsic to the reality of action under conditions of "bounded rationality" (Simon, 1983). Though the aspect of unintended consequences has been largely neglected in psychological and philosophical accounts of action (see Giddens, 1979), it has profound implications from a developmental point of view. The experience of unintended or unexpected effects provides an impetus for the revision and continuing adjustment of individual goals and beliefs; surprise induces exploratory activities through which the inner context of an action is modified and accommodated to external constraints. Unintended effects, and the ways in which individuals cope with them, are dramatizing elements in any personal biography (Bruner, 1990a); they shape future action spaces and developmental options, and provide a corrective for the theories and beliefs that individuals hold about themselves and their environment.

As cultural artifacts, action contexts are to a large part the result of individual and collective actions. Cultures provide means and prosthetic tools to maximize intended effects of actions and to suppress unintended side effects of actions; they create norms and institutions to coordinate the actions of individual actors so that they become mutually compatible. Beyond this, individuals themselves actively control the texture of their action space; actors have an interest in making effects or meanings of their actions converge with their intentions, and they strive to organize the personal action space accordingly. If such efforts fail, individuals may select an ecological niche (Super & Harkness, 1986) that fits better with their intentions or developmental goals. Through these selective and constructive activities, personal action contexts become extensions of the actor's self (e.g., Brandtstädter, 2001; Csikszentmihalyi & Rochberg-Halton, 1981; Thomae, 1968).

In general, individuals select and organize contexts and fields of activity according to a principle of "just manageable difficulty" (G. Brim, 1992). In early childhood, this selection is typically under the control of adult caretakers. Parents structure the activities of the child through limiting access to certain situations and experiences, as well as through encouraging or supporting particular activities; they create "zones of free movement" and "zones of promoted action" (Valsiner, 1987a) that are more or less adjusted to, but at the same time also shape, the "zone of proximal development," that is, the next developmental tasks or steps that a child has partially mastered already but the successful completion of which still requires external support (Vygotsky, 1978; Wertsch, 1984). This structuring of action zones provides a scaffold that organizes and directs developmental progress; examples can be found in the organization of the child's action spaces during meal times or of toddlers' climbing activities (Gärling & Valsiner, 1985; Valsiner 1988a, 1988b).

Harmonizing contextual demands and resources with personal goals and developmental potentials is in itself a fundamental theme of intentional self-development (Kahana, Kahana, & Riley, 1989). Because both external (physical, social, symbolic) contexts and personal resources of action (values, interests, competencies) are involved in historical and ontogenetic change, this mutual accommodation remains a concern over the entire life span, and developmental problems often result from poorness of fit between (or within) these systems of influences at different developmental stages (Brandtstädter, 1985a; Chess & Thomas, 1984; Lerner & Lerner, 1983; Thomas & Chess, 1977). Critical events and transitions in the individual's life course involve particularly strong pressures to revise action spaces and developmental goals. In later life, the changes and limitations of action resources, which typically accompany the processes of aging, enforce readjustments of per-

sonal projects and activities. The importance of such adaptive dynamics for buffering experiences of loss and for preserving a positive view of self and personal development has become a topic in developmental and gerontological research over the past years (e.g., Baltes & Baltes, 1990; Brandtstädter & Renner, 1990). I address this in a later section.

The extent to which external contextual constraints fit, or can be made to fit, with personal interests and potentials deeply affects the long-term balance of successes and failures, or of developmental gains and losses, in the individual's life history. Recurring experiences of noncontingency between one's actions and contextual effects undermine a sense of personal control and self-efficacy and may foster a tendency to avoid tasks and developmental options that involve a risk of failure; yet, it is precisely these challenges that afford opportunities for further personal development (Bandura, 1981, 1997).

DEVELOPMENTAL DIVERSITY AND REGULARITY: ACTION-THEORETICAL RECONSTRUCTIONS

The search for coherence and lawful regularity in human development is a traditional heuristic ideal that has inspired developmental psychology from its very beginnings: "From the colourful play of human changes, we must go back to an invariant order, back as far as possible to the eternal source of phenomenal variation" (Carus, 1823, p. 94; trans. J. B.). This ideal can be traced back to the philosophical teachings of Parmenides (540–480 B.C.) and Plato (427–347 B.C.): For Parmenides, the phenomenal world in all its diversity was merely the appearance of one immutable substance, whereas Plato considered empirical phenomena to be the reflection or imperfect instantiation of timeless and unchanging ideas (see also Toulmin, 1977).

To what extent are action-theoretical perspectives compatible with this influential epistemic stance? At least at first glance, it appears that the rise of action perspectives signals the demise of a Parmenidean or Platonic stance; the arguments that strengthen the latter seem to weaken the former, and vice versa. First, a research heuristic aimed primarily at the disclosure of universal ontogenetic principles tends to detract from the institutional, symbolic, subjective-intentional conditions of development—conditions that seem to breed diversity rather than regularity in human ontogeny (Shweder, 1990). Second, the search for universal laws in ontogeny has not been an extraordinary success, to put it mildly; it has generated massive evidence apparently speaking against the assumption of lawful regularities in development. Thus, longitudinal investigations have documented considerable variability and heterogeneity in developmental patterns for many behavioral domains; correspondingly, long-term predictions have evinced a high degree of indeterminacy (Baltes, Reese, & Lipsitt, 1980; Lerner, 1984; Rutter, 1984; Schaie, 1983). Likewise, there is only scarce support for the traditional claim that personality development over the life course is shaped profoundly by early childhood experiences, as has been argued by psychoanalytic theory and partly also by learning theorists (Clarke & Clarke, 1976; Oyama, 1979). O. G. Brim and Kagan (1980, p. 13) have aptly described the situation: ". . . growth is more individualistic than was thought, and it is difficult to find general patterns."

Not surprisingly, these research experiences have strongly encouraged theoretical views that programmatically emphasize the discontinuous, contextualized, and aleatoric (i.e., coincidental or random) character of development over the life span (Baltes & Reese, 1984; Baumrind, 1989; Emde & Harmon, 1984; Gollin, 1981; Lerner, 1984). There even have been claims as to the basic futility of any search for universality and invariance in ontogeny (e.g., Gergen, 1980; Shweder, 1990). However, a note of caution is required here: As long as we cannot rule out that difficulties in extracting structure and law-like regularity from developmental diversity merely reflect theoretical deficiencies, it would be a weak argument to simply attribute such difficulties to an allegedly unpredictable or inchoate nature of development. Allusions to the fundamental indeterminism of phenomena in quantum physics that recently have become trendy among developmentalists do not seem to be tenable; it may suffice here to note that the uncertainty principle in quantum physics is not a declaration of theoretical ignorance but a powerful predictive device. In any case, it would be a logical mistake to equate lack of evidence for lawful regularity with evidence for the lack of such qualities. Coherence and universality in development are not observable facts that can be established conclusively; these qualities emerge only by way of theoretical abstraction. In a similar way, plasticity and modifiability are not features that characterize development

in an essential or fundamental sense; they have to be conceived as qualities that relate to potentials of change and modification in a given cultural and historical frame.

The Construction and Deconstruction of Developmental Coherence

To account for continuity and coherence in developmental patterns, it is usual to invoke causal mechanisms (e.g., Overton & Reese, 1981). A causal or deterministic stance, however, is rendered problematic by the fact that developing organisms have to be conceived as open systems (see also Ford & Lerner, 1992). Only in a system that is closed to external influences can there be causal chains such that subsequent states are linked in a necessary and invariant fashion; the developing organism, however, is functionally coupled to its physical and social environment by the continuous interchange of stimulation and information. Defenders of a determinist stance might argue that such difficulties could be handled simply by expanding the analytic perspective: "If determinism is assumed, alterations in a system which do not appear to occur as the consequence of the presence or operation of antecedent factors or conditions, must be regarded as belonging to a more inclusive system which is deterministic" (Nagel, 1957, p. 17).

If we widen our explanatory scope to include the physical and social ecologies of development, however, it becomes obvious that regularities in human development are not brought about by causal laws alone but, to a considerable extent, reflect the ways in which institutions, collective agents, and the developing individuals themselves, purposefully or inadvertently, make use of such laws. If the notion of causality is taken to refer to invariant sequences of events in which some antecedent condition inevitably generates some consequence (e.g., Bunge, 1979), the regularities that characterize human development as a product of personal and collective action can hardly be described that way. In cultural contexts, developmental regularities are in large measure patterned and mediated by individual and institutionalized actions, and, by consequence, can also be transformed or suppressed through action. For example, connections between risk factors in early development and unfavorable developmental outcomes generally depend on moderating or mediating variables such as prevailing attitudes in the social environment or the availability of preventive and therapeutic resources (e.g., Busch-Rossnagel, 1981); likewise, age-related decrements in memory, physical stamina, health, and so forth will be expressed more strongly in contexts (and individuals) in which the motivation, knowledge, or resources to counteract functional loss are lacking (Baltes & Schaie, 1974; Salthouse, 1987). A particularly intriguing example of how a seemingly inevitable causal sequence can be broken up through interventive action is the inherited metabolic disease of phenylketonuria (PKU). Formerly, PKU invariantly led to severe mental retardation; today, the metabolic mechanisms involved are sufficiently known so that it has become possible to avoid insidious developmental consequences by a proper dietary regime. The list of examples obviously could be extended *ad libitum.*

Developmental regularities in actional contexts essentially arise from personal and institutionalized agentivity. Thus, the tendency in a given social or personal context *C* to produce or forestall a specified developmental outcome or pattern *D* can be conceived as depending on available resources of intervention, on the cost of such interventions, as well as on the value (which may be positive or negative) that *D* has in *C* (Brandtstädter, 1984c). Accordingly, we would expect that for developmental domains that are amenable to control, transitions from socially undesirable states to positively valued states should be more frequent or probable than the obverse transitions. Consistent with this assumption, longitudinal observations suggest that in regard to traits that are socially recognized as positive, the probability that children at lower levels on the trait later come up to a higher level is greater than the reverse case; likewise, socially deviant behaviors seem to show less developmental stability than behavior that conforms to social norms (Kagan & Moss, 1962; Kohlberg, LaCrosse, & Ricks, 1972). Longitudinal findings also hint, for example, that the probability of a delinquent adolescent exhibiting socially deviant behavior in adulthood is lower than the reverse, retrodictive probability (Rutter, 1984). By the same reasoning, we may infer from the frequent or regular occurrence of a negatively valued developmental pattern or outcome a lack of pertinent preventive knowledge or resources; this argument also accounts for the observation that developmental losses in later life are perceived as less controllable when they involve positively valued domains (J. Heckhausen & Baltes, 1991).

Even biology and developmental genetics no longer provide a safe retreat for deterministic views of invari-

ance and ordered change in development. The genome does not rigidly determine a developmental phenotype. Rather, it defines the norm of reaction or the function that, for a given genotype, maps possible environmental influences onto phenotypic outcomes; "genes . . . code for a range of forms under an array of environmental conditions" (Gould, 1981, p. 56; see also Gottlieb, 1992). From this point of view, developmental patterns appear as genetically fixed only as long as relevant epigenetic conditions are held constant or within critical margins. If we define the heritability of a given developmental phenomenon as the portion of phenotypical variance that is accounted for by genetic sources, the obtained estimate is not a natural constant, but depends crucially on the range of variation in critical environmental conditions that is produced or tolerated in a given cultural context. Ethical norms and codes of justice, for example, limit inequalities in the distribution of developmental resources, public health measures restrain detrimental influences, and theoretical and technological progress permanently spawns new means of preventive and corrective intervention into human ontogeny. Accordingly, the relative portions of phenotypic developmental variation accounted for by genetic and exogenous influences, respectively, can change over a shorter or longer historical interval; but "change the mix and the answers change" (Plomin, 1986, p. 7). Seen from an action perspective on development, heritability coefficients provide only limited evidence as to the lesser or greater external modifiability of a developmental trait; rather, they reflect propensities and limitations in developmental ecology to control critical epigenetic influences (Brandtstädter, 1984b; Lerner & von Eye, 1992; Scarr, 1982).

Developmental Plasticity: Weak and Strong Constraints

The earlier considerations suggest the following proviso when framing propositions about developmental regularities: No developmental tendency exists that cannot be altered, provided that the individual or collective agents concerned both want to alter it and possess the appropriate means to do so (see also Watkins, 1957). On closer examination, this proposition turns out to be irrefutable; it is true by virtue of its logical form alone. It does not implicate, however, an unlimited plasticity or modifiability of human ontogeny, neither are all developmental modifications possible nor are all possible variations desirable or permitted.

We can differentiate between weak and strong constraints on the range of developmental trajectories, that is, between constraints that themselves are, at least in principle, open to change, and those that, for strong reasons, are not. Strong, if also very wide, constraints are imposed on development by the laws of logic (e.g., through logical and mathematical structures); developmental outcomes that involve logical contradictions or combine logically opposed states are a priori impossible. Natural laws also constrain the space of possible developmental phenomena in a strong sense. Human beings are both personal actors and, at the same time, organic systems that are subject to physiological, biochemical, and biophysical laws. These laws can eventually be exploited to generate desired developmental outcomes through deliberate manipulation of antecedent conditions, but they cannot be altered, for reasons inherent to the very notion of a natural law. Developmental trajectories necessarily remain in the limits imposed by natural laws, which are narrower than those imposed by logic.

In contrast, the values, technologies, and theories that provide the orienting framework for social and personal regulation of development are not fixed or rigid in a strong sense, but are factually or in principle open to change. The limits of what is possible and desirable in human development are continuously redefined and renegotiated in the process of cultural evolution; it is certainly not by accident that the progressive expansion of cultural resources for developmental intervention and modification coincides with the rise of theoretical paradigms that emphasize the plasticity, multidirectionality, and variability of human ontogeny.

Finally, ontogenetic processes are also constrained by the semantic rules and conceptual structures that are used, in science as well as in everyday contexts, to analyze, and communicate about, development. The semiotic context not only constitutes and constrains spaces of action but also imposes order on developmental sequences. With regard to the distinction between weak and strong limitations, this type of constraint cannot be classified easily. This is an important point that is discussed more closely when turning to the issue of developmental universals.

To summarize these considerations, we may picture the different constraints as a hierarchy of inclusive sets as shown in Figure 10.2 (see Brandtstädter, 1984c):

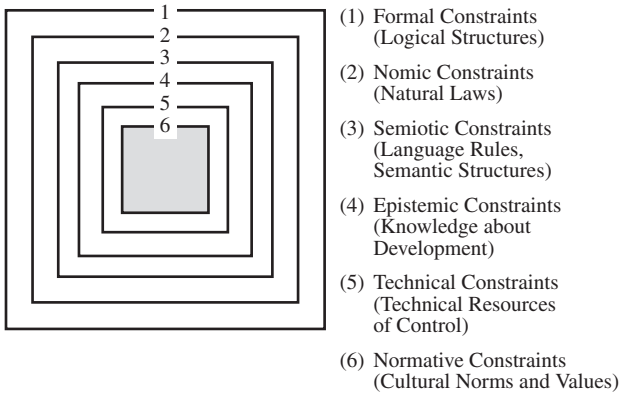

Figure 10.2 Development in action contexts: A system of constraints (see text for further explanation).

From the totality of all logically possible states that a developmental system might assume, only a subset of states is compatible with natural laws and with semiotic constraints; from this subset again, only a smaller portion can be realized within the limits of available theoretical and technological means; and finally, only a selection of developmental pathways that could possibly be realized will also be desired or permitted under prevailing normative constraints (here, the reverse is generally also true). The shaded residual area in Figure 10.2 describes the allowable margins of developmental variation within this system of constraints.

Assumptions regarding developmental phases of higher or lower modifiability play an important role in policy decisions concerning the distribution of educational and intervention resources over the life cycle. Often, such assumptions are based on observed inter- and intraindividual variation in the trait in question. For example, early childhood programs were launched under the premise of a special sensitivity of the early years as compared with later phases in life; this assumption leaned strongly on an analysis of longitudinal variations in the stability of intelligence test scores (e.g., Bloom, 1964; Clarke-Stewart & Fein, 1983). The earlier considerations caution against potential pitfalls of inferring developmental plasticity from observed variation. Because actually observed variation in a developmental trait depends on the affordances, resources, and constraints realized in a given environmental setting, it obviously can provide only a weak estimate of the potential range of variation. As McCall (1981, p. 9) has put it, "the environments not represented in the sample also have implications for the . . . potential for change." To gauge limits of performance and developmental variation, planned experimental interventions seem to offer a stronger basis; efforts to boost memory performance of elderly subjects through mnemonic training may be considered as an example (Baltes, 1993; Kliegl, Smith, & Baltes, 1989). Even through experimental manipulations, however, limits of potential development cannot be determined in any definitive way because the results of such interventions always depend on the theoretical and procedural means available in a given cultural and historical situation, and thus are themselves subject to theoretical and technical limitations.

Invariance and Universality in Development: An Action-Theoretical Account

The notorious difficulties in establishing generally valid developmental patterns reflect the general principle that development—as Hegel (1837/1857) in his philosophy of history once put it—only manifests itself in concrete-historical modifications. Thus, one might suspect that theoretical views that consider context, culture, and intentional action as driving forces in human development are likely to end up in a relativism that renders the search for continuity and universality quixotic (Bruner, 1990b; Gergen, 1980). This is a threatening perspective, at least to those developmentalists who still subscribe to the view that the strength of a theoretical framework comes from its ability to encompass differences as well as regularity and invariance in development (Block, 1971; Brandtstädter, 1984c, 1985b; Lerner, 1984; Rosch, 1977). Expanding arguments from the last section, we explore in the following how the traditional issue of developmental universals may be approached from an action perspective. To preview, an action-theoretical account of invariance and universality differs in some respects from traditional treatments of these issues.

Developmental Universals as Empirical Regularities

As it is commonly used, the notion of developmental universals refers to ontogenetic phenomena manifesting themselves in the same or similar ways across different social, cultural, or historical contexts. Across all cultures, we observe similar structures and sequences in prenatal development, in the maturation of physiological functions, in early sensorimotor development, in language acquisition, in cognitive and affective develop-

ment, as well as in the processes of biological aging (for overviews, see Cole & Scribner, 1974; Kagan, 1981b; Warren, 1980). A theoretical emphasis on diversity and multidirectionality in development should certainly not obfuscate the considerable constancy and transcontextual stability in basic patterns and processes of human ontogeny. Cross-cultural research, with its emphasis on documenting cultural specificity, often tends to overlook the conspicuous commonalities in development (Rosch, 1977).

Although developmental commonalities of the mentioned type emerge across a broad range of environmental variation, they necessarily presuppose constancy in those exogenous influences that have an impact on the given ontogenetic functions. Genetic mechanisms generate similar developmental phenotypes only as long as critical epigenetic influences remain sufficiently stable or—which is the interesting case from an action-theoretical perspective—are actively kept within critical margins. If critical exogenous variations exceed those tolerance margins, for example, as a result of influences that override genetic buffering mechanisms because they occur for the first time in evolutionary history, anomalous developmental patterns emerge: The thalidomide disaster is a dramatic example. The genetic control of ontogenesis presupposes mechanisms and structures that regulate and standardize the distribution, intensity, and temporal patterning of critical exogenous variables. The mediating processes that warrant this epigenetic order involve the selective and constructive activities of the developmental organism itself, as well as the "institutionalized operativity" (Warren, 1980, p. 310) of the social and cultural system. As already stressed, personal and cultural agentivity merge in the regulation of development; both are related to social norms that prescribe and enforce the timing and sequential order of developmental tasks and role transitions across the life span.

An important point that follows from these considerations is that observed regularity of certain ontogenetic forms is not in itself sufficient to establish universality in the strict sense because observations can always cover only a limited range of situations. Even if an empirical rule has been found valid without exception, this does not warrant its universality across time and space; this is the problem of inductive generalization as classically formulated by Hume. Postulates about universal ontogenetic sequences, as they have been set forth in, for example, stage models of cognitive, sociomoral, or emotional development (e.g., Kohlberg, 1976; Piaget, 1970; see also Brainerd, 1978), can eventually be refuted but never be definitively settled on an empirical base alone.

At this juncture, the differentiation between weak and strong constraints of development suggests a corresponding distinction between universality in a weak and a strong sense. Traditional notions of developmental universals, as far as they refer to empirical regularities resulting from commonalities in the social and cultural canalization of development, can at best qualify as universal in a weak sense (even if no exceptions have ever been observed). By contrast, to claim universality in a strict sense, it has to be demonstrated that falsifying events are logically or conceptually impossible, and thus can be excluded on an a priori basis.

Developmental Universals as Structural Implications

As already indicated, the search for universals of human development, at least for universality in the strict sense, is often deemed to be an obsolete research heuristic, being diametrically opposed to a posture that emphasizes the formative impact of context and culture on human ontogeny. However, it seems that consideration of the formal and conceptual structures that constitute development in action contexts opens a fresh perspective on these issues.

The notion of constitutive rules provides a starting point for elaborating this argument. As introduced earlier, constitutive rules establish structural criteria that empirical phenomena must satisfy to count as an instance of certain generic category. According to the constitutive rules defining, for example, the concept of altruism, acts of altruism must involve a sacrifice of own interests to the advantage of others; this feature serves as a criterion to identify altruistic intentions, and it is therefore present in all valid instantiations of this type of act. If there never has been a case of altruistic behavior that did not involve an element of sacrifice, this is not due to some natural law or causal mechanism but reflects constitutive rules that preclude such an event, quite as it would be impossible to "castle" in chess without moving the king two squares toward the rook. In physical theories, we have a similar situation when the measuring of a theoretical variable is based on or derived from some theoretical core assumption; the gathered data cannot disconfirm those parts of a theory whose truth is asserted in the very procedure of observation. According to a structuralist view of theories (Balzer & Moulines, 1980; Balzer, Moulines, & Sneed,

1987), this "theoreticity" of measurements should not be viewed as a methodological weakness but is characteristic of advanced physical theorizing.

Generally, we may assert: When a relationship of the type "If *A,* then *B*" is proposed, and the falsifying event (i.e., the occurrence of *A* without *B*) is excluded for reasons inherent in the formal or conceptual structure—or, as Wittgenstein put it (Waismann, 1979, p. 91), in the "syntax"—of the terms that figure in the proposition, then the proposition becomes a tautology, a statement that is true in all possible worlds. Implications that in this sense structurally preclude the falsifying case may be denoted as *structural implications,* or as propositions involving *implicative structures* (e.g., Brandtstädter, 1987; Lenk, 1987). Structural implications correspond largely with an entailment account of necessary implications as advanced in relevance logic (Anderson & Belnap, 1975). According to relevance logic, the universal validity of necessary implications follows from a relation of entailment in which the meaning of the consequent is nested in the meaning of the antecedent so that a valid verification of the antecedent condition necessarily involves the verification of the consequent. Interestingly, Piaget in his late work has espoused a relevance logic point of view to elucidate the notion of necessity and its ontogenetic acquisition (Piaget, 1986, 1987; Piaget & Garcia, 1983/1991; Ricco, 1993; see also Overton, 1990).

Structural implications may easily be confused with empirical hypotheses, at least as long as the structure of the concepts involved is not analyzed sufficiently. There are numerous examples of such confusions in psychological research (e.g., Brandtstädter, 1982; Kukla, 1989; Smedslund, 1979, 1984). However, drawing firm distinctions between implicative and empirical relations can be problematic; especially when dealing with concepts involving a large array of interpretative specifications ("cluster concepts"; Putnam, 1975), the categorial border between meanings that are structurally implied and empirical correlates of the concept may be blurred (e.g., Brandtstädter, 1987; Lenk, 1987). Despite such reservations, implicative structures offer a vantage point for approaching developmental universals.

The point here is that implicative structures can impose an invariant order on ontogenetic sequences; however, some notes of caution are required in advance to avoid misunderstandings. First, it should be stressed that structural analyses, like empirical ones, are not fail-safe. It is not uncommon, for example, that presumably "logical" ontogenetic sequences actually do not appear (e.g., Carey, 1982; Fischer, 1980); as Flavell (1972) has noted, "the path from logical to developmental priority can be an extremely slippery one" (p. 331). Furthermore, structural analyses can never account for a developmental sequence in any empirical detail. For example, scrutinizing the formal or conceptual implications of a developmental task can yield insights as to the steps involved in the acquisition of the pertinent skills or competencies but may not tell us much about the type of learning experiences or didactic arrangements that might foster this process. By much the same token, structural analyses cannot explain why structurally homologous skills often are acquired at different ages or developmental stages; for example, children develop conservation of substance before conservation of weight, though the tasks have a similar formal structure (e.g., Aebli, 1987; Piaget & Inhelder, 1942/1974).

Paying heed to these caveats, the claim that implicative structures impose an invariant order on ontogenetic sequences should be read as follows: Whenever a developmental state or outcome *D* by virtue of its (formal, conceptual, material) structure entails certain constituent elements *Ci,* than *D* will presuppose *Ci* also in the ontogenetic sequence. It may be an open empirical question whether *Ci* will emerge prior to, or simultaneously with, *D*; but to the extent that the occurrence of *D* without *Ci* can be excluded formally or conceptually, it should be impossible for the same reasons for *D* to precede *Ci* ontogenetically.

In the following, I briefly consider three variants of structural implications that involve different type of structural relationships: (1) formal implications, (2) constructive and conventional implications, and (3) conceptual implications.

Formal Implications

This type of structural implication follows from the formal (logical, mathematical) structure of a given task or competence. As Piaget (e.g., 1970; Inhelder & Piaget, 1958) has shown for the domain of cognitive development, the formal structure of a task is reflected both in the type of cognitive operations necessary for mastering it, as well as in the ontogenesis of these operations. For example, seriating objects according to size presupposes an understanding of the transitivity property of asymmetric relations; balance scale tasks require a grasping of the compensatory relation that holds between the

length of levers and the suspended weights. The competencies implicated by these tasks, in turn, presuppose more elementary ones such as detecting and monitoring differences in size or length, and so on. Though such developmental sequences can be demonstrated empirically by appropriate methods, such as scalogram analysis (Siegler, 1981; Strauss & Ephron-Wertheim, 1986), they obviously do not reflect simple empirical or causal contingencies but follow from the formal characteristics of the particular tasks (see also Smedslund, 1984).

Constructive and Conventional Implications

Actions often involve the competent use of mediating objects; particular skills (e.g., skiing, piano playing) are inherently tied to the competent use of instruments, tools, or other cultural artifacts. Efficient action here presupposes accommodation to the particular constructional features and demands of these mediating means (Kaminski, 1982; Leont'ev, 1978; Oerter, 1991). These structural features often impose strong constraints on the ordering of steps in the acquisitional sequence (e.g., Resnick, 1973). For example, children will not be able to read the hands of a clock and tell the time unless they have acquired other component skills such as distinguishing between big and little hands, translating the positions of the hands into particular numerical relations, and so forth. Though there is no one-to-one relation between structural features of an object or instrument and the developmental steps that lead to its competent use (Fischer, 1980), we can safely assume that in the ontogenetic sequence, a complex skill will not emerge earlier than the constituent skills related to the specific structural features and demands of the objects and instruments involved.

It appears that these arguments apply to all activities that are defined by specific production rules. Actions such as making a promise, dancing a waltz, or cooking spaghetti bolognese imply a recurrent configuration of actional and contextual elements, which is encoded in constitutive rules, prescriptions, or recipes. There may be variants, creative modifications, as well as atypical and less-then-successful realizations of the constitutive rules. Categories may be fuzzy, so that there may even be no criterial feature that would be common to all possible instantiations (Rosch, 1977). In cases like the ones considered earlier, however, we can identify structural features that must invariantly be present because they constitute the act in question: A waltz can only be performed in ¾ time, a promise can only be given by a person who understands the concept of obligation, and so forth. By excluding some ontogenetic sequences as structurally impossible, these structural implications also determine ontogenetic invariances.

Conceptual Implications

The meaning of the terms that we use in describing, and communicating about, behavioral or developmental phenomena essentially results from their position in a conceptual network. The semantic relations constituting such a network may be conceived of as a system of rules that determine which terms or attributes are "copredicable" (Keil, 1979). The concept of "lie," for example, is semantically related to "truth" and "intention"; when we accuse someone of a lie, we mean that he or she has purposely told an untruth. As Piaget (1932) observed, young children often use the word "lie" in a vague manner to refer to naughty words; during the course of language acquisition, the use of the word gradually becomes restricted to untrue statements made with deceitful intent, thus conforming with established conceptual rules. These rules imply that one cannot possibly identify a "lie" before having grasped the concepts of truth and intention, and that one will not be able to perform an act of lying before being able to discriminate between true and untrue and act intentionally.

Invariant ontogenetic sequences such as postulated in cognitive-developmental models of moral judgment likewise can be reconstructed as structural implications. Moral judgments essentially involve ascriptions of guilt and responsibility (Kohlberg, 1976; Turiel & Davidson, 1986); according to conceptual rules that relate responsibility to intentionality, ascribing responsibility, in turn, implies consideration of the actor's motives, intentions, and constraints. From such analyses, we may derive that competent moral judgment ontogenetically presupposes a capability to assess the motives and intentions of other persons; this also corresponds to theoretical postulates about the "necessity but insufficiency" of social-cognitive competence for competent moral judgment (e.g., Selman & Damon, 1975). It is doubtful, however, that we are dealing here with a proposition that is open to empirical refutation; rather, it seems that the falsifying case (moral competence without social-cognitive competence) is conceptually incoherent and cannot occur—given a conceptually valid assessment of moral competence. Another constitutive feature of moral competence is the ability to evaluate prevalent social norms and institutions with respect to general ethical standards.

This assumption is captured in the postulate that principled or postconventional moral judgment presupposes the development of a sociomoral perspective that is system-transcending or "prior to society" (e.g., Kohlberg, 1976). For basic conceptual reasons again, it is difficult to conceive of an ontogenetic pattern that would not conform with this assumption because ethical principles formally implicate a universal, system-transcendent stance.

These examples give an impression of how the structure of language games influences ontogenetic forms. This influence is, of course, particularly obvious in the domain of language acquisition: Through learning and instruction, communicative behavior is gradually brought into forms that conform to the established semiotic order. This constructive process is reflected in what Keil and Batterman (1984; see also Keil, 1989) have described as the "characteristic-to-defining" shift: When using a concept, children initially focus on salient features that, by way of statistical association, characterize typical instantiations of the concept (e.g., for the young child, "mother" may be strongly linked to the feature of "making supper"; see Inhelder & Piaget, 1964). As language development proceeds, the child increasingly heeds to structural invariants that structurally define the concept (e.g., "mother" as defined by a specific kinship relation), and so eventually becomes capable of correctly categorizing atypical examples that do not exhibit the expected characteristic features, as well as invalid cases that do so, but lack the defining features.

Conceptual structures do not only shape language development, as the given examples might perhaps suggest. Rather, they impose constraints on ontogenetic patterns wherever developmental phenomena are produced, defined, or assessed with reference to conceptual categories. To briefly illustrate this point, I consider some examples from the domain of emotional development. Emotion terms are embedded in, and derive their meaning from, a network of other mental concepts that we use when describing and explaining actions. For instance, "envy" is conceptually related to a process of social comparison; "jealousy" implies the perception of a particular social constellation; "worry" or "fear" imply the anticipation of aversive events, as well as doubts concerning one's ability to avert these events; "pride" points to the perception of a personal success, and so on (Brandtstädter, 1987; Mees, 1991). In the guise of causal hypotheses, relationships of this kind have also been proposed in attributional theories of emotion (e.g., Weiner, 1982). However, for a relationship to qualify as a causal contingency, the effect must be verifiable independently of the cause. Whether the cases considered can meet this formal requirement has to be questioned. If we were to ascribe feelings of, for example, envy to someone, while denying at the same time that he or she experiences the criterial cognitions constituting that emotion, this would not be a conceivable observation but rather a case of conceptual confusion. Here again, the conceptual structures define a developmental order: If a particular emotion implies a criterial or defining cognition, it will also ontogenetically presuppose the development of the corresponding cognitive competencies. Such structurally implied sequences of emotional development also emerge in empirical studies (cf. Averill, 1980; Brandtstädter, 1987; Frijda, 1986; Reisenzein & Schönpflug, 1992); however, this does not convert a structural implication into an empirical conjecture but rather attests to the conceptual validity of the empirical procedures employed.

It is important to note that unlike causal structures, semiotic structures or rules have no inherent formative force; their effect on development is mediated by individual and collective action. The processes of socialization or intentional self-development largely aim at bringing individual behavior and development into a form that justifies the application of certain concepts; concepts, for example, that denote competencies, developmental tasks, or positively valued traits. Furthermore, implicative structures that (in the mediated way specified earlier) form development are themselves the product of formative processes (Piaget, 1970; Wartofsky, 1971). Semiotic structures, unless fixed by terminological dictates, are not invariant; they accommodate to changes in socially shared beliefs and values, so that successive modifications of a concept may eventually be connected only by a loose relationship of family resemblance (Putnam, 1975; Rosch, 1978). The same is true for norms, institutions, or conventions and other structures that generate regular and recurrent developmental forms.

How can we look for invariance and universality on such unstable grounds? Although we can imagine cultures or historical periods in which particular language games and rules simply do not exist, it is likewise true that developmental constructs have no independent existence outside the semiotic and institutional structures that constitute them first and foremost. Developmental patterns that are constructed and defined in a given lan-

guage game necessarily follow the rules of that game; these games may change, but "When language games change then there is a change in concepts, and with the concepts the meanings of the words change" (Wittgenstein, 1969, p. 65).

To summarize, it appears that an action-theoretical perspective affords an improved understanding of both diversity as well as invariance in development. In defending this view, I have posited that the range within which developmental processes may vary and be modified is broad, but not unlimited. It is limited by constraints that may change across cultures and epochs (e.g., normative, theoretical, and technological constraints), as well as by constraints that, by definition, are not bound to particular contexts (such as physical laws and logical principles). Constancy and invariance in development often result from commonalities in the ways in which ontogenetic processes are canalized through personal and collective action. We have furthermore tried to show how a stronger concept of developmental universality that goes beyond mere empirical regularity might be derived from a consideration of the formal, conventional, or material structures that are constitutive of particular developmental phenomena. The common claim that the search for universality is antithetical to an understanding of development and diversity in historical and cultural contexts thus appears questionable. An actional perspective on development can apparently encompass both heuristic stances.

INTENTIONAL SELF-DEVELOPMENT AND PERSONAL CONTROL OVER DEVELOPMENT

The idea that individuals are producers or at least coproducers of their own development is not novel. Interactionist, contextualist, and organismic-structuralist approaches have embraced this notion and thus have contributed to discrediting lopsided views that portray the developing subject as being only the passive recipient of formative influences (cf. Bronfenbrenner, 1979; Lerner, 1982; Magnusson, 1990; Reese & Overton, 1970; Sameroff, 1975). These approaches, however—and the organismic models in particular—have primarily conceived of development as the result of person-environment transactions rather than as a target area of intentional action; in other words, the relation between action and development has been conceptualized primarily as a functional rather than an intentional one. This focus seems appropriate for early phases of development: The infant certainly does not engage in interactions with the social or material environment with the intention of promoting his or her development. Even if at very early developmental stages the child's activity shows signs of intentionality, it is not intentionally directed toward some developmental task or goal. Such intentional orientations generally come into play indirectly through other agents, primarily through the caregivers who organize and constrain the child's space of action according to intended developmental agenda, and who thereby shape and canalize the child's further development in co-constructive interaction with the child him- or herself, as well as with the cultural macrosystem (Goodnow & Collins, 1990; Lerner, 1985; Valsiner, 1988c; Wozniak, 1993).

It is during the transition to adolescence and early adulthood that the individual's conceptions of self and personal future become articulate enough to guide intentional activity. External directives and demands originating in the familial and larger social context become increasingly internalized and integrated into processes of self-regulation and self-evaluation; with the progression from a heteronomous, external mode of developmental control to an increasingly intentional and autonomous mode of intentional self-development, a new and higher level in the regulation of ontogeny is reached. This reflexive-intentional mode has been given rather short shrift in developmental research; however, for an actional perspective, it is of focal interest.

In elaborating this point, it will be necessary to heed the reciprocal character of the action-development relationship: Activities of intentional self-development are themselves developmental outcomes, they change over the life cycle in structure and intentional content. In the following, I first try to elucidate the basic process features of such activities. Based on these analyses, I focus more closely on the ontogeny of self-regulatory activities as well as on modifications and changes in these activities across the life span.

Activities of Intentional Self-Development: Structure and Process

Self-regulative activities in contexts of intentional self-development comprise different functional components. Models of self-regulation differentiate mostly between

the following phases or component processes (Bandura, 1986; Carver & Scheier, 1981, 1986; Kanfer & Hagerman, 1981; Karoly, 1993; Schunk, 1991): (a) *processes of self-observation and self-evaluation,* in which the convergence of an actual with a desired situation or course of events is monitored; (b) *predecisional or preparatory processes,* which involve the weighing of alternative options, the specification of goals, and the elaboration of plans for goal implementation; (c) *executive processes* (when goal-directed behavior has to be maintained over longer periods, the executive phase may engage auxiliary processes to buffer implementational intentions against distractive influences and to compensate for the relative absence of external supports); and (d) *evaluative processes,* in which the efficiency of actions is assessed with respect to intended outcomes, and which also serve to gauge self-views of competence and efficacy.

The various phases or levels of action regulation are partly intertwined and often cannot be separated cleanly. In complex, nonroutine tasks, preparatory and executive phases may comprise intermediate action cycles that each involves the whole range of processes distinguished earlier. It has to be emphasized that the transformation of intention into action is not generally a smooth or automatic process; rather, difficulties may occur in the transition between the different phases or levels of action regulation. Such problems deserve particular attention because they often give rise to feelings of helplessness and depression (Kuhl & Beckmann, 1985).

Figure 10.3 (see also Brandtstädter, 1992, 2001) summarizes these considerations and translates them into the realm of development-related action; the figure also serves as an orienting framework for the further discussion.

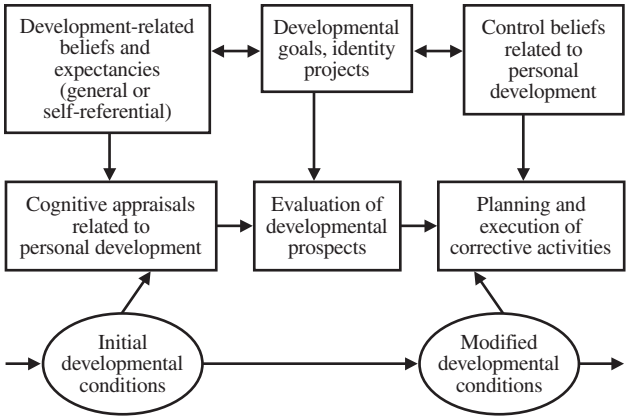

Figure 10.3 Personal control of development: Component processes and constraints.

In Figure 10.3, the connection of self-observational and self-corrective phases resembles a feedback loop. In the typical negative-feedback loop, observed deviations from a preset standard activate corrective measures designed to counteract the discrepancy (for action-theoretical applications of the feedback loop concept, see, e.g., Carver & Scheier, 1981, 1998; G. A. Miller et al., 1960). However, some caveats have to be added. First, it should be clear that activities of intentional self-development may be induced not only by currently perceived but as well by anticipated discrepancies from a desired developmental course or outcome. More important, activities of intentional self-development may involve not only discrepancy reduction but also discrepancy production, as is the case when persons set themselves new and more ambitious goals. Such self-generated discrepancies are not frustrating, but rather provide positive motivation and a sense of meaning in life (Bandura, 1989, 1991). The positive emotional quality of internally induced, as compared to externally produced, goal discrepancies is presumably related to differences in perceived control; generally, individuals only select new goals that they consider to be attainable. Finally, negative-feedback models of self-regulatory behavior do not provide for the important fact that discrepancies between actual and desired situations can be reduced not only by changing the situation in accordance with goals but also, conversely, by adjusting goals and conditions to situational circumstances—for example, through rescaling self-evaluative standards or downgrading ambitions (Brandtstädter & Renner, 1990; Carver & Scheier, 2003; Elster, 1983; Klinger, 1975, 1987). As discussed later, this adjustment of preferences is fundamental to understanding changes in themes and goals of intentional development across the life cycle.

Self-Observation and Self-Monitoring in Intentional Self-Development

In self-observation and self-monitoring, bottom-up or data-driven processes are interlinked with top-down or concept-driven processes. In order to assess, for example, whether some attribute denoting a certain skill or competence applies to oneself, one has to scrutinize behavioral episodes and pertinent representations in episodic memory to ascertain whether they sufficiently match the indicator pattern of the particular attribute;

this process is directed and constrained by conceptual rules that are stored in semantic memory and are activated during the process of self-observation (cf. Berzonsky, 1988; Medin & Smith, 1984).

Through elaborating the meaning and implications of observational data, a semantic link or correspondence with self-concept representations is construed, given that goals and self-evaluative standards also are sufficiently elaborated. Self-evaluative processes will not be activated unless such a correspondence is established. To be compared in an evaluative contrast, goals and observations must be represented on a similar level of specification; this hints at a potential trouble spot in self-regulatory processes.

Processes of self-monitoring can differ inter- and intraindividually with respect to their differentiation, thematic focus, and accuracy. These qualities depend on cognitive resources and motivational dispositions, which, in turn, can change over the life cycle.

Complexity and Differentiation

The more explicit and detailed the monitoring process, the more precise the timing and targeting of corrective interventions can be. For example, weight control is more effective when changes in weight and related parameters such as calorie intake are monitored closely and regularly (Bandura, 1982b; Mace, Belfiore, & Shea, 1989; Schunk, 1991). Explicitness and differentiation of self-observation depend on person-specific and situational factors. Of great importance is the complexity and richness of the individual's knowledge base, which itself is dependent on personal and biographical conditions such as cognitive capacity and expertise (Sternberg & Wagner, 1986). The quality of self-observation also depends on personal interests and motivations because areas of personal importance are generally monitored more intensively and carefully than those of less relevance. In cases in which self-referential feedback has threatening or self-depreciating implications, however, defensive processes may be activated that inhibit a careful scrutiny of information (e.g., Kruglanski, 1990); I discuss this more closely in later sections.

Attentional Focus

Self-observation involves self-focused attention. The readiness to make oneself (and one's self) the target of attentive observation differs between individuals and situations; dispositional differences are addressed by constructs such as "self-awareness" (Duval & Wicklund, 1972), "self-consciousness" (Fenigstein, Scheier, & Buss, 1975), or "self-monitoring" (M. Snyder, 1979). A state of self-attentiveness is likely to occur in situations of high personal concern that have implications for the public or private construal of the agent's self, and in which no routinized pattern of action is readily available (Karoly, 1993). Generally, attention is centered on those elements in an action sequence that lack a safe orientational basis so that additional information has to be gathered or generated to prepare the next steps (Allport, 1987; Carver & Scheier, 1986, 1990; Parasuraman & Davies, 1984).

The regulation of attention engages automatic as well as strategic-intentional processes (Shiffrin & Dumais, 1981; Shiffrin & Schneider, 1977); as an intentional strategy, self-focused attention may serve purposes of self-cultivation, self-management, or self-presention, and may enhance a flexible adjustment to changing social situations (Bandura, 1986; M. Snyder & Campbell, 1982; Tesser, 1986). In biographical contexts, self-focused attention is intensified when a person is faced with disruptive changes or critical developmental transitions that necessitate a readjustment of personal goals, projects, and behavioral routines: Self-attentive and self-corrective tendencies are generally more pronounced among people who are dissatisfied with themselves and their developmental prospects (Brandtstädter, 1989). Self-critical reflection involves a temporary dissociation of the self into a criticizing and a criticized part, a condition that—since Aristotle (see Arendt, 1976)—has often been considered as pathological or pathogenic (e.g., Ellis, 1976). However, it seems more appropriate to consider self-attention not as the cause but rather as a symptom of an adaptive problem, or, more precisely, as a functional component in processes of coping and readjustment.

In a broader sense, self-attention may involve all external conditions that are relevant for personal goals and projects. Phases in the life course in which demands from different and potentially conflicting roles and tasks coincide may involve a particularly high attentional load; in everyday contexts, different goals and courses of action are often pursued simultaneously. The strain that results from simultaneously attending to different goals and tasks can be reduced by a decomposition and sequential arrangement of tasks. Thus, for example, the diversity of adaptive problems that characterizes physical and social development in adolescence is reduced to a manageable format by addressing the

problems sequentially and focusing on only one issue at a time (Coleman, 1980). A decomposition of multiple tasks through sequential focusing is to some extent automatically effected in the process of attention deployment itself (Dörner, 1984). Generally, attention centers on those contents and themes that constitute a person's "current concerns" (Klinger, 1987); with a change in life themes and identity projects, the focus of attention shifts accordingly, even if the individual is not explicitly aware of such changes (Csikszentmihalyi & Beattie, 1979; Erikson, 1959).

Protective and Defensive Mechanisms

Like other perceptual processes, but even more so, the process of representing ourselves is tinged by personal motives, needs, and subjective theories. The processing of self-referential information in particular is subject to constraints that serve to maintain as far as possible the integrity and continuity of the self-theories that we have devised and consolidated over the course of our lives, and that guide us in organizing our future development (Greenwald, 1980). Observations are generally open to multiple interpretations; from alternative explanatory and interpretative options, those will be preferred most readily that fit best with the person's actual motives and beliefs. Individuals tend to doubt the validity of data that are discrepant to prior beliefs; in extreme cases, a rejection or blatant denial of evidence may occur (Festinger, 1957; Nisbett & Ross, 1980; Wicklund & Brehm, 1976). Certainly, the perceptual system is primarily tuned to evaluating, rather than to preserving, the actor's beliefs. But even if evidence is strong enough to enforce a change in the subject's system of prior beliefs, these changes will obey a principle of conservatism that Quine (1951, p. 41), with regard to the dynamics of scientific theories, has put as follows: ". . . our natural tendency is to disturb the system as little as possible." A theoretical proposition can, at least in principle, always be defended against discrepant evidence by making adjustments elsewhere in the theoretical system, and the same is true for the hypotheses that people hold about themselves.

Apart from the consistency effects mentioned earlier, established self-referential beliefs are backed by tendencies of self-verification and self-enhancement. Evidence will generally be negotiated in ways that have positive implications for a self-concept and a personal view of the world, and self-enhancing interpretations will generally be more readily accessible than self-denigrating ones (Kunda, 1990; Steele, 1988; Swann, 1983). Mechanisms of self-enhancement and cognitive consistency generally merge in the processing of self-referential information (C. R. Snyder & Higgins, 1988). However, both tendencies can conflict; for example, self-deprecating or threatening evidence may be so strong that negating it would violate other strong beliefs. There is some evidence that, in such cases, consistency principles dominate over tendencies of self-enhancement (Swann, Griffin, Predmore, & Gaines, 1987).

Concepts such as "self-serving bias," "denial," or "defense" connote a violation of rationality principles; the influence of self-protective mechanisms in information processing seems opposed to a "realistic" self-view, which has been traditionally considered to be a basic requirement of mental health and optimal development. However, even within the limits of rationality, there is generally broad scope to handle evidence in self-serving ways so that the functionality of such mechanisms must be assessed more cautiously (S. E. Taylor, 1989). From a developmental perspective, the potential adaptive value of self-protective mechanisms becomes particularly apparent. For example, as people age, the self-scheme formed in earlier phases of life is threatened by experiences of loss in various functional and social domains; protective and defensive mechanisms help to preserve self-esteem and personal continuity when individuals confront aversive and irreversible developmental changes. Though they operate largely on a nonintentional level, such mechanisms affect activities of intentional self-development in various ways. By dampening perceptions of loss and identity deficits, protective mechanisms may inhibit self-corrective tendencies, but they also serve to arrange priorities for self-corrective intervention and to canalize self-regulatory resources into domains that are amenable to change (Brandtstädter & Greve, 1994; Brandtstädter & Rothermund, 2002a).

Processes of Self-Evaluation

Self-evaluative reactions mediate between self-observation and self-regulative action. In the process of self-evaluation, the actual self-perceptions are contrasted with representations of desired self-aspects as manifested in the individual's goals, ambitions, moral orientations, and identity projects (Higgins, Strauman, & Klein, 1986). As mentioned earlier, both self-evaluative standards and observational data have to be represented on an appropriate level of specification for such an evaluative contrast.

During goal implementation, the focus of self-evaluation may shift to temporal, qualitative, or quantitative modalities of goal attainment (to reach a career goal in a certain biographical span, to maintain a given rate of progress toward a goal, and so forth). Such implementational standards are formed in the transition from intention to action, and they are to some extent necessary for such a transition to occur. When implementational standards become salient as reference points for self-evaluation, a new level of "metamonitoring" (Carver & Scheier, 1986) is established, which is reflected, for example, by the fact that emotions such as disappointment, pride, or shame are no longer determined by the perceived discrepancy or distance from the goal as such, but rather by the perceived rate, quality, or smoothness of progress toward the goal.

Self-evaluative standards can change over the life cycle; this once more highlights the reciprocal influence between action and development. For example, with advancing age, desired features such as health, intellectual efficiency, or professional success may assume partly different meanings, and the corresponding self-evaluative standards may be raised or lowered. Changes in action resources that result from the interaction of age-graded, sociohistorical, and nonnormative factors across the life course (Baltes, Cornelius, & Nesselroade, 1979) may affect the difficulty and, accordingly, the personal costs of realizing certain goals or maintaining certain standards. Shifts in personal goals and standards over the life course may also reflect implicit theories of development and normative age expectations. By defining what expectations persons of a given age should hold for themselves and their future development, normative expectations can legitimate or discredit personal goals and aspirations. Individuals differ with respect to the flexibility with which they adjust goals and standards to changed developmental prospects; as I discuss in more depth later, this accommodative flexibility plays an important role in coping with developmental losses and in securing a sense of personal continuity and efficacy over the life span (cf. Atchley, 1989; Brandtstädter & Renner, 1990; G. Brim, 1992).

Activation and Inhibition of Self-Evaluative Reactions

Self-evaluative reactions depend on how individuals construe the meanings and effects of their actions. It follows that self-evaluative processes, and the ensuing action tendencies, can be enhanced or weakened through destruction or alteration of such meanings and implications. Self-corrective tendencies may be dampened by minimizing or downplaying negative implications of personal conduct or by balancing them against presumed positive effects; the beliefs, theories, or symbol systems that generate negative implications may be doubted or discredited; when the individual's behavior or development deviates from social norms, ascriptions of responsibility, self-reproaches, or feelings of guilt may be neutralized by construing the event as uncontrollable or by portraying it as morally legitimate (Bandura, 1989; C. R. Snyder & Higgins, 1988). Self-evaluation is also crucially affected by chosen comparison standards. For example, when evaluating their health or physical capacities, elderly people typically compare themselves to peers rather than to younger persons (or to themselves at a younger age); in this way, the salience of losses or functional impairments is reduced, and stability of self-descriptions—in the sense of positional stability within a reference group—can be maintained (Brandtstädter & Greve, 1994; J. Heckhausen & Krueger, 1993).

From an action point of view, however, the self-enhancing effects of "downward" comparisons must be balanced against their potential effect of dampening self-corrective intentions. In contrast, "upward" comparisons, such as comparisons with admired ideals or competitors of superior competence, may induce a negative self-evaluation, but they can also provide motivating goals for self-development, at least as long as the individual is confident of having the action resources and developmental reserves necessary for realizing these goals (e.g., Collins, 1996; Wills, 1991).

The cognitive and symbolic processes through which self-evaluations are engaged or disengaged are important targets in self-management; for example, mental simulation of positive or aversive outcomes can be an effective means to spur self-corrective tendencies and to maintain a given course of action against obstacles and temptations (C. Taylor & Schneider, 1989). It would be a mistake, however, to view the earlier-mentioned processes simply as intentional or strategic behaviors that may be activated at will. Rather, such processes basically hinge on the availability and personal accessibility of pertinent information. For example, biographical experiences determine which episodes are available as reference standards for evaluating actual developmental options, and thus can significantly influence the setting of aspiration levels and the individual's readiness to accept the situation (Strack, Schwarz, Chassein, Kern, & Wagner, 1990). Contrast effects of this nature might possibly account for the well-documented fact that older persons, who mostly have suffered wars and economic

crises, seem to be less vulnerable to depression than younger generations (Blazer, 1989; Seligman, 1990). Existential attitudes such as religious beliefs or a belief in a just world likewise can influence the accessibility of specific interpretations; for example, in coping with losses, such attitudes may enhance or impede the construction of palliative meanings, depending on responsibility attributions (Montada, 1992).

Developmental ecologies, in general, may differ as to the particular meanings and comparative standards they afford. Cultural and historical influences, as well as factors related to a person's position in the life cycle, shape and constrain the informational and symbolic space in which processes of self-evaluation operate. Social systems institutionalize conceptions of desirable development, and they tend to stabilize such conceptions through contriving legitimating stories and providing arguments and symbols that support them (Dannefer & Perlmutter, 1990). Furthermore, normative expectations and stereotypes about development and aging provide the backdrop against which views are negotiated as to what should be considered as normal, reasonable, or appropriate for individuals of a given age. It is obvious that such informational and symbolic constraints have a normative and directive influence on processes of intentional self-development.

Emotions in Self-Evaluation

The process of self-evaluation can activate a broad spectrum of positive or aversive emotions. An individual might look back on his or her life course with feelings of pride, anger, or gratitude, and future developmental prospects may evoke hope and confidence, or perhaps fear, worry, or despondency. When developmental prospects are ambiguous or polyvalent, a mixture of such feelings often occurs.

Emotions are linked to, and mediate between, cognitions and action tendencies (e.g., Averill, 1980). In contexts of intentional self-development, emotions signaling a mismatch between intended and actual developmental outcomes are of particular interest because of their inherent potential to enhance corrective action. Examples to consider include affective reactions of guilt, anger, and worry: As a future-oriented emotion involving the expectation of aversive events, *worry* typically engages preventive tendencies, and motivates efforts to acquire knowledge and skills that are deemed instrumental for coping with the aversive event. Feelings of *guilt* or *remorse* involve a belief of having violated specific norms, normative expectations, or moral principles; such emotional states may engage tendencies of self-punishment, recompensation, or activities to stabilize threatened self-definitions through "symbolic self-completion" (Gollwitzer, Bayer, Scherer, & Seifert, 1999; Wicklund & Gollwitzer, 1982). Feelings of *anger* indicate an obstruction of personal goals; they typically involve a proclivity toward destroying the frustrating obstacles. Reactions of anger are particularly strong when positive contrasts are readily accessible (Kahneman & D. T. Miller, 1986; D. T. Miller, Turnbull, & McFarland, 1990). These examples should not be taken to imply that self-referential emotions are important only in self-regulation. Empathetic reactions of pity or sympathy, or feelings of awe or disdain that may be evoked by observing the conduct of other persons, can likewise affect intentional self-development through making salient facets of identity and morality (e.g., C. Taylor, 1989).

Through further analysis and cognitive elaboration of a perceived situation, emotional appraisals as well as the corresponding self-regulatory tendencies may be modified in intensity and quality (Lazarus & Smith, 1988; Parkinson & Manstead, 1992). Depending on how the person, upon further analysis, appraises the implications of a threatening situation as well as his or her capabilities of handling them, feelings of anger or worry may be converted into hope or happiness or either into emotional states of hopelessness and despair. When negative events such as developmental losses or impairments are perceived as global and irreversible, feelings of sadness and hopelessness are the typical result. Such feelings may arise, for example, in later life when the individual realizes that personally important projects cannot be achieved in the remaining lifetime. Feelings of hopelessness may eventually be transformed into more chronic states of depression when goals and ambitions that have drifted outside the feasible range are maintained tenaciously. Depressive reactions are often characterized by a feeling of not being able to be or become the person that one would like to be; such reactions may mark crises as well as turning points in personal development. Often, states of depression can be terminated only by disengaging from barren commitments and turning to new goals; feelings of helplessness may even spur processes of disengagement and reorientation (Brandtstädter & Rothermund, 2002b; Carver & Scheier, 1998; Klinger, 1987).

From Goals to Action: Definition and Implementation of Developmental Goals

When people are asked to report the goals they pursue for their future, answers typically differ in abstractness

and globality. The scope of goal perspectives can range from highly abstract ideals (e.g., to actualize personal potentials, strive for professional competence, fight for peace and justice) to very concrete tasks and day-to-day projects (e.g., visiting a friend or running an errand). Such differences may be related to person-specific factors like value orientations or the range of future perspectives; in later life, the fading of time-yet-to-be-lived may reduce the commitment to long-term projects (e.g., Brandtstädter & Wentura, 1994; Kastenbaum, 1982). Goals on different levels of temporal extension and generality are often pursued simultaneously so that concrete, short-term projects often serve more long-term or abstract purposes. The hierarchical organization of actions and action plans is reflected in the fact that questions about personal motives or reasons for a given activity ("why"?) typically prompt accounts in terms of higher level goals, whereas questions concerning the ways in which a particular activity is carried out ("how"?) tend to evoke low-level, instrumental goals (Kruglanski, 1996; Martin & Tesser, 1989). Differences in the "phrasing level" of goals (Little, 1989), however, may also point to the level of regulation in the transition from goal definition to implementation on which the individual's attention is actually centered (cf. Pennebaker, 1989; Vallacher & Wegner, 1987). Attention centers, preferably, on goals, plans, or steps within an action sequence that pose implementational problems. Pondering about basic personal goals and life themes is increased in situations of crisis and conflict: This converges with findings pointing to an association between depression and a predominant concern with high-level strivings (Emmons, 1992).

Developmental research has traditionally addressed life themes and developmental goals from a very global perspective only; the emphasis was on establishing a general pattern or sequence of basic motivational concerns during the life cycle. For example, Charlotte Bühler (1933; see also Bühler & Marschak, 1969) has posited five basic life tendencies ("need satisfaction," "adaptive self-limitation," "creative expansion," "establishment of inner order," "self-fulfillment"), which she assumed to govern behavior and personal development in different phases of the life cycle from early childhood to late adulthood. Elaborating Bühler's model, Erikson (1959) has portrayed eight stages of identity development across the life cycle, each with its salient psychosocial crisis and task (e.g., the dominant issues of adolescence and of middle and later adulthood were grouped under the labels of "identity," "generativity," and "ego integrity," respectively). In his model of developmental tasks, Havighurst (1948/1974) has made a similar attempt to define a basic pattern of priorities for self-development across the life span, which he thought to reflect the joint influence of biological changes and of age-graded cultural demands. These concepts undoubtedly had a seminal influence in developmental research, but they give short shrift to the variegation of developmental goals in content, complexity, and abstraction and to the processes mediating the definition and implementation of goals. Recent approaches in personality and action research provide a more differentiated treatment of these issues; for example, the concepts of "personal strivings" (Emmons, 1986, 1989, 1992), "personal projects" (Little, 1983, 1998), "life themes" (Csikszentmihalyi & Beattie, 1979; Schank & Abelson, 1977), or "life tasks" (Cantor & Fleeson, 1991; Zirkel & Cantor, 1990) are formulated with explicit reference to the regulative role of goals in personal development (see also Brunstein, Schultheiss, & Maier, 1999).

Goals of intentional self-development are reflected in the plans, projects, and courses of action into which the individual invests time and effort. Only rarely, however, are developmental goals represented from the outset in a format that already specifies the means and procedures necessary for goal attainment. Sociocultural developmental tasks (Havighurst, 1948/1974), too, are usually framed with a degree of abstraction that allows the implementation to be tailored to personal and situational circumstances. The implementation of goals basically depends on three types of constraints: (1) how the goal in question is interpreted, (2) which means are deemed necessary for goal attainment, and (3) whether the relevant means and resources are available on social and personal levels. In the following, I take a closer look at the translation of goals into intentions and of intentions into actions.

Levels of Regulation: Control-System Accounts

According to control-system accounts of action, the process of transforming goals into actions involves a hierarchy of feedback loops; goals on a superordinate level of regulation are converted successively into more specific plans or programs, and further into concrete behavioral sequences (cf. Carver & Scheier, 1986, 1998; Powers, 1973). Thus, for example, the abstract principle of "being helpful" may, depending on situational circumstances, activate specific programs such as "helping an elderly person to cross the street," which are then further specified and translated into behavioral sequences.

This top-down process is also constrained by perceptual input to generate situationally appropriate specifications. Within the hierarchy, the progression from lower to higher levels of regulation is mediated by subroutines such as cognitive scripts or production systems; each level sets subgoals or reference values against which activities on the next lower level are monitored.

Activities of intentional self-development may be easily analyzed in similar terms. The most abstract and general life themes and identity projects would then be represented on a superordinate level of regulation, and would be successively specified and transformed on subsequent levels into situationally appropriate plans and behaviors, as outlined earlier. The heuristic advantages of such hierarchical, top-down concepts of action control are obvious. Perhaps most important, the transition from goals to actions is portrayed as a creative, nondeductive process. For habitualized action patterns, this transition may be partly or fully automatized; in nonroutine situations, however, knowledge structures and heuristic procedures have to be activated to specify and implement goals and intentions. Accordingly, the hierarchic-sequential model also offers vantage points for analyzing disorders in action regulation; obviously, the functional interplay between levels of regulation may be affected if the actor's knowledge, competencies, or skills do not suffice to link abstract goals with concrete meanings, plans, and procedures.

However, it is necessary to add some reservations to this picture. As already mentioned, any plan or behavior may serve different goals simultaneously. Hierarchic-sequential models have notorious difficulties in accounting for the polyvalence of actions and for the conflicts and compromises that may result from it in the definition and execution of goals. Moreover, it often appears to us only in hindsight how our actions relate to superordinate goals and principles; in the ontogenetic sequence, too, the acquisition of certain action patterns can precede an understanding of their meaning and relevance. The most important objection, however, is that the streamlined format of hierarchic-sequential models gives a biased or inadequate picture of acting and planning in complex situations, in which priorities are often rearranged ad hoc, plans are concretized or revised during implementation, and goals may change in an overtly unsystematic and opportunistic manner. Such "planning in action" (Meyer & Rebok, 1985) is particularly characteristic for global, long-term, or vaguely defined goals. Due to its adaptive flexibility, such "muddling through" may be the most reasonable strategy (if it is one) in situations fraught with uncertainty and complexity (Popper, 1961). Under such conditions, planning activities tend to exhibit an incremental, improvised quality rather than a linear, top-down format (Hayes-Roth & Hayes-Roth, 1979); planning about life is perhaps the prototypical case.

These reservations call for a more fine-grained analysis of the processes of goal definition and implementation in intentional self-development. In the following, I first address the semantic and procedural specification of goals, and then turn to issues related to the enactment and maintenance of self-regulatory intentions.

Goal Definition: Semantic and Procedural Specification

To serve as guidelines for intentional self-development, goals have to be specified with respect to their semantic implications, that is, as to their meanings and criteria, as well as with respect to procedural implications related to their implementation. It seems important to distinguish carefully between these two dimensions of the goal definition process because they generally involve different types of knowledge and heuristic procedures. The connection of semantic and procedural specifications of a given goal may be denoted as a *plan* (Friedman, Scholnick, & Cocking, 1987; Nuttin, 1984; J. Smith, 1996, 1999).

Whether we consider professional career goals, goals related to codevelopment in partnerships, or maintenance goals concerning the preservation of physical or mental competencies in later life, the formation of more concrete implementation intentions always requires the unfolding of the semantic implications of the given goal, that is, an explicit representation of criteria or prototypical features that define the intended outcomes. These interpretations may be available already in semantic memory; otherwise, they have to be construed through mediating heuristic activities. Social scripts and institutionalized definitions may aid and direct this interpretative process. Through semantic elaboration, goals are linked with a "recognizer pattern" (Schank & Abelson, 1977) of more explicit indicators, which guides the processing of information in the execution and evaluation of goal-related activities and which, in particular, facilitates retrieval of relevant procedural knowledge from long-term memory (S. E. Taylor & Crocker, 1981).

Semantic specification of goals, however, is not sufficient for regulating goal-related action; representations of intended goal states have to be fleshed out by linking

them to representations of the conditions and activities that are relevant for attaining a given intended state. Such operative links cannot be formed unless the pertinent procedural information is contextually available and cognitively accessible to the actor. When different and equally effective options for accomplishing a goal are available, actors will generally prefer the one that seems to afford the most favorable balance of desirable and undesirable side effects. For example, in accomplishing some career goal, individuals choose an option that appears most compatible with other personal goals and identity projects (such as personal principles of fairness, health-related or family related interests, and so forth). This highlights the important point that the specification and selection of goals for personal development is subject to optimality principles that take into account the whole system of personal goals and projects, or at least parts of it which are eventually affected by a given procedure of goal attainment. As a consequence, the procedural specification of goals often involves compromises that may be suboptimal with respect to the given goal, but promise a greater utility with respect to the more comprehensive array of personal interests. This more comprehensive perspective may even embrace the needs and interests of other persons. In contexts of marital co-development, for example, the life ambitions and developmental goals of partners often have to be mutually adjusted to preserve a stable and satisfying relationship (Brandtstädter et al., 1986; Ickes, 1985). The degree to which an egocentric stance in the choice and procedural specification of goals is transcended also reflects the actor's sociomoral perspective; moral and ethical criteria have the essential function of constraining the selection and implementation of personal goals in ways that heed the interests of co-developing individuals.

Action Paths and Chronic Goals

The procedural specification of goals, and of long-term developmental goals and projects in particular, generally determines a temporal sequence of intermediate steps. The subgoals in a planned action sequence generally encompass a shorter time span than the superordinate or distal goals to which they relate (Carver & Scheier, 1981). The sequential structure of plans is also important from a motivational point of view; through reducing the complexity of the task, it enhances perceived control over the actional sequence and affords proximal reinforcements that contribute to the maintenance of intentions over longer periods (Bandura, 1986; Harackiewicz & Sansone, 1991; Pervin, 1991).

Sequences of action steps or subgoals that are instrumentally related to a common overarching life theme or goal form what may be called an "action path" (Raynor, 1981). The individual's self-view and future perspective critically hinge on the temporal extension of and progress in action paths. The initial steps are motivated primarily through anticipation of further achievements in the path; with further advancement, retrospection on previous achievements becomes increasingly important as a source of self-evaluation. When paths are terminated by the attainment of a desired final outcome ("closed paths"; Raynor & Entin, 1982, 1983), a loss of meaning and purpose may be experienced (e.g., Baumeister, 1986). The emotional quality of personal developmental prospects thus depends crucially on how far the subject succeeds in keeping action paths open or avoiding closure through interlocking paths and creating new and meaningful commitments: "The open path . . . provides a means of understanding the difference between individuals who remain psychologically young through continued becoming and those who become psychologically old through exclusive dependence upon having been . . ." (Raynor, 1982, p. 274). Often, action paths may be extended by a motive to secure, further improve, or embellish what has been achieved (e.g., Schank & Abelson, 1977). The sequential arrangement of developmental tasks and normative social expectations across the life cycle may also facilitate a meaningful interlocking of goals and action paths. With advancing age, however, the shrinking of the temporal horizon tends to cut short and finalize action paths; accordingly, reminiscing about biographical achievements becomes increasingly important in later life as a resource of personal continuity and self-respect (Coleman, 1986).

As already mentioned, not all goals can be finally attained through a sequence of instrumental steps. Apart from the trivial fact that goals might be too difficult for the individual to achieve, some goals are chronic or persistent in the sense that they, by their very nature, cannot be reached conclusively. Goals may be rooted in enduring motivational dispositions for which no conclusive consummatory event can be defined, for example, a striving for health, social recognition, or professional success may (perhaps under continual accommodation of standards and criteria) shape and regulate intentional self-development during an entire life. Other goals may

function like general maxims or rules of conduct that we take into consideration whenever we act, decide, or make plans. For example, identity goals such as sincerity, fairness, altruism, or wisdom denote qualities of action that are manifested in, rather than achieved by, a particular conduct. In addition, competence goals such as professional expertise or artistic productivity, due to their vagueness and complexity, leave room for permanent renegotiation as to their contents and standards (e.g., Atchley, 1989). Chronic or insatiable goals of this kind essentially contribute to keeping action paths and developmental prospects open (Gollwitzer, 1987; Gollwitzer & Moskowitz, 1996; Srull & Wyer, 1986).

Enactment and Maintenance of Self-Regulative Intentions

The enactment of goals can be hampered by a variety of conditions, some of which have been addressed already. Deficits in the semantic and procedural specification of goals are one possible reason why individuals abandon action projects prematurely or fail to initiate them in the first place. In such cases, intentions remain in a rudimentary or degenerated state that may become the source of helplessness and depression (Kuhl & Beckmann, 1985), at least when the goals remain so important that individuals are unable to disengage from them.

The internal and external forces that direct and sustain action (motivational states, incentives, resources, constraints of action) are not stationary but typically change during the implementation of an action or plan. Distractions and enticements may interfere with intentions; unexpected obstacles can alter the subject's balance of costs and benefits; material and physical action resources may become exhausted prematurely. These difficulties arise particularly with long-term projects, and may be aggravated by the lack of concrete, tangible incentives and the considerable delay of gratification that such long-range goals typically involve.

To some extent, intentions are already automatically screened off against competing action tendencies. In predecisional or preparatory stages during which alternative goals and plans are considered, individuals tend to soberly weigh the pros and cons of impending decisions; in contrast, when the die is cast and the person has entered the phase of implementation, cognitions that support maintenance and execution of the plan will become more readily accessible (Gollwitzer, 1990; H. Heckhausen & Gollwitzer, 1987). Furthermore, difficulties encountered in the execution phase can lead to an increase in the attractiveness of the goal, at least as long as the obstacles appear to be surmountable (e.g., Wright & Brehm, 1989); apparently, such reactant increases in goal valence serve to mobilize action resources and to neutralize or counteract inhibiting tendencies. Ambitions of a "just manageable difficulty" (G. Brim, 1992) often are experienced as more attractive than goals requiring low effort, in particular when they are perceived as an opportunity to actualize, and to obtain feedback about, personal competencies (see also Locke & Latham, 1990).

On the other hand, to maintain intentions can itself become an objective of intentional action (Kuhl & Beckmann, 1994). Terms such as *willpower* or *self-discipline* traditionally refer to the capacity to make one's intentions and volitions the target of intentional control. Sometimes, the construct of self-regulation is used to denote just such processes of directional maintenance (e.g., Baumeister, Heatherton, & Tice, 1994; Karoly, 1993). Self-regulation in the given sense comprises a broad gamut of strategies such as stimulus control and milieu selection (e.g., eliminating distractive influences, selecting facilitative environments), attentional resource allocation (e.g., focusing on intention-enhancing aspects of the situation, disregarding interfering stimuli), or emotion and motivation control (e.g., centering on proximal goals, imagining positive consequences). Basically, all these strategies serve to keep the balance between attractive and aversive valences within margins that are necessary for continuing an intended course of action. To some extent, strategies of self-control are already acquired in early socialization (Harter, 1983; W. Mischel, 1983; W. Mischel, Cantor, & Feldman, 1996; W. Mischel & Mischel, 1976); the acquisition of such strategies sets the stage for intentional self-development. The processes of self-control are functionally tied to the medium of language; processes of self-encouragement, self-reinforcement, and self-critique presuppose the capacity of symbolically representing oneself, which forms the basis for a conceptual self (Luria, 1979).

PERSONAL CONTROL OVER DEVELOPMENT: EMERGENCE AND DEVELOPMENTAL CHANGE

The question of how the processes of intentional development themselves develop and change over the life span

leads into an area that is seriously underresearched. The ontogeny of intentional action generally has not been a focus of developmental research, although it has drawn increasing attention during the last few years (e.g., Brandtstädter, 1999; Bullock, 1991; Lewis, 1991; Oppenheimer & Valsiner, 1991; Valsiner, 1987a). Even more conspicuous is the lack of research on the genesis and change of those competencies and activities through which individuals shape and organize their own developmental history.

Development-related action presupposes particular representational capacities. The individual must have formed goals and standards for personal development, and must be able to evaluate the current situation with regard to these self-guides; furthermore, he or she must have acquired some knowledge about probable and possible courses of future development and means and strategies for attaining personally and socially desired outcomes. Moreover, specific regulatory competencies are required for enacting self-regulatory intentions and maintaining them over longer intervals. Personal concepts of actual, desired, and possible selves (i.e., representations of how and what an individual is, should be, could be, and would like to be) provide the motivational basis for such processes (Cantor, Markus, Niedenthal, & Nurius, 1986; Higgins, Klein, & Strauman, 1985); these representations also change, and are socially expected to change in particular ways, over the life cycle.

These preliminary considerations suggest that in analyzing the ontogeny of intentional self-development, three basic lines of development should be considered: (1) the development of intentional action in general and of cognitive and representational processes related to intentionality; (2) the formation of beliefs and competencies related to personal control over development; and (3) the development of the self (or self-concept) as a more or less coherent structure of self-referential values, beliefs, and standards that guides and directs self-regulatory processes.

Intentional Action: Developmental Aspects

Intentionality is intrinsically tied to the capacity to recognize regularities in behavior-outcome contingencies and to anticipate possible effects of one's own behavior (Lütkenhaus & Bullock, 1991). Neonates already show instrumental learning and exhibit some degree of contingency awareness (Olson & Sherman, 1983). However, an understanding of personal agency presupposes the epistemic separation of self and nonself that gradually evolves from the radically egocentric and syncretic mode of experience that characterizes the primordial phase of cognitive development (Kegan, 1983; Piaget, 1936/1952). It is this separation that is the developmental origin of a conceptually differentiated, categorical self (Butterworth, 1990; Case, 1991; Filipp, 1980; Harter, 1983; Lewis & Brooks-Gunn, 1979).

As hallmarks of emerging intentionality, we may consider early behavioral adaptations that obviously aim at producing or evoking particular consequences (Bell, 1974). In contexts of parent-child interaction, such signs can be observed already in the first months of life, for example, in the instrumental use of vocalizations to influence the parent's behavior (Papousek & Papousek, 1989):

> How efficiently a 3-month-old infant can control parental behavior is readily observable, for example, in early interactive tickling games, when the child evokes the next repetition by an irresistible squealing. . . . The effectiveness of the contingency experience can be demonstrated easily by temporarily disrupting the child's expectations (e.g., by having the mother briefly close her eyes or turning unresponsively away from her child). . . . When this happens, even a 2-month-old child will activate a broad repertoire of facial, gestic, or vocal behaviors in an attempt to bring the mother back under his or her control. (Papousek & Papousek, 1989, p. 479; trans J. B.)

Recognition of regularities in behavior-effect contingencies is facilitated through the ritualization and mutual coordination of interactive exchanges between parent and child (Brazelton, Koslowski, & Main, 1974; Papousek & Papousek, 1987). The experience of transactional contingencies provides the raw material from which a working model develops that, initially in a rudimentary way, represents causal structures and instrumental relationships. Children in this early phase of development show exuberant emotional reactions when they become aware of their growing ability to produce interesting effects in a regular and reliable manner (Case, 1991; J. S. Watson, 1966). As mentioned earlier, caregivers arrange the child's action space to promote particular achievements, thus providing a scaffold for further development (Rogoff, 1990; Wood, Bruner, & Ross, 1976). Through affording facilitative means as well as through imposing external barriers and counterforces, the physical and social environment provides

feedback concerning actional potentials and limitations, thereby fostering the progressive differentiation of a conceptual or categorical self (e.g., Lewis & Brooks-Gunn, 1979).

As children come to separate self from nonself and to see external objects as distinct entities in their own right, they also recognize that actions can generate products that exist, and continue to exist, independently of productive activity, and that possess specific social valences. By the age of 18 months, children attentively monitor the products of their own actions: for example, in playing with building blocks, they pause when they have accomplished their task, and contemplate the result. Around this age, children begin to protest against and actively oppose interference with an intended course of action; this attests to a growing capability of goal-directed planning and an emerging sense of personal competence (Geppert & Küster, 1983; H. Heckhausen, 1984; Trudewind, Unzner, & Schneider, 1989).

An important step in the development of intentionality is the use of intermediary actions for achieving some goal, such as when a 10-month-old child removes an obstacle to recover a toy. Intentionality is manifested even more clearly when different means are employed to attain the same goal (Bruner, 1973; Piaget, 1936/1952). The material objects and means that are integrated more and more purposefully into sensorimotor coordinations during the first 2 years of life are not just "affordances" (Gibson, 1977) that expand the individual's action space; rather, it is in interaction with such means that experiences of success and failure are first made. The developmental significance of external objects of action has been stressed particularly in activity-theoretical approaches (Leont'ev, 1978; Oerter, 1991; Valsiner, 1987b; Vygotsky, 1978). The use of tools is the paradigm case: For efficient and successful action, the individual's behavior must accommodate to the functions and features of the tool. Being designed for, and in that sense objectifying, a particular type of problems, the mediating means of action—including external objects as well as "psychological tools" as defined earlier (Vygotsky, 1978)—also implicate particular developmental tasks: Achieving such tasks through adjusting to the functional demands of the tools is fostered by an intrinsic motivation for competence and self-agency (Harter, 1978; White, 1959). In early childhood, caregivers support the successful use of objects through structuring zones of activity; in later developmental stages, the guided acquisition of more complicated cultural practices and techniques typically takes the form of learning through apprenticeship (Rogoff, 1990). Thus, object-related and mediated action constitutes the basic process by which the individual comes to recognize the social nature of action and, gradually, to participate in social networks of knowledge and practice (Lave & Wenger, 1991; Valsiner, 1988a, 1988b; Vygotsky, 1978).

So far, we have addressed some first necessary steps in the genesis of intentional self-development. Further progress is crucially related to the acquisition of language, and to the development of self-related speech in particular. Speech-for-self is a potent means to overcome impediments and unexpected disruptions in an intended course of action and helps to control aversive emotions arising from these experiences (Kopp, 1989; Luria, 1969; Zivin, 1979). In self-referential dialogues, representations of desired and ought selves are actualized and translated into self-directive and self-corrective intentions (Lee, Wertsch, & Stone, 1983). Self-ascription of attributes denoting positively valued personal qualities (e.g., being good, strong, clever, polite) is necessarily tied to the medium of language; thus, emergence of first self-regulative intentions largely coincides and progresses in stride with the development of language. The acquisition of symbolic means to describe and evaluate oneself taps a centrally important source of self-regulatory motivation; as Kagan observes:

> [A]round the world, two- and three-year olds begin to reflect on the correctness, the competence, and the appropriateness of their actions before, during, and after execution. They compare their behavior, thoughts, and feelings against the standards and try to keep in close accord with the standard, as a space vehicle's program corrects its course in flight. (Kagan, 1984, pp. 129–130)

Development of Control-Related Beliefs and Motivations

Intentions of self-correction and self-development emerge through the contrast of two anticipatory beliefs; expectations of how developmental prospects might be ameliorated by corrective intervention are contrasted to the initial or baseline expectation of what would happen without such intervention. Such contrasts between "initial" and "revised" expectations (Valle & Frieze, 1976) become particularly salient in critical transitions and choice points in the life cycle. Generally, the range of feasible developmental options that individuals envisage

for themselves depends on the degree of personal control and efficacy that the actor ascribes to him- or herself.

The extent to which a person has control over life circumstances is jointly determined by personal and situational factors: Specifically, it depends on contingencies of the individual's developmental ecology and on his or her potential to act on these contingencies, which, in turn, depends on the availability of pertinent procedural knowledge as well as on the personal accessibility of such knowledge. These diverse aspects or facets are addressed in differentiations of the control construct such as the distinctions between "contingency judgments" and "competence judgments" (Weisz, 1983; Weisz & Cameron, 1985), between "response-outcome expectancies" and "efficacy expectations" (Bandura, 1977; H. Heckhausen, 1989), between "strategy beliefs" and "capacity beliefs" (E. A. Skinner, 1991, 1995; E. A. Skinner, Chapman, & Baltes, 1988), or, with signs reversed, between "universal helplessness" and "personal helplessness" (Abramson, Seligman, & Teasdale, 1978). It should be noted that the formal relation between these facets of perceived control is not symmetrical, in the sense that universal helplessness (the belief that an outcome is generally uncontrollable) implies personal helplessness, but not vice versa. This asymmetry seems important both from a motivational and developmental point of view because individuals will not form an intention to expand their control capacities unless they recognize that goals that are beyond their actual span of control are not necessarily unattainable in a general or universal sense.

These conceptual distinctions suggest two lines of approach for analyzing the development of control beliefs: We may ask, first, how a sense of personal agency grows from the individual's transactions with his or her social and material environment and unfolds into a differentiated system of control beliefs. Second, we should consider how ontogenetic and age-graded changes in physical, temporal, and social resources of action may affect perceived control and efficacy.

Developing a Sense of Control and Personal Agency

The perception of having control over events in the immediate environment implies the cognitive separation between the acting self and the external objects and effects of action, which is an essential achievement in early sensorimotor development. The progressive integration of instrumental objects, as well as of other persons, into own action sequences promotes an early sense of mediated agency or "proxy control" (Bandura, 1982b) and is germinal for the differentiation of means-end or contingency beliefs from efficacy beliefs. During early childhood, control experiences progressively gain an affective valence that not only stems from the pleasure experienced in the process of producing events but also increasingly reflects the valuation of outcomes in the wider social context. In the process of objectifying and instrumentalizing the physical and social environment, the child also comes to recognize his or her own body, and parts of it, as object and instrument. This is a cornerstone for the reflective processes through which the self as a physical and, later, as a psychological entity can become an object of intentional action.

Self-percepts of personal agency and control originate through the experience of behavior-event contingencies. Contextual factors such as the sensitivity and responsiveness of parents or the extent to which task environments or instructional contexts are adapted to the child's skill level and developmental potentials influence contingencies between actions, intentions, and outcomes and can become a source of interindividual differences in perceived control and self-efficacy (Gunnar, 1980; Lamb & Easterbrooks, 1981; E. A. Skinner, 1985, 1995). Again, generalization of contingency experiences and integration of them into a conceptual self is tied to language development. Between the ages of 2 and 3, children begin to grasp the semantic contents and symbolic qualities of their own behavior and to view themselves as having certain distinct qualities and traits. Preschoolers are motivated increasingly by anticipated self-evaluations, and they eagerly seek for occasions to test and confirm self-descriptions. Discerning competence and contingency as distinct constituents of personal agency, however, requires further cognitive and conceptual achievements; thus, it is not until middle childhood or, in Piagetian terms, until the stage of concrete operations has been reached that children acquire the distinction between alternative "internal" and "external" causes of performance such as ability, effort, task difficulty, and luck, and reflect such distinctions in self-evaluative reactions (Nicholls & Miller, 1984, 1985).

Although beginnings of a purposeful coordination of means and ends can be observed already by the 1st year of life, these early coordinations are practical and intuitive only. Attention is centered on immediate, concrete outcomes of actions; it is not until the emergence of "reflexive abstraction" in later stages of cognitive development (Piaget, 1976, 1978) that attention is turned to the

action processes themselves as well as the mechanisms that mediate between actions and outcomes. The representation of personal competencies and contextual contingencies typically attains the form of an implicit theory during preadolescence. The transition toward a hypothetico-deductive or formal-operational mode of thinking is characterized by a growing capacity to hypothetically project alternative courses of future personal development, which is the basic cognitive process that guides and motivates life planning and intentional self-development in adolescence and adulthood. However, concrete-operational children already begin to reflect about psychological functions such as memory, attention, or comprehension, and to use metacognitive strategies to control and enhance these functions (e.g., mnemonic strategies, techniques of attention control, comprehension monitoring; e.g., Flavell, Speer, Green, & August, 1981; Flavell & Wellmann, 1977; Markman, 1977; P. H. Miller & Bigi, 1979). Maintaining or boosting performance through metacognitive strategies remains an important concern of intentional self-development throughout life and becomes particularly focal in the elderly person's attempts to counteract, and compensate for, functional losses (Baltes & Baltes, 1990; Dixon & Bäckman, 1995).

Action Resources and Perceived Control

The development of action resources over the life span, in many areas at least, tends to follow a curvilinear function; in the earlier segments of the life span, the dominant trend is resource expansion, whereas later segments are characterized by maintenance and differential decrease in physical, temporal, social, and material reserves. A similar pattern of growth and decline has generally been expected for the experience of control and agency through life; however, empirical relationships have proved to be considerably more complex (e.g., Brandtstädter, Wentura, & Greve, 1993; J. Heckhausen & Schulz, 1995).

Individual differences in perceived control become manifest already by preschool age: In achievement-related contexts, for example, such differences are displayed in risk preferences, in reactions to failure, or in differential persistence on difficult tasks (H. Heckhausen, 1984). In contrast, the question regarding how the age variable relates to quantitative or qualitative differences in perceived control is far from being settled decisively. Considering the expansion of physical, psychological, and social action resources as well as the loosening, and progressive internalization, of external directives and regulations, one might expect an increase in internal-autonomous orientations of control from childhood to adolescence; this assumption gains plausibility in view of analogous shifts from heteronomous to autonomous perspectives in moral judgment (Rest, 1982; Selman, 1980). Although some findings seem to converge with this assumption, cross-sectional and longitudinal studies have not borne out a clear-cut and convergent trend (for overviews, see Krampen, 1987b; E. A. Skinner & Connell, 1986). I do not delve here into the methodological difficulties that plague this area of research (e.g., E. A. Skinner, 1995, for a discussion); obviously, an assessment of internality and externality beliefs poses serious conceptual problems as long as the child has not yet developed a corresponding analytic perspective. Generally, the assumption that perceived control or efficacy is a direct function of available action resources seems too simplistic. A personal sense of control and efficacy should depend primarily on the extent to which available action potentials are sufficient to realize personally important goals and developmental ambitions, or, conversely, reflect the extent to which personal goals and ambitions are adjusted to personal action potentials. We have to note at this juncture that after an expansion of action resources, goals and aspirations are often calibrated to a larger scale, which may involve new vulnerabilities. By the same token, a shrinking of action resources does not necessarily lead to losses in perceived control when goals are adjusted to changed developmental opportunities (e.g., Brandtstädter & Renner, 1990; Brandtstädter & Rothermund, 1994; J. Heckhausen & Schulz, 1995).

The theoretical significance of this principle becomes particularly evident when we consider later life. As I discuss in greater detail later, the accommodation of goals and plans to changed action resources is one of the key processes that helps the elderly person to preserve a sense of personal efficacy and a positive view of self and personal future.

Intentional Self-Development and the Developing Self

Activities of intentional self-development are related to the self in two senses. First, these activities as well as the processes of self-observation and self-evaluation on which they are based are reflexive; that is, they are directed back on the acting individuals themselves. Second, and this is a more complicated issue, such activities are also related to the person's self. These two meanings

are often confounded, and in the present context, they have to be distinguished carefully.

It has become customary to conceive the self—the conceptual or categorical self, or the "me" self as described by James (1890)—as a theory that the individual holds about him- or herself, and that grows out from the social requirement to give consistent and satisfying accounts for oneself and one's behavior (Epstein, 1973; Kihlstrom & Cantor, 1984; Markus, 1977). However, not all perceptions and beliefs that individuals may hold to be true about themselves refer to attributes that characterize and individuate them in essential ways. It therefore appears that the self, in the stronger sense of personal identity, is less, and in some sense more, than the totality of self-referential beliefs. To count as constituents of personal identity, self-descriptive attributes have to satisfy particular criteria (Baumeister, 1986; Brandtstädter & Greve, 1994; McGuire & McGuire, 1981). These attributes must be sufficiently enduring and constant: Only attributes that are sufficiently stable (or are construed by the individual as a stable self-descriptive feature) can warrant self-sameness over time. Furthermore, to be identity-relevant, attributes must also possess some distinctive relevance and contribute somehow to establishing the person's individuality. Finally, the attributes must be linked in relevant ways to the person's biography or life course and be seen by the person to form an essential particularity of his or her life. Activities of intentional self-development, as far as they serve to realize, stabilize, and maintain personal identity, will reach their full developmental expression when the individual is able to construe a self-schema of personal identity according to such criteria (Norem-Hebeisen, 1981).

The Ontogeny of the Conceptual Self and of Internalized Control

Objects that are seen by the child as belonging to him- or herself (toys or parts of the body) are the first distinctive markers of individuality (Kopp, 1982; Lewis & Brooks-Gunn, 1979). In early phases of development, identity is often construed by simple discriminative contrasts (child versus adult, boy versus girl); concrete, observable attributes are available earlier and more easily for self-description than abstract qualities (such as attitudes, dispositions, traits) that have to be inferred from observations (Broughton, 1978; Selman, 1980). Stable self-categorizations in terms of essential and invariant characteristics emerge in middle childhood in relationship with the comprehension of physical invariances at the level of concrete operational thinking. A central aspect of self-description, which also assumes a pivotal role in the further elaboration of a stable identity, is gender (Guardo & Bohan, 1971; Harter, 1983; Kohlberg, 1966; Marcus & Overton, 1978); particularly in societies with marked sex-role stereotyping, conceptions of an "ought" self are often introduced as prescriptions of how a girl or boy should behave or typically behaves (e.g., rules concerning the public display of emotions; e.g., Case, 1991; Stangor & Ruble, 1987, 1989).

Self-regulatory activity is based on self-evaluative standards or "self-guides" (Higgins, 1988) that form the person's desired and ought self. Self-evaluation and self-control originate from early, heteronomous states that are characterized by the external regulation of behavior through directives and physical constraints; with advancing representational capacities, children internalize external directives and apply evaluative and judgmental labels to themselves and their own actions. The emergence of internalized control is certainly one of the most central and significant achievements of early childhood (Diaz, Neal, & Amaya-Williams, 1991; Flavell, 1977; Kopp, 1982, 1987). The notion of internalization of normative orientations may be misleading as far as it connotes the simple transposing of external norms into an "inner" language of control. Rather, internalization should be seen as a constructive process by which external evaluations, standards, and norms are assimilated, interpreted, and realized in a manner corresponding to the child's actual developmental state and potential (Lawrence & Valsiner, 1993).

The emergence of internalized control is marked by the appearance of self-affects such as pride, guilt, or embarrassment, which are typically observed in achievement situations around the ages of 3 to 4 (H. Heckhausen, 1984). Children at this age vehemently protest against self-discrepant attributions ("I'm not a bad boy!"). Such early forms of self-assertion foreshadow processes of self-enhancement and self-verification that later become central aspects of intentional self-development (Kagan, 1981a). It is not until middle childhood, however, that self-evaluative concepts or standards are represented in episodic and semantic memory with sufficient complexity so that children can explicitly describe situations in which they would be proud or ashamed of themselves (Harter, 1983). Self-evaluative concepts—for example, personal notions of what it means to be good, competent, fair, or responsible—are continuously redefined and endowed with partly new meanings as cognitive and sociomoral

development advances. This process does not come to a halt at a particular age, but continues throughout life. The capacity and readiness to step back and critically evaluate oneself, one's actions, and later eventually one's personal development and the contour of life from the perspective of the generalized other and with respect to general ideals, maxims, or principles characterizes an advanced level of sociocognitive and sociomoral development that presupposes a formal-operational level of thought (Selman, 1980). It is on this level of cognitive development that individuals first become able to construe a possible self in terms of self-ideals and general ethical principles. Such ideals and principles essentially refer to the relation between the acting subject and his or her social, institutional, and cultural context. As individuals develop a progressively more comprehensive and differentiated view of these relationships, new and broader perspectives become accessible for self-definition and self-evaluation (Damon & Hart, 1982); this change in evaluative perspectives also influences the selection and definition of life goals and identity projects.

Future Selves, Life Plans, and Cultural Scripts

In adolescence and early adulthood, visionary construals of desired possible selves become the main motivational source of intentional self-development. In this transitional phase, constructions of the future self focus mainly on the domains of future occupation and beginning a family and partnership as well as on developmental tasks and prospects related to these domains (Dreher & Oerter, 1987; Nurmi, 1993; Pulkkinen, Nurmi, & Kokko, 2002). Elementary school children formulate ideas and plans about future roles in life, but these are often vague and fanciful. In adolescence, future goals become more elaborated; they reflect a broader range of realistic options and are linked with concrete procedural intentions and implementation goals (Rosenberg & Rosenberg, 1981; Russell & Smith, 1979).

During adulthood, personal projects and goals for the different segments of the life span eventually merge into a more or less comprehensive and coherent plan of life. Considering the ad hoc, incremental nature of planning about life, Rawls's (1971) contention that each individual "has a rational plan of life drawn up subject to the conditions that confront him" (p. 93) has to be taken with some skepticism. Most people have developed at least some ideas concerning the general contour of their life. These ideas are elaborated, adjusted, and reformulated according to actual constraints and affordances; conditions that often arise in an unpredictable fashion. In shaping and elaborating life plans, parents, partners, and significant others in general play a significant role, both as models and as mentors (Goodnow & Collins, 1990; Levinson, 1978; J. Smith, 1996). As individuals come to participate in social role systems of partnership, family, and occupation, it becomes increasingly necessary to coordinate and synchronize personal life plans with those of other individuals; quality and stability of marital partnerships largely depend on the compatibility and mutual adjustment of life goals (Brandtstädter et al., 1986; Felser, Schmitz, & Brandtstädter, 1998).

As the individual comes to relate his or her personal development to the norms and role systems of family and occupational cycles, social representations of "normal" or desirable development gain further influence in personal life-planning. Age-graded societies constrain and canalize intentional self-development through prescriptions or normative expectations concerning the proper scheduling of developmental events and transitions; in interaction with biological changes, such norms constitute a cultural script of a life course (Hagestad, 1991; Neugarten & Hagestad, 1976). Deviations from this script arouse attention and a need for explanation or justification. However, the normative force of cultural scripts of the life course also stems from the fact that deviations from the "normal" pattern have particular symbolic and attributional valences. Divergence from prescripted timetables for developmental transitions may, depending on the particular domain, be taken as a sign of incompetence, irresponsibility, indifference, or carelessness (Kalicki, 1996). As the individual moves through the life cycle, such symbolic valences gain influence in self-evaluation and intentional self-development.

A sense of personal identity and individuality is to an essential degree tied to those elements in the personal life course that deviate from normative or typical patterns; apparently, the cultural standardization of the individual life course tends to reduce its discriminative and individuating value. This problem is somewhat toned down by the fact that developmental tasks and normative expectations about the life course afford some latitude for idiosyncratic interpretation and implementation; thus, it becomes a developmental task of its own to interpret and implement the cultural script of the life course in ways that are compatible with personal goals and identity projects (e.g., Dittmann-Kohli, 1986).

The formation of personal identity does not end with a final and stable outcome but involves continual revisions and readjustments (Gergen & Gergen, 1987). In

response to the biological transitions and role changes across adolescence and adulthood, themes of intentional self-development as well as the personal importance of self-descriptive attributes also change (e.g., Cantor, Norem, Niedenthal, Langston, & Brower, 1987; Dreher & Oerter, 1986; Nurmi, 1992). The individual's position in educational, occupational, and family cycles influences the personal construal of desired, possible, and ought selves; during positional changes across the life cycle, different standards, rules, and comparative perspectives for self-evaluation become salient (Wells & Stryker, 1988). As individuals travel along the developmental and action paths that form their "thread of life" (Wollheim, 1984), they also tend to shift the temporal focus of self-definition; whereas young adults construe their identity primarily with regard to future possible selves, elderly people derive their self-definitions to an increasing degree from past achievements (Wong & Watt, 1991).

To some extent, however, these developmental adaptations also serve to stabilize and protect core elements of the self-system. As with scientific theories, adjustments in some parts of the structure can be necessary to deflect strain from other, more central parts. Generally, change in self-definitions across the life cycle is dampened by an inherent tendency of the self-system to preserve personal continuity and integration. Thus, the majority of longitudinal studies give testimony to an impressive stability of self-descriptions across adulthood (Bengtson, Reedy, & Gordon, 1985; Filipp & Klauer, 1985). This stability is particularly impressive in elderly individuals; the aging self appears to have powerful adaptive mechanisms at its disposal that defend the self-scheme against experiences of loss and limitation (Atchley, 1989). A comprehensive account of intentional self-development must certainly include some mention of the intentional and nonintentional processes that underlie the adjustment of self-evaluative standards and negotiation of gains and losses in the transition to later life. My final considerations address this issue.

Preserving Personal Continuity and Identity: Assimilative and Accommodative Processes

It has become obvious at this point that activities of intentional self-development must be viewed in the larger context of processes that serve to actualize and stabilize personal identity. During the entire life course, the individual is confronted with events and changes that he or she experiences as a gain or a loss, and as congruent or dissonant with the self-schema consolidated in earlier phases of life. Personal continuity, as well as crises and transformations of self-definition, essentially results from the ways in which such changes, in mentation and action, are negotiated.

The transition to old age brings with it particular threats to self-continuity and integrity. The late phases of life are characterized by the accumulation of uncontrollable changes and irreversible losses. Although there is a considerable amount of interindividual variation in biological, psychological, and social parameters of aging (e.g., Baltes & Mayer, 1999; Birren & Schaie, 1990; Rowe & Kahn, 1987; Schneider & Rowe, 1991), the curtailment of physiological reserve capacities, chronic and disabling health problems, and problems of bereavement and social isolation increasingly take their toll. These adaptive problems are further aggravated by the narrowing of lifetime resources; becoming aware that important personal goals can no longer be achieved in the remaining time is a particularly aversive experience in later life (Breytspraak, 1984). The picture of a gradual worsening in the subjective balance of developmental gains and losses also emerges from self-reports of elderly people (Brandtstädter et al., 1993; J. Heckhausen, Dixon, & Baltes, 1989). In sum, action resources tend to wane in later life, and questions regarding the projects and goals in which scarce resources should be invested take on an increasing significance.

Numerous research programs have centered on the plausible assumption that the experiences of loss, functional limitation, and social marginalization should have a negative impact on self-esteem, personal efficacy, and general well-being in later life. This assumption, however, has found surprisingly little empirical support. There is no general evidence that dissatisfaction, depression, or identity problems increase in later life, except perhaps in terminal phases in which severely disabling and life-threatening health problems loom large (Blazer, 1989; Newmann, 1989; Stock, Okun, Haring, & Witter, 1983). Likewise, there is no consistent evidence for reduced self-efficacy or perceived control. At every age, perceived control over personal development correlates positively with subjective and objective indicators of well-being such as health, life satisfaction, and optimism; however, individual differences in perceived control do not appear to be related systematically to the age variable (Fung, Abeles, & Carstensen, 1999; Lachman, 1986; Rodin, 1987).

This rather counterintuitive pattern of findings raises questions as to possible methodological artifacts.

With regard to the age-depression relationship, it has been argued, for example, that findings might be biased by a reduced motivation of depressed persons to participate in investigations; that relationships might be curvilinear; that elderly people might be more reluctant to report psychological problems; that symptoms of depression in old age often take on a masked or somatized form; or—considering the general predominance of cross-sectional over longitudinal investigations in these areas of research—that the empirical data are liable to confound genuine ontogenetic effects with generational differences (Blazer, 1989; Kessler, Foster, Webster, & House, 1992). These arguments are not examined in detail here, but it appears that they are not strong enough to explain away the phenomenal stability and integrity of the aging self; in fact, this phenomenon increasingly draws attention in developmental and gerontological research (Brandtstädter et al., 1993; Staudinger, Marsiske, & Baltes, 1995).

Here, the question arises as to what protective mechanisms the self-system engages to maintain personal continuity and a positive outlook on future development. From an action-theoretical perspective, two basic adaptive processes—or groups of processes—can be distinguished: On the one hand, individuals may try to alter the situation in an attempt to prevent or avoid undesired or self-discrepant outcomes, on the other hand, evaluative standards as well as underlying personal goals and ambitions may be adjusted to situational constraints. We denoted the former adaptive mode as assimilative and the latter as accommodative (Brandtstädter & Renner, 1990; Brandtstädter & Rothermund, 2002b). The present use of these concepts differs from the familiar Piagetian terminology because we are not referring here to modes of cognitive adaptation but rather to two complementary processes of achieving congruence between actual and desired situations or states.

Assimilative activities in the given sense essentially comprise all forms of intentional and problem-solving action that aim to keep developmental prospects in stride with personal goals and standards, or to alleviate goal discrepancies by actively changing situational conditions (personal life circumstances, behavioral patterns, or attributes). In old age, the preservation of personally valued physical, psychological, and social competencies becomes an important source of self-esteem and a dominant concern of assimilative efforts.

When assimilative actions fail to reduce actual discrepancies and losses, accommodative processes tend to be activated. By facilitating disengagement from barren goals, the accommodative process enhances a reorientation and commitment to new goals and self-evaluative standards, which may then become new reference points for assimilative activities. The theoretical distinction between accommodative and assimilative modes partly converges with other action-theoretical models that also imply a dual-process conception of coping, such as the model of problem-focused versus emotion-focused coping (Folkman, 1984; Lazarus & Launier, 1978), the theory of the incentive-disengagement cycle (Klinger, 1975, 1987), or the model of primary versus secondary control (J. Heckhausen & Schulz, 1995; Rothbaum, Weisz, & Snyder, 1982); relationships with these conceptions have been discussed in greater detail elsewhere (Brandtstädter & Renner, 1992).

Here, I shall discuss the assimilative and accommodative processes with regard to functional relationships and underlying mechanisms (see also Brandtstädter & Greve, 1994; Brandtstädter & Rothermund, 2002a, 2002b; Brandtstädter, Wentura, & Rothermund, 1999). The discussion focuses on development in late adulthood, but the basic theoretical principles apply to all situations in personal development that involve developmental losses and threats to personal identity.

Preventing or Alleviating Developmental Losses through Assimilative Activity

Preventive or corrective actions that are explicitly and intentionally designed to maintain desired performance standards or skills may be considered as prototypical cases of assimilative activities in later life. Depending on subjective means-ends beliefs and competencies, the implementation of such maintenance goals can take many forms, like physical exercise, dieting, a careful arrangement of daily routines, using cosmetic or pharmacological tools, and so on. Such self-corrective tendencies generally increase as experiences of functional losses and deficits loom larger; the strength of these relationships generally depends on the degree of perceived control over one's development and aging as well as on the personal importance of the domain in question (Brandtstädter, 1989).

Compensatory actions are another variant of assimilative activities that become particularly relevant when some functional losses are already irreversible. Compensation as such is a basic category of mediated human action, and, in a very general sense, any activity that employs auxiliary strategies and means to achieve some

goal that otherwise could not be attained involves an element of compensation (Vygotsky, 1960/1979). In later life, acts of compensation specifically aim at maintaining some desired standard of performance in spite of losses in task-relevant functions or skills. Because performance in particular tasks is generally determined by different skill components and external factors, a deterioration of particular components can often be offset by selective use or strengthening of those components that are still functioning well; depending on the functional domain under consideration, compensation may also involve the use of particular metacognitive strategies (e.g., mnemonic aids) or of external prosthetic means (Bäckman & Dixon, 1992; Baltes & Baltes, 1990; Salthouse, 1987). Activities of compensation tend to be most pronounced in areas that have high discriminative and biographical relevance and are of central importance to the person's identity. Like other activities of intentional self-development, compensatory actions depend on the availability of pertinent theoretical and technological knowledge as well as on its personal accessibility.

A further important category of assimilative activity comprises activities of self-verification (Swann, 1983). The self-verification construct refers to a general (but differentially expressed) tendency to preferentially select social or informational contexts that are likely to provide self-congruent feedback on those dimensions of self-description that are central or constitutive to personal identity (Greve, 1990; Rosenberg, 1979; Wicklund & Gollwitzer, 1982). To some extent, self-verification tendencies are already operative on automatic levels; for example, strong self-beliefs have an inherent tendency to reject or discredit discrepant information. This conservative effect may ward off self-discrepant evidence (at least as long as the evidence is not sufficiently strong to override the protective forces) and, in this case, would inhibit assimilative and accommodative responses equally. Only those activities of self-verification that intentionally aim at the purpose of reducing the salience of losses or avoiding self-discrepant feedback, however, should be considered as assimilative. For example, elderly people may strategically select social interactions to serve such self-enhancing intentions (e.g., Carstensen, 1993; Ward, 1984). People may even change their external appearance (e.g., through cosmetic surgery) in an attempt to elicit social feedback that conforms to their self-views (Swann, 1983).

A common feature of all assimilative activities is a tenacious adherence to certain goals, ambitions, or standards. Intensity and duration of assimilative activities essentially depend on perceived personal competence and efficacy; if initial control beliefs are strong, difficulties in executing assimilative intentions may incite additional assimilative effort, and even induce a reactant increase of the blocked goal's valence (Klinger, 1975; Wortman & Brehm, 1975; Wright & Brehm, 1989). When the individual is confronted with factually irreversible losses or impairments, however, this tenacity may lead to an inefficient use of resources and eventually aggravate feelings of helplessness and depression. Here, possible dysfunctional implications of control beliefs then become apparent, and these implications are gaining increasing attention in clinical and developmental research (Coyne, 1992; Janoff-Bulman & Brickman, 1982; Thompson, Cheek, & Graham, 1988).

As long as assimilative processes dominate, accommodative reactions are inhibited; if personal standards or ambitions can be maintained without difficulty, there is no need for revising them. However, when action resources decrease, assimilative activities may become increasingly difficult and taxing. To borrow terms from economics, the "production-possibility frontier" (Samuelson & Nordhaus, 1985) narrows with decreasing production reserves, so that a desired level of production in one domain can be maintained only by lowering levels in other domains. The shrinking of action resources in later life should have analogous effects: To maintain desired standards in some specific domain, the individual may be forced to downgrade standards in other domains. For example, in some fields of athletic activity, older individuals may successfully maintain performance levels through forced training and sophisticated use of physical reserves (Ericsson, 1990); with advancing age, however, such efforts become increasingly taxing. The psychological problems of aging largely stem from the fact that efforts to compensate for functional losses are subject to a principle of diminishing returns, so that the opportunity costs of maintaining particular standards eventually outweigh the benefits. Under such circumstances, the only way of avoiding or neutralizing feelings of permanent frustration and helplessness is by adjusting goals and ambitions to situational constraints and changed action resources.

Accommodative Processes: Adjusting Goals to Actional Resources

Notions of gain and loss in development involve evaluative elements; whether developmental outcomes or

changes are individually experienced as gains or losses depends on how they relate to the person's goals and projects. Accordingly, losses or goal discrepancies may be eliminated not only by changing the actual situation but also by accommodating goals and self-evaluative standards. Such processes largely operate on nonintentional levels. Thus, the consideration of these mechanisms take us partly beyond the scope of the paradigm of intentional action; it is nevertheless of central importance to understanding the dynamics of intentional self-development over the life course (see also E. A. Skinner, 1995).

Prototypical facets of the accommodative mode involve the devaluation and disengagement of blocked goals, the rescaling of aspirations, and the positive reappraisal of alternative options. Accommodative processes also include interpretative processes that lead to an acceptance of an initially aversive situation, and thus may facilitate disengagement from barren ambitions. Whereas assimilative activities imply a tenacious adherence to goals and standards, the accommodative process is characterized by the flexible adjustment of goals to situational constraints. Rescaling of standards and aspirations has often been considered to be an inferior form of coping, and has been associated with notions of hopelessness, resignation, or depression. Such connotations are misleading; in fact, feelings of hopelessness and helplessness indicate difficulties in letting go of blocked goals or deficits in accommodative flexibility.

Empirical findings from different lines of research hint at the importance of accommodative processes for neutralizing experiences of loss and stabilizing a positive sense of self in later life. Thus, people tend to devalue developmental goals that have drifted beyond feasible ranges; this tendency appears to be less expressed in depressive subjects (Brandtstädter & Baltes-Götz, 1990). Similarly, persons suffering physical impairments tend to adjust to their handicaps by rearranging goals and ambitions (Schulz & Decker, 1985). Conversely, the difficulty in letting go of barren ambitions appears to be a characteristic of depression (Carver & Scheier, 1990); thus, in later life, continued pursuit of "youthful" goals and self-ideals may thus become a source of continued discontent (Miskimins & Simmons, 1966). Measures of accommodative flexibility have been found to predict coping with problems such as chronic pain, reduced health, or physical handicaps (Brandtstädter et al., 1993; Schmitz, Saile, & Nilges, 1996). Moreover, the intriguing stability of generalized control beliefs in later life seems to depend essentially on the accommodation of goals to available resources (Brandtstädter & Rothermund, 1994; G. Brim, 1992). With advancing age, preferred modes of coping shift from assimilative-offensive to accommodative forms; in view of the increase of uncontrollable and irreversible losses in later life, this shift is consistent with theoretical expectations.

The readiness or ability to accommodate goals to situational constraints depends on situational and personal conditions. Individuals will find it most difficult to disengage from goals that are central to their identity and for which substitutes or functional equivalents are not easily available. High "self-complexity" (Linville, 1987), that is, a highly diversified and multifocal self-structure may enhance disengagement from barren life projects and commitment to new goals. A further significant factor that may differ across situations and persons concerns the ability to shift the meanings of aversive states or losses so that these eventually become acceptable. In aversive mood states, accessibility of palliative meanings seems to be lowered by a tendency of the cognitive system to generate mood-congruent cognitions (Blaney, 1986). We should therefore expect that accommodative processes engage mechanisms that override such congruency effects (e.g., S. E. Taylor, 1991).

As suggested earlier, such auxiliary mechanisms presumably operate on a subpersonal, automatic level. Accommodation of goals and ambitions needs not to be and often cannot be actuated intentionally, although it may have a directive influence on the individual's intentions and decisions. The process of accommodation, however, does not start but rather ends with a decision to abandon a goal or dissolve a commitment. Disengagement from barren commitments can be enhanced to some extent by the planful use of self-management and self-instruction techniques, but, like other nonintentional or automatic processes, it can be brought under personal control only in such mediated, technical ways. Just as we cannot accept any beliefs apart from those that seem sufficiently plausible within the context of the beliefs we already hold, so too we are unable to discard a goal merely because it seems advantageous to do so (e.g., Gilbert, 1993; Kunda, 1990). Action-theoretical research increasingly pays attention to the role that such unintentional or subpersonal automatisms play in the regulation of action (Bargh & Chartrand, 1999; Brandtstädter, 2000).

Among the automatisms that support the accommodative process, mechanisms of attention regulation are of prime importance. As already discussed, atten-

tion generally focuses on situational aspects that are relevant to an ongoing course of action: This suggests that scarce attentional resources tend to be withdrawn from problems that are perceived to be uncontrollable or have turned out to be so (Brandtstädter & Renner, 1992). Decentering of attention from uncontrollable problems may be supported by a compensatory tendency to focus on affectively incongruent stimuli (i.e., on stimuli with positive affective valence) after negative feedback (Derryberry, 1993; Rothermund, 2003; Tipper & Cranston, 1985). Particular types of problems, however, may continue to bind attention even after repeated futile attempts to solve them; this is particularly true of problems that are personally so important that continued assimilative efforts have a high subjective utility even under very low probability of success. Under such conditions, problem-focused thinking may degenerate into ruminative thinking that cycles around the blocked goal and its implications (Martin & Tesser, 1989; Martin, Tesser, & McIntosh, 1993); in the dual-process model, such ruminative thought would be symptomatic of difficulties in shifting from assimilative to accommodative modes. However, ruminative thinking may also promote accommodation because it may enhance the finding of positive meanings, which, due to their palliative effects, should also have a greater chance to be accepted as valid (Brandtstädter & Renner, 1992; Wentura, 1995). Generally, to deconstruct aversive implications of a problem, information has to be generated that invalidates or undermines the aversive conclusions or the underyling premises; this form of focused, preference-driven thinking involves a positivity bias because the search for further information tends to be stopped after the desired positive result has been reached (Kruglanski, 1990; Kunda, 1990).

The distinction between assimilative and accommodative processes that we have addressed in these final considerations may recall traditional distinctions between active and passive concepts of happiness (Tatarkiewicz, 1976); philosophical notions of wisdom have emphasized the importance of finding the right balance between these two stances. Wisdom, however defined, implies not only knowledge as to which goals are important in life and how these goals may be achieved but also involves a sense as to which limitations are unavoidable and how necessities can be accepted (Kamlah, 1973; Nozick, 1989). Intentional self-development across the life span is based on this interplay between engagement and disengagement, between tenacious goal pursuit and flexible goal adjustment. From the theoretical analysis of these complementary tendencies, a better understanding is gained of how continuity and change both pervade and enable each other in personal development during the life span.

SUMMARY AND CONCLUSIONS

Cultural systems maintain and perpetuate themselves by regulating and controlling developmental processes during the life span; within the matrix of sociocultural affordances and constraints, the developing person builds and tries to optimize his or her personal course of development. Throughout life, individuals are actively engaged in keeping their development in stride with social and personal representations of "successful" development over the life span, and they strive to achieve a favorable balance of developmental gains and losses that conforms to their self-definitions and identity goals. Proceeding on these basic tenets, I have advanced the view that human ontogeny, in theory and research, cannot be understood adequately without taking into account the representational and regulative processes through which individuals control their own and others' development. Goal-directed action is both a driving force and an outcome of personal development over the life span, and the present chapter has made an attempt to integrate both facets.

In contrast to traditional programmatic debates, I hold the view that the merits of any developmental "paradigm" should not be judged on an a priori basis, but in light of its heuristic power and with regard to the quality of related research. In this sense, a general strength of action perspectives, which has been stressed throughout this chapter, lies in their potential to integrate cultural, historical, and personal aspects of human ontogeny. This integrative power essentially stems from the fact that the concept of action is inherently linked to these different analytical levels. Related to this point, action perspectives on development are distinctive in how they account for phenomena of stability and change, of diversity and universality in human ontogeny. An action perspective suggests that stability as well as diversity of developmental patterns are essentially related to the particular arrangement of developmental affordances and constraints prevailing in a given sociohistorical context and reflect the ways in which individuals, through constructive and selective activity, make use of and act on these contextual conditions. Thus, the action paradigm provides a framework for integrating theoretical

stances that emphasize the malleability and contextual relativity of developmental trajectories. This does not necessarily imply that the traditional issues of continuity, connectedness, and universality would be anathema to an action perspective on development. I have argued to the contrary that the consideration of the different types of constraints that shape and constitute development in cultural and personal contexts of action may help to gain a better understanding of these traditional issues. Though not discarding the notion of causal connectivity in development, an action perspective posits that coherence and continuity in development essentially depend on the way in which, on the cultural and personal level, causal mechanisms are exploited to construct and deconstruct developmental contingencies.

As has become evident throughout this chapter, an action perspective on development cannot be reduced to a single theory in the formal sense. Accordingly, it would be questionable to single out a particular research program as prototypically representative of this stance. The research examples given in the present chapter cover a broad spectrum of themes across the whole life span. With regard to child development, researchers have documented the role that co-constructive interactions between the child and the material and social environment play in the formation of skills and competencies, and in the genesis of self-representations from which activities of intentional self-development originate. In the field of adolescent and adult development, efforts have been made to elucidate how personal goals, values, and control beliefs interact in the processes of life-planning and intentional self-development, and how personal and contextual influences shape and modify these orientations as the individual moves through his or her developmental history. With regard to later life, increasing emphasis is laid on the activities and processes by which the aging person maintains personal continuity, counteracts developmental losses, and adjusts personal projects to changes in functional reserves. Action-theoretical constructs such as life tasks, personal strivings, self-regulation, future perspectives, self-efficacy, perceived control, life planning, self-verification, or compensation have served as guiding concepts in this research and have become the nuclei of productive theorizing. Although action-theoretical approaches traditionally have an affinity toward hermeneutic or interpretative methods, it is increasingly recognized that a comprehensive analysis of the functional interdependencies between development, culture, and action would be hampered by any methodological parochialism. Current research freely uses, and often strategically combines, a broad gamut of methods ranging from experimental and microprocessual analyses to observational strategies and biographical interviews.

Beyond the theoretical issues on which this chapter has primarily centered, an action perspective on development has particular practical and ethical implications. As long as developmental processes are viewed from a narrow causalist or mechanist stance, they are not amenable to rational or moral evaluations. When we consider the personal and collective actions that shape and constrain development, then such evaluations become possible and legitimate. The assumptions, expectations, and theoretical premises that guide goal-directed activities may be evaluated for consistency and validity; goals and plans of action may be analyzed with respect to their realizability, intra- and interindividual consistency, and compatibility with ethical standards. This is equally true for activities related to the control of development; all the more so because developmental problems often reflect incompatibilities in the system of goals, values, affordances, and constraints that shape development on personal and social levels of action. An action perspective on development thus suggests that any effort at "optimizing" development should involve a critical analysis of the beliefs and normative expectations that, tacitly or explicitly, undergird the personal and social regulation of human ontogeny. It also may sensitize developmentalists to the fact that the results of their research and theorizing, when reintroduced into the contexts of socialization and intentional self-development, become part of the antecedent conditions of the processes that they are studying.

CHAPTER 11

Life Span Theory in Developmental Psychology

PAUL B. BALTES, ULMAN LINDENBERGER, and URSULA M. STAUDINGER

Life span developmental psychology, now often abbreviated as life span psychology, deals with the study of individual development (ontogenesis) from conception into old age (P. B. Baltes, 1987, 1997, 2005; P. B. Baltes & Goulet, 1970; P. B. Baltes & Smith, 2004; Brim & Wheeler, 1966; Dixon & Lerner, 1988; Li & Freund, 2005; Neugarten, 1969; J. Smith & Baltes, 1999; Staudinger & Lindenberger, 2003; Thomae, 1979). A core assumption of life span psychology is that development is not completed at adulthood (maturity). Rather, ontogenesis extends across the entire life course and lifelong adaptive processes are involved. A further premise is that the concept of development can be used to organize the evidence about lifelong adaptive processes, although it is necessary to reformulate the traditional concept of development for this purpose (Harris, 1957). The reformulation required highlights that adaptive changes across life can be more open and multidirectional than the traditional concept of development with its strong focus on development as growth in the sense of maturation and advancement may suggest.

Sequencing in the life span gives temporal priority to earlier times and events in life. Aside from this temporal order of any developmental process, however, life span researchers expect each age period of the life span (e.g., infancy, childhood, adolescence, adulthood, old

age) to have its own developmental agenda and to make some unique contribution to the organization of the past, present, and future in ontogenetic development. Moreover, life span developmental scholars, if they focus on processes and mechanisms of mind and behavior (such as identity of self or working memory) rather than on age, proceed from the assumption that these processes and mechanisms themselves express manifestations of developmental continuity and change across the entire life span.

Psychology deals with the scientific study of mind and behavior, including practical applications that can be derived from such scientific inquiry. Within this substantive territory of psychology, the objectives of life span psychology are: (a) To offer an organized account of the overall structure and sequence of development across the life span; (b) to identify the interconnections between earlier and later developmental events and processes; (c) to delineate the biological, psychological, social, and environmental factors and mechanisms which are the foundation of life span development; and (d) to specify the biological and environmental opportunities and constraints that shape life span development of individuals including their range of plasticity (modifiability). With such information, life span developmentalists further aspire to determine the range of possible development of individuals, to empower them to live their lives as desirably (and effectively) as possible, and to help them avoid dysfunctional and undesirable behavioral outcomes.

To this end, life span researchers have focused on searching for models and definitions of successful (effective) development. In general, and despite the search for universal considerations, life span researchers have highlighted individual and cultural variations in what is considered success or healthy. One general approach to this topic has been to define successful development as the maximization of gains and the minimization of losses and to consider in the definition of what constitutes gains and losses individual, group, and cultural factors (M. M. Baltes & Carstensen, 1996; P. B. Baltes, 1987; P. B. Baltes & Baltes, 1990a, 1990b; Brandtstädter & Wentura, 1995; Marsiske, Lang, Baltes, & Baltes, 1995). Such an approach is consistent with the postulate that there is no development (ontogenetic change) without a loss, just as there is no loss without a gain (P. B. Baltes, 1987). What is considered a gain in ontogenetic change and what is considered a loss is a topic of theoretical as well as empirical inquiry and defies an absolutist definition. The nature of what is considered a gain and what is considered a loss changes with age, involves objective and subjective criteria, and is conditioned by theoretical predilection and cultural context, as well as historical time.

We offer one more introductory observation on the objectives of life span psychology that it shares with other developmental specialties. Methodologically speaking, the study of ontogenesis is inherently a matter of general *and* differential psychology. Thus, life span research and theory is intended to generate knowledge about three components of individual development: (1) commonalities (regularities) in development, (2) interindividual differences in development, and (3) intraindividual plasticity in development (P. B. Baltes, Reese, & Nesselroade, 1977; R. M. Lerner, 1984; S.-C. Li & Freund, 2005; J. R. Nesselroade, 1991a, 1991b; Staudinger & Lindenberger, 2003). Joint attention to each of these components of individual variability and intra-individual potential, and specification of their age-related interplays, are the conceptual and methodological foundations of the developmental enterprise. Recognizing the methodological significance of the distinction among, and subsequent theoretical integration of, commonalities in development, inter-individual differences in development, and intra-individual plasticity has been a continuing theme in life span research and theory since its inception (Tetens, 1777).

What about the status and location of life span psychology within the territory of developmental psychology? Is life span developmental psychology a special developmental psychology, is it the overall integrative developmental conception of ontogenesis, or is it simply one of the many orientations to the study of development (P. B. Baltes, 1987)? Perhaps most scholars view life span psychology as one of the specializations in the field of developmental psychology, namely, that specialization that seeks to understand the full age spectrum of ontogenesis. In this case, the lens of life span psychologists is focused on the entire life course with less consideration for the details of age-related specificities.

Life span theory, however, can also be seen as the coordinated integration of various age-based developmental specializations into one overarching, cumulative framework of ontogenesis. Using such a life span-coordinating lens, one could argue that, if there is a general theory of ontogenetic development, it needs to be a theory that takes into account that ontogenesis extends from conception into old age. Thus, even if one is primarily inter-

ested in the study of infants and infant development, part of one's intellectual agenda requires attention to life span development (Brim, 1976). One example relevant for infancy researchers is the interest in the sequelae of infancy, in the search for its long-term consequences. Another example is the developmental context of infancy, which includes adults as socialization agents who themselves develop. Thus, to understand infant-adult interaction, it is important to recognize that adults are not fixed personages but that they are themselves subject to developmental goals and challenges (Brim & Wheeler, 1966; Hetherington, Lerner, & Perlmutter, 1988; Lachman, 2001; see also Elder & Shanahan, Chapter 12, this *Handbook,* this volume).

What about the organizational frame of life span theory? On a strategic level, there are two ways to construct life span theory: *Person-centered (holistic)* or *function-centered.* The holistic approach proceeds from consideration of the person as a system and attempts to generate a knowledge base about life span development by describing and connecting age periods or states of development into one overall, sequential pattern of lifetime individual development (see also Magnusson, 2001; Magnusson & Strattin, Chapter 8; Thelen & Smith, Chapter 6, this *Handbook,* this volume). An example would be Erikson's (1959) theory of eight life span stages. Often, this holistic approach to the life span is identified with *life course psychology* (Bühler, 1933; see also Elder, 1994; Elder & Shanahan, Chapter 12, this *Handbook,* this volume). Part of a holistic approach includes also efforts where behavioral profiles across a wide range of psychological functioning are in the center of attention and different age groups are contrasted in their profiles and longitudinal interconnections (J. Smith & Baltes, 1997).

The second way to construct life span theory is to focus on a category of behavior or a function (such as perception, information processing, action control, identity, personality traits, etc.) and to characterize the life span changes in the mechanisms and processes associated with the category of behaviors selected. An example would be the life span comparative study of the developmental organization, operation, and transformation of working memory, fluid intelligence, or the cognitive system as a whole (Craik & Bialystok, in press; Salthouse, 1991).

To incorporate both approaches to life span ontogenesis, the holistic person-centered and the function-centered one, the concept of *life span developmental psychology* (P. B. Baltes & Goulet, 1970) was advanced. From our point of view, then, life course psychology is a special case of life span psychology. However, this distinction between life course and life span developmental psychology should not be seen as categorically exclusive. It's more a matter of pragmatics and scientific history. In the history of the field, scholars closer to the social sciences, the biographical study of lives, and personality psychology display a preference for using the term life course development (e.g., Bühler, 1933; Caspi, 1987; Elder, 1994; Settersten, 2005). Scholars closer to psychology, with its traditional interest in mechanisms and processes as well as the decomposition of mind and behavior into its component elements, seem to prefer life span developmental psychology, the term chosen when the West Virginia Conference Series on the field was initiated (Goulet & Baltes, 1970).

HISTORICAL INTRODUCTION

While this section may seem to speak more about the past than the present, it is important to recognize that present theoretical preferences are in part the direct result of historical contexts of science and cultural scenarios rather than of carefully elaborated theoretical arguments. Some of the current issues surrounding life span psychology and its location in the larger field of developmental psychology are difficult to appreciate unless they are seen in their historical and societal contexts (P. B. Baltes, 1983; Brim & Wheeler, 1966; R. M. Lerner, 1983; Lindenberger & Baltes, 1999; Reinert, 1979). For instance, how is it that, especially in North America, life span developmental psychology is a relatively recent advent? This is not true for Germany where life span thinking has a long history.

Many German developmental historians, for instance, consider Johann Nicolaus Tetens as the founder of the field of developmental psychology (P. B. Baltes, 1983; Lindenberger & Baltes, 1999; Müller-Brettel & Dixon, 1990; Reinert, 1979). To Anglo-American developmentalists, however, Tetens is a relatively unknown figure. When Tetens published his two-volume monumental work on human nature and its development *Menschliche Natur and ihre Entwicklung* more than 200 years ago, in 1777, the scope of this first major opus covered the entire life span from birth into old age (see also Carus, 1808, for another early contribution to the

field of developmental psychology). In addition, the content and theoretical orientation of this historical classic by Tetens included many of the current-day signatures of what has become known as the life span developmental theoretical orientation. For instance, development was not only elaborated as a lifelong process by Tetens, but also as a process that entails gains and losses, a process embedded in and constituted by sociocultural conditions, and as a process that is continuously refined and optimized *(vervollkommnet)* by societal change and historical transformations (see Table 11.1).

The second major early work on human development, written some 150 years ago by the Belgian Adolphe Quetelet (1835/1842), continued in a similar tradition. His treatment of human qualities and abilities was entirely life span in orientation, and because of his analysis of the dynamics between individual and historical development, Quetelet prefigured major developments in developmental methodology (P. B. Baltes, 1983). For instance, he anticipated the distinction between cross-sectional and longitudinal study designs as well as the need to conduct successions of age studies in order to disentangle effects of age from those of secular change and historical period (P. B. Baltes, 1968; Schaie, 1965; Schaie & Baltes, 1975).

The 1777 work of Johann Nicolaus Tetens was never translated into English. It is unfortunate because reading Tetens' deep, although largely conceptual and not empirical insights into the interplay among individual, contextual, and historical factors is a humbling experience. Equally impressive are his many concrete everyday examples and analyses of phenomena of human development (e.g., in the area of memory functioning), which make clear that ontogenetic development is not simply a matter of growth but the outcome of complex and multilinear processes of adaptive transformation. Because of these consistencies between the early work of Tetens and Quetelet and modern research in life span development, life span researchers like to argue that these are examples of why and how a life span orientation spawns a particular theoretical and methodological manner of looking at human development (P. B. Baltes, 1987; P. B. Baltes, Reese, & Lipsitt, 1980; Staudinger & Lindenberger, 2003).

TABLE 11.1 Table of Contents

Chapter	Title
1	On the perfectability of human psyche (Seelennatur) and its development in general
2	On the development of the human body
3	On the analogy between the development of the psyche (mind) and the development of the body
4	On the differences between men (humans) in their development
5	On the limits of development and the decline of psychological abilities
6	On the progressive development of the human species
7	On the relationship between optimization (Vervollkommnung) of man and his life contentment (Glückseligkeit)

Source: From *On the Perfectability and Development of Man,* volume 2, by J. N. Tetens, 1777, Leipzig, Germany: Weidmanns Erben und Reich.

There are several reasons why German developmental psychology treated and treats ontogenesis as lifelong development (P. B. Baltes et al., 1980; Groffmann, 1970; Reinert, 1979). In German-speaking countries, for instance, philosophy, in addition to biology, was a major springboard for the emergence of life span psychology. Because of this close tie to philosophy and the humanities, human development in Germany was widely understood to reflect factors of education, socialization, and culture. In addition, there was also a focus on the topic of human development beyond early adulthood. The widespread knowledge and discussion of essays on old age, such as the ancient texts of Cicero (44B.C./1744) or the then contemporary text of Grimm (1860), are examples of this nineteenth-century interest among German scholars in issues of development beyond early adulthood. According to these traditions, fueled primarily by philosophy and the humanities, a widely held position among German scholars was that it was within the medium of "culture" that individuals "developed." With very little biological science on maturity or growth at that time, there was no reason to assume that development should be identified with physical growth and, therefore, should stop at adolescence or early adulthood.

In contrast, the Zeitgeist in North America and also in some other European countries, such as England, was different when developmental psychology emerged as a specialty around the turn of the century (1900). At that time, the newly developed fields of genetics and biological evolution (such as Darwinism) were in the forefront of ontogenetic thinking. From biology, with its maturation-based concept of growth, may have sprung the dominant American emphasis in developmental psychology on child psychology and child development. In North America, at least until the advent of social-learning and operant psychology-based theory in the 1960s (Bandura & Walters, 1963; Reese & Lipsitt, 1970), biological con-

ceptions of growth and maturation (Harris, 1957) led the organization and intellectual agenda in ideas about development. Not surprisingly, therefore, in combination with other political and social forces, children became the primary focus of attention in North American developmental psychology.

The focus on childhood was so pervasive that historical accounts of developmental psychology published in the centennial birth year of American psychology (Parke, Ornstein, Rieser, & Zahn-Waxler, 1991) were entirely devoted to child and adolescent development. No mention was made of the major historical life span scholars such as Tetens, Bühler, or Pressey. Even Sheldon White (1992), the author of the centennial article on G. Stanley Hall, one of the major figures in early American developmental psychology who late in his career turned to adulthood and old age to complete his agenda of developmental studies (see Hall, 1922), ignored this opportunity to treat ontogenesis as a lifelong phenomenon.

Before the life span view of ontogenesis entered the field of developmental psychology more forcefully in North American circles in the 1960s and 1970s, several earlier contributions attempted to broaden developmental psychology toward a consideration of the entire life span (e.g., Hollingworth, 1927; Pressey, Janney, & Kuhlen, 1939; Sanford, 1902). These early American publications on themes of life span development resulted not so much in redirecting developmental psychology from child psychology, but in setting the foundation for the emergence of the field of adult development and aging (gerontology). Indeed, many of the active life span psychologists who promoted life span thinking were closely affiliated with efforts to build a psychological science of aging (Goulet & Baltes, 1970; Havighurst, 1948, 1973; Kuhlen, 1963; Neugarten, 1969; Riegel, 1958; Schaie, 1970; Thomae, 1959, 1979).

As a consequence, in American psychology there evolved a strong bifurcation between child developmentalists and researchers on adult development and aging. One indication of this bifurcation was the creation of two relatively independent divisions concerned with lifelong ontogenesis within the American Psychological Association (Division 7: Developmental Psychology; Division 20: Maturity and Old Age, later renamed into Adult Development and Aging). This divide was also reflected in scholarly publications involving age-specific specialties. On the one hand, the creation of a multitude of organizations and journals heralded the arrival of a comprehensive behavioral science of ontogenesis, a trend that continues. The most recent addition of a "new" age specialty is midlife, and not inappropriate for the beginning of a new century, the first handbook on the topic was published (Lachman, 2001). The emergence of this field of midlife development was much enhanced by the work of a MacArthur Network on Midlife Development chaired by one of the early leaders of the life span field, Orville G. Brim (e.g., Brim & Wheeler, 1966; see also Brim, Ryff, & Kessler, 2004). On the other hand, for life span developmental scholars, these age-specific creations were unfortunate events because they did not promote an integrative effort at constructing life span theory.

That a life span approach became more prominent during the recent decades was dependent on several other factors and historical trends. A major factor was a concurrent concern with issues of life span development in neighboring social-science disciplines, especially sociology and economics. In sociology, life course sociology took hold as a powerful intellectual force (Brim & Wheeler, 1966; Elder, 1985, 1994; Mayer, 2003; Riley, 1987; Riley, Johnson, & Foner, 1972; Settersten, 2005).

Within psychology, and aside from the intellectual forces that may have been inherent in the life span field itself (see later sections in this chapter), three external conditions nurtured the burgeoning of interest in life span development (P. B. Baltes, 1987). First, demographically speaking, the population as a whole was aging. Meanwhile, this historical change in the demographic context of human development has been fully reflected in the organization of the American Psychological Association (APA). Perhaps surprising to child developmentalists, the Division (20) devoted to adult development and aging has grown larger than Division 7, called developmental psychology but which, when using the focus of the work of the scholars elected to its presidency, or the scope of its primary journal as indicators, is more or less entirely devoted to the topic of development from infancy through adolescence.

The second related historical event of life span work in the study of ontogenesis was the concurrent emergence of gerontology (aging research) as a field of specialization, with its search for the lifelong precursors of aging (Birren, 1959; Birren & Schaie, 1996; Cowdry, 1939). The Gerontological Society of America, for instance, is as large or larger than its counterpart organization, the Society for Research in Child Development. In fact, linking the study of gerontology to the study of

life span development is a critical task of current developmental theory. Are theories of development the same as theories of aging? Do we need different conceptions of ontogenesis to characterize development and aging (P. B. Baltes & Smith, 2004)? For instance, does one approach deal with phenomena of growth, and the other with decline?

A third factor, and a major source of rapprochement between child developmentalists and adult developmentalists, was the "aging" of the participants and of the researchers in the several classical longitudinal studies on child development begun in the 1920s and 1930s (Elder, 1974; Kagan, 1964). What are the effects of child development on later life? Which childhood developmental factors are positive or risk-prone for later healthy development? These were questions that were increasingly pursued beginning in the 1970s as the children of the classical longitudinal studies reached early adulthood and midlife. Some of these studies have even provided a basis for a better understanding of processes in the last phases of life (Block, 1971, 1993; Eichorn, Clausen, Haan, Honzik, & Mussen, 1981; Elder, 1985, 1986, 1994; Holahan, Sears, & Cronbach, 1995; Kagan & Moss, 1962; Sears & Barbee, 1977).

Out of these developments has emerged new territory in developmental scholarship. The need for better collaboration among all age specialities of developmental scholarship, including child development, has become an imperative of current-day research in developmental psychology (Hetherington et al., 1988). But for good life span theory to evolve, it takes more than courtship and mutual recognition. It takes a new effort and serious exploration of theory that—in the tradition of Tetens (1777)—has in its *primary* substantive focus the structure, sequence, and dynamics of the entire life course.

TOWARD PSYCHOLOGICAL THEORIES OF LIFE SPAN DEVELOPMENT: FIVE LEVELS OF ANALYSIS

We approach psychological theories of life span development in five sequential but interrelated steps. Each step will bring us closer to specific psychological theories of life span development. As shown in Table 11.2, we move from the distal and general to the more proximal and specific in our treatment of life span ontogenesis. This movement also implies a movement from the metatheoretical to the more empirical.

TABLE 11.2 Toward Psychological Theories of Life Span Development: Five Levels of Analysis

Level 1:	Biological and Cultural Evolutionary Perspectives: On the Incomplete Architecture of Human Ontogenesis and the Life Span Developmental Dynamics between Biology and Culture
Level 2:	Dynamics of Gains and Losses: Life Span Changes in the Relative Allocation of Resources in Development to Functions of Growth versus Maintenance/Resilience versus Regulation of Loss
Level 3:	A Family of Metatheoretical Propositions about the Nature of Life Span Development
Level 4:	An Example of a Systemic and Overall Theory of Successful Life Span Development: Selective Optimization with Compensation
Level 5:	Life Span Theories in Specific Functions and Domains: Intelligence, Cognition, Personality, Self

Specifically, we consider five levels of analysis. Level 1, the most distal and general one, makes explicit the cornerstones and "norms of reaction" or "potentialities" (P. B. Baltes, 1997; P. B. Baltes & Smith, 2004; Brent, 1978a, 1978b; R. M. Lerner, 2002; S.-C. Li, 2003; Schneirla, 1957; see also Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume) of life span ontogenesis. With this approach, which is also consistent with the levels of integration notion of Schneirla or more recently S.-C. Li (2003), we obtain information on what we can expect about the general scope and shape of life span development based on evolutionary, historical, and interdisciplinary views dealing with the interplay between biology and culture during ontogenesis.

Levels 2 and 3 move toward psychological theories of individual development. On these levels of analysis, while keeping the initial overall framework in mind, we shall describe, using an increasingly more fine-grained level of analysis, specific conceptions of life span developmental psychology. On Level 4, we advance one concrete illustration of an overall life span developmental theory, a theory that is based on the specification and coordinated orchestration of three processes: Selection, optimization, and compensation. Subsequently, and corresponding to a putative Level 5, we move to more molecular phenomena and functions. Specifically, we characterize life span theory and research in areas of psychological functioning such as cognition, intelligence, personality, and the self.

We have chosen this approach—of proceeding from a broad level of analysis to more and more specific and microlevels of psychological analysis—because it illustrates

one of the central premises of life span psychology, that development is embedded in a larger evolutionary, historical, and cultural context (P. B. Baltes et al., 1980; Durham, 1991; Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Finch & Zelinski, 2005; Hagen & Hammerstein, 2005; R. M. Lerner, 2002; S.-C. Li, 2003; Magnusson, 1996; Riegel, 1973; Schaie, Willis, & Pennak, 2005). Recognizing the powerful conditioning of human development by biological and cultural evolution and co-evolution emphasizes that the future is not fixed either, but includes features of an open system. In other words, the future is not something we simply enter but also something that we help create and that is dependent on the partially always novel co-construction of genetic, environmental, and cultural conditions (P. B. Baltes, Reuter-Lorenz, & Rösler, 2006). This is especially true for the second half of life and old age. It is there that the relative incompleteness of the biology- and culture-based architecture of human development becomes most conspicuous (P. B. Baltes, 1997; P. B. Baltes & Smith, 2004).

The Overall Architecture of Life Span Development: A First View from the Perspectives of Biological and Cultural Co-Evolution and Biocultural Co-Construction (Level 1)

We now turn in our quest for understanding life span development to the first level of analysis chosen, the overall biological and cultural architecture of life span development (P. B. Baltes, 1997).

Questions about the how and why of the role of biology (heredity) and culture (environment) have formed one of the main intellectual frames in developmental psychology. What is the role of cultural and biological factors in ontogenesis, how do they interact, condition, and modify each other? What is the "zone of development," the "norm of reaction," the "range of plasticity" that we can expect to operate during ontogenesis? Based on genetic and evolution-based factors and on cultural structures, for instance, only certain pathways can be implemented during ontogenesis, and some of these are more likely to be realized than others. Despite the sizeable plasticity of humans, not everything is possible in ontogenetic development. Development follows principles that make universal growth impossible (Hagen & Hammerstein, 2005; S.-C. Li & Freund, 2005).

With a view on the future and future societal changes, we need to recognize first that the overall architecture of human development is incomplete (P. B. Baltes, 1997; P. B. Baltes & Smith, 2003): The overall biological and cultural architecture of human development continues to evolve and in this process co-constructs and modifies each other (P. B. Baltes, et al., 2006). A second insight is that what is most "undeveloped" in the gene-environment interplay is both the genetic base and the culture of old age. While earlier age periods of the life course have a long tradition of biological and cultural co-evolution and co-construction (P. B. Baltes et al., 2006; Durham, 1991; Finch & Zelinski, 2005; Tomasello, 1999) and fine-tuning, the anthropological tradition of biological and cultural co-evolution for later phases of life, historically speaking, is younger. As we move from childhood to old age, the evolutionary (biological and cultural) incompleteness of the overall architecture of the life span increases.

Figure 11.1 illustrates the main lines of argument (P. B. Baltes, 1997; see also Kirkwood, 2003). Note first that the specific form (level, shape) of the functions characterizing the overall life span dynamics is not critical. What is critical is the overall direction and reciprocal relationship between these functions. Figure 11.1 identifies three such directional principles that regulate the nature of ontogenetic development.

Evolutionary Selection Benefits Decrease with Age

The first part of Figure 11.1 represents a conclusion that derives from an evolutionary perspective on the nature of the genome and its age-correlated changes in expressivity (Charlesworth, 1994; Finch, 1990, 1996;

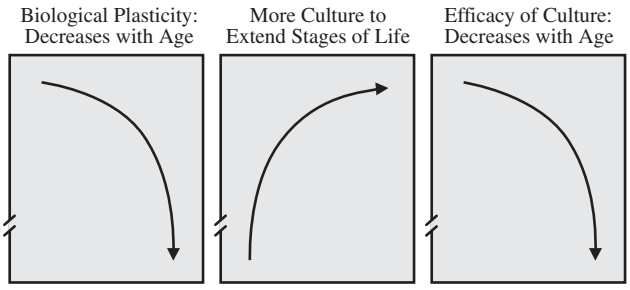

Figure 11.1 Schematic representation of basic facts about the average dynamics between biology and culture across the lifespan. There can be much debate about the specific forms of the functions but less about directionality. From "On the Incomplete Architecture of Human Ontogeny: Selection, Optimization, and Compensation as Foundation of Developmental Theory," by P. B. Baltes, 1997, *American Psychologist, 52,* pp. 366–380.

Kirkwood, 2003; Martin, Austad, & Johnson, 1996; Medawar, 1946). The central argument is that the benefits resulting from evolutionary selection display a negative age correlation, that is, that there is an age-associated declining process of evolution-based natural selection.

During evolution, the older the organism, the less the genome benefited from the genetic advantages associated with evolutionary selection. As a consequence, and certainly after maturity, *the expressions and mechanisms of the genome lose in functional quality as organisms age*. Evolutionary selection was tied to the process of reproductive fitness and its midlife location in the life course. As a consequence, reproductive fitness-based evolutionary selection pressure—which in the long run resulted in a better and better genome—operated *primarily* and more strongly during the first half of life. This general statement holds true even though there are "indirect" positive evolutionary selection benefits carried into and located in old age, for instance, through processes of grandparenting, coupling, or exaptation (Gould, 1984).

During evolution, this age-associated diminution of evolutionary selection benefits was further enhanced by the fact that in earlier historical times only few people reached old age. Thus, evolutionary selection could not operate as frequently to begin with when it came to older individuals. Most individuals died before possible negative genetic attributes were activated or possible negative biological effects of earlier developmental events became manifest. Therefore, and quite aside from other factors of the biological processes of aging (Finch, 1990; Kirkwood, 2003; Martin et al., 1996; Osiewacz, 1995; Yates & Benton, 1995), it has been argued that genes active at later stages of the life course are more often deleterious or dysfunctional genes than those operative at earlier times in the life span.

One concrete illustration of this aging-based weakening of evolutionary selection benefits is the existence of late-life illnesses such as Alzheimer dementia (for other examples see Martin et al., 1996). This disease typically does not become manifest until age 70. After age 70, however, it increases markedly in frequency such that among 90- to 100-year-olds Alzheimer dementia has a prevalence of about 50% (Helmchen et al., 1999). This disease is at least in part a late-life disease because reproductive fitness based evolutionary pressure was unable to select against it. Martin et al. (1996) called such an outcome "selection neutrality."

There are other aspects of a biology of aging that imply an age-associated loss in biological functioning. One is the disposal soma theory of aging that attributes senescence to the accumulation of damage and faults in cells and tissues. Related models of biological aging are wear-and-tear theories, entropy-based conceptions as well as interpretations related to the sources of age-accumulated increases in mutations. Note that some of the factors involved are associated directly with the mechanisms and operative processes of ontogenesis itself. Currently, for instance, age-associated increases in oxidative damage are proffered as a key possibility to account for aging-associated losses in biological efficacy (Kirkwood, 2003; Martin et al., 1996). One variant is the so-called counterpart theory of aging (Birren, 1988; Yates & Benton, 1995). It proffers that aging processes in part are the negative by-products of the early life process of growth. Related to this view is the genetic mechanism of "antagonist pleiotropy" (Martin et al., 1996).

These various considerations about the role of genetic factors result in a converging conclusion regarding the biological architecture of life span development (P. B. Baltes, 1997). Where evolutionary selection and the ontogenetic biology of aging are concerned, the life span of humans displays a loss in plasticity and, in addition, an increasingly unfinished architecture. These insights may be captured with the sentence: "Biology is not a good friend of old age." With age, the genetic material, associated genetic mechanisms, and genetic expressions become less effective and less able to generate or maintain high levels of functioning.

Increase in Need for Culture as Human Development Is Extended in Level and Age Range

What about the role of culture and culture-related factors in preparation of and during ontogenesis? By culture, we mean the entirety of psychological, social, material, and symbolic (knowledge-based) resources which humans developed over millennia; and which, as they are transmitted across generations, make human development as we know it possible (P. B. Baltes et al., 2006; Cole, 1996; Damon, 1996; D'Andrade, 1995; Durham, 1991; S.-C. Li, 2003; Shweder, 1991; Tomasello, 1999; Valsiner & Lawrence, 1997). These cultural resources include cognitive skills, motivational dispositions, socialization strategies, physical structures, the world of economics as well that of medical and physical technology.

Figure 11.1 summarizes our view of the life span dynamics associated with culture and culture-based processes (P. B. Baltes, 1997; P. B. Baltes, Staudinger, & Lindenberger, 1999). The middle section represents the proposition that for ontogenetic development to be extended in level and span of life, an increase in the level and quality of cultural resources is required to continue a productive interplay between culture and age across the life span. There are two parts to the argument for an *age-related increase in the need for more culture*.

The first argument is that for human ontogenesis to have reached higher and higher levels of functioning and to extend itself longer spans of life, whether in physical (e.g., sports) or cultural (e.g., reading and writing) domains, there had to be a conjoint evolutionary increase in the richness and dissemination of culture. Thus, human development the way we know it in the modern world is essentially and necessarily tied to the evolution of culture and its impact on genetic evolution and the kind of life environments individuals transact with as they develop during ontogenesis. And the further we expect human ontogenesis to extend itself into adult life and old age, the more it will be necessary for particular cultural factors and resources to emerge to make this possible.

To appreciate the power of the evolution of such culture-based resources in the process of biocultural co-production consider what happened to average life expectancy during the twentieth century in industrialized countries. It was not the genetic make-up of the individual or the population that evinced marked changes during this time. Economic and technological innovations were the central factors. Similarly, the dramatic increase in literacy rates over the past centuries in industrialized nations was not the result of a change in the genome, but above all a change in environmental contexts, cultural resources, and strategies of teaching.

To prevent a possible misunderstanding: The trajectory depicted in the middle panel of Figure 11.1 does not mean that children require little cultural input and support. Biocultural co-construction always operates though in varying combinations (P. B. Baltes et al., 2006; P. B. Baltes & Singer, 2001; Li, 2003). Early in ontogenetic life, because the human organism is still undeveloped biologically, infants and children need a wide variety of psycho-social-material-cultural support. But in terms of overall resource structure, this support in childhood is focused on basic levels of functioning such as environmental sensory stimulation, nutrition, language, and social contact. Subsequent age stages, however, require increasingly more and more differentiated cultural resources, especially if one considers the high levels of knowledge and technology that adults need to acquire in order to function well in modern societies. Thus, it is primarily through the medium of more advanced levels of culture in the biocultural co-construction process that individuals have the opportunity to continue to develop across the higher ages of the life course.

There is a second argument for the theory that, with age, the need for the supportive role of culture increases. Because of the age-related biological weakening and reduced plasticity described in the left part of Figure 11.1, an age-associated increase in "need" for culture is also necessary because more environmental support is necessary to maintain efficacy. Thus, if and when individuals aspire to maintain their previous levels of functioning as they age, culture-based resources (material, social, economic, psychological) are necessary to maintain high levels of functioning. In the aging literature, the work of Craik (1986; Craik & Bialystok, in press) on the role of environmental support to maintain memory efficacy is exemplary.

Age-Related Decrease in Efficiency of Culture

The right panel of Figure 11.1 illustrates a further overall characteristic of the life span developmental dynamic between biology, culture, and age. Here, the focus is on a third cornerstone of the overall architecture of the life course, that is, the efficacy or *efficiency* of cultural factors and resources (P. B. Baltes, 1997).

During the second half of life, we submit that there is an age-associated reduction in the efficiency of cultural factors. With age, and conditioned primarily by the negative biological trajectory of the life course, the relative power (effectiveness) of psychological, social, material, and cultural interventions becomes smaller and smaller. Take cognitive learning in old age as an example (P. B. Baltes, 1993; Craik & Salthouse, 2000; Lindenberger, 2001; Salthouse, 2003; T. Singer, Lindenberger, & Baltes, 2003). The older the adult, the more time, practice, and more cognitive support it takes to attain the same learning gains. And moreover, at least in some domains of information processing, and when it comes to high levels of performance, older adults may never be able to reach the same levels of functioning as younger adults even after extensive training (P. B. Baltes & Kliegl, 1992; Kliegl, Smith, & Baltes, 1990; T. Singer, Lindenberger, et al., 2003).

We submit that the three conditions and trajectories outlined in Figure 11.1 form a robust fabric, a biocultural, and because of its incompleteness, dynamic architecture of the life span (P. B. Baltes, 1997). This biocultural is not fixed, but subject to further processes of biocultural co-construction. We argue that the general script of this biocultural fabric represents a first tier of life span theory. They represent constraints on the degree of openess of the developmental life span system. Whatever the specific content and form of a given psychological theory of life span continuity and change, we maintain that it needs to be consistent with the frame outlined in Figure 11.1. For instance, we conclude that any theory of life span development positing "general" positive advances across broad domains of functioning in later adulthood is probably false.

The immediate future of old age, therefore, will depend to a large measure on our ability to generate and employ culture and culture-based technology in compensating for the unfinished architecture of biology, for the age-correlated decrease in biological functioning, for the growing gap between mind and body. In the long run, the changing dynamics in the relative impact of genome- and culture-based influences also suggests that interventions into the biogenetic system itself are necessary to generate more desirable states of aging, especially in the oldest-old. Biocultural co-construction is a concept that reflects the need for both biology and culture to cooperate in such aspirations (P. B. Baltes et al., 2006; P. B. Baltes & Singer, 2001; S.-C. Li, 2003).

Life Span Changes in the Relative Allocation of Resources to Distinct Functions of Development (Level 2)

Having characterized the overall biocultural landscape of human development, we move toward a level of organization closer to central concepts of developmental psychology. In Table 11.2, this was designated as Level 2. We take this next step by reflecting about functions (goals) and outcomes of development.

Growth versus Resilience (Maintenance) versus Regulation of Loss

To what degree does the overall biocultural architecture outlined in Figure 11.1 prefigure pathways of development and the kind of adaptive challenges individuals face as they move through life? One possibility is to distinguish between three functions of ontogenetic development. The first two are known from research in child development: *growth* and *resilience* (maintenance and recovery) of functioning (Cicchetti, 1993; Garmezy, 1991; Rutter, 1987). Life span researchers have added to these two functions that of management or *regulation of losses* (P. B. Baltes, 1987, 1997; Brandtstädter & Baltes-Götz, 1990; Brandtstädter & Greve, 1994; Brim, 1988; Dixon & Bäckman, 1995; Heckhausen & Schulz, 1993; Labouvie-Vief, 1982; Staudinger, Marsiske, & Baltes, 1993, 1995). This addition was invoked because, as the growing incompleteness of the biocultural architecture postulates, the foundational frame of lifelong development includes not only conditions of growth and health, but also conditions of permanent loss that, in principle, are not avoidable.

Figure 11.2 displays our general life span developmental script about the allocation of available resources for these three major adaptive tasks of growth, maintenance/recovery (resilience), and regulation of loss (P. B. Baltes, 1987; Staudinger et al., 1993, 1995). With the adaptive tasks of *growth,* we mean behaviors aimed at reaching higher levels of functioning or adaptive capacity. Under the heading of *maintenance* and *resilience,* we group behaviors which are aimed at maintaining levels of functioning in the face of challenge or returning to previous levels after a loss. With the adaptive task of management or *regulation of loss,* we identify those behaviors which organize adequate functioning at lower levels when maintenance or recovery, for instance, because of external-material or biological losses, is no longer possible.

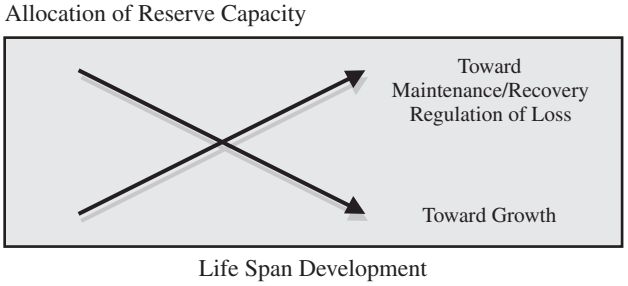

Figure 11.2 Life span changes in the allocation of resources into distinct functions (objectives) of development: growth, maintenance and recovery (resilience), and regulation (management) of loss. *Source:* From "Resilience and Reserve Capacity in Later Adulthood: Potentials and Limits of Development across the Life Span" (pp. 801–847), by U. M. Staudinger, M. Marsiske and P. B. Baltes, in *Developmental Psychopathology: Vol. 2. Risk, Disorder, and Adaptation,* D. Cicchetti & D. Cohen (Eds.), 1995, New York: Wiley.

In childhood and early adulthood, the primary allocation of resources is directed toward growth. During adulthood, allocation toward maintenance and recovery (resilience) is on the increase. Research by Freund and colleagues has shown that individuals of different ages hold mental scripts and preferences that are consistent with this life span change in the focus of allocation (Freund & Ebner, 2005; Riediger & Freund, in press). In advanced adulthood and especially in old age, more and more resources are directed toward regulation (management) of loss, although this need may not be realized as often as desired since the application of compensatory behaviors is effortful (P. B. Baltes & Baltes, 1990a; Freund & Baltes, 2002b). In old age, few resources remain available to be allocated to growth. Consistent with this general view, older adults invest more time into compensation than optimization (M. M. Baltes & Carstensen, 1996; Freund, in press). However, some targets for positive change continue to be realistic, such as advances in emotional and spiritual regulation or wisdom (P. B. Baltes & Staudinger, 2000; Carstensen, 1995; Carstensen, Isaacowitz, & Charles, 1999; Kunzmann, 2004; Staudinger, Freund, Linden, & Maas, 1999). Such a characterization is an oversimplification because individual, domain, and contextual differences need to be taken into account. Thus, the characterization is one about relative probability.

In our view (e.g., P. B. Baltes, 1987; Freund & Baltes, 2002b; Staudinger et al., 1995; for related arguments, see also Brandtstädter & Greve, 1994; Brim, 1992; Edelstein & Noam, 1982; Heckhausen, 1997; Labouvie-Vief, 1982), the life span shift in the relative allocation of biology- and culture-based resources to the functions of growth, resilience, and the management of loss is a major issue for any theory of life span development. This is true even for those theories that, on the surface, deal only with growth or positive aging (e.g., Erikson, 1959; Perlmutter, 1988; Ryff, 1984, 1989a). In Erikson's theory, for instance, the acquisition of generativity and wisdom are the positive developmental goals of adulthood. Despite the growth orientation of these constructs, even in Erikson's theory their attainment is inherently tied to recognizing and managing issues of generational turnover as well as of one's finitude and impending death. Another example is research on another facet of positive aging, wisdom (P. B. Baltes & Staudinger, 2000; Kunzmann & Baltes, 2003a, 2003b; Sternberg & Jordan, 2005). The expression of wisdom becomes more and more difficult as the oldest ages are reached, and its very content includes the recognition and mastery of the losses of life.

To illustrate this dynamic of coordinating in an adaptive manner facets of growth, maintenance, and regulation of loss, see Margret Baltes and her colleagues' research (M. M. Baltes, 1995, 1996; M. M. Baltes & Silverberg, 1994; M. M. Baltes & Wahl, 1992). This work focuses on the interplay between autonomy and dependency in different age groups including children and the old. While the primary focus of the first half of life is the maximization of autonomy, the developmental agenda changes in old age. In old age, to deal effectively with age-based losses and to retain some independence, the productive and creative use of dependency becomes critical. By invoking dependency and support, resources are freed for use in other domains involving personal efficacy and growth.

According to Margret Baltes, for older adults to maintain autonomy in select domains of functioning, the effective exercise and use of dependent behavior is a compensatory must. By invoking dependency and support, resources are freed up for use in other domains involving personal efficacy and growth. Furthermore, this program of research also showed that the three-fold developmental-function script is present in how others approach behavioral interactions with members of different age groups. In children, the primary script in the social world is one of supporting independence. The reverse (a dependency-support script) is true when interacting with older persons (M. M. Baltes, 1996).

In sum, a further step in developing life span theory is to recognize and specify the nature of the dynamics of individual as well as social resource allocation for growth, maintenance (resilience), and regulation of loss. Of particular importance is the nature of the shift in this systemic interplay and orchestration over the life course. Research presented later in this chapter on the theory of selective optimization with compensation (P. B. Baltes & Baltes, 1990a; Freund & Baltes, 2002a) will show how this general conceptual emphasis is translated into the study of specific domains such as cognition or motor behavior.

Deficits as Catalysts for Progress (Growth)

The attention given to the age-related weakening of the biological foundation in Figures 11.1 and 11.2 may have suggested that the consequences of such a loss in biological quality implies also a pervasive age-related loss in behavioral functioning, in other words, that there may be no opportunity for growth at all in the

second half of life in those domains where biological factors are important.

To prevent this possible misunderstanding, we next describe why this is not necessarily so, why deficits in biological status also can be the foundation for progress, that is, antecedents for positive changes in adaptive capacity. At least since the publication of "Limits of Growth" by the Club of Rome, there has been increasing public awareness that more is not always better and that progress is possible even in the context of limitations and constraints. Biocultural co-construction was already introduced as a metascript. Similar perspectives derive from considerations of the adaptive processes in evolution as well as from consideration of the function of compensation during ontogenesis (see also P. B. Baltes, 1991, 1997; Brandtstädter, Chapter 10, this *Handbook,* this volume; Dixon & Bäckman, 1995; Durham, 1991).

The most radical view of the notion that deficits can spell progress is contained in the notion of *culture as compensation.* That is, the condition of a limitation or a loss generates new forms of mastery and cultural innovation. As researchers study what is not yet known, cultural attention shifts to those areas where there is an objective or subjectively perceived lack or a deficit. In this line of thinking, the human organism is by nature a "being of deficits" (*Mängelwesen;* Gehlen, 1956) and social culture has developed or emerged in part to deal specifically with biological deficits.

Memorization strategies, for instance, were developed in part because human memory is not optimal. To give another example: The fact that humans are biologically vulnerable regarding outside temperatures (lack of perfect thermo-regulation) is among the reasons for a highly developed body of knowledge, values, and technology about textiles and clothing. This applies both to cultural evolution on the societal level and to individual ontogenesis. Research on psychological compensation is a powerful illustration of the idea that deficits can be catalysts for positive changes in adaptive capacity (Bäckman & Dixon, 1992; M. M. Baltes & Carstensen, 1996; P. B. Baltes & Baltes, 1990b; Dixon & Bäckman, 1995; Marsiske et al., 1995; Rowe & Kahn, 1987).

A Family of Metatheoretical Propositions about Life Span Developmental Theory (Level 3)

Because of the complexities associated with life span ontogenetic processes and the challenge involved in the articulation of adequate theoretical concepts, there has been much discussion in life span work about metatheory of development (e.g., P. B. Baltes, 1987; P. B. Baltes et al., 1980; Labouvie-Vief, 1980, 1982; R. M. Lerner, 1991, 2002; J. R. Nesselroade & Reese, 1973; Overton & Reese, 1973; Reese, 1994; Riegel, 1976). Included in this discussion was a continuing dialogue about the shortcomings of extant conceptions of development as advanced primarily by child developmentalists (e.g., Collins, 1982; Harris, 1957). A *family of metatheoretical propositions* intended to characterize the nature of life span development was one outcome of this extensive discussion (P. B. Baltes, 1979a, 1987; R. M. Lerner, 1983).

In the following discussion, we attempt to update this effort at a metatheory of life span development (Table 11.3). In doing so, we also point out that similar metatheoretical work exists in other quarters of developmental theory, particularly in conceptual work associated with cultural psychology, evolutionary psychology, and systems theory (see also Fischer & Bidell, Chapter 7; Gottlieb et al., Chapter 5; Thelen & Smith, Chapter 6, this *Handbook,* this volume). In the present context, however, we emphasize the uniqueness of the positions advanced by life span scholars.

Reformulating the Concept of Development from a Functionalist Perspective: Development as Change in Adaptive Capacity

From a life span theory point of view, it was important to articulate concepts of development that go beyond unidimensional and unidirectional models that had flourished in conjunction with the traditional biological conceptions of growth or physical maturation. In these traditional conceptions (Harris, 1957; Sowarka & Baltes, 1986), attributes such as qualitative change, ordered sequentiality, irreversibility, and the definition of an end state played a critical role. Primarily by considering ontogenetic development from a functionalist perspective (Dixon & Baltes, 1986), the traditional conception of development was challenged.

Development as Selection and Selective Adaptation (Optimization). The traditional concept of development emphasizes a *general* and *universal* development of an entity geared toward a higher level of functioning which, in addition, continuously incorporates most if not all previously developed capacities (Harris, 1957; R. M. Lerner, 1983, 2002; H. Werner, 1948). Historically, this view of ontogenetic development has been pictured as the unfolding and emergence of an entity,

TABLE 11.3 Family of Theoretical Propositions Characteristic of Life Span Developmental Psychology

Life span development: Ontogenetic development is a lifelong process that is co-constructed by biology and culture. No age period holds supremacy in regulating the nature of development.

Life span changes in the dynamic between biology and culture: With age and certainly after adulthood, there is a growing gap between biological potential and individual-cultural goals. This gap is fundamental to ontogenesis as the biological architecture of life is incomplete and inevitably results in loss of adaptive functioning and eventually death.

Life span changes in allocation of resources to distinct functions of development:growth versus maintenance versus regulation of loss: Ontogenetic development on a systemic level involves the coordinated and competitive allocation of resources in three distinct functions: (1) growth, (2) maintenance including recovery (resilience), and (3) regulation of loss. Life span developmental changes in the profile of functional allocation involve a shift from the allocation of resources for growth (more typical of childhood) toward an increasingly larger and larger share allocated to maintenance and management of loss.

Development as selection (specialization) and selective optimization in adaptive capacity: Development is inherently a process of selection and selective adaptation. Selection is due to biological, psychological, cultural, and environmental factors. Developmental advances are due to processes of optimization. Because development is selective and age-associated changes in potential, compensation is also part of the developmental agenda.

Development as gain/loss dynamic: In ontogenetic development, there is no gain without loss, and no loss without gain. Selection and selective adaptation are space-, context-, and time-bound. Thus, selection and selective adaptation imply not only advances in adaptive capacity but also losses in adaptivity for alternative pathways and adaptive challenges. A multidimensional, multidirectional, and multifunctional conception of development results from such a perspective.

Plasticity: Much intraindividual plasticity (within-person variability) is found in psychological development. The key developmental agenda is the search for the range of plasticity and its age-associated changes and constraints.

Ontogenetic and historical contextualism as paradigm: In principle, the biological and cultural architecture of human development is incomplete and subject to continuous change with biological and cultural factors, conditions, and co-constructing and modifying each other. Thus, ontogenetic development varies markedly by historical-cultural conditions. The mechanisms involved can be characterized as principles associated with biocultural contextualism. As an illustration, development can be understood as the outcome of the interactions (dialectics) between three systems of biological and environmental influences: (1) normative age-graded,
(2) normative history-graded, and (3) nonnormative (idiosyncratic). Each of these sources evinces individual differences and, in addition, is subject to continuous change.

Toward a general and functionalist theory of development: The effective coordination of selection, optimization, and compensation: On a general and functionalist level of analysis, successful development, defined as the (subjective and objective) maximization of gains and minimization of losses, can be conceived of as resulting from collaborative interplay among three components: (1) selection, (2) optimization, and (3) compensation. The ontogenetic pressure for this dynamic increases with age, as the relative incompleteness of the biology- and culture-based architecture of human development becomes more pronounced.

Updated from "Erfolgreiches Altern als Ausdruck von Verhaltenskompetenz und Umweltqualität" (pp. 353–377), by M. M. Baltes, in *Der Mensch im Zusammenspiel von Anlage und Umwelt,* C. Niemitz (Ed.), 1987, Frankfurt-am-Main, Germany: Suhrkamp; see also P. B. Baltes, 1987, 1997, and P. B. Baltes et al., 2006.

primarily formed from sources within that entity and by mechanisms of transformation or stage-like progression.

Such a unidirectional, growth-like view of human development appeared contradictory to many findings in life span psychology, which included negative transfer from earlier development to later developmental outcomes, differences in rates, age-onsets, and age-offsets of developmental trajectories, multidirectional patterns of age-related change, as well as discontinuities in prediction. Figure 11.3 represents an early representation of this differentiated view of development elicited by life span thinking and findings, which posed a challenge to traditional conceptions of development as unilinear and holistic growth (see also Labouvie-Vief, 1980, 1982).

Historically, one approach to this gap between theory and findings was to explore the usefulness of the distinction between development and aging (Birren, 1964). Life span theorists, at least within psychology, opted for a different strategy (P. B. Baltes, 1987). They attempted to either modulate the traditional definitional approach to development or to offer conceptions that highlighted the view that ontogenetic development was not identical with the notion of holistic and unidirectional growth. In these efforts, life span scholars shared the goal of reformulating the concept of development, although they differed in the degree of radicality and in specifics. Labouvie-Vief (1980, 1982; see also Pascual-Leone, 1983; Riegel, 1976), for instance, introduced new forms (stages) of systemic functioning for the period of adulthood, based on conceptions of development as adaptive transformation and structural reorganization, thereby opening a new vista on Neo-Piagetian constructivism. In our work (e.g., P. B. Baltes, 1983, 1987; P. B. Baltes et al., 1980), but also that of others such as Brandtstädter, Featherman, and Lerner (Brandtstädter, 1984; Featherman & Lerner, 1985; Featherman, Smith, &

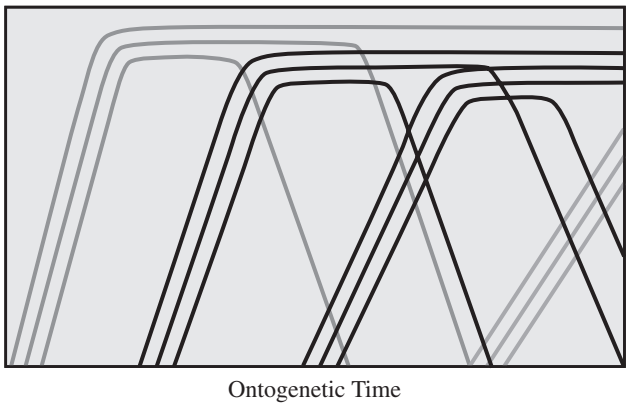

Figure 11.3 Hypothetical examples of life span developmental processes. Developmental functions (behavior-change processes) differ in onset, duration, termination, and directionality when charted in the framework of the life course. Moreover, developmental change is both quantitative and qualitative: Not all developmental change is related to chronological age, and the initial direction is not always incremental. *Source:* From "Plasticity and Variability in Psychological Aging: Methodological and Theoretical Issues" (pp. 41–66), by P. B. Baltes and M. M. Baltes, in *Determining the Effects of Aging on the Central Nervous System,* G. E. Gurski (Ed.), 1980, Berlin, Germany: Schering.

Peterson, 1990; R. M. Lerner, 1983), we were perhaps more radical in our departure from extant theoretical models of development. We attempted to approach the conceptualization of development by a theoretical framework of neofunctionalism (Dixon & Baltes, 1986) and contextualism (R. M. Lerner, 1991; Magnusson, 1996). Within that approach, the nature of adaptive change with life span development was driven by consideration of a larger set of influences and the kind of challenges that people face as their lives unfold. In our view, such a neofunctionalist approach was the most open to a full consideration of the new facets of ontogenetic change (such as multidirectionality, multifunctionality, adaptive specificities, and predictive discontinuity) that life span researchers were confronted with. At the same time, this broadened conception of development permitted maintaining traditional growth-like conceptions of development as a special class of developmental phenomena.

The result was to go beyond the traditional conception of development as growth and open the concept of development to a larger framework of changes. In our own work, we opted for defining development as *selective age-related change in adaptive capacity.* Development as selection and selective adaptation displays many attributes. For instance, it can be active or passive, conscious or subconscious, internal or external, and continuous or discontinuous. Moreover, in the long run or in different circumstances, it can be functional or dysfunctional.

This intellectual movement toward a broadly based functionalist conception of ontogenesis entailed a number of features. For instance, to reflect more accurately their understanding of the empirical evidence about life span changes, and also drawing from alternative conceptions of ontogenesis such as canalization and selective neuronal growth (Edelman, 1987; Waddington, 1975), self-organization (Barton, 1994; Maturana & Varela, 1980; Prigogine & Stengers, 1984), as well as expert systems (Chi, Glaser, & Rees, 1982; Ericsson & Smith, 1991; Weinert & Perner, 1996), life span researchers began to emphasize that any process of development is not foremost the unfolding of an entity. Rather, they focused on development as ontogenetic selection from a pool of more or less constrained potentialities and the subsequent selective optimization of the entered pathways including the construction of novel pathways that were not part of the original system (P. B. Baltes, 1987; Labouvie-Vief, 1982; Marsiske et al., 1995; Siegler, 1989). As a given pathway of ontogenetic development is chosen and optimized, others are ignored or suppressed. In short, some life span theorists ventured a new start and suggested treating ontogenetic development as a process of dynamic and selective adaptation reflecting the interaction of biological, cultural, and contextual factors as well as the proactive role of individuals in shaping their course of development (P. B. Baltes, Reuter-Lorenz, et al., 2006; Brandtstädter & Lerner, 1999). Thus, with the focus on selection and selective adaptation, life span researchers were able to be more open about the pathways of lifelong ontogenesis.

Development as a Gain-Loss Dynamic. Not surprisingly, a related change in emphasis advanced in life span theory and research was on viewing development as *always* being constituted by gains and losses (P. B. Baltes, 1979a, 1987; P. B. Baltes et al., 1980; Brandtstädter, 1984; Brim, 1992; Labouvie-Vief, 1980, 1982; J. Smith, 2003). Aside from functionalist arguments, there were several empirical findings that gave rise to this focus.

One example important to life span researchers was the differing life span trajectories proposed and obtained for the fluid mechanics and crystallized prag-

matics of intelligence (P. B. Baltes, 1993; Cattell, 1971; Horn, 1970; Horn & Hofer, 1992; S.-C. Li, Lindenberger, et al., 2004; McArdle, Ferrer-Caja, Hamagami, & Woodcock, 2002; Schaie, 1996, 2005). Very much in line with the life span dynamic between biology and culture expressed in Figure 11.1 (pp. 575), intellectual abilities that are thought to reflect the neurobiologically based mechanics of intelligence—like working memory and fluid intelligence—typically showed normative (universal) declines in functioning beginning in middle adulthood. Conversely, intellectual abilities that primarily reflect the culture-based pragmatics of intelligence—such as professional knowledge, language competence, and wisdom—may show stability or even increase into late adulthood. As to the ontogenesis of intelligence, then, gains and losses do co-exist.

Thus, as some life span theorists considered substituting the concept of an age-related selection-based change in adaptive capacity for the concept of development, one of the topics that motivated their agenda was the importance of viewing as fundamental to any ontogenetic change the notion of simultaneous gains and losses associated with these changes. From a functionalist point of view (Dixon & Baltes, 1986), it is more or less understood that changes in adaptive capacity can be positive or negative, that a given change in developmental capacity may imply different consequences depending on the outcome criteria and the adaptive contexts involved. Thus, the radical view was advanced that, contrary to traditional conceptions of development, there was *no gain in development without loss, and no loss without gain* (P. B. Baltes, 1987). Life span researchers, then, conceive of ontogenetic development not as a monolithic process of progression and growth, but as an ongoing, changing, and interacting system of gains and losses in adaptive capacity. Throughout life, development always consists of the joint occurrence of gains and losses, both within and across domains of functioning. Such an approach does not preclude that on some level of systemic analysis (i.e., considering the entirety of adaptive capacity in a fixed cultural context), ontogenetic development evinces an overall increase or decrease in adaptive capacity.

To strengthen the general case for reformulating the concept of development, life span researchers also suggested applying this multifunctional, multidimensional, and multidirectional view of development to the field of child development (P. B. Baltes, 1976, 1987; Labouvie-Vief, 1982). Consider as an example the ontogenesis of language recognition and language acquisition in childhood. When one language is acquired as mother tongue, sound recognition and sound production capacity for other languages decreases, especially if such second and third languages are acquired after early childhood (Levelt, 1989).

The study of tasks requiring probability-based imperfect rather than logic-based perfect solutions is another example (P. B. Baltes, 1987). The more advanced the cognitive status of children (in the sense of capacity for formal-logical reasoning), the less children are able to respond to cognitive problems that are essentially not perfectly solvable and therefore require the use of maximization rather than optimization strategies. Weir (1964) conducted an early critical experiment on this question in the domain of probability-based learning. In probability learning tasks without perfect solutions, there is the seemingly paradoxical finding that very young children outperformed older children and college students. Considering adaptive trade-offs between levels (stages) of cognitive functioning, this finding becomes meaningful. It is likely that the older children and young adults achieved lower performance outcomes because they understood the experimental task as a logical problem-solving task and, therefore, continued to employ task-inappropriate but developmentally more "advanced" cognitive strategies aimed at "perfect" optimization.

In retrospect, it is perhaps not surprising that the gain-loss dynamic was identified primarily by life span researchers as a central topic of ontogenetic analysis. On the one hand, life span researchers, because of their concern for long-term processes, were pushed toward recognizing the varied forms of developmental change associated with cultural evolution. On the other hand, on a subjective-phenomenological level, the issue of gains and losses becomes more conspicuous as one considers adult development and aging. In this phase of life, declines and losses, especially those due to biological aging, are difficult to ignore.

Recently, one additional concept has been advanced to characterize the nature of life span changes in adaptive capacity. This concept is *equifinality.* Equifinality highlights the fact that the same developmental outcome can be reached by different means and combination of means (Kruglanski, 1996). The role of equifinality (a related notion is the concept of overdetermination) is perhaps most evident when considering the many ways by which individuals reach identical level of subjective

well-being (P. B. Baltes & Baltes, 1990b; Brandtstädter & Greve, 1994; Staudinger et al., 1995). Other examples come from research on goal attainment conducted in the framework of action psychology (Brandtstädter, Chapter 10, this *Handbook,* this volume; Gollwitzer & Bargh, 1996). In this approach, researchers have distinguished between two general categories of equifinality: equifinality associated with contextual (contingency) match and equifinality based on substitutability (Kruglanski, 1996). In life span research, notions of equifinality are important, for instance, when attempting to speak of general-purpose mechanisms and ways to compensate, both in the domains of intelligence and personality. The potential for developmental impact is larger if the resources acquired during ontogenesis in the sense of equifinality carry a broad scope of generalization and use in rather different contexts.

A Focus on Plasticity and Age-Associated Changes in Plasticity

Arguably, plasticity is the concept most emphasized by life span researchers (P. B. Baltes & Schaie, 1976; P. B. Baltes & Willis, 1982). Note that plasticity does not refer to complete or arbitrary malleability of behavior. Rather, it denotes that behavior is always open and constrained at the same time. Hence, the focus on plasticity highlights the search for the potentialities of development including its boundary conditions. This notion of plasticity also implies that any given developmental outcome is but one of numerous possible outcomes, and that the search for the conditions and ranges of ontogenetic plasticity, including its age-associated changes, is fundamental to the study of development. Taken to the extreme, the notion of plasticity can be taken to challenge the conceptual foundation of any genetically based fixity in ontogenesis including the notion of an immutable norm of reaction (see also Gottlieb, 1998). While such vistas are intellectually stimulating, they are likely overextending the scope of the empirical evidence as well as the constraints of evolutionary theory (Hagen & Hammerstein, 2005). The very concept of plasticity of biological plasticity depends on genetically based prerequisites and related constraints for life and its developmental course.

For several reasons, life span researchers increasingly moved in the direction of making the study of plasticity a cornerstone of their metatheoretical posture and empirical work. In retrospect, we emphasize three such reasons. First, as many life span researchers did work in the field of aging, plasticity-related ideas were invoked to counteract the prevailing negative stereotype of aging as a period of universal decline with no opportunity for positive change (P. B. Baltes, 1987; P. B. Baltes & Labouvie, 1973; P. B. Baltes & Willis, 1977; Labouvie-Vief, 1977; S.-C. Li, 2003; Perlmutter, 1988). Thus, when aging researchers demonstrated in intervention-oriented research the enhancement possibility of the aging mind, even in domains such as fluid intelligence and memory in which decline was the norm, this was counterintuitive evidence. Such evidence made clear that aging, as we observe it today, is but one expression of what is possible in principle. It makes conspicuous why the intellectual and societal project of constructing aging is still in the making (P. B. Baltes, 1987, 1997; Rowe, 1997).

Second, the concept of plasticity accentuated that life span development does not follow a highly constrained (fixed) course, especially when culture- and knowledge-based phenotypic expressions are concerned. Thus, the focus on plasticity brought into the foreground that "humans have a capacity for change across the life span from birth to death . . . [and that] the consequences of the events of early childhood are continually transformed by later experiences, making the course of human development more open than many have believed" (Brim & Kagan, 1980, p. 1). Such views of lifelong plasticity have become prominent in biological quarters as well (e.g., Cotman, 1985; Finch & Zelinski, 2005; Kempermann, in press).

Third, the concept of plasticity opens new vistas on interdisciplinary perspectives. A view, more recently developed (P. B. Baltes et al., 2006) is that the basic questions of plasticity can be linked to similar concepts in the social sciences. Thus, the insistence on lifelong plasticity in human development is also consistent with the argument advanced most prominently by social scientists that much of what happens in the life course is a direct reflection of the goals, resources, and norms of a given society and that societal contexts differ in the structure, emphases, and sequential ordering of such factors (Brim & Wheeler, 1966; Mayer, 1990; Riley, 1987; Settersten, 2005). For this purpose, Figure 11.4 specifies three types of plasticity: neuronal/bodily, behavioral, and societal (see also P. B. Baltes & Singer, 2001; Baltes, Reuter-Lorenz, & Rösler, 2006; S.-C. Li, 2003; S.-C. Li & Linderberger, 2002).

Neuronal/bodily, behavioral, and societal plasticity, as defined in Figure 11.4, form a frame within which the contributions to questions of potential and its realiza-

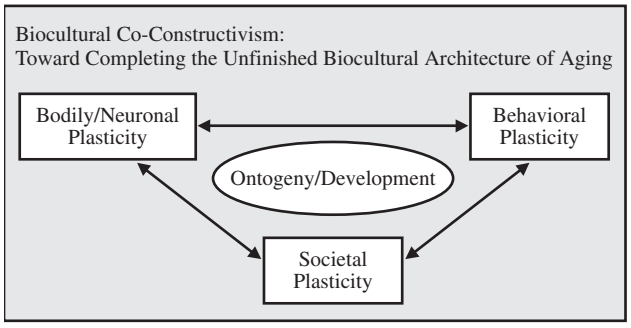

Figure 11.4 Each of the major scientific disciplines concerned with human development have developed a focus on plasticity to understand mechanisms and variations in outcomes: Genetic/neuronal/bodily, behavioral, and societal plasticity are important examples. *Research Report of the Max Planck Institute for Human Development,* 2003–2004. See P. B. Baltes, P. Reuter-Lorenz, & F. Rösler, 2006, for further elaboration.

tion offered by the various life, behavioral, and social sciences engaged in the study of human development can be understood and interrelated. Each of the components depicted does not operate in isolation. Rather, in the sense of biocultural constructivism they interact and modify each other.

Research on neuronal/bodily plasticity uses outcomes such as neurogenesis, synaptic powering, and other indicators of brain differentiation to represent individual brain development and interindividual differences therein. Work on behavioral plasticity highlights outcomes on the level of mind and behavior associated with differing conditions of life experiences, including cognitive practice. Societal plasticity illustrates variations at the macrolevel (e.g., resources and norms associated with gender, social class, ethnicity, etc.) and the role of social constraints and opportunities. Relevant evidence is typically collected by comparative social-science work on groups or nations rather than individuals and on theories of societal influences (e.g., norms, socialization) that shape developmental trajectories and their social differentiation. A societal plasticity perspective presumes that individuals belonging to different groups have similar potentialities which, however, are realized to different degrees and qualities (see also Settersten, 2005).

Returning to developmental psychology: As work on individual behavioral plasticity progressed and showed large variation in developmental manifestations, the concept of plasticity became a mental script that supported the general idea of development as being more open and pluralistic than traditional views of behavioral development during childhood and beyond seemed to suggest. Thus, the concept of plasticity highlighted the metatheoretical posture *that any course of development is but one of a pool of potentialities;* that the "nature" of human development is not fixed; and that (aside from the fact of finitude) there is no single end state to human development.

The perhaps most important line of inquiry was the quest for understanding interindividual differences and *age-related developmental changes in plasticity.* While plasticity as a phenomenon was extended beyond childhood, there were theoretical and empirical reasons why plasticity should not be age-less but changing with age. Thus, the search for the range of plasticity resulted not only in evidence for malleability and plasticity; it also produced new evidence on individual and age-based constraints in the range (norm of reaction) of possible development (P. B. Baltes & Lindenberger, 1988; Kliegl et al., 1990; Plomin & Thompson, 1988). In work on cognitive aging, for instance, the goal was to learn about maximum potential in different age groups.

This line of inquiry suggested different facets of behavioral/developmental plasticity. One was the differentiation between *baseline reserve capacity* and *developmental reserve capacity.* Baseline reserve capacity identifies the current level of plasticity available to individuals. Developmental reserve capacity is aimed at specifying what is possible in principle if optimizing interventions are employed to test future ontogenetic potential. Furthermore, major efforts were made to specify the kind of methodologies, such as developmental simulation, testing-the-limits, and cognitive engineering, that lend themselves to a full exploration of ontogenetic plasticity and its limits (P. B. Baltes, 1987; P. B. Baltes & Willis, 1982; Kliegl & Baltes, 1987; Kliegl, Mayr, & Krampe, 1994; Lindenberger & Baltes, 1995b).

Within the frame of sizeable plasticity, then, the expression of human development is a matter of collaboration and co-construction between different factors and mechanisms. Indeed, an increasingly more full-blown constructivist perspective on human potentialities has become a modern theme of developmental research (Aspinwall & Staudinger, 2003; P. B. Baltes et al., 2006; P. B. Baltes & Smith, 2004; Brandtstädter & Lerner, 1999; S.-C. Li, 2003; S.-C. Li & Lindenberger, 2002). With a constructivist perspective one highlights the notion that human development is

constructed by the interplay of biological, psychological, and social forces. Part of this construction relies on agentic behavior of individuals. Individuals are contributors to their own development. The resulting concept is that of *developmental biocultural co-constructivism* (P. B. Baltes, Freund, & Li, 2005; P. B. Baltes & Smith, 2004; S.-C. Li, 2003). With the advent of biocultural co-constructivism, the quest for interdisciplinary collaboration has attained a new state of urgency. In our view, the life span approach with its emphasis on viewing the conditions of human development as historically incomplete and more open than traditionally assumed has been a major partner in advancing this intellectual position.

Ontogenetic and Historical Contextualism as Paradigm

Highlighting the notion of plasticity as a cornerstone of life span research on human development alludes to another key feature of life span metatheory, the paradigm of contextualism. In evolutionary selection theory and the evolutionary basis of adaptive fitness, the role of context is paramount. Recently, P. B. Baltes and Smith (2004) have shown how modern versions of contextualism include the perspective of biocultural co-constructivism to avoid the idea that context is strictly environmental in origin.

Therefore, as developmental psychologists attempted to move beyond microgenetic representations of the learning process as a marker of experience to capture context as a system of influence, they engaged themselves into metatheoretical perspectives on contextualism. Such a contextualist view, rather than a focus on "mechanist" or "organismic" models of development (Overton & Reese, 1973; Reese & Overton, 1970), evolved with force in the 1970s (Datan & Reese, 1977; Riegel, 1976), and as already described in the preceding section, it continues into the present. This approach was similar to the evolution of ecological-contextualist perspectives offered by cultural psychology (Bronfenbrenner, 1977; Bronfenbrenner & Ceci, 1994; Cole, 1996).

According to contextualism and also action theory (see Brandtstädter, Chapter 10, this *Handbook,* this volume), individuals exist in contexts that create both special opportunities for, and limitations to, individual developmental pathways. Delineation of these contexts in terms of macrostructural features, like social class, ethnicity, roles, age-based passages and historical periods, is a major goal for the sociological analysis of the life course (e.g., Elder, 1994; Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Heckhausen, 2000; Kohli & Meyer, 1986; Mayer, 2003; Riley, 1987; Settersten, 2005). In fact, this was a time when sociologists and developmental psychologists attempted to interrelate their various endeavors (e.g., Sorensen, Weinert, & Sherrod, 1986). For life span psychologists, and perhaps also for child developmentalists (P. B. Baltes, 1979b), this dialogue opened their vista on the scope, temporal patterning, and differentiation of biological and social forces (incidentally much instigated by various committees on human development arranged by the U.S. Social Science Research Council).

A Macro-Model of Developmental Influences

During this time of intensive collaboration between life course sociologists (e.g., Riley et al., 1972) and life span psychologists, the first author and his colleagues (P. B. Baltes, Cornelius, & Nesselroade, 1979; P. B. Baltes et al., 1980) proposed a heuristic model that attempted to integrate biological, sociological, and psychological considerations in one framework in order to understand the entire fabric of development-producing contexts: Three biocultural components were considered at the foundation of human ontogeny: *Normative age-graded influences, normative history-graded influences,* and *nonnormative (idiosyncratic)* influences. Normative in this context refers to a high degree of generality. Nonnormative factors highlight the more individualized conditions such as winning in a lottery.

To understand a given life course, and interindividual differences in life course trajectories, this model suggests that it is necessary to consider the operation and interaction among these three classes of influences (Figure 11.5). Note that these sources contribute to similarities in development, but also, because they exist in systematic group variations, for instance by social class, genetic dispositions, and ethnicity, they also contribute to systematic interindividual variations and subgroup-specific patterns of life span development (P. B. Baltes & Nesselroade, 1984; Dannefer, 1989; Riley et al., 1972).

Age-graded influences are those biological and environmental aspects that, because of their dominant age correlation, shape individuals in relatively normative ways for all individuals. Consider the temporal and domain structure of life span developmental tasks (Havighurst, 1948), the age-based process of physi-

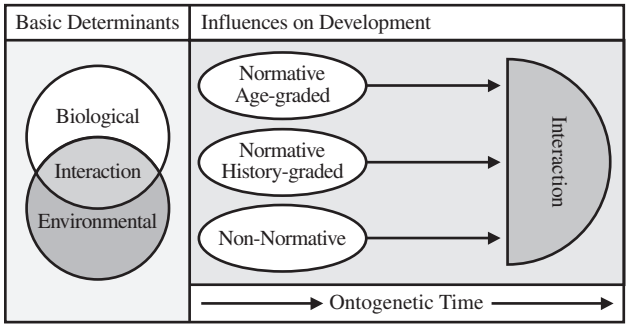

Figure 11.5 Representation of the operation of three major biocultural influence systems on life span development: (1) normative age-graded, (2) normative history-graded, and (3) nonnormative life events. These influence systems vary in their level and interactions for different individuals and for different behaviors. As a whole, the operation of these systems produces commonalities and individual differences in ontogenesis. *Source:* From "Plasticity and Variability in Psychological Aging: Methodological and Theoretical Issues" (pp. 41–66), by P. B. Baltes and M. M. Baltes, in *Determining the Effects of Aging on the Central Nervous System,* G. E. Gurski (Ed.), 1980, Berlin, Germany: Schering.

cal maturation, or the sequential arrangement of developmental contexts (family, school, work, etc.) as examples.

History-graded influences are those biological and environmental aspects that may make ontogenetic development different across historical cohort and periods. Consider the historical evolution of the educational and professional system as an example, or, for a more punctuated period-specific example, the advent of a war. Thus, a given ontogeny proceeds at the same time in the contexts of age-based ontogenetic time as well as historical cohort time. This position has been argued most fervently by Matilda Riley (1987). In the early phases of life span psychology, research on birth-cohort effects has made the strongest case for consideration of historical contextualism (Elder, 1974, 1990; J. R. Nesselroade & Baltes, 1974; Schaie, 1965, 1996). The topic of historical embeddedness, and the extricating of age-based versus cohort-based differences in ontogenetic development, was also the foundation for the formulation of new developmental methodologies such as cross-sectional and longitudinal sequences (see the following discussion).

Nonnormative influences on development, finally, reflect the individual-idiosyncratic biological and environmental events that, while not frequent, can have powerful influences on ontogenetic development (Bandura, 1982; Brim & Ryff, 1980). The influence of these nonnormative events (such as winning a lottery, losing a leg in an accident) is especially powerful because they generate conditions that are less predictable, less amenable to social control and support, and therefore may represent extreme situations of challenge (approaching testing-of-limits), not unlike the concept of *Grenzsituation* introduced by the philosopher Karl Jaspers (Kruse, 1992; Maercker, 1995).

In life span theory, these three sources of influence create the contexts within which individuals act, react, organize their own development, and contribute to the development of others. None of these patterns of biologically and environmentally based influences is likely to operate independently from the other. They are part of biocultural co-construction with reciprocal and modifying influences. Such a focus on the dynamics of biocultural co-construction also makes explicit the lack of full predictability of human development as well as the boundedness that individuals experience as they engage in the effort to compose and manage their lives (Brandtstädter, 1984; Brandtstädter & Lerner, 1999; R. M. Lerner, 1984, 1991). And finally, such a focus on contextualism places individual development in the context of the development of others. It is not surprising, therefore, that life span researchers have easily embraced concepts such as collaborative development, collaborative cognition, or interactive minds (P. B. Baltes & Staudinger, 1996a; Resnick, Levine, & Teasley, 1991). However, what remains underdeveloped in life span psychology is the empirical counterpart to this theoretical position. Only more recently have we witnessed research efforts to include these contextual- and social-interactive approaches in the study of interactive networks such as communities of learning (Mandl, Gruber, & Renkl, 1996), life course convoys (Kahn & Antonucci, 1980), mentors (Bloom, 1985), cohort formations (Riley, 1987), kinship relationships (Hammerstein, 1996), cohort-related changes in education and health (Schaie, 1996, 2005), the role of neighborhoods, or changing policies in retirement and elderly care.

Methodological Developments

Life span research opened new territories and because of the temporal, contextual, and historical complexities involved required much attention to developmental methodology (P. B. Baltes, Reese, & Nesselroade, 1988; Cohen & Reese, 1994; Hertzog, 1985; Magnusson, Bergman, Rudinger, & Törestad, 1991; J. R. Nesselroade

& Reese, 1973). In our view, this concern about adequate methodology was so important to life span researchers because their orientation toward long-term ontogenetic processes and linkages and the decomposition of the biocultural dynamic represented an extreme challenge to the goals and methods of developmental analysis.

From Cross-Sectional to Longitudinal to Sequential Methodology. A first example is the development of methods appropriate to the study of age-related change, interindividual differences in age-related change, and the role of historical changes in the contexts of development. Traditionally, the main designs used in developmental psychology were the cross-sectional and the longitudinal method (P. B. Baltes & Nesselroade, 1978, for historical review). The focus on the interplay between age-graded, history-graded, and nonnormative factors suggested, however, that such methods were insufficient (P. B. Baltes, 1968; N. B. Ryder, 1965; Schaie, 1965). This challenge to track both historical and individual-ontogenetic change resulted in the formulation of so-called sequential methods (P. B. Baltes, 1968; Schaie, 1965, 1996, 2005).

Figure 11.6 depicts the basic arrangement of what Schaie and Baltes (1975) have come to label as *cross-sectional* and *longitudinal sequences.* Cross-sectional sequences consist of successions of cross-sectional studies; longitudinal sequences of successions of longitudinal studies. When applied in combination, the two types of sequential designs produce, on a descriptive level, exhaustive information about age- and cohort-related change as well as about interindividual differences in change trajectories. The sequential design also permits the identification of punctuated historical effects, so-called period effects. In contrast to cohort effects, which extend over longer time spans of historical change (such as effects associated with mass education or the introduction of computer technology), the concept of period effects is typically applied to more transient historical events and their consequences, such as a natural catastrophe or a war.

There is much research in human development that has demonstrated the important role of historical cohort effects. Schaie (1996, 2005), for instance, has compared both in cross-sectional and longitudinal sequences the adult-age development of several birth cohorts from 1956 to the present and presented impressive evidence that, during middle adulthood, cohort effects can be as

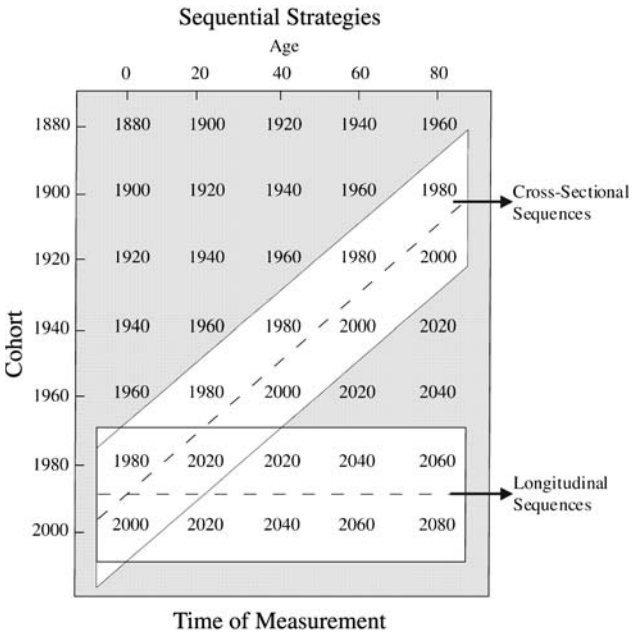

Figure 11.6 Illustration of cross-sectional and longitudinal sequences (bottom). *Source:* From "Longitudinal and Cross-Sectional Sequences in the Study of Age and Generation Effects" by P. B. Baltes, 1968, *Human Development, 11,* pp. 145–171; From "A General Model for the Study of Developmental Problems" by K. W. Schaie, 1965, *Psychological Bulletin, 64,* pp. 92–107.

large as age effects. Schaie's work has also shown that the directionality of age and cohort gradients can differ. Similarly, J. R. Nesselroade and Baltes (1974), in an early application of longitudinal sequences to the study of adolescence, presented evidence that personality development during adolescence in such measures as achievement and independence evinced major cohort differences over time intervals as short as 2 years. Their interpretation focused on the role of the Vietnam War as the critical modulator variable and its impact on U.S. youth culture, including how adolescents changed in their developmental personality gradients.

Meanwhile, through application of sequential methods, there is a large body of evidence on cohort effects available in developmental psychology, but especially in comparative sociology; evidence that makes explicit one of the important ingredients to life span theory, namely, the interplay between individual development and a changing society (cf. Elder & Shanahan, Chapter 12, this *Handbook,* this volume; Settersten, 2005). Also important in this work is the growing recognition of when cohort ef-

fects are likely to be relevant and when not. For instance, life span researchers now distinguish between at least three types of cohort effects requiring different kinds of interpretative efforts (J. R. Nesselroade & Baltes, 1979): (1) cohort as a *theoretical process* denoting historical change that alters fundamental aspects of human ontogeny (e.g., changing gender roles); (2) cohort as a *dimension of quantitative generalization* (e.g., higher levels of cognitive skills due to an increase in education); and (3) cohort as a *transitory disturbance* (e.g., fluctuant changes in attitudes due to singular events as often reported in opinion survey research).

In part as a response to the growing availability of longitudinal and sequential data sets, methodologists from different research traditions including life-span psychology have refined and expanded statistical methods for the study of interindividual differences in developmental trajectories (Baltes, Reese, & Nesselroade, 1977; for a recent overview, see Hertzog & Nesselroade, 2003). Various longitudinal modeling techniques such as multilevel modeling, latent growth curve modeling, and latent difference score modeling allow researchers to examine the structure of interindividual differences in change (e.g., Ghisletta & Lindenberger, 2004). These methods attenuate complications commonly associated with change scores such as lack of reliability (e.g., Cronbach & Furby, 1970), and some of them, such as multivariate extensions of the dual change score model, permit testing of dynamic hypotheses linking one aspect of behavior to changes in another aspect (e.g., McArdle, Hamagami, Meredith, & Bradway, 2000; for applications to changes in intellectual and sensory functioning, see Ghisletta & Lindenberger, 2005). A related methodological development spurred on by life-course sociologists, in particular, concerns methods to organize and study the temporal flow, correlates, and consequences of life events. Models of event-history analysis and associated methods such as hazard rate analysis are especially important (Blossfeld, Hamerle, & Mayer, 1991; Blossfeld & Rohwer, 2001; Featherman & Lerner, 1985; Greve, Tuma, & Strang, 2001; Magnusson et al., 1991; Schaie, 1988; Willett & Singer, 1991). Note, however, that advanced statistical methods for analyzing multivariate longitudinal change often are based on strong assumptions such as sample homogeneity, in general, and cross-sectional/longitudinal convergence, in particular. Also, the psychometric properties of these methods have not yet been fully explored and understood (Hertzog, Lindenberger, Ghisletta, & Oertzen, 2004).

.

The Experimental Simulation of Development. A further strategy developed primarily by life span researchers is the explicit use of simulation paradigms in the study of human development. Again, use of such an approach was enhanced by the fact that life span ontogenetic processes are time-extensive and, therefore, difficult to study without simulation (P. B. Baltes & Goulet, 1971; Lindenberger & Baltes, 1995b).

Table 11.4 summarizes the approach of developmental simulation. In a general sense, the experimental simulation approach is a theory-testing device that arranges for conditions thought to be relevant for the phenomenon of interest. Thus, experimental developmental simulations simulate or mimic variations that are thought to exist in real-time and real-world ontogenesis. As a research strategy, the design of developmental simulation consists of a coordinated sequence of seven steps that, however, do not need to be performed in the sequence specified. A developmental phenomenon is considered to be well understood if knowledge based on all steps is available.

In life span research, such simulations have been used, for instance, to examine the effects of aging-associated changes in sensory input. For this purpose, auditory and visual acuity of adults was reduced to the level of older

Baltes, 1995b, *Human Development, 38,* pp. 349–360; and *Life-Span Developmental Psychology: Introduction to Research Methods,* by P. B. Baltes, H. W. Reese, and J. R. Nesselroade, 1988, Hillsdale, NJ: Erlbaum. Reprint of the 1977 edition.

persons and then tested for cognitive performance (Dickinson & Rabbitt, 1991; Lindenberger, Scherer, & Baltes, 2001). Another example is a research program by Margret Baltes on the many faces of dependency and autonomy in old age (1988, 1996; M. M. Baltes & Wahl, 1992). In this research program, the key questions were concerned with the conditions and range of autonomy and dependence including their multifunctional characteristics and plasticity.

The opening steps (1 to 3 in Table 11.4) of this research on autonomy and dependency in old age conducted by Margret Baltes and her colleagues were observations in the living environments of elders concerning their transactions with others. Negative aging stereotypes were assumed to play a major role in the observed age-associated emergence of dependent rather than independent behavior. To examine this hypothesis, a series of experimental laboratory studies were conducted to explore the effects of learning conditions (stimulus control, practice, reinforcement schedules) on self-care behavior in older adults. This work demonstrated that many aspects of older adults' dependent behaviors were found to be reversible, supporting the notion that environmental factors (e.g., behavioral contingencies) exert some influence on the aging-associated emergence of dependency or loss of autonomy. In subsequent work, reflective of steps 4 to 6 in Table 11.4, Margret Baltes and her colleagues observed the social conditions surrounding the occurrence of self-care in the elderly in the natural environment. Supportive of their position, a dependency-support script and an independence-ignore script were identified. In other words, social partners of older persons in the context of self-care exhibited a high frequency of behaviors indicative of support of dependence. Finally, research was conducted to manipulate the relevant causal variables in the natural environment of older persons. For this purpose, the researchers (see M. M. Baltes, 1996; M. M. Baltes, Neumann, & Zank, 1994) intervened in the social environment of older persons in nursing homes. This was done by training nursing home staff to downplay the dependence-support script, and to move toward an independence-support script. By and large, these changes in the natural environment resulted in the expected outcome. Older persons displayed a higher level of independence in self-care.

Researchers interested in more narrow age spectrums use similar strategies of experimental simulation of development (Siegler, Chapter 11, this *Handbook,* Volume 2). However, we claim that life span researchers are particularly dependent on the creative use of such arrangements; and, moreover, that life span researchers are especially aware of the many methodological limitations (such as lack of measurement equivalence, isomorphy, and external validity) associated with such and with other age-comparative research. The explicit use of the term of simulation to denote these limitations underscores this awareness.

Testing-the-Limits. An additional example of methodological innovations involves a strategy that life span researchers have developed to examine the scope and limits of behavioral *plasticity* (P. B. Baltes, 1987; Kliegl & Baltes, 1987), another key aspect of the family of propositions advanced in life span theory. This method is similar to efforts in child development to study the zone of proximal development, for instance, through methods of microgenetic analysis or cognitive engineering (Brown, 1982; Kliegl & Baltes, 1987; Kuhn, 1995; Siegler & Crowley, 1991).

Again, because of the long timeframe of life span ontogenesis, it is very difficult in life span research to identify the sources and scope of intraindividual plasticity (malleability) and its age-related changes. At the same time, one key question for life span researchers is: What is possible in principle in human development across the life span? One of the perennial questions of cognitive aging researchers, therefore, was whether aging losses in functions reflect experiential practice deficits with cognitive activities rather than effects of biological aging (P. B. Baltes & Labouvie, 1973; Denney, 1984; Salthouse, 1991; Willis & Baltes, 1980).

The resulting method has been labeled the *testing-the-limits paradigm* (Kliegl & Baltes, 1987; Lindenberger & Baltes, 1995b; Schmidt, 1971). In testing-the-limits research, the goal is to compress time by providing for high density developmental experiences; and by doing so to arrange for the best conditions possible and to identify asymptotes of performance potential (plasticity). These asymptotes, obtained under putatively optimal conditions of support, are expected to estimate the upper range of the age-specific developmental potentiality comparable to the traditional notion of the upper limit of the "norm of reaction." The use of testing-the-limits procedures has generated new insights into what is and what is not possible in development.

Testing-the-limits research, however, is not only relevant for the study of long-term ontogenetic processes. It is equally relevant for other important aspects of developmental research and theory. Two examples illustrate this. The first is the question of sex or gender differences in cognitive functioning. What would be most necessary is to depart from simple, noninterventive comparative research and to invest scientific resources into testing-the-limits work. A testing-the-limits approach would be based on the premise that the relevant information is knowledge about differences in asymptotic (peak) levels of functioning. Small, carefully selected samples could be used for this purpose (e.g., P. B. Baltes & Kliegl, 1992; Kliegl & Baltes, 1987; Lindenberger, Kliegl, & Baltes, 1992). The same perspective would hold true for another hotly debated topic; that is, research into genetic differences. Rather than investing most of the available resources into largely descriptive behavior-genetics studies, an alternative would be to expose smaller samples of participants to time-compressed experiential interventions and to search for interindividual differences at the upper or lower levels of functioning (e.g., S.-C. Li, Huxhold, & Schmiedek, 2004; Lindenberger & Oertzen, in press).

An Example of a Systemic and Overall Theory of Life Span Development: Selective Optimization with Compensation (Level 4)

Next, we take one further step toward a more psychological level of analysis of the nature of life span development. For this purpose, we describe a model of development, selective optimization with compensation (SOC), which Margret Baltes, Paul Baltes, and their colleagues have developed over the past decade (M. M. Baltes, 1987; M. M. Baltes & Carstensen, 1996; P. B. Baltes, 1987; P. B. Baltes & Baltes, 1980, 1990b; P. B. Baltes, Dittmann-Kohli, & Dixon, 1984; Freund & Baltes, 2002b; S.-C. Li & Freund, 2005; Marsiske et al., 1995; Riediger, S.-C. Li, & Lindenberger, in press; see also Featherman et al., 1990). This model offers a systemic view of human development across the life span involving many of the features of life span development presented in the previous sections. Heckhausen and Schulz (1995; Schulz & Heckhausen, 1996) developed a similar model. Finally, the notion of *vicariance,* prominent in francophone differential and developmental psychology (e.g., Lautrey, 2003; cf. Reuchlin, 1978), bears much resemblance to the notion of compensation in SOC theory.

The SOC model in its generality is still located at a level of analysis that is distant from specific theory. Thus, as the model is applied to specific domains of psychological functioning (such as autonomy or professional expertise), it requires further specification to be derived from the knowledge base of the domain of functioning selected for application (e.g., Abraham & Hansson, 1995; B. B. Baltes & Heydens-Gahir, 2003; M. M. Baltes & Lang, 1997; Featherman et al., 1990; Freund & Baltes, 1998, 2002b; S.-C. Li & Freund, 2005; Marsiske et al., 1995). At the same time, however, because of this generality in formulation, the model of SOC is rather open as to its deployability and domain-specific refinement.

In principle, the theory of SOC is considered a general theory of proactive and adaptive development (P. B. Baltes, 1997; Li & Freund, 2005). As a general theory of development, it pursues two objectives: First, an account of how developmental resources are *generated,* and second, how resources once they are developed are *allocated* to master the tasks of life including in situations where resources are insufficient.

Definition of Selection, Optimization, and Compensation

As mentioned earlier, we proceed from the assumption that any process of development involves selection and selective changes in adaptive capacity (P. B. Baltes, 1987; Featherman et al., 1990; Freund & Baltes, 2002b; Krampe & Baltes, 2003; Marsiske et al., 1995). Selection from a potential pool of developmental trajectories makes directionality in development and higher levels of functioning possible. We further assume that for selection to result in successful development (maximization of gains while minimizing losses), it needs to work in conjunction with processes of optimization and compensation.

If approached within an action-theoretical framework, which is only one of the many possible theoretical frames, the following characterizations of the three components hold: *Selection* involves goals or outcomes; *Optimization* involves goal-related means to achieve success (desired outcomes); and *Compensation* involves a response to loss in goal-relevant means in order to maintain success or desired levels of functioning (outcomes). Table 11.5 summarizes this approach and offers as illustrations items from a study on proverbs and items from a self-report measure developed to assess

TABLE 11.5 Selection, Optimization, and Compensation: Brief Definitional Frames and Examples from Proverbs and Questionnaire Items

Strategy	Role in Development	Sample Proverb (Freund & Baltes, 2002a)	Sample Questionnaire Item (Freund & Baltes, 2002b)
Selection1[a]	Concerns directionality and focus of developmental outcomes such as goals.	Jack-of-all-trades, master of none.	I always focus on the most important goal at a given time.
		Those who follow every path, never reach any destination.	When I think about what I want in life, I commit myself to one or two important goals.
		Between two stools you fall to the ground.	To achieve a particular goal, I am willing to abandon other goals.
Optimization	Concerns the acquisition and refinement of means and their coordinaton to achieve goals/outcomes.	Practice makes perfect.	I keep working on what I have planned until I succeed.
		If at first you don't succeed, try, try, and try again.	I keep trying until I succeed at a goal.
		Strike the iron when it's hot.	When I want to achieve something, I can wait for the right moment.
Compensation	Concerns maintenance of functioning by substitution of means in situation of losses of means.	Those without a horse walk.	When things don't work the way they used to, I look for other ways to achieve them.
		There are many hands; what one cannot do, the other will.	When things aren't going so well, I accept help from others.
		When there's no wind, grab the oars.	When things don't go as well as they used to, I keep trying other ways until I can achieve the same result I used to.

[a] Two facets of selection are distinguished in SOC theory: (1) elective selection and (2) loss-based selection, which encompasses restructuring of goal hierarchy, reducing the number of goals or various processes such as adjusting the level of aspiration, or developing new possible goals to match available resources.

the degree to which individuals report to use SOC-related behaviors. The resulting definitions of selection, optimization, and compensation may suggest that the relevant processes are often conscious and intentional. This is not necessarily so. Each of these elements or components can be active or passive, internal or external, conscious or unconscious.

Six additional characterizations help to place SOC into a larger perspective. First, we postulate that SOC is akin to a general-purpose mechanism of development. If available and well practiced, it will produce higher functioning in all domains of functioning. Second, we assume that SOC behaviors are universal processes generative of development. Third, we assume that SOC are inherently relativistic in that their phenotypic expressions depend on person- and context-specific features. Fourth, SOC in itself is a developmental construct. We assume that its peak expression is in adulthood. In childhood and adolescence, the system is acquired and honed, in old age, individuals work on maintenance (see Freund & Baltes, 2002b, for data on age trajectories). Fifth, we acknowledge that the functional utility of SOC is not given but remains a question of empirical validity. There are contexts where SOC may not be adaptive. Sixth, the function of the SOC components such as compensation in a given behavioral unit are not fixed. Their logical status can change, for instance, from active to passive. Similarly, a behavior that originally evolved in the context of a compensation for a loss may later be activated in a process where it serves as an optimizing means.

An everyday example may help to clarify the distinctions, drawn from the context of aging research that we used in our early efforts at developing the SOC model (P. B. Baltes, 1984). Into his late 70s and early 80s, the concert pianist Arthur Rubinstein continued to perform with great success. When asked how he managed to maintain such a high level of expert piano playing, he hinted in several interviews at the coordination of three strategies. First, he mentioned that he played fewer pieces (selection); second, he indicated that he now practiced these pieces more often (optimization); and third, he counteracted his loss in mechanical speed of playing by producing larger contrasts

in speed so to make the faster pieces appear faster (compensation).

Selection: Elective and Loss-Based. As noted already, *selection involves directionality, goals, and specification of outcomes.* There are two kinds of selection: elective selection and loss-based selection. Elective selection involves directionality that is self-initiated and considered desirable. Its motivational force is agent-driven. Loss-based selection is the consequence of a loss in functioning and typically involves making adjustments such as changes in level of aspiration or a change in goal structures or goal priorities.

Strictly speaking, selection already begins in embryonic development with features of the sensory system, such as differential sensitivity to light and pattern configurations. Neurophysiological processing of information represents another fundamental example of selection and selection-based specialization. Selective pruning of cells in early biological development is another example. Another concrete illustration of selection in development can be associated with a concept from developmental biology: Selection as the "canalized" (Waddington, 1975) realization of a set of outcomes from the "potentialities of ontogenesis" (plasticity). Another example of selection is the goal system (ranging from skills to attitudes and values) that defines the social and personal frames of desirable development. Selection can also involve the avoidance of specific outcomes of development such as the undesired self. In fact, life span development can be seen as involving a systematic age-related shift in the relative weight and frequency of approach versus avoidance goals (Freund & Ebner, 2005).

Optimization. The focus of optimization is on goal- or outcome-relevant means or resources. Thus, while selection is a necessary condition for achieving development (defined as the maximization of gains and minimization of losses), selection is not a sufficient condition for development to become manifest.

In addition, conditions and procedural mechanisms of goal-attainment are required, that is, methods or means of optimization. Optimization, then, involves processes aimed at the generation and refinement of means-ends resources and motivational-goal explication to achieve development-oriented positive outcomes (goals). For a psychologist, means include such processes as the learning of a skill or the acquisition of the motivational ability to persist or delay gratification. In general, the complexity of the system of optimization depends on the goal or outcome pursuit. If these are complex, optimization is not the refinement of a single means. Rather, in more complex situations, optimization requires a mutually enhancing coalition of factors, including health, environmental, and psychological conditions.

As was true for selection, optimization can be active and passive, conscious and subconscious, internal or external. Moreover, optimization can be domain- and goal-specific as well as domain- and goal-general. The most domain-general notion of optimization is the generation of what in our work we have called *developmental reserve capacity* (P. B. Baltes, 1987; Kliegl & Baltes, 1987), or what developmental life scientists might call *general plasticity* at the neuronal, behavioral, and social level. Because of its investability into many activities, generating a high level of general plasticity is the perhaps most significant target for successful development.

Compensation. The component process called *compensation involves a functional response to the loss of goal-relevant means* (see also Brandtstädter & Wentura, 1995; Dixon & Bäckman, 1995). This definition of compensation is more specific or restricted than the one proposed by Bäckman and Dixon (1992)—that is, it restricts compensation to responses to losses of means (resources) once available for goal attainment.

Two main causes give rise to a compensatory situation (Freund & Baltes, 2002b; Marsiske et al., 1995). Compensation can be the consequence of the very fact of selection and optimization. For reasons of limited capacity of time and effort, selection of and optimization toward a given goal implies the loss of time and means-related resources, relevant for the pursuit of other goals. Development is always a gain-loss dynamic. When an athlete aims for a high level performance in the shot put, it is unlikely that comparable high levels of performance can be achieved in other types of sports such as gymnastics. Another example is negative transfer. The acquisition of a targeted expert skill system A can result in negative transfer to another skill system B (Ericsson & Smith, 1991).

A second category of causes of compensation stems from negative changes in biological, social, and environmental resources in the conditions that represent the foundation of resources and their use for development (see also Hobfoll, 2001, on resource theory). Changing from one environment to another may involve a

loss in environment-based resources (means) or may make some acquired personal means dysfunctional. Losses due to the biology of aging are perhaps the best known age-associated negative changes in resources. With aging, there is a reduction in the rate and scope of plasticity (Cotman, 1985; Finch & Zelinski, 2005; S.-C. Li & Freund, 2005; Nelson, 2006; Reuter-Lorenz, 2002). As a result, the evolution of compensatory responses, in addition to loss-based selection, is a continuously changing dynamic of development in the second half of life.

Understanding this changing developmental dynamic is particularly important regarding the conceptual distinctiveness of optimization and compensation (Marsiske et al., 1995). At the point of origin, for instance, some behavior may have been compensatory (such as acquiring nonverbal techniques of communication due to a loss of foreign language proficiency), at later points in ontogeny or in different contexts these same compensation-based behavioral means (nonverbal techniques of communication) can be used as a technique of optimization, such as when improving one's performance as an actor. It is important, therefore, to specify the context and the developmental space in which a given behavioral event is considered when deciding about its category allocation to either selection, optimization, or compensation.

Because the model of SOC does not designate the specific content and form of desirable developmental outcomes, it is applicable to a large range of variations in goals and means of development. In this sense, then, SOC is at the same time *universal* and *relativistic.* Its universalism rests in the argument that any process of development is expected to involve components of selection, optimization, and compensation (P. B. Baltes & Baltes, 1990b; Marsiske et al., 1995). Its relativity lies in the variations of motivational, social, and intellectual resources, as well as in the criteria used to define successful development, which can be multivariate and involve both objective and subjective indicators (P. B. Baltes & Baltes, 1990a).

In the following two sections, which deal with life span developmental theory and research in two domains of functioning, we occasionally return to SOC-related interpretations. However, our intent is not to elevate that model or theory to the one overarching model of life span development. This would be inappropriate. In our view, the model of selective optimization with compensation is but one of the theoretical efforts that life span research and theory have spawned. However, we believe SOC to be a theory that displays much consistency across levels of analysis and can be usefully linked to other current theoretical streams in developmental psychology, such as to dynamic systems theory. Krampe and Baltes (2003) have illustrated in another area, the field of intelligence, how application of SOC theory leads to a different conceptualization of the structure and function of intelligence.

Empirical Evidence on SOC Theory

The articulation and testing of SOC theory is proceeding in a variety of domains. In general, the evidence has been supportive of the theoretical approach. People who report the use of SOC-related behaviors show higher levels of functioning. Moreover, on the behavioral level, research has shown that individuals manifest behaviors that are consistent with SOC theory. These outcomes carry a promissory note.

Age Gradients. Figure 11.7 summarizes evidence on cross-sectional age gradients. Young, middle-aged, and older adults answered a self-report instrument to assess preferred use of SOC strategies. As expected, the peak of using all SOC components was obtained for adults. In earlier and later phases of life, the SOC system seems less fully acquired, activated, or coordinated. In young adulthood, the task of life planning in a focused and concerted manner needs practice and refinement (e.g., J. Smith, 1999). Desires and volitions are less orchestrated. Similarly, in aging individuals, they need to master situations

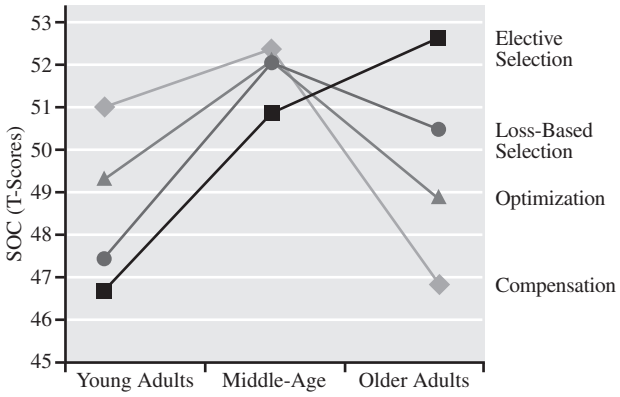

Figure 11.7 Age-group mean differences in four components of SOC (elective selection, loss-based selection, optimization, and compensation): Middle-aged adults report the highest and perhaps most integrated endorsement of SOC. *Source:* Modified from "Life-Management Strategies of Selection, Optimization, and Compensation: Measurement by Self-Report and Construct Validity" by A. M. Freund and P. B. Baltes, 2002b, *Journal of Personality and Social Psychology, 82,* pp. 642–662.

in which they have fewer resources. SOC behaviors themselves are effortful and require resources. Therefore, it is not surprising that older individuals show lesser frequency of use of optimization and compensation. As shown in Figure 11.7, the primary focus in older ages is on elective selection and loss-based selection.

Processes of selection, optimization, and compensation also are present in mental representations associated with the management of everyday lives. Freund and Baltes (2002a) have used proverbs to examine this question. They presented life problems to people and asked which proverb fits this situation best. Adults preferred proverbs that indicated SOC behaviors. Moreover, the choice reaction times of the oldest adults, when selecting the fitting proverb, was as fast as those of younger adults. Because reaction speed typically decreases with age during the age span studied, the finding suggests that SOC-based mental representations are well exercised.

Management and Mastery of Life Tasks. Another area of research is the management of the family career interface (B. B. Baltes & Heydens-Gahir, 2003; Wiese, Freund, & Baltes, 2002). Partners who reported higher use of SOC-related behaviors obtained higher scores on perceived developmental status in the two domains and higher levels of well-being; cross-sectionally and longitudinally. Similar findings were obtained with the task of college study behavior (Wiese & Schmitz, 2002). Regarding tasks of old age, work by Margret Baltes, Frieder Lang, and their colleagues is relevant (e.g., Lang, Rieckmann, & Baltes, 2002). They demonstrated that older individuals, especially when in situations of high difficulty, benefited from showing behaviors that were consistent with SOC theory. Another topic of life span research concerns the management of critical life events including illness. In this line of inquiry, Gignac, Cott, and Badley (2002) have shown that older people suffering from osteoarthritis managed their illness by use of behaviors that are consistent with selection, optimization, and compensation.

Dual-Task Research and Behavioral Indicators. An additional area where SOC theory turned out to be promising is dual-task research. Dual- or multiple-task research explores the degree to which individuals can perform several tasks concurrently and whether concurrent performance of several tasks (such as walking and memorizing) facilitates or interferes. Such multitask situations are prototypical of the ecology of everyday behavior. Moreover, with age children become better in handling multiple tasks simultaneously and minimize what is usually called dual-task costs. With aging, the reverse is true.

Dual-task research is a prime model to study development as a system of co-changing and collaborative processes, and of the process of differential allocation of resources. Several studies have tested SOC theory within this model or examined whether the findings are consistent with predictions from the theory. In a later section, we will describe these studies in more detail. Here, suffice it to briefly mention one series of studies.

In our laboratories, we focused on the joined performance of motor behavior (such as walking and keeping one's motor balance) and various processes of memory and solving cognitive tasks. Although older adults showed greater dual-tasks costs, they also exhibited clear preference in their task allocation. For instance, they invested a larger share of their resources into motor behavior (likely because falling is a high-risk in aging) and were more ready to de-invest from the cognitive task. Moreover, on the behavioral level, older adults were effective in using compensatory skills to maintain a higher level of performance (K. Z. H. Li, Lindenberger, Freund, & Baltes, 2001; Lindenberger, Marsiske, & Baltes, 2000).

These initial self-report and observational as well as experimental studies lend support to the perspective of the SOC theory of adaptive development. The pattern of findings suggests that individuals who select, optimize, and compensate are better able to *generate* new developmental resources and through effective *allocation* more effective available resources to manage the tasks of life. Thus, SOC functions like a development-enhancing and loss-preventing general-purpose mechanism. As a general theory of adaptive development, it characterizes a system of strategies that permits individuals to master the general tasks of life, including those that result from the overall life span script outlined earlier when we outlined a systematic change toward a greater proportion of dealing with losses rather than gains.

FIRST LEVEL 5 EXAMPLE: INTELLECTUAL FUNCTIONING ACROSS THE LIFE SPAN

In the following two sections, we focus on two broad areas of human development—intellectual functioning and personality—to present more specific life span research and theory. In general, our approach is to

present this work such that the general theoretical perspectives outlined provide an umbrella under which this research can be positioned and interpreted. Throughout, we attempt to highlight also the pervasiveness of the concept of developmental biocultural co-constructivism (P. B. Baltes et al., 2006).

The productivity of a life span orientation to developmental change depends critically on articulating the theoretical propositions regarding the macroscopic overall landscape of the entire course of ontogeny with more microscopic research on specific developmental functions, processes, and age periods. Specifically, the knowledge bases generated by researchers interested in different aspects of infancy, childhood, adolescence, adulthood, and late life need to be combined and compared with each other, and organized by the themes and propositions that guide the life span approach. The resulting life span integration of perspectives and findings, in turn, is hoped to feed back into the more age- and process-specific developmental specialties, providing for larger interpretative frameworks and provoking the investigation of new or formerly neglected research questions (Lindenberger, 2001).

The field of *intellectual development,* that captured early (Hollingworth, 1927; Sanford, 1902) and continuing attention in life span psychology (e.g., Craik & Bialystok, in press) is ideally suited to demonstrate the potential of this dynamic. Central themes of intellectual development such as relative stability (i.e., covariance change over time), directionality (i.e., mean change over time), plasticity (i.e., the malleability of mean and covariance changes), and the role of knowledge-based processes in cognitive development also have played a prominent role in life span theorizing, and are well suited to exemplify the dynamics between specialized research contexts and overarching conceptions of life span development.

The Biology and Culture of Life Span Intellectual Development

Our proposed view of the overall landscape of ontogenesis as summarized in Figure 11.1 puts constraints on the possible form and content of theories about life span intellectual development. Foremost, any model or theory on life span intellectual development needs to recognize that ontogenesis is a co-construction of two intertwined streams of inheritance, the biological and the cultural (Durham, 1991; see also P. B. Baltes et al., 2006; S.-C. Li, 2003), and needs to provide a framework for the developmental investigation of these two streams of inheritance in different domains, and at different levels of analysis. Specifically, the model should be consistent with the three-fold characterization of the life span dynamics between biology and culture summarized in Figure 11.1, and with the family of theoretical propositions summarized in Table 11.3.

The Two-Component Model of Life Span Cognition: Mechanics versus Pragmatics

In the past, initiated by one of us (P. B. Baltes, 1987, 1993, 1997) but soon co-developed with others (e.g., P. B. Baltes et al., 1984; P. B. Baltes, Staudinger, & Lindenberger, 1999; S.-C. Li, 2002; Lindenberger, 2001), have proposed a theoretical framework for the study of intellectual development in which two main categories or components of intellectual functioning are set apart: The mechanics and the pragmatics of cognition. Juxtaposing the two does not imply that they are independent or exclusive; rather, they interact across ontogenetic and microgenetic time in the production of intelligent behavior. As a general principle, the cognitive mechanics, because of their evolutionary base, evolve earlier in human ontogeny, and are being "invested" into the acquisition of higher and knowledge-based cognitive functions (for similar assumptions in the context of Gf/Gc theory, see Cattell, 1971).

Historically, our views on the overall landscape of human development were developed in close connection with the broadening and systematization of the mechanic-pragmatic distinction (P. B. Baltes, 1987, 1997; P. B. Baltes, Lindenberger, & Staudinger, 1998; S.-C. Li, 2003). Specifically, we construe the mechanics of cognition as an expression of the neurophysiological architecture of the mind as they evolved during biological evolution (cf. Gigerenzer & Todd, 1999) and unfold during ontogeny (McClelland, 1996; W. Singer, 1995). In contrast, the pragmatics of cognition are associated with the bodies of knowledge available from and mediated through culture (see upper portion of Figure 11.8).

The Cognitive Mechanics. The mechanics of cognition are closely linked to biological including neurophysiological brain conditions, and the predominant age-graded ontogenetic pattern is one of maturation, stability, and aging-induced decline. Especially early and late in ontogeny, age-based changes in this component are assumed to primarily reflect factors closely related to biological brain status, albeit in fundamentally different ways (P. B. Baltes, 1997; S.-C. Li, Lindenberger, et al., 2004; Lindenberger, 2001). Early in ontogeny (i.e., during embryogenesis, infancy, and early

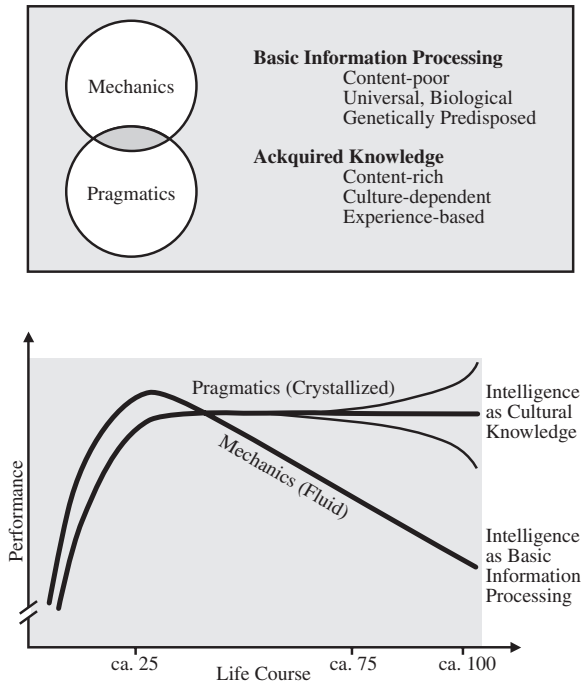

Figure 11.8 Life span research on two components of cognition: (1) fluid mechanics and (2) crystallized pragmatics. The top section defines the categories; the bottom section illustrates postulated lifespan trajectories. *Source:* Modified based on "Psychological Aspects of Aging: Facts and Frontiers" (pp. 427–459), by P. B. Baltes and P. Graf, in *The Life-Span Development of Individuals: Behavioural, Neurobiological and Psychosocial Perspectives,* D. Magnusson (Ed.), 1996, Cambridge, England: Cambridge University Press; From "Major Abilities and Development in the Adult Period" (pp. 44–99), by J. L. Horn and S. M. Hofer, in *Intellectual Development,* R. J. Sternberg & C. A. Berg (Eds.), 1992, New York: Cambridge University Press.

childhood), age-based changes in the mechanics are assumed to consist, for the most part, in the unfolding and active construction of more or less domain-specific and genetically predisposed processing capabilities (Elman et al., 1996; Wellman, 2003). In contrast, negative changes in the mechanics of cognition late in life presumably result from brain-related consequences of less effective phylogenetic selection pressures operating during this period (Kirkwood, 2003; Thaler, 2002; see "The Mechanics and Pragmatics in Very Old Age"). In that sense, the life span trajectory of level changes in the mechanics of cognition can be derived from the life span changes shown in the left panel of Figure 11.1.

The cognitive mechanics, then, reflect fundamental organizational properties of the central nervous system (W. Singer, 1995). In terms of psychological operations, we assume that the cognitive mechanics are indexed by the speed, accuracy, and coordination of elementary processing operations as they can be assessed in tasks measuring the quality of information input, sensory and motor memory, discrimination, categorization, and selective attention, as well as reasoning ability in highly overlearned or novel domains (Craik, 1986; Craik & Bialystok, in press; Craik & Salthouse, 2000; Hommel, Li, & Li, 2004; Salthouse & Kail, 1983). At the neuronal level, age-graded anatomical, chemical, and functional changes in the brain and their complex relations to the cognitive mechanics are being uncovered with increasing precision and scope (P. B. Baltes et al., in press; Cabeza, Nyberg, & Park, 2004; Craik & Bialystok, in press; Lindenberger, Li, & Bäckman, in press).

The Cognitive Pragmatics. In contrast to the mechanics, the cognitive pragmatics of the mind reveal the power of human agency and culture (Boesch, 1997; Cole, 1996; Valsiner & Lawrence, 1997; S.-C. Li, 2003; Shweder, 1991). The cognitive pragmatics also are at the center of socialization events that follow the principles of co-construction (P. B. Baltes et al., in press; S.-C. Li, 2003). Some of these events are normative but specific to certain cultures (e.g., formal schooling), others are more universal (e.g., mentoring), and still others are idiosyncratic or person-specific (e.g., specialized ecological and professional knowledge). In any case, the corresponding bodies of knowledge are represented both internally (e.g., semantic networks) and externally (e.g., books).

The pragmatics of cognition direct the attention of life span developmentalists toward the increasing importance of knowledge-based forms of intelligence during ontogeny (P. B. Baltes & Baltes, 1990a; Ericsson & Smith, 1991; Hambrick & Engle, 2002; Krampe & Baltes, 2003; Labouvie-Vief, 1982; Rybash, Hoyer, & Roodin, 1986). Typical examples include reading and writing skills, educational qualifications, professional skills, and varieties of everyday problem-solving, but also knowledge about the self and the meaning and conduct of life (P. B. Baltes & Staudinger, 2000; Blanchard-Fields, 1996; Bosman & Charness, 1996; Marsiske et al., 1995; Staudinger et al., 1995; see "Face and Facets of the Study of Personality Development across the Life Span"). Such bodies of pragmatic knowledge are acquired during ontogeny but may build on evolutionarily prestructured, domain-specific knowledge (Charness, 2005; Elman et al., 1996; Tomasello, 1999).

Divergence in Life Span Trajectories between Mechanics and Pragmatics. The preceding considerations imply specific predictions regarding the shape of

ontogenetic trajectories for mechanic and pragmatic aspects of intellectual functioning (see lower portion of Figure 11.8). Specifically, two different sources of influence are assumed to govern the level of performance within these two categories: biological-genetic for the mechanics, and environmental-cultural for the pragmatics. The expected divergence in age trajectories is seen as a consequence of this difference in composition.

Empirical evidence in support of a two-component conceptualization of life span cognition comes from a great variety of different research traditions (see discussion that follows). Probably the most longstanding supportive evidence is the difference between maintained and vulnerable intellectual abilities (Salthouse, 1991; cf. Jones & Conrad, 1933). Abilities that critically involve the mechanics, such as reasoning, memory, spatial orientation, and perceptual speed, generally show a pattern of monotonic and roughly linear decline during adulthood, with some further acceleration of decline in very old age. In contrast, more pragmatic abilities, such as verbal knowledge and certain facets of numerical ability, remain stable or increase up to the 6th or 7th decade of life, and only start to evince some decline in very old age.

Figure 11.9, based on the fifth data collection of the Seattle Longitudinal Study (Schaie, 1996; see also Schaie et al., 2005), may serve as an illustration. It displays cross-sectional adult age gradients based on multiple indicators for six intellectual abilities (Schaie & Willis, 1993). Verbal ability and number ability peak during middle adulthood and show little or no age decrements before the age of 74, whereas perceptual speed, inductive reasoning, spatial orientation, and verbal memory show steady monotonic decline. Recent analyses based on longitudinal as well as longitudinal/cross-sectional convergence data provide additional and more direct support for a basic divergence between mechanic and pragmatic age gradients in adulthood and old age (Salthouse, 1991; Schaie, 1996; Schaie, Maitland, Willis, & Intieri, 1998; T. Singer, Verhaeghen, Ghisletta, Lindenberger, & Baltes, 2003).

In a recent cross-sectional study, Shu-Chen Li and colleagues (2004) investigated whether dissociations in age trajectories between mechanic and pragmatic intellectual abilities across can be observed across the entire life span, as life span psychology would predict. The authors administered a psychometric battery comprising fifteen tests assessing three marker abilities of the fluid mechanics (perceptual speed, reasoning, and fluency) and two marker abilities of the crystallized pragmatics (verbal knowledge and fluency) to individuals aged 6 to 89 years. Participants were classified into six age groups, childhood (6 to 11 years), adolescence (12 to 17 years), early adulthood (18 to 35 years), middle adulthood (26 to 54 years), late adulthood (55 to 69 years), and old age (70 to 89 years). In addition, S.-C. Li et al. (2004) also administered basic reaction time tasks to index processing speed (i.e., a person's average speed of responding across the five tasks) and processing robustness (i.e., the inverse of a person's average within-task reaction-time fluctuation). As expected, the life span trajectories of the two information processing and the fluid-mechanic composite stood in contrast to the trajectory of the crystallized-mechanic composite (see Figure 11.10). Moreover, within the mechanic domain, the trajectories for the two

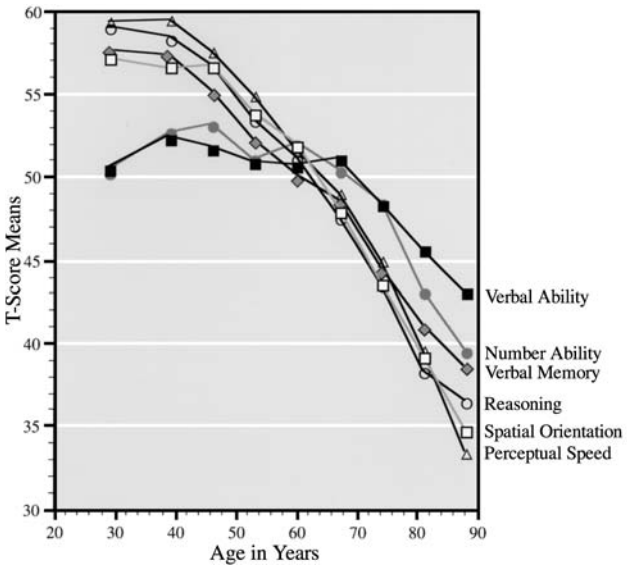

Figure 11.9 Cross-sectional age gradients in six primary mental abilities ($N = 1628$). Abilities were assessed with 3 to 4 different tests and are scaled in a T-score metric (i.e., *mean* = 50, $SD = 10$). Verbal ability and number ability peak during middle adulthood and show little or no age decrements before the age of 74. In contrast, perceptual speed, inductive reasoning, spatial orientation, and verbal memory show steady monotonic decline. This differential pattern of prevailing growth, maintenance, and subsequent loss supports two-component theories of life span intellectual development such as the distinction between fluid and crystallized intelligence made by Cattell (1971) and J. L. Horn (1982) or the juxtaposition of the mechanics and the pragmatics of cognition proposed by P. B. Baltes (1987, 1993). *Source:* From "Age Difference Patterns of Psychometric Intelligence in Adulthood: Generalizability within and across Ability Domains," by K. W. Schaie and S. L. Willis, 1993, *Psychology and Aging, 8,* pp. 44–55.

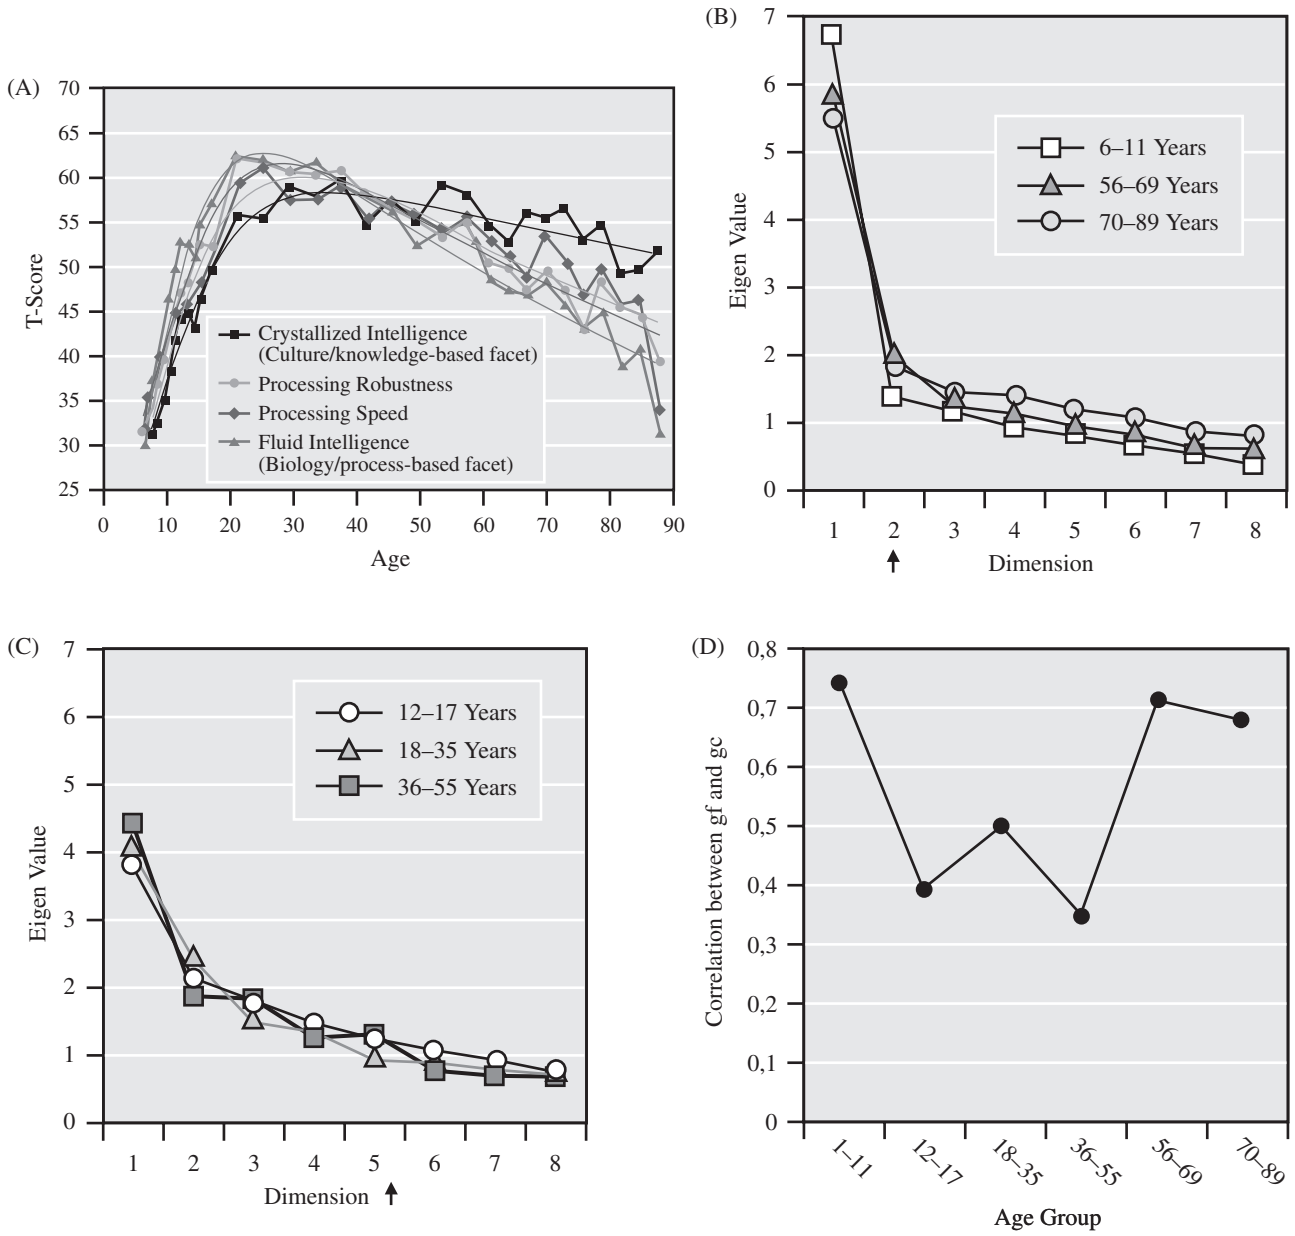

Figure 11.10 Intellectual abilities across the life span. (A) Cross-sectional age trajectories for crystallized intelligence, processing robustness, processing speed, and fluid intelligence. Crystallized intelligence represents the cognitive pragmatics, whereas processing robustness, processing speed, and fluid intelligence represent the cognitive mechanics. The divergence in age gradients between pragmatics and mechanics lends support to two-component theories of cognitive development. (B, C) Results from principal component analyses of 15 intellectual ability tests for each of six age groups. The arrows indicate the estimated number of principal components with eigenvalues greater than unity. (D) Correlations between broad fluid and crystallized intelligence for the same six age groups. Panels B-D support the hypothesis that the structure of intellectual abilities is less differentiated in childhood and old age than during adolescence and adulthood. *Source:* From "Transformations in the Couplings among Intellectual Abilities and Constituent Cognitive Processes across the Life Span" by S.-C. Li, U. Lindenberger, B. Hommel, G. Aschersleben, W. Prinz, and P. B. Baltes, 2004, *Psychological Science, 15,* pp. 155–163.

information-processing composites showed an earlier cross-sectional life span peak than the trajectory for the fluid-mechanic component, supporting the contention that the admixture of pragmatic variance contaminates standard assessments of broad fluid intelligence.

The Two-Component Model: Relations to Other Multiple-Component Theories

Arguably, Tetens (1777) provided the earliest comprehensive formulation of a two-component model of life span cognition (Lindenberger & Baltes, 1999); his definition of absolute and relative capacities closely approximated the definition of the mechanics and pragmatics of cognition, respectively. The closest relative, both conceptually and historically, to the two-component model of life span intellectual development is the theory of fluid (Gf) and crystallized (Gc) abilities by Cattell (1971) and Horn (1982; for comparative discussion, see P. B. Baltes et al., 1998; Lindenberger, 2001). Other approaches related to the two-component model include Ackerman's (e.g., 1996) process, personality, interests, and knowledge (PPIK) model, Hebb's (1949) distinction between intelligence A (i.e., intellectual power) and intelligence B (i.e., intellectual products), the encapsulation model of adult intelligence proposed by Rybash et al. (1986; Hoyer, 1987), and Sternberg's (1985) triarchic theory of intelligence, especially its developmental interpretation by Berg and Sternberg (1985a).

Here, the two-component model will be further elaborated in three separate sections: Mechanics, pragmatics, and their interrelations. The aim of these three sections is not to be comprehensive, but to further specify the two components of cognition as well as their interaction.

The Fluid Mechanics of Cognition

We start this section with a life span summary of research on constructs that have been proposed to cause or mediate age-based changes in the mechanics of cognition. We then argue that much of the available evidence about age-based changes in the mechanics derives from measures that are contaminated by pragmatic influence, and we underscore the need to arrive at more valid estimates of individual differences in upper limits of mechanic functioning. In line with the two-component model, we predict that age differences in the mechanics are magnified under purified measurement conditions and provide an empirical example from adulthood in support of this prediction.

The Search for Determinants of Mechanic Development

Despite a large overlap in approaches to the study of intellectual development, there are surprisingly few attempts to pursue the themes of infant and child development into adulthood and old age, or to identify thematic and predictive antecedents of adulthood and old age in childhood (see S.-C. Li, Lindenberger, et al., 2004). An important exception in this regard concerns work on age changes in general information-processing constraints on intellectual functioning across the life span, or what we would call research on the determinants of age-based changes in the mechanics of cognition. Researchers both in the fields of child development (Bjorklund, 1997; Case, 1992; McCall, 1994; Pascual-Leone, 1983) and cognitive aging (Birren, 1964; Cerella, 1990; Craik & Byrd, 1982; Hasher & Zacks, 1988; S.-C. Li, Lindenberger, & Sikström, 2001; Salthouse, 1996) have been trying to identify developmental determinants or "developables" (Flavell, 1992) that regulate the rate of age-based changes in cognitive and intellectual functioning. Some scholars have begun to link these two lines of inquiry by attempting to provide unified accounts of age-based changes in the structure and/or efficiency of information processing (e.g., Craik & Bialystok, 2006; Hommel, Li, & Li, 2004; S.-C. Li, Lindenberger, et al., 2004; Salthouse & Kail, 1983; Wellman, 2003).

In many cases, the central goal of these endeavors is to identify the number (dimensionality), nature, and causal dynamics of age-graded changes in the mechanics of cognition. Though this task seems conceptually straightforward, it is methodologically quite intricate (P. B. Baltes & Labouvie, 1973; Hertzog, 1985; Hertzog & Nesselroade, 2003; Lindenberger & Pötter, 1998; Reinert, Baltes, & Schmidt, 1966). Chronological age carries a multitude of causal agents with different and intertwined temporal dynamics and timescales such as distance from birth, distance from death, distance from disease inception, but also number of hours of practice or formal training. For instance, when two variables assumed to index two causal agents follow a similar path over ontogenetic time, this does not imply that the two causes are functionally related. Therefore, evidence about determinants of mechanic development needs to be evaluated with caution, especially if based on age-heterogeneous cross-sectional data sets (Lindenberger & Pötter, 1998).

In the following section, we selectively review research on possible determinants of life span changes in

the mechanics of cognition. We start with three constructs located at the information-processing level of analysis, and end with a consideration of select age-graded changes at the neuronal level. Progress in understanding determinants of life span changes in the mechanics of cognition field will depend on integrating these two levels of analysis both empirically and conceptually (Buckner, 2004; Craik & Bialystok, in press; S.-C. Li, in press; S.-C. Li & Lindenberger, 1999; Lindenberger, Li, & Bäckman, in press).

At the information-processing level, processing rate (Cerella, 1990; Salthouse, 1996), working memory (Baddeley, 2000; Just, Carpenter, & Keller, 1996), and inhibition (Hasher & Zacks, 1988) have been studied most extensively. Apparently, functional levels of these three mechanisms follow the inverse U-shape pattern predicted by the two-component model for the mechanics of cognition. In principle, then, any combination of these mechanisms could act as a pacemaker of life span development in the mechanics of cognition.

Processing Speed. Across a wide variety of cognitive and perceptual tasks, speed of responding increases dramatically from childhood to early adulthood, and continuously decreases thereafter. This observation has led to the processing rate hypothesis of life span cognitive development. Probably, this hypothesis holds a more central place in cognitive aging research (e.g., Birren, 1964; Cerella, 1990; Salthouse, 1996; Welford, 1984) than in research on child development (e.g., Hale, 1990; Kail, 1996). In the case of cognitive aging, the general slowing-down of cognitive behavior with advancing age is portrayed as the consequence of a general decrement in information processing rate. In cross-sectional studies, psychometrically assessed perceptual speed accounts for most or all negative adult age differences in other intellectual abilities, even if these other abilities are assessed under time-relaxed or untimed testing conditions (for a summary, see Verhaeghen & Salthouse, 1997). However, psychometrically assessed perceptual speed is not a unitary construct or processing primitive but a factorially complex entity whose composition may change as a function of age. Also, attempts at identifying neuronal correlates of age-based differences in processing speed have yielded mixed results (e.g., Bashore, Ridderinkhof, & van der Molen, 1997).

Working Memory. Generally, working memory denotes the ability to preserve information in one or more short-term stores while simultaneously transforming the same or some other information (Baddeley, 2000; Just et al., 1996). Age differences in working memory have been invoked as a possible cause for intellectual growth during childhood (Case, 1985; Chapman & Lindenberger, 1992; Halford, 1993; Pascual-Leone, 1970), and for age-based decrements during adulthood and old age (Craik, 1983; Oberauer & Kliegl, 2001). With respect to childhood, Neo-Piagetian theorists have argued that changes in working memory are among the primary pacemakers of intellectual child development (e.g., Pascual-Leone, 1970).

Positive age differences during childhood and negative age differences during adulthood are more pronounced when demands on processing are increased (Mayr, Kliegl, & Krampe, 1996). Despite this supportive evidence, the explanatory power of the working-memory construct is difficult to judge. For instance, age-based changes in working memory are often explained by alluding to changes in processing efficiency or processing speed (Case, 1985; Salthouse, 1996). Another problem concerns our limited knowledge about a central function of working memory—the (conscious) control of action and thought. In the most influential working-memory model (Baddeley, 2000), this task is assigned to the central executive. Evidence from developmental psychology (Houdé, 1995; McCall, 1994), cognitive-experimental and differential psychology (Engle, Kane, & Tuholski, 1999), and the cognitive neurosciences (Miller & Cohen, 2001) suggests that the abilities to inhibit actions and thoughts and avoid interference from competing processing streams are crucial for the efficient functioning of this component, rather than working-memory capacity per se.

Inhibition and Interference. During the past decades, developmentalists from different traditions and fields of research have intensified their interest in mechanisms of inhibition and interference (Bjorklund, 1997; Engle, Conway, Tuholski, & Shishler, 1995; Hasher & Zacks, 1988; Houdé, 1995; McCall, 1994). Curvilinear life span age gradients that resemble those found for measures of perceptual speed have been obtained with typical tests of interference proneness such as the Stroop color-word test, suggesting that children and especially older adults have greater difficulties in suppressing currently irrelevant action tendencies than young adults (Dempster, 1992; Hommel et al., 2004; Mayr, 2001). However, it has proven difficult to separate

inhibition-based explanations of this phenomenon from activation-based explanations of selective attention and working memory capacity (Engle et al., 1995; Hommel et al., 2004).

Cognitive Neuroscience Approaches to Mechanic Development: The Sample Case of Prefrontal Circuitry. The advent of brain imaging methods has allowed researchers to intensify empirical links between behavioral and neuronal levels of analysis. The conceptual and empirical implications of this trend for developmental psychology are discussed more fully elsewhere (e.g., P. B. Baltes et al., in press; Cabeza et al., 2004; Craik & Bialystok, in press; S.-C. Li, 2002; Lindenberger et al., in press). In the following discussion, we restrict our presentation to maturational and senescent changes in prefrontal circuitry. Available evidence suggests that these changes may contribute in important ways to changes in the cognitive mechanics during childhood and old age.

We begin with some evidence on regional brain development. In early ontogeny, prefrontal cortex and associated neural networks undergo profound anatomical, chemical, and functional changes that extend well into adolescence. Neural plasticity during corticogenesis entails the production and experience-dependent elimination of neuronal connections (Huttenlocher & Dabholkar, 1997). During brain development, the zone of maximum plasticity moves from primary sensory and motor over secondary association to prefrontal areas (Chugani, Phelps, & Mazziotta, 1987). Computational models suggest that later maturing areas require input from earlier maturing areas to represent higher-order concepts (Shrager & Johnson, 1996). Arguably, the gradual and orderly progression of the corticotrophic wave provides a chronotopic constraint for cerebral cortex organization.

In later adulthood, prefrontal cortex and the functionally connected basal ganglia also show greater and earlier signs of decline than most other areas of the brain. In a comprehensive review of the neuroanatomical literature, Raz (2000) reported average linear reductions in brain weight and volume of about 2% per decade during adulthood, which were more pronounced for anterior parts of the brain (for longitudinal evidence, see Raz, Lindenberger, et al., 2005). At the neurochemical level, changes in the catecholaminergic system, most notably dopamine, play a prominent role (Bäckman & Farde, 2004). Finally, neurofunctional studies point to profound age-associated changes in the functional organization of prefrontal cortex such as a reduction in the asymmetry of hemispheric activation (e.g., Cabeza, 2002).

The links between behavioral development and regional brain differentiation are only beginning to emerge (e.g., Lindenberger et al., in press), and the precise relations between life span changes in prefrontal circuitry and behavioral changes remain to be uncovered. Functions similar to working memory and typically subsumed under the heading of "executive functions" or "cognitive control" appear to be involved (Engle et al., 1999; Kliegl, Krampe, & Mayr, 2003). Situations deemed to be particularly dependent on prefrontal circuitry require the coordination of multiple tasks or task components. Typical examples include the suppression of stimulus-driven action tendencies (Metcalfe & Mischel, 1999; Salthouse & Meinz, 1995), multitasking (Mayr et al., 1996; Salthouse, Hambrick, Lukas, & Dell, 1996) and response selection under high stimulus ambiguity (Kramer, Hahn, & Gopher, 1999; Kray & Lindenberger, 2000). Differential susceptibility to coordinative demands may help to explain why life span age differences in marker tests of fluid intelligence such as Raven's matrices tend to persist when participants are given unlimited amounts of time to solve the items (cf. the simultaneity mechanism in Salthouse, 1996).

Future research needs to explicate the link between life span changes in prefrontal circuitry and the mechanics of cognition with greater precision. Given the fundamentally different etiology of changes in prefrontal circuitry early and late in ontogeny, and given that late-life changes are taking place in a cognitive system with a rich and idiosyncratic learning history, any expectation of a close resemblance between brain-behavior mappings early and late in life seems unwarranted.

Age-Based Differences in the Mechanics of Cognition: The Need for Purification of Measurement

Observed age differences or age changes on intellectual tasks and tests, as obtained in standard cross-sectional and real-time longitudinal research, cannot be regarded as direct and pure reflections of age-based changes in the mechanics of cognition. Rather, in addition to the mechanics, such differences or changes are influenced by a wealth of additional factors, ranging from pragmatic components of cognition (e.g., task-relevant preexperimental knowledge) to other person characteristics (e.g., test anxiety or achievement motivation; cf. Fisk & Warr, 1996). A

likely indication for this admixture of pragmatic variance to supposedly mechanic measures is the secular rise in performance on typical psychometric marker tests of fluid intelligence (cf. Flynn, 1987; Schaie et al., 2005). In our view, it seems an open question whether the preferred interpretation by Flynn that these historical changes reflect changes in fluid intelligence per se is correct. Unless more pure measures of basic fluid intelligence were included, we hold it more likely that these historical changes are changes in the pragmatics rather than the mechanics (see also Schaie et al., 2005).

The need for better estimates of individuals' performance potential in the mechanics of cognition is further nurtured by the life span proposition that epigenesis is probabilistic but not random; hence, plasticity is more or less constrained (P. B. Baltes, 1987; Gottlieb, 1998; Hagen & Hammerstein, 2005; R. M. Lerner, 1984; see Table 11.3). If the goal is to separate the possible from the impossible over age, and to solidify the evidence on age differences in the mechanics of cognition, the context of measurement needs to be moved toward upper limits of performance potential. This line of reasoning resembles claims made by other research traditions, such as clinical and developmental diagnostics (Carlson, 1994; Guthke & Wiedl, 1996), the differentiation between performance and competence, gestalt and cultural-historical theoretical orientations (Vygotsky, 1962; H. Werner, 1948), and early work on life span differences in learning (B. Levinson & Reese, 1967). Discrepancies in epistemology and purpose notwithstanding, all these traditions are inspired by an interest in exploring individuals' upper limits of intellectual performance.

Testing the Limits of Age Differences in the Mechanics of Cognition. Within life span developmental psychology and as alluded to earlier, the testing-the-limits paradigm has been introduced as a research strategy to uncover age differences in the upper limits of mechanic functioning across the life span (P. B. Baltes, 1987; Kliegl & Baltes, 1987; Lindenberger & Baltes, 1995b). The main focus of this paradigm is to arrange for experimental conditions that produce maximum (i.e., asymptotic) levels of performance. Thus, similar to stress tests in biology and medicine (M. M. Baltes, Kühl, Gutzmann, & Sowarka, 1995; Fries & Crapo, 1981), testing-the-limits aims at the assessment of age differences in maximum levels of cognitive performance by providing large amounts of practice and/or training combined with systematic variations in task difficulty. Furthermore, and in line with the microgenetic approach to the study of change (Siegler & Crowley, 1991; Siegler, Chapter 11, this *Handbook,* this volume), the testing-the-limits paradigm is based on the assumption that the study of microgenetic change and variability may help to identify mechanisms underlying ontogenetic change (see H. Werner, 1948). Thus, in addition to the more general goal of measurement purification, the detailed analysis of time-compressed developmental change functions is assumed to enhance our understanding of the mechanisms and the range of medium- and long-term developmental changes (Hultsch & MacDonald, 2004; S.-C. Li, Huxhold, et al., 2004; Lindenberger & von Oertzen, in press).

A Prototypical Example: Adult Age Differences in Upper Limits of Short-Term Memory (Serial Word Recall)

Figure 11.11 shows the result of a study involving a total of 38 sessions of training and practice in the Method of Loci, a mnemonic technique for the serial recall of word lists. Two findings from this study are noteworthy. First, adults in both age groups greatly improved their memory performance. This finding confirms earlier work on the continued existence of cognitive plasticity in cognitively healthy (i.e., nondemented) older adults (P. B.

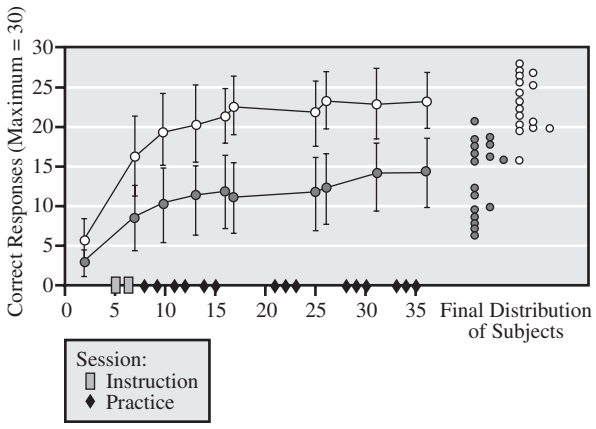

Figure 11.11 Testing-the-limits research, which is aimed at the identification of asymptotes of performance potential, suggests the existence of robust age-related losses in the mechanics of cognition. The example given involves a memory technique, the Method of Loci. After 38 sessions of training, most older adults did not reach the level of performance reached by younger adults after only a few sessions. In the final distribution, no older person was performing above the mean of the young adults. Adapted from P. B. Baltes & Kliegl, 1992.

Baltes & Lindenberger, 1988; P. B. Baltes & Willis, 1982; Verhaeghen, Marcoen, & Goossens, 1992). Second, practice and training resulted in a close-to-perfect separation of the two adult age groups, thereby demonstrating the existence of sizeable negative age differences at limits of functioning. Even after 38 sessions of training, the majority of older adults did not reach the level of performance that young adults had reached after only a few sessions. Moreover, at the end of the study, not a single older person functioned above the mean of the young-adult group. A more recent investigation has shown that upper limits of performance are further reduced in very old age (T. Singer, Lindenberger, & Baltes, 2003).

The findings obtained with the testing-the-limits paradigm are consistent with our general notion that the mechanics of cognition decrease during adulthood and old age. Given our assumptions regarding life span changes in adaptive capacity of the mechanics of the mind and the knowledge-contaminated nature of standard assessments, we predict that life span peaks in performance levels are shifted toward younger ages when individuals are given the opportunity to come close to their upper limits of mechanic potential. Results from a recent experimental study have confirmed these expectations (Brehmer, Li, Müller, Oertzen, & Lindenberger, 2005).

In addition to encompassing wide age ranges, future explorations of life span differences in behavioral plasticity may also include functional and anatomical neural measures to identify life span differences in the relation between behavioral and neuronal plasticity (for exemplary work, see Kramer et al., in press; Nyberg et al., 2003). Also, the focus on age differences in maximum level should be complemented by an emphasis on age-differential changes in variances and covariances with practice (Hertzog, Cooper, & Fisk, 1996; Labouvie, Frohring, Baltes, & Goulet, 1973). Specifically, to better understand neuronal correlates of age differences in the acquisition of expertise, it seems productive to study life span differences in the brain's adaptation in response to intensive training programs.

At present the major conclusion regarding the plasticity of the mechanics across the lifespan is that plasticity may be substantial in childhood, that it decreases markedly with age, and that it's demonstrated plasticity after middle adulthood is modest at best. This conclusion holds especially, if one defines a high threshold for assessing whether a given training program resulted in a true improvement of the mechanics themselves (Baltes & Lindenberger, 1988). For instance, it is not easy to argue against alternative interpretations, such as that the improvement in the cognitive system is due to adding pragmatic rather than mechanical components to the solution process. We would need more purist measures of the cognitive mechanics than are currently available. Moreover, issues of transfer and maintenance are at stake. If the results were an improvement in the mechanics themselves, the evidence should include the demonstration of improvement in learning gains across a wide range of new tasks, or at least within the "modularity" class within which the training tasks are putatively located. The absence of such evidence my be due to the fact that many training programs are behavioral in origin. It will be interesting to see whether biochemical interventions, such as memory pharmaceuticals to improve the transmission from primary to secondary memory might be more powerful in improving the cognitive mechanics in a more direct manner. Here, the newly evolving cooperation between biochemically oriented neuroscientists and behaviorally-oriented learning psychologists may offer a new window on the plasticity of the cognitive mechanics during adulthood as well (see also Goldberg & Weinberger, 2004; Kempermann, 2006).

The Crystallized Pragmatics of Cognition

We now direct our attention to the ontogeny of the cognitive pragmatics, or the cultural and knowledge-rich dimension of intellectual life span development. First, we discuss the relation between mechanics and pragmatics from an evolutionary perspective. Then, we introduce the distinction between normative and person-specific forms of pragmatic knowledge, and discuss stage- and knowledge-oriented approaches. We end this section with examples from our own research on expert knowledge about the fundamental pragmatics of life (wisdom).

Mechanics and Pragmatics in Evolutionary Perspective

In recent decades, nativist approaches to infant cognitive development have revealed the evolutionary informed nature of the human processing system (e.g., Spelke, Vishton, & von Hofsten, 1995). Through innovative advances in experimental methodology, it has become increasingly clear that infants and young children cannot be considered a cognitive tabula rasa, as extreme

interpretations of constructivist (e.g., Piaget, 1967/1971, but see Piaget, 1980, pp. 11–12) or behaviorist (e.g., B. F. Skinner, 1966) theorizing may suggest. Rather, not unlike members of other species, humans begin their extra-uterine lives with a well-orchestrated set of domain-specific constraints and expectations that guide behavior and form the basis for later acquisitions (Elman et al., 1996; Saffran, Aslin, & Newport, 1996).

We assume that the pragmatics of cognition, or the bodies of knowledge provided by culture build on, extend, and reorganize these prestructured core domains, both during evolution and during ontogeny (Gigerenzer, 2003; Wellman, 2003). These processes of extension and transformation eventually give rise to forms of knowledge and behavior that are, in part by virtue of necessity, *compatible* with the biological architecture of the mind, but cannot be characterized as the *direct consequence* of evolutionary selection pressures.

The resulting potential of human ontogeny to create and adapt to the new (Gottlieb, 1998), or the productive tension between current functions and evolutionary history, has been referred to as exaptative generalization or *exaptation* (Gould & Vrba, 1982). As a mechanism of biocultural co-construction, exaptation helps to explain why members of the human species are good at doing things that were certainly not directly at the focus of natural selection, such as reading a book or driving a car (Sherry & Schacter, 1987). Put more generally, exaptation reminds us that the evolution of culture must reflect some degree of match with, and reciprocal influence on, evolution-based genetic disposition (Durham, 1991; Gottlieb et al., Chapter 5, this *Handbook,* this volume). For instance, pragmatic knowledge may evolve from and/or mimic predisposed knowledge in evolutionarily privileged domains but come with the advantage of being tuned to the idiosyncratic demands of specific cultures, biographies, and contexts (Siegler & Crowley, 1994).

Note, however, that culture sometimes appears to have produced bodies of knowledge that are antithetical, disconnected, or at least not easily articulated to biological predispositions. For instance, Gigerenzer and Todd (1999) have argued that formal-logical expressions such as Bayes' theorem do not take advantage of humans' predisposition to base judgments about feature conjunction probabilities on frequency counts. Put differently, mathematical formalisms about conditional probabilities do not build on mechanisms of perception and action that directly support the detection of conjunctive feature frequencies; rather, such formalisms are cultural products whose acquisition requires specialized instruction. Another example from a completely different field is the need to culturally countershape the manifestation of evolution-based aggressive and interpersonal power tendencies.

Normative versus Person-Specific Pragmatic Knowledge

An important, albeit necessarily imperfect, distinction within the pragmatics of cognition concerns normative versus person-specific knowledge. Normative bodies of knowledge are of general value to a given culture. Typical examples include verbal ability, number proficiency, and basic general knowledge about the world (e.g., Ackerman, Beier, & Bowen, 2000). Individual differences in these domains are closely linked to years of education and other aspects of social stratification, and are amenable to psychometric testing (Cattell, 1971). In contrast, person-specific bodies of knowledge that branch off from the normative knowledge-acquisition path are less closely tied to mandatory socialization events, and result from specific combinations of experiential settings, personality characteristics, motivational constellations, and cognitive abilities or talent (Marsiske et al., 1995). As a consequence, these bodies of knowledge often escape psychometric operationalization, and are more amenable to study within the expertise paradigm (Ericsson & Smith, 1991; Gobet et al., 2001; Krampe & Baltes, 2003). Therefore, psychometric research on crystallized abilities needs to be supplemented by approaches with a more explicit focus on knowledge acquisition and utilization to more fully capture the diversity and specificity of pragmatic knowledge.

For the most part (but see Brown, 1982; Chi & Koeske, 1983; Schneider & Bjorklund, 2003; Weinert & Perner, 1996; Wilkening & Anderson, 1990), developmental research on person-specific bodies of knowledge has been undertaken with adults. A typical approach has been to identify the effects of domain-specific knowledge by comparing the performance of experts and novices both inside and outside their domain of expertise. Examples include the classical domains of expertise research such as chess (Charness, 1981) and card games (Bosman & Charness, 1996), but also domains such as baseball knowledge (Hambrick & Engle, 2002) or professional expertise (e.g., Salthouse, 2003; for an overview, see Charness, 2005).

Two main conclusions can be drawn from this research. First, expertise effects, or the consequences of specific bodies of declarative and procedural knowledge, rarely transcend the boundaries of the target domain. Specifically, there is little evidence to suggest that the mechanics of cognition are transformed by domain-specific knowledge (Salthouse, 2003). Whenever there is evidence for effects of a more general kind, at least after the age periods of childhood and adolescence, transfer of pragmatic knowledge (positive or negative) appears to be a more plausible explanation than a basic change in the mechanics. One example comes from longitudinal work by Kohn and Schooler (1983; Schooler, Mulatu, & Oates, 1999) on the relationship between the substantive complexity of work and ideational flexibility. Kohn and Schooler found that work complexity predicts increments in ideational flexibility over a period of 10 years, even after controlling for initial differences in ideational flexibility. A related finding is the recent observation that social participation attenuates decline in the cognitive mechanics in old and very old age (Lövdén, Ghisletta, & Lindenberger, 2005). Note, however, that the interpretation of findings of this type in terms of experiential factors is complicated through nonrandom placement of individuals into experiential settings and the fact that the measures of the cognitive mechanics used include crystallized pragmatic components (Scarr & McCartney, 1983).

The second major conclusion concerns the power of pragmatic knowledge to make up for losses in the mechanics within the domain of expertise (Charness, 2005; Krampe & Baltes, 2003). Here, the results from several studies suggest that acquired knowledge endows aging individuals with a form of natural and local (e.g., domain-bound) ability to withstand or at least attenuate the consequences of aging-induced losses in the mechanics. This finding is of central importance for the issue of successful intellectual aging, and supports the general life span theory of selective optimization with compensation (P. B. Baltes, 1993; Freund & Baltes, 2000; Staudinger et al., 1995). The postulate of a compensatory relation between pragmatic knowledge acquisition and mechanic decline receives additional support by attenuated adult age differences in knowledge-rich domains of everyday relevance. For instance, compared to standard psychometric or cognitive-experimental assessments, negative adult age differences tend to be less pronounced or absent in practical problem solving (Sternberg, Wagner, Williams, & Hovath, 1995), social intelligence (Blanchard-Fields, 1996), memory in context (Hess & Pullen, 1996), and interactive-minds cognition (P. B. Baltes & Staudinger, 1996b; Dixon & Gould, 1996; T. Singer et al., 2004; Staudinger, 1996; Staudinger & Baltes, 1996).

Intellectual Growth during Adulthood: Stage Conceptions versus Functionalist Approaches

Historically, much of the search for more advanced forms of reasoning and thought in adulthood originated from Piaget's theory of cognitive development (Chapman, 1988b; Pascual-Leone, 1983; Piaget, 1970; Riegel, 1976), positing the emergence of one or more postformal or dialectical stages of cognitive development after the advent of formal operations. The conceptual description of these stages often connects personality development (e.g., generativity in the Eriksonian sense) with logical considerations (e.g., awareness and acceptance of contradiction). As a consequence of this particular linkage, the emergence of such stages is assumed to bring about increments in reflexivity and general awareness for the human condition (see the next section). Evidence in support of such stages is scarce, which is not surprising given the difficulties in obtaining reliable indicators of stage-like cognitive change (e.g., Molenaar, 1986; L. B. Smith & Thelen, 2003).

Despite his constructivist and dialectical epistemology (e.g., Chapman, 1988; Lourenço & Machado, 1996; Piaget, 1980), Piaget himself was reluctant to posit any stages beyond formal operations. Instead, he argued on one occasion (Piaget, 1972) that the notion of horizontal décalage gives sufficient room to adult intellectual growth and variability within his theory. Specifically, he expected that late adolescents and adults would exhibit formal-operational reasoning within their areas of expertise but not necessarily across all possible domains of knowledge. This view seems consistent with the two-component model of fluid-crystallized or mechanic-pragmatic intelligence in that the potential for adult intellectual growth is linked to factors operating within rather than across domains (Flavell, 1970; Krampe & Baltes, 2003).

Nevertheless, the quest for identifying structural transformations in the organization of thought and action in the course of life span development continues to be of great theoretical appeal (L. B. Smith & Thelen, 2003). To ease the detection of such transformations, if they exist, it seems advisable to increase the density of observations within persons, and to use data-analytic tools as well theoretical approaches that highlight rather than cover the structural dynamics one seeks to identify (e.g., Lindenberger & von Oertzen, in press; Molenaar,

Huizenga, & Nesselroade, 2003; C. S. Nesselroade & Schmidt McCollam, 2000). Empirically, the emergence of automaticity during skill acquisition provides perhaps the best evidence for structural change (e.g., Ackerman & Cianciolo, 2000), albeit of a different kind than envisioned by structuralist life span theoreticians.

Expanding the Concept of Cognitive Pragmatics: Wisdom as Expertise in the Fundamental Pragmatics of Life

Individual differences in intellectual functioning also reflect and influence individual differences in personality and motivation. In the child development literature, a good example is school achievement, which is studied in relation to ability, effort, and other personality characteristics. In life span psychology, such a view becomes conspicuous when attempting to understand expert levels of intellectual performance, for instance, by means of models of expertise (Ericsson & Smith, 1991). Similarly, investment theories of intelligence emphasize that cognition pervades cognitive, motivational, and emotional aspects of behavior (Krampe & Baltes, 2003).

To illustrate the point of viewing intelligence in a larger context of human functioning, we use research on wisdom (see also P. B. Baltes & Kunzmann, 2004; Kunzmann & Baltes, 2003a). Wisdom is close to conceptions of intelligence broadly conceived, as it denotes a high level of performance in the domain of practical and social intelligence. At the same time, wisdom also is a personality characteristic since its acquisition and expression depends on values and motivation. For instance, it is part of wisdom-related knowledge to understand that wisdom is oriented simultaneously toward the well-being of oneself and that of others. This commitment to the common good highlights the constituent role of personality and motivation in wisdom-related thought and behavior. Hence, we see wisdom as an ideal combination of mind and virtue (P. B. Baltes & Kunzmann, 2004; P. B. Baltes & Smith, 1990; P. B. Baltes & Staudinger, 2000). Cognitive, motivational, and emotional attributes need to converge to produce wisdom as the highest form of human excellence in mind and character. Thus, strictly speaking, intelligence is only a part of wisdom, unless one was to expand the concept of intelligence production to cover personality as well (for a further discussion of these issues, see Ardelt, 2004; Aspinwall & Staudinger, 2003; P. B. Baltes & Kunzmann, 2004; Krampe & Baltes, 2003; Sternberg, 2004).

In the Berlin work on wisdom (e.g., P. B. Baltes & Kunzmann, 2004; P. B. Baltes & Smith, 1990; P. B. Baltes & Staudinger, 2000), we treat wisdom as the highest form of knowledge and judgment about human excellence involving the meaning and conduct of life. Specifically, we define wisdom as "an expertise in the fundamental pragmatics of life permitting exceptional insight and judgment involving complex and uncertain matters of the human condition including its developmental and contextual variability, plasticity, and limitations." Operationally, this definition corresponds to a family of five criteria, factual knowledge, procedural knowledge, contextualism, value relativism, and uncertainty. Clearly, advances along these dimensions require the joint operation of cognitive, motivational, and emotional factors.

Thus far, our main methodological strategy in investigating wisdom as an expertise in the fundamental pragmatics of life has been to ask persons to think aloud about difficult life problems such as, "Imagine a 14-year-old girl who wants to leave home and get married, what should one think about this?" The think-aloud responses to such or similar life problems are then evaluated on the five wisdom-related criteria by a trained rater panel. Figure 11.12 displays the results of one of these studies (P. B. Baltes, Staudinger, Maercker, & Smith, 1995). In the figure, an overall wisdom score

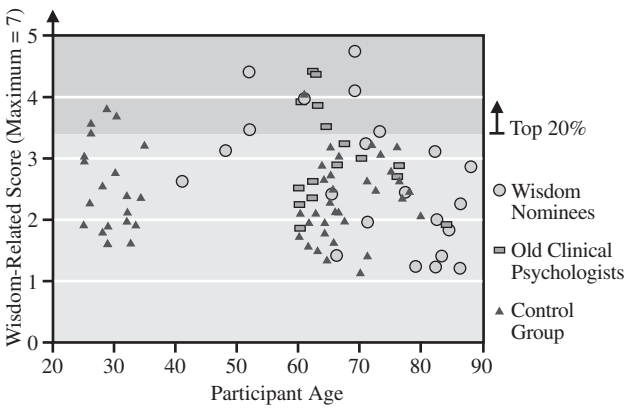

Figure 11.12 Wisdom-related performance of four different groups of individuals averaged across two wisdom-related tasks and five evaluative criteria (factual knowledge, procedural knowledge, contextualism, relativism, and uncertainty). There were no age differences in the age range from 25 to 80 years. In addition, wisdom nominees and clinical psychologists provided significantly more high-level (top 20%) performances than the old control group. Max. = maximum. *Source:* From "People Nominated as Wise: A Comparative Study of Wisdom-Related Knowledge," by P. B. Baltes, U. M. Staudinger, A. Maercker, and J. Smith, 1995, *Psychology and Aging, 10,* pp. 155–166.

based on all five criteria is plotted against age for four different groups: Wisdom nominees (i.e., distinguished individuals nominated as being wise in a two-step Delphi technique), experienced clinical psychologists, and two control groups involving adults with comparable advanced levels of education (young and old).

Two findings are noteworthy. First, there was no indication of a negative age trend in wisdom-related performance when comparing adults of about 25 to 75 years of age. This finding has been replicated in five other studies (Staudinger, 1999a). Second, older persons with wisdom-facilitative experiences (e.g., older clinical psychologists and wisdom nominees) contributed a disproportionately large share to the top responses (see also J. Smith, Staudinger, & Baltes, 1994; Staudinger, Smith, & Baltes, 1992). Both findings stand in clear contrast to the negative age gradients observed for the cognitive mechanics (see Figure 11.10, both panels), thereby providing further support for the two-component model.

The findings also underscore that living long (age) in itself is not a sufficient condition for the development of wisdom (or for any other form of expertise). Rather, as suggested by our working model of wisdom ontogeny (see Figure 11.13), it appears that favorable macrostructural contexts (e.g., historical period), expertise-specific factors (e.g., experience and training in the fundamental pragmatics of life, strive for excellence, mentorship), and general person factors (e.g., fluid mechanics, cognitive style, openness to experience) need to work in coalition to move people toward wisdom (e.g., Staudinger, 1999b). Some of these wisdom-facilitative factors, such as generativity, are age-associated; however, there are also wisdom-debilitating influences, such as rigidity and decrease in the cognitive mechanics, that might come with age. On average, the net result of age-related facilitators and debilitators seems to equal out. Only under favorable conditions, facilitators outweigh debilitators and permit increase of wisdom-related performance with age.

The theoretical framework of our work on wisdom, and its close connection with dimensions of personality and emotionality, has been supported by a variety of findings (P. B. Baltes & Kunzmann, 2004; P. B. Baltes & Staudinger, 2000; Kunzmann & Baltes, 2003b). For instance, in adulthood, personality and cognitive style measures are more important predictors of wisdom-related performance than traditional measures of intelligence (Staudinger, Lopez, & Baltes, 1997; Staudinger,

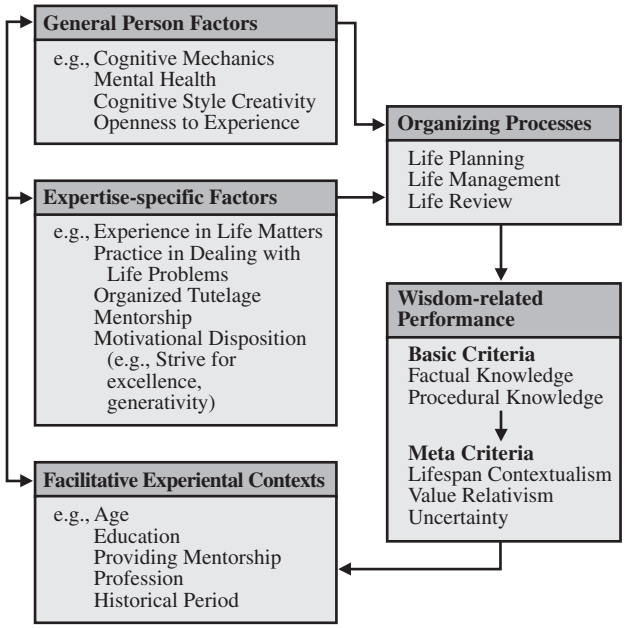

Figure 11.13 A research framework describing antecedent factors and mediating processes for the acquisition and maintenance of wisdom-related knowledge and skills across the life span. The likelihood of attaining expert levels of performance in this prototypical domain of the cognitive pragmatics is assumed to depend on an effective coalition of experiential, expertise-specific, and general person-related factors (modified after Baltes & Smith, 1990; Baltes & Staudinger, 2000). Adapted from "The Psychology of Wisdom and Its Ontogenesis" (pp. 87–120), by P. B. Baltes and J. Smith, 1990, in *Wisdom: Its Nature, Origins, and Development,* R. J. Sternberg (Ed.), New York: Cambridge University Press; and "Wisdom: A Metaheuristic to Orchestrate Mind and Virtue Towards Excellence," by P. B. Baltes and U. M. Staudinger, 2000, *American Psychologist, 55,* pp. 122–136.

Maciel, Smith, & Baltes, 1998). In contrast, intelligence is a more salient predictor in adolescence, when intellectual prerequisites for wisdom-related characteristics such as the abilities to self-reflect and decenter are undergoing rapid developmental advances (Pasupathi, Staudinger, & Baltes, 2001). To embed wisdom into a more holistic context involving personality and the self, we also examined the correlation between wisdom-related knowledge and virtue-related outcomes such as prosocial values and interpersonal conflict-resolution styles (Kunzmann & Baltes, 2003b; see also Sternberg, 1998). People high on wisdom-related knowledge exhibited a more complex and modulated structure of emotions and preferred conflict resolution strategies that are based on dialogue rather than power. Of special interest is that high wisdom-related knowledge correlates nega-

tively with the search for personal enjoyment and material happiness.

In addition to illustrating how the pragmatics of cognition are intertwined with other sectors of human development, our research on wisdom also illustrates how culture and culture-based activities shape development during adulthood. During normal adulthood, the biology of the body and brain is sufficiently developed and ready for investment. It is culture-based learning and development that defines the agenda (see also P. B. Baltes, Freund, & Li, in press; Lachman, 2001). In this sense, work on wisdom serves to highlight the *relative independence of the pragmatics of cognition vis à vis the biology-based mechanics.* Within the normal range of adult mechanic functioning, the mechanics' contribution to individual differences on wisdom-related tasks is small, both in absolute terms and relative to other factors such as personality and task-relevant life experience. The most important contributors to wisdom-related performance during the adult life span tend to be personality characteristics as measured by the Neuroticism Extraversion Openness Questionnaire (NEO) as well as wisdom-relevant professional training and the nature of lifetime experience, rather than psychometrically assessed intelligence or chronological age. In very old age, however, the mechanics of cognition again appear to delimit wisdom-related performance if they fall below a critical threshold of functional integrity (P. B. Baltes et al., 1995).

Varieties of Mechanic/Pragmatic Interdependence

As has become clear by now, the mechanics and pragmatics of life span intellectual development are intertwined in many ways and at various levels of analysis (cf. Charness, in press; Salthouse, 2003), both among each other and with other aspects of behavior. Phylogenetically, they are connected in the sense that members of the human species are biologically predisposed to acquire cultural knowledge (e.g., Plessner, 1965; Wellman, 2003). Ontogenetically, the interdependence also runs both ways. For instance, the potential to acquire and use pragmatic knowledge is conditioned by the development of the mechanics. At the same time, mechanics alone are of little use for problem solving in highly specialized domains of knowledge; in many cases, domain-specific knowledge is critical (Gobet et al., 2001).

In the following discussion, we further elucidate different facets of this interdependence. This approach is in line with the view of biocultural co-construction (P. B. Baltes et al., 2006; S.-C. Li, 2003) mentioned earlier. We then argue, with respect to the overall landscape of life span development, or the ontogenetic dynamics of gains and losses, that the mechanic-pragmatic interdependence converges on the notion of a *compensatory relation between mechanic efficiency and pragmatic knowledge.* As SOC theory suggests, this compensatory relation is reciprocal and part of the entire life course. However, we submit that the role of compensation increases in importance and culminates in old age.

The Mechanic-Pragmatic Interdependence: Evidence at the Cortical Level

An early neurocognitive demonstration for the interdependence between mechanic and pragmatic development concerns the increased cortical representation of the left hand in players of string instruments (Elbert, Pantev, Wienbruch, Rockstroh, & Taub, 1995; for other examples, see Draganski et al., 2004; Petersson & Reis, in press). Compared to normal individuals, areas of the somatosensory cortex representing the fingers of the left hand occupy more space in string players. Most likely, this increase in cortical representation has been induced by large amounts of goal-directed and deliberate practice (cf. Ericsson, Krampe, & Tesch-Römer, 1993). In line with the notion of a bio-culturally co-constructed brain (P. B. Baltes et al., in press; S.-C. Li & Lindenberger, 2002), this research finding illustrates the potential of individuals to acquire and represent pragmatic knowledge.

Elbert et al. (1995) also provided evidence in support of age-graded differences in cortical plasticity. Specifically, the brain's physiological aptness to provide more cortical space for the fingers of the left hand was found to depend on the chronological age at inception of musical practice. As this example illustrates, the ability to acquire pragmatic knowledge (e.g., the potential for developmental change in the pragmatic component) is conditioned by the age-graded status of the mechanics (Güntürkün, in press; Kempermann, in press).

The Age of Peak Performance in Complex Skills

The mechanics of cognition not only condition the acquisition but also the expression of pragmatic knowledge, especially at high levels of performance (Bosman & Charness, 1996; Hambrick & Engle, 2002; Molander & Bäckman, 1993). A good example is the difference in

peak age for tournament versus correspondence chess (Charness, in press). The mean age at which a world championship is first won is about 46 years of age for correspondence chess, but about 30 years of age for tournament chess. In correspondence chess, players are permitted 3 days to deliberate a move; in tournament chess, deliberation averages three minutes per move. Thus, the difference in peak age between the two activities seems to reflect differences in the relative importance of cognitive/perceptual speed and knowledge (e.g., Burns, 2004).

This example points to a general dilemma governing the relation between the mechanics, the pragmatics, and age/time. The acquisition of expertise takes time. For instance, Simon and Chase (1973) argued that 10 years of deliberate practice are needed to reach excellence in a particular domain of functioning. For this reason alone, experts tend to be older than novices (cf. Lehman, 1953). On the other hand, decrements in certain aspects of the mechanics, such as perceptual speed, can be reliably identified by age 30 (S.-C. Li, Lindenberger, et al., 2004; Salthouse, 1991). Therefore, differences in peak age across domains can be seen as ontogenetic compromises between biology and culture, and are probably good indicators of the relative importance of pragmatic knowledge and mechanic processing efficiency.

An exclusive focus on ages of peak productivity or peak achievement would hide essential and unique features of late-life intellectual growth. For instance, some exceptional individuals seem to escape mechanic decline well into the 9th decade of their lives. If these individuals also happen to be experts in a particular domain, they can produce outstanding works throughout their life. One example would be Sophocles (497–406B.C.), who won his first prize for the best drama of the year at age 28, wrote over 120 dramas, and developed a new dramatic style in his 80s. Commenting on his own late-life artistic development, Sophocles said that he finally had liberated himself from the artificiality of his earlier style, and had found a language that was the best and the most ethical (Schadewaldt, 1975, p. 75; for related evidence on classical composers, see Simonton, 1988, 1989).

A Third Prototypical Example: Speed and Knowledge in Aging Typists

A good empirical demonstration of the gain/loss dynamic between the cognitive mechanics and the cognitive pragmatics comes from a study on aging typists using the so-called molar equivalence/molecular decomposition approach (Salthouse, 1984). In this paradigm, adults of different ages are equated in general (e.g., molar) task proficiency to investigate whether equal levels of criterion performance are attained through age-differential profiles of "molecular" component processes (Charness, 1989). Thus, age differences at the molecular level of analysis are seen as a reflection of age-based changes in the relative contribution of knowledge and basic processing efficiency to criterion performance.

Salthouse (1984) studied a total of 74 transcription typists ranging from 19 to 72 years of age. Figure 11.14 displays an interpretation of the main findings of this study in terms of the two-component model. In this sample, age and level of typing skill (i.e., net words per minute) were uncorrelated (e.g., molar equivalence). Age was negatively related to measures of perceptual/motor speed (e.g., tapping speed), but positively related to eye-hand span. In other words, older typists were slower in tapping speed but looked further ahead in the text to be typed. These findings are consistent with the interpretation that aging typists extend their eye-hand span to counteract the consequences of aging losses in perceptual/motor speed, and illustrate the compensatory relationship between knowledge and speed.

To the extent that selective attrition does not play a prominent role, the performance pattern of older typists may, in part, reflect *loss-induced development,* or compensation in the strict sense of the term (P. B. Baltes & Baltes, 1990b; Dixon & Bäckman, 1995; Salthouse, 1995). With respect to methods, this example

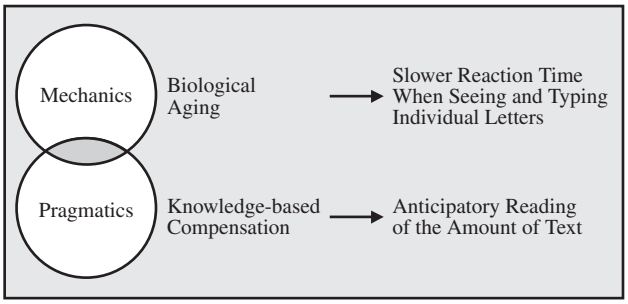

Figure 11.14 Older typists can maintain a high level of functioning by reading farther ahead in the text to be typed, despite a loss in reaction time when typing individual letters. The example illustrates the compensatory relationship between the pragmatics and the mechanics of cognition and suggests that selective optimization with compensation may play an important role in successfully adapting to aging-induced losses in the mechanics of cognition. *Source:* From "Effects of Age and Skill in Typing," by T. A. Salthouse, 1984, *Journal of Experimental Psychology: General, 113,* pp. 345–371.

demonstrates how the combination of expertise and information-processing approaches may lead to a better understanding of the compensatory relation between acquired bodies of cultural knowledge and basic aspects of information processing efficiency (cf. Abraham & Hansson, 1995; Lang et al., 2002).

Malleability (Plasticity) in Intellectual Functioning across Historical and Ontogenetic Time

As is true for development in general, life span changes in intellectual functioning represent the overdetermined antecedents, correlates, and outcomes of a large variety of different sources of influence (e.g., mechanics, pragmatics, motivation, personality, societal opportunity structures). Therefore, differences in level of intellectual performance reflect, within the age-graded boundaries provided by the mechanics, variations in physical and sociocultural aspects of environmental conditions (P. B. Baltes et al., in press; Klix, 1993). In the following, we report two interrelated lines of research in support of this contention. The first line of research addresses environmental change at a large (i.e., historical) time scale. The second example refers to the malleability of adult-intellectual functioning in the context of cognitive intervention studies.

Cohort Effects, Period Effects, and Environmental Change

As expected on the basis of life span contextualism, ontogenetic processes unfold in a constantly changing social and cultural environment. As a consequence, age gradients in intellectual abilities are not fixed but reflect history-graded systems of influence, such as enduring differences between individuals born at different points in historical time (cohort effects), specific influences of historical events across chronological age (period effects), or generalized and enduring shifts in the environment affecting individuals of all ages and subsequent cohorts (general environmental change). For methodological reasons, discriminating among these varieties of environmental change is not easy (P. B. Baltes, 1968; P. B. Baltes et al., 1979; Lövdén, Ghisletta, & Lindenberger, 2004; Magnusson et al., 1991; Schaie, 1965, 1994, 2005).

A first step to discern effects of large-scale environmental change is to compare the performance of same-aged individuals across historical time (i.e., time-lagged comparisons). With some exceptions (e.g., number ability; cf. Schaie, 1989; Schaie et al., 2005), the general picture resulting from such comparisons is that higher test scores are obtained at more recent times (Flynn, 1987; Schaie, 1996). Probably, this historical increase in test scores across historical time is not due to changes in the genetic composition of the population or differential sampling bias, but reflects some general change (i.e., improvement) in health- and education-related conditions. The magnitude of these effects can be quite large. For the U.S. population during the twentieth century, for instance, they sometimes exceeded a standard deviation within a 30-year range of historical change (Schaie, 1996). It should be cautioned, however, that we do not know whether environmental-change effects of the same order of magnitude would be observed with pure indicators of the mechanics of intelligence. For instance, much of the measures used in the battery of the Seattle Longitudinal Study (Schaie, 1996) have a strong cultural-knowledge component, and are more likely to be affected by historical change and dissipation than other, less knowledge-loaded measures of brain efficiency. With respect to the Seattle Longitudinal study (Schaie, 1996), the convergence between cross-sectional and independent-sample same-cohort comparisons suggests that the more positive age gradients found with longitudinal samples may be partly due to practice effects and selective attrition (see also Salthouse, 1991). Analyses of longitudinal data from the Berlin Aging Study (BASE) are fully consistent with both predictions (Lindenberger, Singer, & Baltes, 2002; Lövdén, Ghisletta, & Lindenberger, 2004; T. Singer, Verhaeghen, et al., 2003).

Theoretically, the direction and precise magnitude of historical-change effects is generally of little importance. From a history-of-science point of view, however, such effects, and especially their interpretation as culture-based cohort effects, were instrumental in pointing to the substantial malleability (plasticity) of intellectual performance during all periods of the adult life span (P. B. Baltes, 1973). The resulting growth in awareness for the existence of life span plasticity eventually led to advances in life span theorizing, and to more controlled investigations into the range of intellectual plasticity and its age-based limits (P. B. Baltes & Kliegl, 1992; P. B. Baltes & Lindenberger, 1988; P. B. Baltes & Willis, 1982; T. Singer, Lindenberger, & Baltes, 2003; Willis, 1990). Specifically, multidirectional cohort differences in intellectual trajectories may entice interdisciplinary collaboration with medicine and nutritional sciences, educational neuroscience, and sociology

to understand their proximal antecedents and consequences (Schaie et al., 2005).

Cognitive Intervention Work: Activation of Learning Potential among Older Adults

Intervention work (P. B. Baltes & Willis, 1982; Kramer & Willis, 2002; Willis, 2001) is a more direct (i.e., experimentally controlled) way to explore the degree of plasticity in intellectual functioning than cohort-comparative research. In the field of adult development and aging, intervention studies have been undertaken to examine whether age-based decrements in standard psychometric tests of intellectual functioning are reversible, in full or in part, through training and practice (Willis & Nesselroade, 1990). For the most part, interventions involved older adults only, and focused on tests from the broad fluid domain.

The major results of this cognitive intervention work can be summarized in five points (e.g., P. B. Baltes & Lindenberger, 1988; Kramer & Willis, 2002): (1) Training gains in the practiced tests among healthy older adults are substantial (i.e., they roughly correspond to the amount of naturally occurring longitudinal decline between 60 and 80 years of age); (2) transfer, however, is limited to similar tests of the same ability; (3) training gains are maintained over lengthy periods of time up to several years (Neely & Bäckman, 1993; Willis & Nesselroade, 1990); (4) the factor structure of the ability space is not altered substantially through training (Schaie, Willis, Hertzog, & Schulenberg, 1987); and (5) in persons at risk for Alzheimer's disease or afflicted by other forms of brain pathology, training gains have been found to be restricted to experimental conditions of high external support (Bäckman, Josephsson, Herlitz, Stigsdotter, & Viitanen, 1991) or to be nonexistent (M. M. Baltes et al., 1995; M. M. Baltes, Kühl, & Sowarka, 1992).

These results indicate that the majority of healthy older adults, including those who display the typical pattern of age-related losses in the mechanics of cognition (e.g., fluid abilities) under untrained conditions, are able to greatly improve their performance after a few sessions of task-related training or practice. Thus, among healthy older adults, the mechanics of cognition are sufficiently preserved to permit the acquisition of task-relevant declarative and procedural knowledge. However, there is little evidence to suggest that training gains generalize to related abilities or to everyday functioning. Moreover, the results of testing-the-limits research presented above clearly indicate that the *amount* (scope) of plasticity decreases with advancing age, at least during adulthood. At limits of mechanic functioning, older adults definitely display less potential. To what degree such cognitive training in older adults changes the mechanics themselves is unclear but possible (Kempermann, 2006).

A related line of intervention research has found that aerobic fitness attenuates age-related decrements in cognitive control (e.g., multitasking) in later adulthood (Kramer et al., 1999). This finding can be explained in at least two ways. First, from the perspective of SOC theory, increasing bodily fitness may reduce older adults' needs to continuously invest portions of their cognitive resources into the coordination of their increasingly fallible sensory and motor functions (e.g., Lindenberger et al., 2000). In other words, training the sensamotor function required for bodily functioning "frees" up resources for other cognitive tasks. Second, recent brain-imaging evidence suggests that aerobic fitness has direct beneficial effects on prefrontal cortex functioning (Colcombe et al., 2003), which may enhance performance on cognitive tasks that put high demands on cognitive control. Clearly, the two explanations are not mutually exclusive.

Relative Stability in Intellectual Functioning across the Life Span

The issue of continuity and discontinuity, or stability and change, has a long tradition within developmental psychology at large (Kagan, 1980), and life span intellectual development, in particular (P. B. Baltes & Smith, 2003; Hertzog, 1985; Lövdén & Lindenberger, 2004; McArdle & Epstein, 1987; J. R. Nesselroade, 1991; Schaie, 1965). Different forms of stability, such as stability in level, rank order, and profiles, have been set apart (Caspi & Bem, 1990). The main emphasis of the following life span synopsis of intellectual development is on interindividual rank order, or on what Kagan (1980) has called relative stability, which denotes the extent to which individual differences during later periods of ontogeny can be predicted on the basis of individual differences observed during earlier periods.

In most cases, evidence on the relative stability after infancy is based on undifferentiated measures of general intelligence, or IQ tests. We agree with others that an exclusive focus on these omnibus measures hides essential features of life span intellectual development and

the structure of intelligence (Cattell, 1971; Horn, 1989). Specifically, such measures can be seen as mixtures of mechanic and normative-pragmatic components of intellectual functioning that approximate, to varying degrees, the centroid of the intellectual ability factor space (i.e., Spearman's g). With this qualification in mind, we restrict the following discussion, with one exception (i.e., infant development), to undifferentiated or IQ-like measures of intellectual functioning.

Predicting Childhood Intelligence on the Basis of Infant Behavior

Until the 1950s, it was generally believed that intelligence was an immutable characteristic of the individual, which led to the unchallenged assumption that individuals maintain their rank order on measures of intellectual functioning throughout life. Starting in the 1960s, however, it was found that stability in early mental test performance was low (McCall, 1979). On the basis of this evidence, it was concluded that standardized tests of infant development do not predict later intelligence at useful levels of prediction until after 18 to 24 months of age. This majority view of ontogenetic instability of interindividual differences during infancy was again challenged and ultimately replaced by more recent research using habituation and recognition-memory paradigms. In contrast to standardized infant tests of sensorimotor capacities, these two paradigms were originally based on operant-conditioning and/or information-processing perspectives, and refer to infants' tendency to change their behaviors as a function of prior exposure to a stimulus (e.g., decrements in attention in the case of habituation, or novelty preference in the case of recognition memory). On average, individual differences in habituation and recognition memory performance between 2 and 8 *months* were found to be moderately correlated with standard tests of intelligence such as the Wechsler, Bayley, or Binet administered between 1 and 8 *years* (median correlation, $r = .45$; after attenuation for unreliability, $r = .70$; Bornstein, 1989; McCall & Carriger, 1993; for recent evidence, see F. Smith, Fagan, & Ulvund, 2002). A more recent meta-analysis has confirmed these results (Kavsek, 2004). Behavior-genetic research suggests that individual differences in at least some of the measures used for prediction have a genetic component (Benson, Cherny, Haith, & Fulker, 1993; Cardon & Fulker, 1991).

Both relative change *and* relative stability shape life span intellectual development from its very beginning. According to one interpretation (e.g., Bornstein, 1989), infants who habituate more efficiently, and who tend to look at the novel object, rather than the old, are better able to inhibit action tendencies associated with already existing representations (e.g., Diamond, 2002; McCall, 1994). The hypothesis that inhibition may mediate the predictive link is consistent with neuropsychological investigations of infants' recognition memory (e.g., Diamond, 2002; Johnson, Posner, & Rothbart, 1991). It also supports the more general claim that inhibition ability and novelty preference are central features of intelligence (Berg & Sternberg, 1985a).

Relative Interindividual Stability after Infancy

For reasons that are not yet well understood (Cardon & Fulker, 1991; McCall & Carriger, 1993), the magnitude of the correlation between infant measures of habituation (i.e., 2 to 8 months) and childhood measures of intelligence (i.e., 1 to 12 years) is temporally stable or even increasing (Cardon & Fulker, 1991), rather than decreasing over time. In contrast, relative stability after infancy is rather well described on the basis of quasi-simplex assumptions (Humphreys & Davey, 1988; Molenaar, Boomsma, & Dolan, 1991). Thus, adjacent time points in ontogeny tend to be more highly correlated than more distant time points In addition, stability coefficients computed over identical lapses of time show a considerable increase in magnitude from childhood to adolescence into middle adulthood and early old age (Hertzog & Schaie, 1986, 1988; Humphreys & Davey, 1988; for review, see Lövdén & Lindenberger, 2004).

In agreement with others (e.g., Humphreys & Davey, 1988; Molenaar, Boomsma, & Dolan, 1993), we propose that these *age-based changes in relative interindividual stability should be interpreted in connection with age-based changes in level* (e.g., Lövdén & Lindenberger, 2004). According to this line of reasoning, interindividual differences change more rapidly early in development because the intellectual repertoire is smaller but growing faster than at later points during ontogeny, thereby giving room for larger amounts of new variance per unit time (both environmental and genetic). By the same token, aging-induced losses and age-associated pathologies (e.g., Alzheimer's disease) may not only lead to decrements in level but also to a reshuffling of individual differences in very old age (Mitrushina & Satz, 1991; cf. P. B. Baltes & Smith, 2004).

Changes in Heritability across the Life Span

We now turn to the study of age-based changes in the contribution of genetic and environmental sources of interindividual variability to individual differences in intelligence. We start with a consideration of general and ability-specific effects, and then turn our attention to life span changes in heritability estimates for general (i.e., undifferentiated) measures of intelligence across the life span.

A Note on the Nature of Behavior-Genetic Evidence

Before we summarize the relevant evidence, we will sketch out our views on the meaning, strength, and limitations of the behavior-genetics approach (P. B. Baltes et al., 1988). Given the critical debates surrounding the interpretation of behavior-genetic data (e.g., Bronfenbrenner & Ceci, 1994; Gottlieb et al., Chapter 5, this *Handbook,* this volume; R. M. Lerner, 1995; Molenaar et al., 2003; Scarr, 1993), such a note may help to avoid possible misunderstandings. We restrict our comment to three points that are relevant both for the following section on intellectual functioning as well as on personality and the self. More detailed treatment is provided in P. B. Baltes et al. (1998).

First, heritability coefficients in human research (where selective inbreeding and exposure to extreme environments is limited) are statements about the scope of interindividual differences more so than statements about the processes and mechanisms of genetic expression at the individual and intraindividual level of analysis. In other words, population-based behavior genetics provides clues about the existence of genetically based variation in a given population but does not provide direct evidence about gene locations or epigenetic events producing this variation (for emerging links between behavior and molecular genetics, for example, Dick & Rose, 2002; de Geus & Boomsma, 2002).

Second, standard behavior-genetic models do not provide the best test of the overall role of environmental forces. The power of such forces is better tested by studies that examine the role of the impact of environmental factors across the population and across interindividual differences in genetic make-up. Specifically, high heritability estimates do not preclude the existence of environmental factors that alter performance levels in all individuals of a given sample (for an experimental demonstration, see Fox, Hershberger, & Bouchard, 1996).

Third, heritability estimates are fixed-level statistics (P. B. Baltes et al., 1988; Plomin & Thompson, 1988), indicating what consequences (phenotypic expressions) are produced under a given and specific set of interindividual differences in genetic and environmental conditions. Strong evidence demonstrating the environmental malleability of heritability estimates comes from data on 7-year-old twins participating in the National Collaborative Perinatal Project (Turkheimer, Haley, Waldron, D'Onofrio, & Gottesman, 2003). A substantial proportion of the twins in this sample were raised in families living near or below the poverty level. The authors found that the proportions of IQ variance attributable to genes and environment varied nonlinearly with socioeconomic status. In impoverished families, the shared environment accounted for 60% of the variance in IQ, and the contribution of genes was close to zero. In affluent families, the result was almost exactly the reverse. Apparently, factors associated with low socioeconomic status such as deprivation from developmental opportunity structures hindered the behavioral expression of genetically based interindividual differences in intellectual functioning.

Despite these qualifications, behavior-genetic evidence provides important information about sources of interindividual differences in life span development, especially if linked to molecular research on specific genetic polymorphisms (Goldberg & Weinberger, 2004), to intermediate phenotypes at the level of brain organization (e.g., Anokhin et al., in press), or both. Such findings, especially if based on longitudinal (e.g., Finkel, Pedersen, McClearn, Plomin, & Berg, 1996), experimental (e.g., Fox et al., 1996), and cross-cultural (e.g., Turkheimer et al., 2003) data, provide *estimates* of the degree to which, on a population level of analysis, *interindividual differences in developmental outcomes* are co-determined by interindividual differences in genetic predispositions and extant environmental variations. Thus, everything else being equal, high heritability estimates of a given behavioral outcome suggest that *interindividual differences* in this behavioral outcome and in this "life space" are strongly genetically determined than *interindividual differences* in behavioral outcomes with low heritability estimates.

Genetic and Environmental Influence over Ontogenetic Time: Specific and General Effects

Numerous studies have shown that genetic and environmental influences can be operative in the regulation of individual differences at both ability-specific and more

general levels (e.g., Cardon & Fulker, 1994). In longitudinal analyses of hierarchically organized intellectual abilities obtained from genetically informative data sets, it is possible to determine the genetic and environmental contributions to stability and change in rank order and mean level both at the level of specific abilities and at the level of a general factor (e.g., Cardon & Fulker, 1994). An interesting example for the class of findings that can be obtained with this method comes from child cognitive development. Specifically, data from the Colorado Adoption Project indicate that strong novel contributions of genetic variance at the level of general ability emerge at the ages of three and seven but seem to be absent during the transition from childhood to adolescence, when genetic variance contributes exclusively to continuity of individual differences.

Estimates of Heritability of Interindividual Differences across the Life Span

Similar to life span changes in stability, heritability in intellectual functioning (e.g., the amount of interindividual variance attributable to genetic differences) increases from about 20% to 50% during childhood and adolescence to about 80% in early and middle adulthood (e.g., McGue, Bouchard, Iacono, & Lykken, 1993). Interestingly, in old age (e.g., beyond age 75), heritability tends to decrease to values around 60% (e.g., McClearn et al., 1997). In contrast, shared environmental influences on interindividual differences generally do not persist beyond the period of common rearing (McGue, Bouchard, et al., 1993). As stated before, these findings are based on samples representing the normal range of environments and genes, and cannot be generalized beyond this normal range (e.g., to extremes of environmental deprivation or reshuffled environments). Within this normal range, however, the life span increase in heritability of interindividual differences is consistent with the notion that adolescents and adults have more of a chance to actively select environments that match their genes than infants and children (Scarr & McCartney, 1983).

Based on the preceding summaries, it appears that relative stability and heritability exhibit similar life span age gradients (see Plomin & Thompson, 1988). More multivariate and longitudinal behavior-genetic evidence is needed to fully understand the covariance dynamics of this life span parallelism. One possibility would be that individual differences in intellectual functioning around middle adulthood are highly stable because the genetic variance component has stabilized at a high level (e.g., not much new genetic variance is added over time), and because environments (which, in part, have been selected on the basis of genetic endowment) also tend to be stable during this period of the life span. Similarly, the breakdown of well-orchestrated genome expression in very old age may cause late-life decrements in level, relative stability, and heritability. Note, however, that selective mortality may counteract the identification of these trends at the population level in very old age (T. Singer, Verhaeghen, et al., 2003).

The Mechanics and Pragmatics in Very Old Age

So far, our discussion of life span intellectual development was organized around topics, rather than age periods. In this last section, we deviate from this practice by giving special attention to the life period of very old age. In our view, this last phase of life merits such attention because it represents a natural boundary condition for the validity of the two-component model of intelligence and cognition. Specifically, we expect that an increasing portion of the very old population eventually attains levels of mechanic functioning that are sufficiently low to impair intellectual functioning in a relatively global manner. A number of recent empirical cross-sectional and longitudinal observations from the BASE (P. B. Baltes & Mayer, 1999; P. B. Baltes, Mayer, Helmchen, & Steinhagen-Thiessen, 1993) support and qualify this prediction (for a detailed summary, see Lövdén et al., 2004). Three results from this very old sample are most pertinent to the two-component model (P. B. Baltes & Lindenberger, 1997; Lindenberger & Baltes, 1995a).

Covariance Dedifferentiation

First, ability intercorrelations both between and within fluid-mechanic and normative-pragmatic domains were of much higher magnitude in old age than corresponding ability intercorrelations during middle and early adulthood. Based on these data, the amount of covariation among interindividual differences in intellectual abilities, or the prominence of *g,* seems to increase in very old age (P. B. Baltes & Lindenberger, 1997). The idea that *g* may vary as a function of age and/or ability level dates back to Spearman (Deary & Pagliari, 1991), and has led to the differentiation/dedifferentiation hypothesis of life span intelligence (Garrett, 1946; Lienert &

Crott, 1964; Reinert, 1970). Despite methodological difficulties in testing this hypothesis (J. R. Nesselroade & Thompson, 1995), the evidence obtained so far seems generally supportive (for a summary, see Lövdén & Lindenberger, 2004). For instance, Li, Lindenberger, et al. (2004) performed life span-comparative exploratory principal component analyses of fifteen intellectual ability tests. The results of these analyses are shown in the lower panel of Figure 11.10. In childhood, late adulthood, and old age, only two components with eigenvalues greater one were extracted, but in adolescence, young, and middle adulthood, five components displayed eigenvalues greater than unity. Also, fluid and crystallized intelligence were more highly correlated in childhood, late adulthood, and old age than in adolescence, young, and middle adulthood.

From the perspective of the two-component model of cognitive development, the decrease of ability intercorrelations during childhood and the increase of intercorrelations in very old age point to age-based changes (i.e., decrements and increments) in the importance of domain-general processing constraints. Cross-sectional data from the BASE (P. B. Baltes & Lindenberger, 1997; Lindenberger & Baltes, 1994) suggest that old-age dedifferentiation transcends the cognitive domain, and also affects sensory functioning (e.g., Ghisletta & Lindenberger, 2005) and sensorimotor functioning (e.g., balance/gait). In line with these correlational findings, recent neurocognitive evidence demonstrates that processing pathways and brain activation patterns are less differentiated in older adults than in young adults (Cabeza et al., 2004; Park et al., 2004).

Directionality Dedifferentiation

The second finding from the BASE concerns the directionality of the age gradients (Lindenberger & Baltes, 1997). In very old age, differences in the directionality of cross-sectional age gradients between mechanic and normative-pragmatic abilities are on the wane. Instead, gradations of negativity have been observed, with perceptual speed showing the strongest and verbal knowledge the weakest negative age relations.

These cross-sectional observations have been corroborated and qualified by longitudinal evidence (T. Singer, Verhaeghen, et al., 2003). Using latent growth curve modeling (see McArdle, Hamagami, Ellias, & Robbins, 1991), T. Singer, Verhaeghen, et al. (2003) compared cross-sectional and longitudinal age gradients under three different data selection conditions: (1) the cross-sectional/longitudinal convergence age gradients for the T4 longitudinal sample ($n = 132$) using all available data points (i.e., T1, T3, and T4 data); these gradients combine cross-sectional and longitudinal information over chronological age (hence convergence); (2) the cross-sectional T1 gradient of the T4 longitudinal sample (i.e., the same sample as before; $n = 132$); here, the T1 cross-sectional age gradient was examined for individuals who survived and participated up to T4; and (3) the cross-sectional T1 gradient of the original T1 sample ($n = 516$). The three age gradients are shown in Figure 11.15.

With respect to both fluid mechanics and crystallized pragmatics, age-associated decrements in cognition were less pronounced for the longitudinal sample at T1 than for the full cross-sectional sample at T1. Specifically, negative gradients prevailed for all four abilities in the full T1 sample but verbal knowledge did not decline significantly in the longitudinal sample. This pattern of age gradients suggests that decline in the fluid mechanics is normative and age-based, whereas decline in verbal knowledge appears to be partially or primarily associated with closeness to death. The third class of age gradients, the longitudinal convergence gradients for the T4 sample, reinforces this impression.

Maintenance of Divergence in Explanatory Correlational Patterns

Given the two preceding findings, one may begin to wonder whether the distinction between the mechanics and the pragmatics of cognition loses all of its empirical foundation in very old age. Figure 11.16 that compares the correlational patterns of perceptual speed, a fluid-mechanic ability, and verbal knowledge, a normative-pragmatic marker, with variables related to individual differences in sociostructural-biographical or biological status suggests that this is not the case.

Without exception, correlations to indicators of biological functioning were more pronounced for perceptual speed (e.g., the mechanics) than for verbal knowledge (e.g., the pragmatics). The reverse was also true: Correlations to sociostructural-biographical markers were more pronounced for verbal knowledge than for perceptual speed. Apparently, then, the mechanic-pragmatic distinction does not dissolve completely in very old age, but is maintained in the guise of divergent relations to biological and cultural systems of influence.

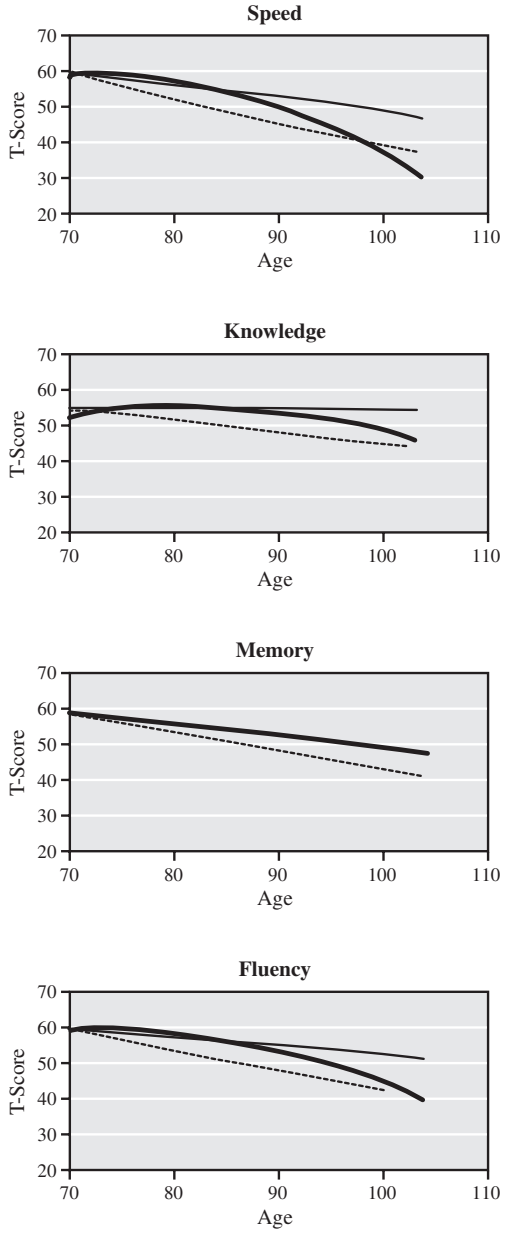

Figure 11.15 Intellectual ability age gradients observed in the Berlin Aging Study as a function of sample and measurement occasion. Thick solid lines represent cross-sectional/longitudinal convergence gradients of the longitudinal sample ($n = 132$), and encompass measurements from T1, T3, and T4, which encompass an average longitudinal observation period of 6 years. Thin solid lines represent cross-sectional gradients of the same longitudinal sample ($n = 132$), and are based on measurements taken at T1. Finally, dashed lines represent cross-sectional gradients for the total T1 sample ($n = 516$). *Source:* From "The Fate of Cognition in Very Old Age: Six-Year Longitudinal Findings in the Berlin Aging Study," by T. Singer, P. Verhaeghen, P. Ghisletta, U. Lindenberger, and P. B. Baltes, 2003, *Psychology and Aging, 18,* pp. 318–331. Copyright © 2003 by the American Psychological Association. Adapted with permission.

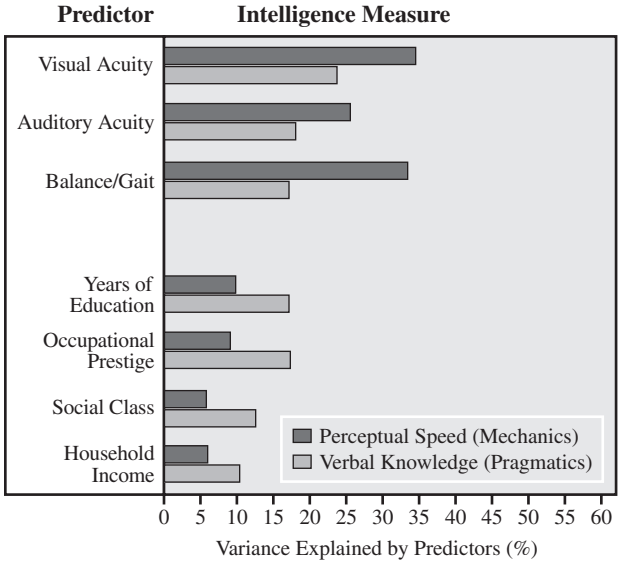

Figure 11.16 The divergent validity of the two-component model of life span intellectual development continues into very old age. The figure displays differential correlational links of perceptual speed, a marker of the fluid mechanics, and verbal knowledge, a marker of the crystallized pragmatics, to indicators of sociostructural-biographical and biological (e.g., sensory) status. Perceptual speed was more highly correlated with biological indicators than verbal knowledge, and verbal knowledge was more highly correlated with sociostructural-biographical indicators than perceptual speed. Thus, despite a general tendency toward dedifferentiation due to age-based losses in the mechanics, the two components of life span cognition continue to show signs of divergent external validity. Data are taken from the Berlin Aging Study ($N = 516$, *age range* = 70–103 years). *Source:* From "The Fate of Congition in Very Old Age: Six-Year Longitudinal Findings in the Berlin Aging Study," by T. Singer, P. Verhaeghen, P. Ghisletta, U. Lindenberger, and P. B. Baltes, 2003, *Psychology and Aging, 18,* pp. 318–331.

LIFE SPAN INTELLECTUAL DEVELOPMENT: CONCLUSIONS

Based on the foregoing (admittedly selective) review of research and theory, we would like to propose the following synopsis of the overall ontogenetic landscape of life span intellectual development.

1. To capture the life span dynamics and biocultural co-construction between biology and culture in the domains of intelligence and cognition (P. B. Baltes, 1987, 1997; P. B. Baltes et al., 1998), we contrasted the mechanics with the pragmatics, and propose a two-component model of intellectual development. This model is inspired by the psychometric theory of fluid and

crystallized intelligence (Cattell, 1971; Horn, 1970, 1989; cf. Tetens, 1777) but calls for a wider range of conceptualization, including evolutionary-psychological, cognitive-experimental, expertise, and neuroscience approaches, to arrive at more valid and comprehensive representations of life span intellectual development. The two-component model accurately predicts a relatively late life span peak followed by maintenance for the knowledge-saturated cognitive pragmatics, and a much earlier life span peak followed by monotonic decline for the cognitive mechanics. It also accurately predicts differential ontogenetic sources of explanation.

2. In terms of mechanisms, age-related changes in information processing rate, working memory capacity, and the inhibition of irrelevant information are among the most prominent candidates for the explanation of life span changes in the mechanics of cognition. At present, these constructs tend to suffer from a lack of formalization, a lack of direct evidence at the physiological level, and from difficulties in making differential predictions. Closer links to the cognitive neurosciences, in particular to chemical, anatomical, and functional life span changes in prefrontal functions, are expected to foster further progress in this area of research.

3. Extant measures of mechanic functioning tend to be contaminated by pragmatic influences. To arrive at more accurate descriptions of life span gradients in the mechanics of cognition, and to move toward explanation in terms of critical components and mechanisms, measurement needs to be purified through the utilization of methods that are better able to assess individuals' upper limits of functioning. As predicted by theory, the use of such methods (e.g., testing-the-limits) results in cleaner separations of individuals from different ages than the use of standard measures (see Figure 11.9).

4. In contrast to the mechanics, the knowledge- and culture-based pragmatics of cognition offer the potential for positive change during adulthood and old age. Within the pragmatic domain, we proposed the distinction between normative and person-specific bodies of knowledge. Normative bodies of knowledge are acquired in the context of general socialization events, such as basic cultural skills and educational curricula, and in general are well amenable to psychometric testing (e.g., vocabulary tests, aptitude tests). Person-specific knowledge refers to specialized knowledge systems that branch off from the normative (average) path, with professional expertise being the most prominent example studied so far. Our suggestion is, and this is based on SOC theory, that highest levels of pragmatic skills in the last third of life carry a strong individualized component.

5. The acquisition of expert levels of knowledge during adulthood may lead to an increasing fragmentation of the intellectual system, but it also may offer the opportunity for acquiring bodies of knowledge with a wide range of applicability, generality, and integration. Wisdom-related knowledge, or knowledge about the meaning and conduct of life, is a prototype. The likelihood of acquiring such domain-general bodies of person-specific knowledge depends on a special coalition of experiential, expertise-specific, and person-related factors (Krampe & Baltes, 2003; Sternberg, 1985).

6. Throughout ontogeny, the pragmatics and mechanics of cognition are intertwined. In everyday life, intellectual functioning and intellectual products represent joint effects of both. For instance, the emergence of domains of pragmatic knowledge builds on, and presumably extends and modifies, evolutionarily predisposed core domains. The mechanisms of this pruning of cultural knowledge onto species-specific architecture await further study. Another example of pragmatic/mechanic interdependence concerns the acquisition and use of pragmatic knowledge to compensate for mechanic decline. In close agreement with our general conception of the overall landscape of life span development, this compensatory function of the pragmatics increases in importance but loses in efficiency with advancing age.

7. The study of plasticity (malleability) of intellectual functioning has been a cornerstone of life span research (P. B. Baltes, 1987). Within the limits provided by the mechanics, which remain to be fully explored, intellectual performance is malleable throughout life. Evidence in support of this contention comes both from the study of long-term environmental change and from cognitive intervention studies. With some exceptions (e.g., dementia of the Alzheimer type), there is room for sizeable plasticity at all ages and for all individuals. However, plasticity decreases with advancing age, reflecting losses in the mechanics of cognition. The resulting bounded openness of life span intellectual development is consistent with the biocultural contextualist framework of life span psychology.

8. The joint consideration of different strands of research reveals a striking congruence between three different life span trajectories: Heritability of interindividual differences, relative stability, and level changes

in the normative pragmatics (e.g., crystallized intelligence). In all three cases, there is an increase from childhood to middle and late adulthood, coupled with indications of decline in very old age. This life span parallelism between the genetic component of interindividual differences, continuity of interindividual differences, and general knowledge is consistent with the notion of gene-environment correlations in behavioral genetics (Scarr & McCartney, 1983), and the notion of niche picking in ethology (Dawkins, 1982). Whether one likes it or not, this parallelism testifies to the existence of a powerful life span synergism between sociostructural and genetic interindividual differentiation, at least within the range of developmental conditions offered by Western industrialized societies.

SECOND LEVEL 5 EXAMPLE: THE STUDY OF PERSONALITY DEVELOPMENT ACROSS THE LIFE SPAN

In the following, we illustrate what life span theory has to offer in organizing and stimulating the study of personality development. To do so, we first introduce three approaches that in our view need to be taken into account when studying personality development: (1) a trait approach, (2) a self-system approach, and (3) a self-regulation approach.[1] These three approaches are usually treated in different literatures, and cross-links are still rare, especially with regard to life span development. In the following, we consider all three approaches whenever using the term personality or personality system.

The levels-of-analysis approach introduced in the beginning of the chapter is used as an integrating framework for presenting research from the three approaches. Thus, theory and evidence available on personality development across the life span are used to illustrate the biology-culture interface and the notion of differential allocation of resources. Furthermore, three of the life span propositions introduced earlier that bear special relevance for personality development across the life span are discussed in more detail. These three issues are stability and change in personality development across the life span, opportunities and constraints of personality development, and the adaptive potential or reserve capacity of personality.

Three Approaches to the Study of Personality Development

Research and theory building in the study of personality have been quite diverse (e.g., Pervin & John, 1999). Yet, three longstanding and overarching concerns can be identified, that is, structure/content, dynamics, and development of personality (Funder, 2001). Historically, these three concerns have been linked with the three approaches to the study of personality mentioned earlier (Staudinger, in press).

Under the *trait approach* to the study of personality, we subsume efforts to characterize individuals in terms of fundamental attributes and behavioral dispositions, a line of research that originated primarily in the psychometric tradition. Research in this area focuses on the identification of the structure of personality, on interindividual differences, and the extent of longitudinal stability (e.g., Costa & McCrae, 1994; Goldberg, 1993). The emergence, maintenance, and transformation of personality structure, and the conditions of constancy and change in interindividual differences clearly are of importance for a life span perspective on personality (Brim & Kagan, 1980). In addition, however, a life span perspective is aimed at discerning the degree to which these personality attributes and behavioral dispositions evince intraindividual change trajectories and intraindividual plasticity (malleability). Such questions are pursued in the exemplary research programs involving scholars such as Block (e.g., 1995), Helson (e.g., Helson & Kwan, 2000), or John Nesselroade (e.g., 2002).

Content and structure have also been of great interest in a *self-system approach* to the study of personality. But the self-system approach has also been very much interested in understanding the dynamics of personality (Markus & Wurf, 1987). Under the heading of the *self-system approach,* we subsume lines of work that characterize individuals as multifaceted dynamic structures of a relatively stable array of self-conceptions (e.g., Baumeister, 1992; Greenwald & Pratkanis, 1984;

[1] Note that selecting "personality" as the overarching term does not entail that we attribute greater importance to the trait approach. In the 1998 edition of the chapter, we had chosen "self and personality" as a label. This, however, seems impractical and is diverting from the goal to integrate the three approaches. Therefore, we would like to suggest using "personality" or "personality system" as the overarching term to denote the field of study comprising all three approaches. This is also in line with early personality theorists such as Allport or Murray who certainly did not link their usage of the term personality exclusively to the trait approach.

Markus & Wurf, 1987). Self-conceptions are not meant to encompass any self-referent attitude but rather are confined to those beliefs or cognitions that constitute important (fundamental) self-components. Whenever the social meaning of such self-referent attitudes is in the foreground, the notion of "identity" rather than self-concept is used (e.g., Waterman & Archer, 1990). Different situations or contexts activate different subsets of this composite structure of self-conceptions or self-schemata. Markus and Wurf (1987) have called this the working self-concept. This view of the self-system as both stable and dynamic fits life span conceptions that emphasize the potential for continuity as well as change as a characteristic feature of transactional adaptation during development.

In contrast to the trait approach to personality that aims at inferring behavioral dispositions "from the outside," research on self-conceptions is often (but not necessarily) related to what J. L. Singer (1984) has called the study of private experience or private personality, and Ryff (1984) has labeled as the study of personality "from the inside." Operationally, however, at least most of the adult research of both traditions, that is, the trait and the self-system approach, rely on self-report. Besides the classics such as Erikson (e.g., 1959) or Bühler (e.g., 1933), research programs around scholars such as Loevinger (e.g., 1976), D. J. Levinson (e.g., 1986), Ryff (e.g., 1991), Whitbourne (e.g., 1987), Dittmann-Kohli (e.g., Dittmann-Kohli, Bode, & Westerhof, 2001), Diehl (e.g., Diehl, Hastings, & Stanton, 2001), and Herzog and Markus (1999) focus on the life span development of the self-concept and of its adaptive qualities.

Focusing on personality dynamics or the processes underlying microgenetic personality change is yet a third approach, the study of self-regulatory processes (Carver & Scheier, 1998). Under the heading of *self-regulatory processes,* we subsume all efforts that are aimed at characterizing the organized abilities and skills a person brings to bear on monitoring behavior and experience. With regard to life span development, it is the regulatory behaviors of promoting growth as well as those of reaching, maintaining, and regaining psychological equilibrium including in a context of age-related loss—in particular one's sense of coherence, continuity, and purpose under conditions of microgenetic and ontogenetic change—that are of particular interest.

A host of constructs discussed in the literature can be subsumed under this heading, such as self-evaluative processes, goal-related processes, coping, control beliefs and self-efficacy, or emotion-regulation. The focus of such research is on investigating the self-related adaptive potential and the reserve capacities as well as their limits in the course of life span development. Because this field encompasses many different constructs, the group of scholars engaging in this type of endeavor is quite large and still growing. Thus, we can only mention a few laboratories in order to illustrate the type of work we include under the heading of self-regulatory processes from a life span perspective, such as the ones instigated by Brandtstädter (e.g., 1998; Brandtstädter & Rothermund, 2003; Greve & Wentura, 2003), Cantor (e.g., Cantor & Fleeson, 1994), Carstensen (e.g., Carstensen et al., 1999), Filipp (e.g., 1996), Labouvie-Vief, (e.g., Labouvie-Vief et al., 2003), Lachman (e.g., Lachman & Weaver, 1998), and Blanchard-Fields (e.g., 1996). Other examples are the theory of selective optimization with compensation (e.g., P. B. Baltes & Baltes, 1990a; Freund & Baltes, 2002b) and the related endeavor by Heckhausen and Schulz (1995) to construct a life span theory of self-based developmental control.

A number of recent efforts have been made to integrate these rather disconnected fields of research (e.g., Cloninger, 2003; Hooker, 2002; McAdams, 1996; McCrae et al., 2000). The life span focus in these integrative efforts clearly is on relating structure, content and process-related dynamics such that both stability and change characterize personality development during adulthood (e.g., Roberts & Caspi, 2003; Staudinger & Pasupathi, 2000). In the following section, we not only present relevant information, but also attempt to integrate the three approaches to the study of personality within a life span perspective. As we attempt this integration, a necessary by-product is that we may occasionally transform the foci that were at the core of the work of the original proponents.

Key Features of a Life Span Approach to the Study of Personality Development

We define personality to denote *the ways in which human beings behave/act, experience, believe, and feel with regard to themselves, others, and the material world.* With regard to the sources and outcomes of human development, personality has *multiple causes and functions* (cf. principles of multicausality and multifunctionality). First, personality develops, that is, it is the outcome of developmental processes. Different pathways can lead to similar if not the same outcome. Second, personality also operates as an antecedent for

developmental processes and co-regulates outcomes. And finally, personality is the correlate of other developmental processes.

Taking a life span view implies (a) that we are concerned with the *commonalities* across individuals in how personality develops. This is reflected in developmental models like the one presented by Erikson (e.g., 1959) but also in theories about the driving forces and the mechanisms of personality development (e.g., Bandura, 1984; R. W. White, 1959). At the same time, as life span developmentalists we are interested in (b) the *interindividual differences* in personality development. For instance, do developmental trajectories become less and less similar as transactions between a given personality make-up and particular environmental conditions accumulate across the life span? Finally, we want to learn about (c) the *intraindividual variability or plasticity* in the ways an individual behaves/acts, experiences, believes, and feels about him/herself, others, and the material world. Is it possible, for example, that an extraverted person under certain circumstances behaves more like an introvert? In extreme cases this plasticity can also result in system lability and lack of coherence. Do these plasticity-related phenomena increase or decrease with age, or do they remain unchanged?

These three questions of commonalities, interindividual differences, and of intraindividual variability (plasticity) can be pursued within a *structural* and a *process-oriented* approach to the study of personality and its development. Under the heading of form or structure, it is primarily the classic personality dispositions and the self-conceptions, schemata, or images that are considered. Under the heading of process research, self-regulatory mechanisms are most prominent. At least five categories can be distinguished within that category: emotion regulation, control beliefs, coping, self-evaluation, and the goal system (goal seeking, goal pursuit, goal restructuring).

Finally, all three facets of structure, process, and function can be approached from a *componential* (multivariate) and a *holistic* (ipsative) view. The componential approach is illustrated by evidence on the Big Five personality factors (e.g., Costa & McCrae, 1994; Goldberg, 1993). Block's ipsative approach to personality assessment (e.g., Block, 1995) is an inspiring example of the holistic approach as is the conceptual and empirical work by Magnusson (e.g., Magnusson & Mahoney, 2003). Taking a typological approach to the study of personality development, for instance, by using cluster analysis can also be subsumed under that rubric (e.g., P. B. Baltes & Smith, 2003). Like Magnusson, John Nesselroade, and others, we suggest that life span work on personality development profits from integrating a componential and a holistic approach.

The Search for General-Purpose Mechanisms in the Area of Personality Development

Throughout this chapter, we have emphasized the significance in life span work of the search for the conditions of successful (adaptive) development. From the field of cognitive psychology, we have taken the idea of general-purpose mechanisms. Thus, we ask whether in the field of personality as well it is possible to articulate *general-purpose mechanisms*. With general-purpose mechanisms, we mean (internal and external) resources and capacities that individuals employ to master developmental challenges in a variety of contexts and at different stages of developmental time. General-purpose mechanisms in the field of personality might help the individual to organize and coordinate the ways in which he or she behaves, experiences, believes, and feels with regard to him/herself, others, and the material world such that the goal of maximizing gains and of minimizing losses is approached. In our own work, the theory of selective optimization with compensation (e.g., P. B. Baltes, 1997) is one such general-purpose mechanism; located at a high level of aggregation.

There seems to be a foundation of research on which to build when exploring the notion of general-purpose mechanisms. Empirical evidence, especially when focusing on longitudinal studies that search for predictors of adaptive developmental outcomes, has identified a number of candidate concepts. Impulse control or ego control, perceived control, delay of gratification and ego resilience/flexibility, for instance, suggest to us that they might possess the characteristics of such general-purpose mechanisms in the personality domain (e.g., Bandura, 1993; Block, 1993; Caspi, 1998; Masten, 2001; Mischel, Shoda, & Rodriguez, 1989; Rutter & Rutter, 1993; E. E. Werner, 1995). As is true in cognitive psychology, such general-purpose mechanisms will not function by themselves. Rather, they are part of a system of personality characteristics and self-regulatory mechanisms that are functional or adaptive only under specific circumstances.

One reason why we chose to explore the power of the notion of general-purpose mechanisms is the relative openness of human development (Maciel, Heckhausen, & Baltes, 1994). From a life span point of view, there is no single endpoint of development of any facet of self and personality. The challenge is to coordinate resources under varying conditions. Thus,

there seems to be theoretical and empirical grounds for the assumption that personality functioning is efficacious if (a) many different ways of being are available (e.g., being internally as well as externally controlled, being optimistic as well as pessimistic, being introverted as well as extraverted) and if (b) adaptive algorithms that monitor the dialectic between such supposedly antagonistic states are accessible (e.g., Blanchard-Fields & Norris, 1994; Colvin & Block, 1994; Staudinger, 1999b). By means of such algorithms the most functional personality characteristic for a given time, place, and circumstance is exhibited. This restates in different terms what has been characterized as a wise person (e.g., Staudinger, 1999a; Sternberg, 1998). The approach is also similar to the notion of fluid intelligence in the domain of intellectual functioning (see previous discussion). It is a special characteristic of that category of the intellect that in the sense of a general-purpose mechanism it can be applied to (invested into) a large variety of cognition problems (Cattell, 1971).

The Executive Function of Personality

Life span theory further suggests a *systemic view* on psychological phenomena. This systemic view has at least two consequences for the way we think about personality (Staudinger, 1999b). First, we believe that the different components of personality, introduced earlier, *together* form the personality system. Dynamic systems theory postulates that, by means of recursive interactions, such components form the basis of self-organization as well as the emergence and stabilization of new forms (e.g., Ford & Lerner, 1992; Thelen & Smith, 1998). Second, the systemic view directs our attention also to the cross-linkages between personality and other subsystems of the developing individual, such as physiological and cognitive functioning (e.g., Mischel, 2004; Pervin, 2001). As mentioned already, it seems that personality has something like an *orchestrating or executive function* with regard to these other systems and the developmental changes occurring in these systems (e.g., Erikson, 1959; Waterman & Archer, 1990). Besides the (dynamics) systems approach to the study of personality, the psychology of action has been suggested as a unifying framework for the microgenetic study of the interplay of cognition, emotion, and motivation (Gollwitzer & Bargh, 1996). The extension of action psychology to issues of life span development has begun to be explored (e.g., Brandtstädter, 1998; Brandtstädter & Rothermund, 2003). There is first evidence accruing that the developmental model of selective optimization with compensation, introduced previously, also holds promise in this respect (e.g., Freund & Baltes, 2002b).

Third, and finally, personality develops to serve a self-reflective function. Personality reflects and evaluates developmental changes in the other subsystems and tries to integrate them. This integrative and adaptive function of personality is also mirrored in the fact that subjective measures of adaptation such as subjective well-being or happiness are even used as measures of self (e.g., Bengtson, Reedy, & Gordon, 1985). Self-reflection is pivotal with regard to evaluating one's standing in the developmental matrix of possible life goals and outcomes (e.g., Staudinger, 2001).

Providing Links from Infancy to Old Age

A further issue with regard to a life span perspective on the study of personality development concerns encompassing the ontogenetic course from *infancy* to *old age*. Empirically and theoretically, this distance may often still appear as a gap. Infancy and childhood research on the one hand and adulthood and old-age research on the other typically proceed independently from each other with little overlap in concepts, methodology, and consequently empirical data basis. Although much progress has been made, especially by longitudinal researchers whose participants have grown into adulthood (Pulkkinen & Caspi, 2002), the caveats expressed in the past continue to exist: For example: Which measures are age-invariant? How to capture explanatory continuity when combined with descriptive discontinuity?

Bridging this gap and establishing connections indeed is not easy (e.g., Brim & Kagan, 1980). It seems necessary to identify constructs that have been used to describe personality development across the life span or have at least shown predictive relationships. This concerns the question of homotypic and heterotypic continuity, a terminology introduced by Kagan and Moss (1962), or of Block's notion of temporal coherence (e.g., Block, 1993). The notion of heterotypic continuity implies that the phenotypic behavior might change between childhood and adulthood, but that specific behaviors in childhood might still be conceptually consistent with adult behaviors. Phenotypically different but conceptually related responses might be derivatives of earlier behavior (e.g., Moss & Sussman, 1980). R. G. Ryder (1967), for example, found that childhood task persistence was related to adult achievement orientation.

There are a number of interesting candidates that serve as examples of constructs that span a lifetime, such as attachment style, control beliefs, the self-concept, or temperament. For temperamental features, for instance, extensive longitudinal evidence is available that has demonstrated quite strong predictive links between temperament in early infancy and personality in adulthood and even old age. In this work, five temperamental features are distinguished, activity level, positive affect, negative affect, avoidance/approach, persistence. Longitudinal relations show that, for instance, activity level is related to extraversion and lower levels of conscientiousness or negative affectivity predicts neuroticism and lower levels of agreeableness (e.g., Caspi, 1998; Friedman et al., 1995; Kagan & Snidman, 1991; J. V. Lerner & Lerner, 1983). These kinds of predictive relationships, however, should not be interpreted as a deterministic argument. Rather, work by Chess and Thomas (1984) and J. V. Lerner and Lerner (1983) demonstrated that depending on the "goodness-of-fit" between the child's temperament and expectations of the environment, temperamental constellations can be aggravated or alleviated.

Recently, there has been notable progress in identifying some of the mechanisms that might link infant temperament and adult personality and that might enable a joint organization of concepts of temperament and personality (e.g., Strelau & Angleitner, 1991; Zuckerman, 1995). Zuckerman (1995), for example, has proposed what he calls the turtle model of personality. In this model, personality traits at the top are linked to genetics at the bottom through (from top down) social behavior, conditioning, physiology, biochemistry, and finally neurology. This model is not meant to be reductionistic; it is necessary to study each level of analysis with its own intellectual agenda to gain a complete understanding. As Zuckerman (1995, p. 331) puts it, "We do not inherit temperamental patterns as such. What is inherited are chemical templates that produce and regulate proteins involved in building the structure of nervous systems and the neurotransmitters, enzymes, and hormones that regulate them. We are born with differences in reactivities of brain structure and differences in regulators." Very much in line with our systemic emphasis, it is included in this multiple levels of analysis model of Zuckerman that the type of temperamental pattern, which initially may have a strong genetic component, attains features of contextually based self-organization. Thus, the temperamental pattern is transformed by context and experience in ways that it becomes an outcome of a multicausal and self-organizing process.

In sum, in this first section we have attempted to engage the reader in an integrative view on research on the development of personality, self-concepts, and self-regulatory processes. In order to gain an understanding of the life span development of self and personality, it seems useful to consider structure and processes, as well as functions (Mischel & Shoda, 1999). A dynamic systems approach to development provides a useful theoretical framework for the integration of the different components of personality discussed in the literature. In addition, interest of a life span perspective centers on features—such as temperament—that allow to study continuity and discontinuity across the whole life span and also demonstrate predictive power from childhood into adulthood. Based on this conceptualization, we will now apply the level of analysis approach, introduced in the beginning of this chapter, to the field of self and personality.

Illustrations of the Role of Biology and Culture in Personality Development

How does Figure 11.1 apply to the field of personality? Working from the assumption that the genome and its expressions, by means of evolution, are not optimized with regard to old age, and that genetic programs potentially are less orderly and integrated for late than for young adulthood (e.g., Kirkwood, 2003), what are the implications for personality functioning across the life span? Recently, there has been growing interest in explicating the evolutionary base of personality, both in terms of biological and cultural-social forces in the sense of co-evolution (e.g., Barkow, Cosmides, & Tooby, 1992; Klix, 1993). This trend, however, is only beginning to reach the second half of life (e.g., Plomin & Caspi, 1999).

As selection primarily operates through fertility and parenting behavior, most of the evolutionary work in the field of personality (in the widest sense) has focused on gender differences in altruism, cooperative behaviors, sexual competition, or jealousy (e.g., DeKay & Buss, 1992; Hammerstein, 1996). In addition, however, arguments have been raised that the ability for self-deception might have been favored by evolution because it seems to increase the ability to deceive others and thereby gain a survival advantage (e.g., Gigerenzer, 1996; Trivers, 1985). The evolutionary importance of

the ability to deceive others in turn is related to the crucial role of reciprocal relationships for reproductive fitness (e.g., Axelrod, 1984). We would like to suggest that this ability "to deceive oneself," or one could also say "redefine reality," indeed serves an important adaptive function across the life span and probably increasingly so in old age.

Thus, the fact that the evolutionary base has been less "optimized" for the postreproductive phases of life than for younger ages may not be as detrimental for the ontogenesis of self and personality as for biological and cognitive functioning. Perhaps what is relevant here is that the "mechanics of the mind" which evince definite aging losses (see earlier discussion), either carry little implication for personality functioning, or that evolutionary selection in humans provided a better basis for personality than for intellectual functioning.

This interpretation of findings from evolutionary psychology, that personality is less at a disadvantage than cognition and biological functioning, is supported by findings on the genetic component of interindividual differences in personality functioning as advanced by behavior-genetic research. Evidence from the cross-sectional as well longitudinal analyses of the genotype and the phenotype of personality characteristics indicate that none of the personality traits is without a 40% to 50% genetic variance component. There are still too few data sets, however, that would allow disentangling methods effects. Mostly twin and adoption studies have used self-report data to assess personality. When comparing genetic variance components as derived from self-report with those based on peer ratings clear differences emerge that suggest that observational assessment and/or test-based assessment of personality may still yield other results. Based on the few data sets that allow for multimethod testing it seems that genetic factors largely account for what is in common across assessment methods (Plomin & Caspi, 1999). Across the life span, genetic variance components seem to follow a different pattern than the one just reported for the domain of intellectual functioning. During the life course, stability or even slight *de*creases in heritability coefficients have been found (e.g., Pedersen & Reynolds, 2002).

This very general summary statement needs qualification and differentiation. So far, only few behavior-genetic studies of personality based on longitudinal data with extensive age intervals are available, let alone using multiple assessment techniques. Highly complex statistical methods that allow modeling of the genetic architecture of development (Pedersen, 1991) by simultaneously taking into account mean levels and growth curves (e.g., McArdle & Bell, 1999; J. R. Nesselroade & Ghisletta, 2003) have become available. However, due to the lack of appropriate data sets and to the recency of their availability, they have not been widely applied yet. Therefore, authors in the field of behavioral genetics consider the available evidence as preliminary (e.g., Pedersen & Reynolds, 2002).

Taking such limitations into account, the following preliminary insights into the developmental behavioral genetics of personality seem to find consensus among behavioral geneticists (e.g., Pedersen & Reynolds, 2002). First, results of behavior-genetic analyses of personality assessments are difficult to compare with the equivalent analyses of intelligence assessments because the latter are based on behavioral performance measures, whereas personality measures typically refer to self-reports. Thus, strictly speaking, personality-related analyses refer to the heritability and its life span changes in how people report about themselves. Second, the extent to which genetic influences account for phenotypic variability in personality measures is smaller than for measures of intelligence, with heritability coefficients between .4 and .6 depending on the personality trait and the age of assessment. Third, the importance of genetic influences on interindividual differences in personality seems to decrease slightly with increasing age (e.g., McGue, Bacon, & Lykken, 1993; Pedersen & Reynolds, 2002). And fourth, there is initial evidence for a quite high overlap in the genetic effects (i.e., stability) operating on personality expression at different ages, although at each point in time they account for not more than half of the variance (e.g., McGue, Bacon, et al., 1993; Pedersen & Reynolds, 2002).

One of the more recent and exciting directions for genetic research on personality involves the use of molecular genetic techniques to identify some of the specific genes responsible for genetic influences on personality (Hamer & Copeland, 1998). It is too early to be certain, but it is possible that ultimately this molecular genetic analysis will become more and more prominent. That it will shift our attention away from focusing on quantifying genetic influences to a focus on the causal mechanisms from cells to social systems that will elucidate how genes affect and are affected by personality development. Currently, progress is

being made with regard to the molecular analysis of temperamental features such as approach/avoidance or positive/negative emotional tone (see the following discussion). In the long run, such molecular genetic analysis may help to answer questions of heterotypic continuity much more clearly than currently is the case when referring to behavioral measures (Plomin & Caspi, 1999).

The Allocation of Resources in Personality Functioning

In an earlier section, we emphasized the life span developmental script of a reallocation of resources, from a predominant allocation into growth to an increase in relative allocation into maintenance, repair, and management of losses (see also Staudinger et al., 1995). In contrast to the domain of cognitive functioning where resources in old age are depleted to maintain a certain level of functioning, the resource situation for life span growth in self and personality might present itself more favorably. Taking a system's view on psychological functioning, we can assume therefore that personality by virtue of being the self-reflective head of the living system "human being" (a quality emerging during childhood) might be able to continue to deliver its orchestrating or executive function with regard to managing the gains and losses across various domains of functioning until at least the third age (cf. Staudinger et al., 1995).

It is less and less certain, however, whether, on average, personality-related resources are available in old age to promote further development of the personality-system itself. In other words, as life reaches old age, it becomes more and more necessary for available personality-related resources to be invested in managing cognitive, physical, and social declines and losses. Possibly only under very favorable developmental conditions would personality-related resources be sufficient to invest in further development of personality itself. Although, in principle, life span changes in personality could include advances, we do not expect them to occur in everyone. Under very favorable conditions, however, personality growth might even involve such high goals as wisdom (cf. Erikson, 1959; see also P. B. Baltes, Smith, & Staudinger, 1992).

Further, we assume that the personality-system also manages and organizes the extension of internal resources (e.g., cognitive capacity, physical strength, personality characteristics) by referring to others and the physical and institutional context as resources (for overview see Staudinger et al., 1995). Others can help to do things that one's own health or time or ability does not allow. External memory aids can help to compensate for the loss in memory performance. Given this line of thought, one can also conceive of a situation that allows personality to optimize the use of external resources such that enough internal resources are left for further personality development, for example, toward wisdom. An extreme case for such personality-based orchestrating of resources aimed at selective optimization is the loss of independent functioning. There the task is to accept dependency in such domains as household management in order to free up resources for other purposes (M. M. Baltes, 1996).

The notion that personality performs an orchestrating or executive function with regard to the management and identification of resources raises the following question: Is it possible to distinguish the mechanisms and characteristics that support the overarching orchestrating or executive functions from those that constitute one of the three domains of psychological functioning, that is intelligence and cognition, self and personality, and social relations, or are both inextricably intertwined? This question is discussed in research on *resilience* (Staudinger et al., 1995). By taking such a research perspective on the origins, maintenance, and consequences of personality—ideally in a longitudinal manner—it becomes possible to identify, for instance, whether, or how, personality manages itself while at the same time having to manage extraordinary challenges such as losses in cognitive functioning or losses of significant others due to death, or to challenges of one's own finitude. Each process and each characteristic constituting personality can thus be identified as a phenomenon in itself but also in its executive and orchestrating function.

We next discuss in more detail three issues of personality development across the life span. The first is the question of stability and change across the life span. Aside from questions of stability in individual rank order, this issue can also be phrased as investigating the gains, maintenance, and losses in mean levels in personality functioning. The second issue relates to the opportunities and constraints of personality development. And finally, the third issue will illustrate the adaptive personality-related potential across the life span, which arguably might present the most comprehensive general-purpose mechanism involved in life span development.

Personality Development as Lifelong Transactional Adaptation: Continuity and Change

Before we explore further the question of continuity and change (gains, losses) in personality development, it seems useful to consider the question what it means to speak about gains and losses in the context of personality functioning. Using the notions of growth and decline or gain and loss with regard to personality characteristics makes the criterion problem of what is a gain and what a loss even more obvious and pressing than it is with regard to intellectual functioning. In cognitive research, it seems obvious that the more words one can remember, the better; the faster we can complete a problem-solving task, the higher the level of performance. But even with regard to intellectual functioning such criteria of adaptive fitness, of what is a gain and what a loss, are subject to contextual conditions. When it comes to personality, we are presented with the problem of determining a "best" direction of personality development. What is the desirable end state of personality development? Is there one, or are there many potentially incompatible ends depending on the outcome criteria we examine? To what degree do subjective and objective criteria converge?

For example, let us take extraversion and assume that being extraverted is set as an aspired goal of personality development. We can think of occasions, however, when, on the contrary, introversion turns out to be the more adaptive personality feature. Similarly, it is very important to strike a balance between affiliation and solitude or between autonomy and dependence. Such considerations remind us of the argument presented previously about general-purpose mechanisms. We argued there that it is the flexibility and the availability of a monitoring algorithm that is "best" with regard to self and personality functioning, rather than one or the other personality characteristic (e.g., Aspinwall & Staudinger, 2003; Staudinger, 1999b). Similar views can be applied to coping research. There, high domain-specificity with regard to the functionality of coping behaviors has been identified. Furthermore, coping behaviors that are adaptive as immediate responses need not be adaptive in the long run. Thus, even with regard to coping, implications for everyday functioning are not fully known (Filipp & Klauer, 1991).

One approach to deal with the question of functionality is to invoke subjective assessments, for instance, about the perceived desirability or undesirability of a given self-related attribute. In a series of studies on beliefs and expectations about development, Heckhausen and Baltes found that people have quite clear conceptions about what they consider to be a desirable and what an undesirable developmental outcome and also when it is supposed to occur. For example, only two desirable personality characteristics were reported to continue to grow in old age, that is wisdom and dignity, whereas many other positive characteristics were mentioned as emerging for the periods of young and middle adulthood (Heckhausen, Dixon, & Baltes, 1989). It was also found in these studies that people of different ages and socioeconomic backgrounds agree about how personality develops and about what is a desirable and what an undesirable personality development, that is, what is a gain or a loss.

In the following, as we characterize gains and losses in life span development of self and personality, we use two approaches (see also Staudinger & Kunzmann, 2005). A first is based on evaluating developmental changes with regard to the adaptivity and functionality of the outcome for the individual, be it from a subjective (e.g., subjective well-being) or an objective perspective (e.g., longevity). The second refers to theoretical growth models of personality (e.g., ego maturity, integrity, generativity) when making a judgment about gains and losses. We alert the reader to the problem that these categorizations are preliminary and by no means absolute.

Be it gains or losses, it is the core assumption of a life span perspective that personality does not simply passively unfold as a consequence of the prewired maturational programs or the mechanistic reaction to environmental stimuli. Personality develops out of a constant and active process of the individual's transactions with changing internal and external influences, including biological changes and changes in historical conditions of society. "Transactional adaptation" (e.g., R. M. Lerner, 1984, 2002) or person-environment interaction (e.g., Magnusson, 1990; Magnusson & Stattin, Chapter 8, this *Handbook,* this volume) are considered the central developmental processes. In this process of transactional adaptation of personality, systemic principles of self-organization are key ingredients. This basic life span premise about personality development is further elaborated by the differentiation between the mechanics and pragmatics of life and how it pertains to our understanding of personality development.

The Mechanics and Pragmatics of Life as Relevant to Personality Functioning

As described earlier the contribution of the mechanics and pragmatics as well as their dynamic interaction is quite well understood with regard to cognitive develop-

ment (see also P. B. Baltes et al., 2006; Cabeza, 2002). With regard to personality, however, we are still at the beginning of understanding the interaction between mechanic and pragmatic elements in producing developmental trajectories. The developmental trajectories of the cognitive mechanics and pragmatics are well established at least in terms of the behavioral level. We also know that with increasing age the cognitive pragmatics help to compensate functional deficits in the mechanics (e.g., Salthouse, 1984; see also P. B. Baltes et al., 1998; Staudinger et al., 1995). Do we expect to see similar developmental trends when investigating the mechanics and pragmatics as relevant to personality functioning?

It may be useful to extend the notion of cognitive mechanics and pragmatics to encompass personality functioning. Thus, instead of speaking of cognitive mechanics and pragmatics one may consider to use the more general notion of mechanics and pragmatics of life (see also Staudinger & Pasupathi, 2000). Clearly, this model is of a heuristic nature; that is, we do not assume that any phenomenon in the area of personality can be assigned to *only* representing the mechanics or the pragmatics. Rather, we assume that it may be useful to categorize aspects of personality functioning according to their relative position on the continuum between the mechanics and pragmatics of life. In the following, these more general notions of mechanics and pragmatics are explicated with regard to their relevance for personality functioning and development.

The Mechanics of Life as Relevant to Personality Functioning. The life mechanics relevant to personality functioning refer to a unique configuration of elements that contribute to interindividual differences in self-concept, self-regulation, or trait personality such as basic emotional and motivational tendencies as they are studied in temperament research (positive/negative emotional tone, approach/avoidance, novelty seeking; Schindler & Staudinger, 2005a; Staudinger & Pasupathi, 2000). This configuration entails basic emotional and motivational tendencies, as well as cognitive processes that can be observed on the behavioral as well as on the neurophysiological level.

The mechanics of life encompass complex interactions between the cellular, neural, endocrine, and immunological system, which in turn provide the basis for basic behavioral indicators of cognition, emotion, motivation, and behavior/action. On the behavioral level basic temperamental features such as emotional, motor and attentional reactivity as well as their regulation are considered (e.g., Rothbart, 2001). On the level of physiological indicators, it is impossible to clearly separate from each other aspects of the mechanics that underlie either cognition, or emotion, or motivation. For instance, changes in heart rate such as acceleration can be observed during negative affective episodes, but also during mental arithmetic (cf. Baltissen, 2005; Levenson, 2000). With regard to neuroanatomy, there is evidence for specialized brain areas (e.g., the amygdala, prefrontal cortex) that contribute to the formation of both basic emotions and basic motivational tendencies but not to higher cognitive functioning (e.g., Davidson, Jackson, & Kalin, 2000). A further differentiation between emotion and motivation, however, so far seems not possible. The emotion of fear, for instance, is inextricably linked to avoidance motivation. Temperamental dimensions also tend to show substantial interrelations, reflecting an underlying affective-motivational system rather than separate qualities (cf. Rothbart & Bates, 1998).

The Pragmatics of Life as Relevant to Personality Functioning. The pragmatics of life as they are relevant to personality functioning represent the power of experiences and contextual influences. They encompass self-related knowledge as well as self-regulatory competencies (Staudinger & Pasupathi, 2000). Knowledge about the self pertains to trait conceptions of personality as well as to the self-concept. It includes all that we know about our behavior, past experiences, anticipated and idealized futures, needs and wishes, abilities, or weaknesses that characterize our selves. The concept of who we are and what we are like is closely related to how we pursue goals, evaluate our selves or adjust our self-views or goals under threat. Thus, self-regulation constitutes the procedural part of our self-knowledge.

The Dynamic Interaction of the Mechanics and Pragmatics of Life as Relevant to Personality Functioning. The mechanics and pragmatics of life mutually influence each other. As mentioned previously, we follow Cattell's (e.g., 1971) investment theory and consider the life mechanics as the building blocks promoting developmental progress in the life pragmatics (Staudinger & Pasupathi, 2000). At first sight, it seems that the mechanics constrain the pragmatics, and to a certain degree that is true. But most genetic as well as recent brain research has demonstrated that, for instance, the richness or poverty of the (factual and procedural) knowledge we accumulate feeds back into the life mechanics and indeed may even change them (genetic

expression, brain structures; Kirkwood, 2003; W. Singer, 2003; see also S.-C. Li, 2003). Extremely inhibited children, for instance, are able to gain control of their fearful behavior, changing not only their psychological state but also the underlying reactive sympathetic nervous system (Kagan, 1998). This reciprocal interaction of mechanics and pragmatics highlights the limits of the hardware-software metaphor introduced earlier (at least as our current understanding of hardware is concerned).

The life span conception of ontogenesis (e.g., P. B. Baltes et al., 1998; Brandtstädter, 1998) as a product of the interaction between biology (i.e., life mechanics), culture, and automated as well as purposeful attempts at regulating one's development (i.e., life pragmatics) implies that it is impossible to clearly separate the mechanics from the pragmatics of life. Starting at conception, biology, culture, and the developing "person" interact. We just showed that, for instance, basic temperamental dimensions (i.e., mechanics) and personality characteristics (i.e., pragmatics) show predictive relations across the life span (e.g., Caspi & Silva, 1995). But we do not know yet how exactly the underlying mechanics play out in the development of traits. For instance, do changes in the life mechanics result in the age-related decrease in openness to experience (e.g., decay in the physiological basis of the approach system, or reduced biological resources "demand" parsimonious; i.e., habituated, rather than novel functioning) or is it rather the result of years of experience (e.g., losing interest because I have seen it all before), that is, the life pragmatics? Or is it both? Despite the seemingly inextricable interaction, it may nevertheless be useful for heuristic purposes to distinguish between the life mechanics and pragmatics of personality and use this distinction to better understand personality development across the life span. We start by reviewing some first and still scarce evidence on the life span development of the mechanics followed by results with regard to the life pragmatics of personality.

The Development of Neurophysiological Indicators of Life Mechanics of Personality

When we consider the mechanics of life it is not trivial to identify indicators that have a clear emphasis on the mechanic side and that at the same time can be used to assess participants across the whole life span. Especially on the behavioral level, such as basic behavioral indicators of temperament are usually not applied throughout the life span but are substituted by personality trait measures when adults are assessed. In our terminology, however, trait measures of personality are the result of many cumulative interactions between the biological basis of personality, context and individual choices. Thus, they are much closer to the pragmatic than the mechanic end of the continuum.

Behavioral operationalizations of basic temperament dimensions clearly are closer to the mechanic end of the continuum even though we need to be aware that the pragmatic component gains importance whenever self-report is involved (cf. P. B. Baltes et al., 1998; Kagan, 1998). Nevertheless, with regard to affective tone it is possible to consult basic behavioral findings from life span emotion research. Also, there is some scarce behavioral evidence on the approach/avoidance system stemming from research on the goal system.

In addition, one can have a look at neurophysiological indicators of personality functioning in order to learn about the development of the mechanics of life. Two neurophysiological indicators have been—reliably and across different laboratories—identified as biological indicators of basic dimensions of affectivity and motivation: (1) autonomic reactivity and (2) cerebral asymmetry (see also Schindler & Staudinger, 2005a). Those two indicators seem to be rather "pure" reflections of the life mechanics given presently available measurement paradigms and they have received most of the empirical attention.[2] In the following, we will first present developmental evidence for the two neurophysiological indicators. Subsequently, progressing from the mechanics a little further toward the pragmatics end of the dimension, we present developmental evidence on the behavioral data about emotional tone and about the approach/avoidance tendency.

Autonomic reactivity (heart rate, heart rate variability). The parasympathetic and sympathetic branches of the autonomic nervous system influence the activity of the heart. Both higher sympathetic reactivity (e.g., Kagan, 1998) and a weaker influence of the parasympathetic nervous system (e.g., Porges & Doussard-Roosevelt, 1997) have been linked to behavioral inhibition (i.e., withdrawal/avoidance). Our focus is on the relationship

[2] These two indicators only present a subset of the physiological indicators of temperament and additional indicators that may be discussed in this context are excitability levels of the amygdala, asymmetric activation of the amygdala, norepinephrine, cortisol, or dopamine levels (e.g., Davidson et al., 2000; Depue & Collins, 1999; Kagan, 1998; Rothbart & Baltes, 1998).

between heart rate and heart rate variability on the one and basic dispositions such as approach/avoidance or positive/negative emotional tone on the other hand.

On the one hand, a low and variable resting heart rate is generally related to approach behavior and positive affect, but also to regulatory disorders and angry irritable affect (e.g., Porges & Doussard-Roosevelt, 1997; Rothbart & Bates, 1998). These two findings seem contradictory, but match the special nature of anger. Albeit considered a negative affective state, anger is associated with a motivation to approach rather than to avoid or withdraw (e.g., Davidson et al., 2000; Harmon-Jones & Allen, 1998). On the other hand, higher resting heart rate combined with lower variability and high reactivity shows relations to inhibitory or avoidance behaviors (e.g., Kagan, 1998). These findings highlight the necessity to consider the regulation of the heart rate in response to stimulation in addition to the resting heart rate. Indeed, it is the physiological regulation of cardiac activity that has been suggested as "an antecedent substrate for emotional, cognitive, and behavioral regulation" (Doussard-Roosevelt, McClenny, & Porges, 2001, p. 58). Infants who have a low and variable resting heart rate *and* demonstrate appropriate heart rate modulation tend to show more optimal developmental outcomes (at age 3) such as fewer depressive and aggressive behaviors and more socially competent behaviors (e.g., Porges & Doussard-Roosevelt, 1997).

During childhood stability of resting and stress-tested heart rate as well as its variability reach close to perfect levels (Porges, Doussard-Roosevelt, Portales, & Suess, 1994). Mean-level decreases in resting heart rate and increased levels of variability have been observed between 9 months and 3 years of age (Porges et al., 1994). Unfortunately, no studies investigating mean-level stability of heart rate and its variability from childhood into adulthood and old age are yet available. But there is evidence that the resting heart rates of older adults hardly differ from those of young adults, while maximum heart rate is considerably reduced with increasing age (Folkow & Svanborg, 1993). Heart rate reactivity is also attenuated in older adults (e.g., Levenson, Carstensen, Friesen, & Ekman, 1991; see Baltissen, 2005, for an overview). In addition, once the ANS is activated, there is at least some first indication from emotion research that the activation tends to persist for longer time periods in old compared with younger adults (Levenson et al., 1991). To date, however, no data exist about possible changes of the relation between autonomic reactivity and behavioral indicators of approach/avoidance or other personality indicators across the life span.

Cerebral Asymmetry. Over the last 15 years different laboratories have developed theories and accumulated empirical evidence concerning the idea that approach (Gray, 1981), activation (Cloninger, 1987), and engagement (Depue, Krauss, & Spoont, 1987) motivation on the one hand, and avoidance, withdrawal (Davidson, 1984), and inhibition (Cloninger, 1987; Gray, 1981) motivation on the other hand are related to different neural substrates, different basic emotions, and have distinct influences on action. The approach/engagement system facilitates appetitive behavior, generates particular types of approach-related positive affect, and is related to relative increases in left-sided prefrontal activation. There is some evidence that dopaminergic pathways play a central role in that system (e.g., Depue & Collins, 1999). The withdrawal/inhibition system, in contrast, responds to threats or signals of punishment. Its engagement inhibits ongoing behavior (Gray, 1981) or supports withdrawal behavior (Davidson, 1984) and involves negative affective states such as anxiety, disgust, and heightened vigilance. The activation of the inhibition/withdrawal system is associated with relatively stronger activation of the right prefrontal cortex.

Interindividual differences in baseline prefrontal activation asymmetry are related to differences in dispositional affect, inhibition, and differential reactivity to negative stimulation (Davidson et al., 2000). For instance, infants with higher relative right anterior cortical activation at baseline are more likely to cry in response to being separated from their mothers compared to infants that do not show that asymmetrical activation pattern. Children with asymmetric right-sided anterior activation show a tendency toward inhibited behavior. During adulthood, greater relative activation of the right anterior cortex at rest has been related to higher levels of general negative affect, higher self-reported behavioral inhibition, stronger negative affect in response to unpleasant film clips, and slower recovery following a negative affective stimulus (for an overview see Davidson et al., 2000).

Although there is evidence of internal consistency and test-retest reliability of measures of prefrontal asymmetry (Tomarken, Davidson, Wheeler, & Kinney, 1992), our knowledge about the intraindividual development of cerebral asymmetry especially over longer time spans is

still very limited. Rank-order stability of baseline prefrontal asymmetries seems to be very low over an 8-year period during childhood (Davidson & Rickman, 1999), but stability is assumed to increase after puberty when the prefrontal cortex has stopped to undergo developmental change (Davidson et al., 2000).

Again, there is no study yet that compares the relative magnitude of prefrontal asymmetry between infants, children, and adults. Cerebral asymmetry has been demonstrated during the 1st year of life (cf. Davidson et al., 2000), but it is unclear whether these interindividual differences in brain activity stay stable during further development. It has been speculated that the later development of left-brain abilities might be accompanied by a maturational shift toward better emotion-regulation (see Rothbart & Bates, 1998). Similar to research on heart rate and its variability, there seems to be hardly any evidence on the mean-level stability of prefrontal asymmetry in old age. We only found one study of odor perception in older adults that showed that left frontal brain activation in response to pleasant stimuli was uncompromised. However, brain activity in response to unpleasant stimuli did not differ from that to neutral stimuli (Kline, Blackhart, Woodward, Williams, & Schwartz, 2000). This may imply that the right prefrontal cortex area undergoes stronger age-related losses in functioning than the left prefrontal area. We will see in the next section that on a behavioral level of assessment there is evidence accruing for differentially reduced frequency of negative emotions as well as reduced reactivity to negative stimuli.

Some Conclusions about the Development of Neurophysiological Indicators of the Mechanics of Personality Functioning. To date, there are few studies on either mean-level or rank-order stability of the selected physiological indicators of the life mechanics of personality and the majority of extant findings come from studies on infancy and childhood. Thus, we can only draw some very preliminary conclusions about life span development. Substantial stability coefficients are attained past adolescence. Thus, these physiological indicators may possibly contribute to continuity on the behavioral level. The mechanics underlying basic motivational and emotional tendencies show smaller mean-level changes than the cognitive mechanics across the life span. But there are some decreases such as the declining physiological reactivity of the ANS in old age and the possibly reduced asymmetry in prefrontal brain activation. Please, note that these changes in the mechanics by no means have to play out as losses on the behavioral level but rather—as discussed next—the opposite may be the case.

Overall, our understanding of life span changes in the life mechanics of personality as well as their relation with behavioral indicators is still limited. We need studies linking differential age-related change in physiological indicators to differential intraindividual change in personality. For instance, what happens to inhibited individuals who have a tendency to show strong heart rate acceleration in response to challenge when they reach old age? We know that heart rate acceleration probably declines with increasing age due to reduced reactivity of the ANS. But is there any age-related change in behavioral inhibition as a result of declined heart rate reactivity? Or what happens to emotion-regulation in old age given the changes in brain activity discussed previously? Is there a mechanic basis to the age-related changes found in emotion-regulation (e.g., Labouvie-Vief, Lumley, Jain, & Heinze, 2003)? These and related questions are especially relevant when we describe and explain the findings about the development of behavioral indicators of emotional tone and approach/avoidance that are much closer to the pragmatics of personality next.

The Development of Behavioral Indicators of Life Mechanics of Personality

Emotional Tone and Reactivity. The physiological patterns are maintained, however the magnitude of physiological responses seems to be reduced (e.g., Levenson et al., 1991). Studies assessing emotion via self-reported positive and negative affect, that is indicators much closer to the pragmatic side of emotion-regulation, supported the view of a gain in affective functioning in old age. Overall the subjective salience of emotion seems to increase with age (e.g., Carstensen et al., 1999). Negative affect has been shown to either stay stable or decline in old age. Positive affect was found to be rather stable or even increasing with age depending on the study and the age range under investigation (e.g., Charles, Reynolds, & Gatz, 2001; Diener & Suh, 1998; Kunzmann, Little, & Smith, 2000). Increased affective complexity (i.e., more factors underlying emotional experience, plus higher potential for the co-occurrence of positive and negative affect) and improved reported emotional control were also linked to increasing age (e.g., Gross et al., 1997). A common interpretation of those findings is an age-related emotional maturation as

a result of accumulated experience and knowledge about emotions as well as a changing time horizon (e.g., Carstensen et al., 1999), that is, changes in the life pragmatics of personality. Based on the findings about neurophysiological indicators of the mechanics of personality presented earlier, we would like to offer some speculations about how those changes may contribute to these changes in emotional tone and emotion-regulation observed on the behavioral level.

First, as noted, there is indication that ANS activity (particularly the cardiovascular system) in reaction to elicited emotions is smaller and refraction times are longer in older adults in comparison with younger adults. Further, an age-related reduction of the asymmetry of prefrontal brain activity seems to occur. These changes (and we have only looked at a small selection of possible mechanic indicators) may contribute to the changes observed in emotional tone and emotion-regulation. For instance, lower ANS reactivity may make it easier to deal with upsetting emotional experiences. Decreased asymmetry in prefrontal brain activation during emotional experiences may contribute to differences in the relative frequency of specific emotional experiences and may predispose toward the processing of a particular kind of emotional quality.

Second, with regard to emotional control there is indication that in contrast to self-report assessment, behavioral measures of emotional control actually find no age-related increases but rather that older adults seem to overestimate their own ability to regulate their emotions as measured by physiological indicators (Kunzmann, Kupperbusch, & Levenson, 2005). And there is first indication that when using highly age-relevant emotional stimuli (loss of a loved one) older people actually report to experience *stronger* negative reactions (sadness) than younger ones (Kunzmann & Grühn, in press). Thus, it may be the case that certain constellations of emotional reaction are practiced more often than others and thus by pragmatics means (i.e., exercise) developmental trends based on the life mechanics of personality are "compensated." In sum, we suggest that the interplay between mechanic and pragmatics components of personality development is far from being understood but that the heuristic distinction between the mechanics and pragmatics of life may be quite helpful in order to increase our understanding of emotional functioning across the life span.

Approach and Avoidance Goals. Corresponding to the age-related declines in the mechanics of life, goal-focus is expected to shift with increasing age from growth, that is, trying to reach higher levels of functioning, toward maintenance, that is, preserving levels of functioning in the face of challenge, and regulation of loss, that is, organizing functioning at lower levels (Staudinger et al., 1995). Inspecting findings from research on the goal system (e.g., Emmons, 1996) that distinguishes goals focusing on gains, that is, approach goals, and goals focusing on the avoidance of loss, that is, avoidance goals, can be used to test this hypothesized developmental trend. And indeed in line with the assumption, it has been demonstrated that growth (approach) goals were more frequent in adolescence, while maintenance (avoidance of loss) goals increased in frequency during middle adulthood and into old age (Ebner & Freund, 2003; Freund, 2002; Heckhausen, 1997; Ogilvie, Rose, & Heppen, 2001). Further, maintenance goals still increase in frequency during very old age (J. Smith & Freund, 2002). Nevertheless, in spite of middle-aged and old people becoming more invested in maintenance and loss management, approach goals persist throughout life (Ogilvie et al., 2001). When asked about their future selves, even a majority among the very old consistently reported to pursue improvement goals across two measurement points (J. Smith & Freund, 2002). And elective selection is the component of the SOC theory that is maintained into old age (Freund & Baltes, 2002b). This pattern of findings is replicated across different methodological approaches, such as coding of goals by raters, self-rating of goals, and goal-selection behavior. Further, with regard to a systems view on goals it was demonstrated that one goal could receive ratings on the approach as well the avoidance dimensions (Ebner & Freund, 2003). Relating these behavioral and self-report findings on approach and avoidance to the evidence based on neurophysiological indicators it is striking that it is the right anterior cortex, which is related to avoidance behavior that seems to undergo stronger age-related declines in functioning suggesting that the goal-related approach/avoidance findings are more closely linked with the life pragmatics rather than the life mechanics of personality.

Evidence on the Development of the Life Pragmatics of Personality

In this last part of reviewing evidence on personality development, we turn to constructs that on our mechanic-pragmatic continuum are much closer to the pragmatic end such as personality traits, the self-concept but also

self-regulatory processes. A frequent distinction drawn in reviews of personality and aging (Kogan, 1990) is the one between trait and growth models of personality development.

Radical trait theorists equate personality with personality traits, that is, dispositional behaviors and attributes. Some even argue that personality is "set like plaster" after age 30 (Costa & McCrae, 1994). *Trait models of personality* approach the question of continuity and discontinuity and stability and instability from the continuity side. Trait-oriented researchers are interested in exploring and possibly arriving at a structure of personality characteristics that captures an individual's experiences and behaviors in a way that is as comprehensive and continuous as possible.

Among a large number of trait personality researchers there is consensus that personality can be reasonably well described by the so-called "Big Five." The Big Five have been identified by means of factor analysis across different instruments and different samples, though labels vary somewhat among authors. We have chosen Costa and McCrae's factor names to convey the information: Extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience.

Growth models of personality, in contrast, like the most influential one by Erik Erikson (e.g., 1959), contend that we continuously adapt to changing internal and external requirements and thereby grow. If all requirements are successfully met, at the end of an ideal trajectory, Erikson envisions a person full of hope, will power, purpose in life, competence, fidelity, love, care, and wisdom. Clearly, this outcome is not the rule but rather the exception.

More and more empirical evidence based on either of the two models, however, has demonstrated that *both* stability *and* change (i.e., gains and losses) characterize personality development in adulthood and old age. Thus, the focus of this overview will be on presenting this evidence and suggesting ways to better understand the dialectic between stability and change in personality development.

Development of Trait Personality. When asking about stability or change of personality traits, this implies three questions rather than one, that is, stability or change of (1) mean levels within a group of individuals, (2) inter-individual differences between individuals (variance), and (3) of the structural interrelationships of dimensions of personality (covariances). To start, a meaningful comparison between different age groups is solely possible if personality dimensions measure the same characteristics at different ages. For the Big Five factorial model of personality cross-sectional as well longitudinal information on structural invariance is available (Costa & McCrae, 1994; Small, Hertzog, Hultsch, & Dixon, 2003). Such studies have demonstrated high structural invariance during adulthood and into old age.

According to a recent meta-analysis (Roberts & DelVecchio, 2000), the rank-order stability of the Big Five increases almost linearly across the life span with stability levels in the .40 to .50 range during adolescence and a peak in stability at over .75 in middle adulthood (50 to 59 years). This peak of personality consistency at age 50 to 60 contradicts earlier arguments that the consistency of personality traits should plateau after age 30 (Costa & McCrae, 1994). Comparison among the five dimensions showed that extraversion and agreeableness had slightly higher stabilities than the other three dimensions (see also Vaidya Gray, Haig, & Watson, 2002). In this meta-analysis (Roberts & DelVecchio, 2000), stability estimates did neither vary by assessment method (i.e., self-report, other-report, projective test) nor by gender. Finally, controlling for sample attrition did not alter the results. The findings from this meta-analysis are confirmed with regard to old and very old age by recent publications from two longitudinal aging studies (Mroczek & Spiro, 2003; Small et al., 2003). In both studies, consistencies across 12 and 6 years, respectively, were around .7. No evidence has been found for cohort differences in consistency. Please note that even though a consistency of .75 at age 50 and 60 is high, on the assumption of higher reliability than stability, it leaves room for individual change. In this vein, recent studies using latent growth modeling found that with increasing age individual differences in personality change also increase (Pedersen & Reynolds, 2002; Small et al., 2003). As no age-graded increase but rather a decrease in the relative importance of genetic effects on personality development has been found, this increasing interindividual variability of change most likely is related to interindividual differences in life circumstances (Pedersen & Reynolds, 2002). Alternatively, it may also be the case that overall system robustness is reduced with age and thus greater intraindividual variability emerges (S.-C. Li, Aggen, Nesselroade, & Baltes, 2001; J. R. Nesselroade, 2002).

Finally, what happens with the mean levels of personality traits? Do we become less extravert and less open, but also less neurotic, as we move through adulthood and old age? Taking into account cross-sectional and longitudinal evidence, it seems that neuroticism decreases across adulthood (Mroczek & Spiro, 2003) and may show some increase again very late in life (Small et al., 2003). Some decrease is also found for openness to experience and extraversion (e.g., Costa, Herbst, McCrae, & Siegler, 2000). In contrast, agreeableness and conscientiousness increase to some degree (Helson & Kwan, 2000).

This mean-level decrease in neuroticism, increase in agreeableness and conscientiousness across adulthood and into old age can be described as an increase in social adaptation, in the sense of becoming emotionally less volatile and more attuned to social demands (Helson & Wink, 1987; Staudinger, 2005; Whitbourne & Waterman, 1979). The decrease in openness to experience, in contrast fits a different developmental pattern that is discussed next.

McCrae and others (e.g., 2000) lately offered an interesting proxy of a longitudinal study. Comparing samples between age 14 and 83 years from Korea, Portugal, Italy, Germany, Czech Republic, Turkey, they found cross-country consistency with regard to the pattern of mean-level changes just described. The authors argue that the observed similarity across cultures makes it unlikely—given the very different historical and cultural circumstances in these different countries—that such age differences are indeed cohort differences. Instead the authors suggest that this developmental pattern may reflect changes in genetic expression selected for by evolution (McCrae et al., 2000). Thus, using the terminology introduced in this chapter, McCrae and others view those results as reflecting changes in the life mechanics underlying personality functioning.

Knowing the many different ways that genes and environment interact in order to produce stability (cf. Plomin, DeFries, & Loehlin, 1977; Roberts & Caspi, 2003) and also how important specific life experiences are in personality development (e.g., Magnus, Diener, Fujita, & Pavot, 1993), we are somewhat reluctant in accepting this explanation as the only valid alternative. For example, the transition to partnership during early adulthood is accompanied by decreases in neuroticism and shyness and increases in conscientiousness (Neyer & Asendorpf, 2001). Thus, personality changes can also be attributed to normative, in the sense of culturally shared, life events. For instance, a recent cross-sequential study found that two cohorts differed in their development of neuroticism between the ages of 70 and 75 (Mroczek & Spiro, 2003). The older cohort (1897 to 1919) showed stability whereas the younger cohort (1920 to 1929) showed decline in neuroticism pointing to the fact that aging might express itself differently in different cohorts.

In sum, when we return to our heuristic dual-component model of the mechanics and pragmatics of life, we question the degree to which the Big Five are prototypical elements of the life mechanics, as McCrae and others (2000) suggest. In our view, the Big Five are prototypical elements of the life pragmatics. They are the result of an endless number of interactions between biology, culture, and the person. Thus, aside from stable genetic components, their relative high degree of stability can also be located in the physical and social environments in which individuals live and which, as sociological theories of human development and social differentiation suggest (Settersten, 2005), evince systematic and stable interindividual differences. Therefore, in our view personality traits likely are much less of an exclusively biological nature than is assumed to be the case for the more fundamental elements of the personality system such as basic emotional tone and basic motivational tendency.

Using a psychometric approach to the study of *growth-aspects of personality* replicates and extends the finding of increased social adaptation just described for the Big Five. Measuring dimensions such as "environmental mastery," "autonomy," or "personal growth" and "purpose in life," Ryff and Keyes (1995) find that the first two dimensions increase with age during adulthood and old age and the latter two level off after midlife. The increases in environmental mastery and autonomy can be described as being highly functional and adaptive for mastering adult life.

Personal growth and purpose in life, however, level off in midlife. This developmental trend fits well with the decline observed in openness to new experiences in old age. It has been argued (Staudinger, 2005), that these observed declines in self-reported openness, personal growth and purpose in life, may indicate that in contrast to social adaptation, personal maturity is less likely to come with age for most people. And indeed studies of wisdom (e.g., Staudinger, 1999b) and of ego development (e.g., Labouvie-Vief et al., 1987) find no normative increase with age during adulthood.

Self-Concept Development. When studying the self-concept both content and structure need to be considered (e.g., Filipp & Mayer, 2005; Staudinger & Pasupathi, 2000). Therefore, developmental trajectories of both will be covered next.

The *content* of the self-concept refers to the beliefs we hold about ourselves and to the domains we employ when describing ourselves. Answers to questions like "Who am I?" (e.g., Freund & Smith, 1999) are indicators of the content of the self-concept. The content of spontaneous self-descriptions shows change, but also stability (Filipp & Klauer, 1986). There is, for instance, substantial stability in the content of self-definitions across different age groups when it comes to central domains of life (e.g., health, social relations; Filipp & Klauer, 1986). But there is also change that can be attributed to the influence of a succession of developmental tasks, critical life events, and also changes in the life mechanics. During childhood the academic self-concept and school achievement assume a central role, in adolescence we are very much concerned about our physical appearance (for an overview cf. Filipp & Mayer, 2005). With increasing age, however, people define themselves more and more in terms of health and physical functioning, life experiences, and hobbies (Dittmann-Kohli, 1991; Freund & Smith, 1999). Another aspect of this adaptation to aging seems to be that activity and agency become important parts of the self-definition in old age, as they are no longer self-evident (Freund & Smith, 1999; Herzog, Franks, Markus, & Holmberg, 1998).

The *structure* of the self-concept refers to the organization of the self-concept. This organization is often investigated in terms of its complexity and integration (cf. Campbell, Assanand, & Di Paula, 2003). One classic definition of complexity (or differentiation) taps the number of nonredundant self-aspects or content categories of the self-definition (Linville, 1987). Integration often is assessed as the correlation of trait ratings across different domains of the self-concept (Donahue, Robins, Roberts, & John, 1993).

Cognitive representations of the self emerge during the 2nd year of life (cf. Harter, 1998) and can be characterized with regard to the degree of differentiation (measured in terms of correlations among different self-concept domains) as early as 4 to 5 years of age (Marsh et al., 2002). During childhood, the average correlation among self-concept domains has been shown to become smaller. This trend of decreasing integration levels off during adolescence, where no further decline in average correlations between preadolescence and late adolescence has been demonstrated (cf. Marsh et al., 2002). In contrast, there is evidence that the self-structure becomes more integrated again and that self-complexity increases between 18 and 22 years of age (Elbogen et al., 2001). For the age range from 20 to 88 years, cross-sectional findings indicate an U-shaped relationship between self-concept integration and age (Diehl et al., 2001). Currently, there is not much evidence on the rank-order stability of self-complexity or differentiation. 1-week test-retest correlations for measures of self-complexity and integration are in the .60 range (Campbell et al., 2003). No knowledge about long-term stability is available.

In sum: It seems that mean levels of integration of the self-concept increase until adolescence, decrease up to midlife and increase again thereafter. In contrast, the trajectory of self-complexity (in the sense of number of relevant self domains mentioned) follows an inverted U-shape function during adulthood. Thus, in contrast to the orthogenetic principle proposed by Heinz Werner (1926), one of the pioneers of developmental psychology, normatively there seems to be no coexistence of complexity and integration. In this vein, recently an effort has been made to develop a measure of self-concept growth, which incorporates this combination of differentiation and integration, and no significant age differences have been found during adulthood (Staudinger, Dörner, & Mickler, 2005).

Development of Self-Regulatory Processes. Having discussed some of the major evidence on the content and structure of self and personality, we turn next to results about the self-related processes. Self-regulation includes both the agentic (assimilative, primary control, problem-focused coping) and yielding qualities (accommodative, secondary control, emotion-focused coping; P. B. Baltes & Baltes, 1990b; Brandtstädter & Greve, 1994; Brandtstädter & Rothermund, 2003; Heckhausen & Schulz, 1995). Accommodative and yielding qualities have consistently been found to increase with age (e.g., Brandtstädter & Renner, 1990). Most likely this is a pragmatic response to the declines in the mechanics of life. In contrast, theoretical predictions and findings with respect to the development of agentic and assimilative qualities are inconsistent. Different authors speak of declining (Brandtstädter & Renner, 1990), stable (Heckhausen & Schulz, 1995), and even increasing

(Heckhausen, 2000) primary control across adulthood. In line with findings of increase and stability of primary control is evidence that demonstrates that older adults report elective, self-governed selection (within the model of selective optimization with compensation) as their primary action strategy (Freund & Baltes, 2002b).

Human beings are producers of their development (R. M. Lerner & Busch-Rossnagel, 1981), but there are also times when to accept the limits of our agency and to cope with challenges, threats and losses (see P. B. Baltes et al., 1998; P. B. Baltes & Smith, 2004; Brandtstädter, 1998; Staudinger & Lindenberger, 2003). And indeed, it may be that with age self-regulatory behaviors differ markedly in their prioritization. In order for people to maintain active involvement as composers of their lives, it is crucial to believe in one's ability to control and select environments, optimize outcomes, and to have compensatory strategies dealing with emotions in situations of failure and stress (e.g., Freund & Baltes, 2002b). In the following, we are interested in the developmental trajectories of various facets of self-regulation, such as (a) internal and external control beliefs, (b) emotion-regulation, as well (c) goal setting and goal pursuit.

Control and Self Efficacy Beliefs. When considering the development of control beliefs and related beliefs such as self efficacy (Bandura, 1997), one variable in the equation has to be the actual potential for control afforded by current psychological and nonpsychological resources. Based on the overall life span architecture presented earlier (P. B. Baltes, 1997), there is reason to assume that our capacity to influence outcomes in the external world follows an inverted U-shaped trajectory across the life span (primary control potential: Heckhausen & Schulz, 1995). Thus, the rise in objective control potential during childhood and adolescence may be reflected in increasing internal control beliefs, while the declining control potential in old age may be accompanied by declining internal and increasing external control beliefs. However, the ontogenesis of control beliefs is a little more complicated than this assumption would suggest.

If the two dimensions are considered separately, which is the current state of the art in research on control beliefs (E. A. Skinner, 1996), interesting differences between the development of internal and external control beliefs have been found. For instance, children from age 8 to 14 show no systematic *mean-level change* in internal control beliefs, but external control beliefs (powerful others) decline (cf. E. A. Skinner & Connell, 1986). Further, stability and even increases in internal control beliefs with increasing age are observed. In adult samples, no clear-cut changes in perceived internal control and a tendency for older adults to report more external control are found (Brandtstädter & Rothermund, 1994). A global measure of perceived internal control demonstrates increases between young adulthood and old age (up to age 75; Lachman & Weaver, 1998).

Recent findings from the Berlin Aging Study (a sample of old and very old adults) indicate that a high sense of internal control can be maintained into very old age, that is, in spite of losses and functional decline the old adults did not report diminished internal control over desirable outcomes. Simultaneously, however, mean levels of perceived others' control increased (Kunzmann, Little, & Smith, 2002). Thus, there seems to be a consistent pattern of increasing externality in control beliefs with increasing age. Results for internal control beliefs are less clear. We can conclude that beliefs in one's ability to control desirable outcomes are relatively stable during adulthood and might even show some increases with age. In other words, the belief in our agency "survives" actual losses in resources. Age differences in domain-specific control beliefs show that control over children and sex life decreases, while control over work, finances, and marriage increases between young adulthood and old age (Lachman & Weaver, 1998). Control over mental functioning and health declines in very old age (Lachman, 1991).

Selected evidence on the *rank-order stability* of control beliefs points to moderate stability estimates ranging between $r = .45$ and $r = .57$ (Brandtstädter & Rothermund, 1994; Kunzmann et al., 2002; Lachman, 1986b). In sum, findings on the stability of control beliefs suggest increases (external control) or stability (internal control) and moderate stability in interindividual differences across time.

Coping. When we turn to age-comparative research on coping, Folkman, Lazarus, Pimley, and Novacek (1987), for example, found that older respondents were less likely to seek social support or use confrontive coping and were more likely to use distancing and positive reappraisal. In fact, more and more of the recent evidence supports this "growth" view of coping in adulthood and old age (e.g., Aldwin, Sutton, & Lachman, 1996; Costa & McCrae, 1993;

Labouvie-Vief, Hakim-Larson, & Hobart, 1987; Rott & Thomae, 1991) or at least speaks for stability in coping behavior. With respect to the developmental stability of coping behavior during adult life, it has also been observed that individual differences in the endorsement of coping mechanisms are more a function of the type of stressful event than of age (McCrae, 1989).

Furthermore, older adults seem to be more flexible in adapting their coping response to the characteristics of the situation (e.g., controllability) than younger adults (e.g., Aldwin et al., 1996). Such evidence is congruent with findings that, in comparison to younger adults, older adults have been found to demonstrate an accommodative coping style in the face of adversity or failure; that is, older adults were more flexible and better able to adjust their strivings to changed circumstances than were young adults (Brandtstädter & Renner, 1990). Conversely, younger adults were more likely to adhere to their once established goals (i.e., assimilative coping), even if they were no longer realizable. With age, Brandtstädter and Renner (1990) have demonstrated that adults favor *accommodative* (goal flexible) over *assimilative* (goal persistent) coping. In a similar vein, Heckhausen and Schulz (1993) have proposed and presented empirical evidence (Heckhausen, 2000) that an age-related shift from *primary* to *secondary control* strategies takes place in order to master the tasks of aging.

Personal Life Investment (PLI) and the Goal System. Self-regulation is also reflected in goal setting and goal pursuit (cf. Cantor & Blanton, 1996). The *goals* people hold at different points in their life and how they try to achieve these goals in part are reflections of developmental contexts and developmental tasks. For instance, although family related goals are prominent throughout adulthood, young adults frequently mention marriage and family goals, whereas the goals of middle-aged adults relate to the lives of their children (Nurmi, 1992). Another well-established finding is that occupational goals lose priority with increasing age, while health-related pursuits do gain (e.g., Frazier, Hooker, Johnson, & Klaus, 2000). Ryff (1989b) demonstrated that younger people strive for accomplishment and career, whereas older people are more likely to aim at good health and the ability to accept change. In another vein, Riediger, Freund, and Baltes (2005) have suggested that the degree of goal convergence and interference may be considered another kind of relevant age-related change in the goal system.

Thus, whether the goal system shows more change or stability seems to be an issue of perspective. Although change in the goal system is evident, continuity has also been demonstrated (Frazier et al., 2000; Smith & Freund, 2002). For instance, across a 5-year period, people in late adulthood and old age tended to consistently mention the same domains of possible (future) selves at two measurement occasions (Frazier et al., 2000). And even for the old and oldest old more stability than change was reported with regard to the domains of possible selves across a 4-year period (Smith & Freund, 2002). Obviously, as was true for our discussion of the trait literature, evidence suggests that continuity as well as discontinuity play a role in age-related changes of the goal system.

Personal life investment (PLI), one aspect of the goal system, is defined as the amount of energy and effort (in terms of both acting and thinking) that people invest in central life domains (e.g., Staudinger et al., 1999). This broad conception of investment in terms of thought and action allows to capture all aspects of the motivational process, that is, goal selection, planning, and goal pursuit, but also disengagement from blocked goals and restructuring of goal hierarchies. The development of PLI in ten life domains (health, cognitive fitness, independence, well-being of one's family, relationships with friends, sexuality, hobbies, one's occupation or similar activities, thinking about one's life, and one's death and dying) has been studied across the entire adult life span.

Cross-sectional evidence from a sample ranging in age from 14 to 103 years demonstrated that the investment patterns across these ten life domains indeed reflect the developmental tasks of the respective life periods (Staudinger & Schindler, 2005). Certainly, age and its related social and biological demands is only one developmental context influencing investment patterns. In addition, socioeconomic characteristics and personality play an important role in moderating age-related differences in investment patterns. Finally, a distinction between investment related to age-graded societal and biological demands (obligatory) and self-selected investment (optional) turned out to be useful. These two types of investments follow stable and declining trajectories, respectively, as analyses with the longitudinal data from the BASE showed (Schindler & Staudinger, 2005b).

Summary on Stability and Change in Personality across the Life Span

Considering the evidence on the development of personality structure presents only half of the picture. Without the investigation of personality processes, we may be lead to think that personality and aging is about some increases in social adaptation and decreases in personal growth. Taking self-regulation and developmental regulation into account, however, "complicates" the story. Yes, there is stability that can be associated with enduring genetic and contextual influences. And there is a psychological need for coherence and stability that allows us to have a sense of enduring self. Stability, however, should not be completely equated with standstill. Rather, stability is also reflective of resilience. Considerable regulatory processes "produce" that stability. In addition to biological changes, change on the structural level of personality occurs when self-regulation cannot withstand the pressure for modification any longer. In the future, we need to better understand the biological underpinnings of personality functioning and how they change with age and interact with contextual features and individual choices.

Reserve Capacities of Self and Personality Development

As a further life span problematic, we have selected the notion of reserve capacity and resilience for further elaboration. This notion gains special importance for a functional perspective on personality development, that is, for perspectives that aim at an analysis of the orchestration of self and personality as a system of adaptive functioning. The topic of reserve capacity and resilience in the domain of self and personality relates to the allocation of resources introduced earlier but discusses this theme at a more microanalytic level of analysis. What are the self-related mechanisms and characteristics that either show or contribute to reserve capacity?

Traditionally, the central role of reserve capacity, or related concepts such as resilience, is articulated within the province of child development (e.g., Cicchetti & Cohen, 1995). More recently, this view was extended to include adulthood and old age (e.g., Brandtstädter, Wentura, & Rothermund, 1999; Staudinger et al., 1995; Vaillant, 1993). For the present purpose we have chosen aging as a forum of illustration. We make this selection for several reasons. One is the relative novelty of this age period for researchers in child development. Another is because presenting research on aging permits us to elaborate more clearly the theme of gains and losses and the dynamic of differential allocation of resources into growth, maintenance, and management of losses.

We discussed that there is little or no correlation between age and trait-based personality structure. In a similar vein, there is little correlation between age and various self-related indicators of adaptation (e.g., P. B. Baltes, 1993; Brandtstädter, Wentura, & Greve, 1993), including self-esteem (e.g., Bengtson et al., 1985), sense of personal control (e.g., Lachman, 1986b), or happiness and subjective well-being (e.g., Costa et al., 1987; Ryff, 1989a). This also includes 70- to 80-year-olds (J. Smith & Baltes, 1993). Only in advanced old age, do we seem to observe more salient changes toward a lower level of desirable functioning in trait-like dispositions (P. B. Baltes & Smith, 2003; J. Smith & Baltes, 1999). Thus, on the group level, for the larger part of the adult age spectrum, age does not seem to be a "risk" factor for these aspects of the personality system (note, however, that age challenges become larger when comparison with younger ages are requested).

The absence of strong relationships between age and self-related indicators of well-being, despite what we have characterized above as an increase in risks and potential losses with advancing age, but also for certain especially disadvantaged groups, is theoretically and methodologically important. Indeed, the discrepancy between an increasing number of risks on the one hand, and maintenance of adaptive functioning in the self on the other, is perhaps one of the most persuasive indicators of the power of the personality system in dealing with reality (P. B. Baltes & Baltes, 1990b; Greve & Staudinger, in press; Staudinger et al., 1995). It is suggested that the personality system exhibits resilience, or reserve capacity, in the face of age-related risks and primarily health-related losses. In a similar way, it has been argued in childhood research conducted in the field of developmental psychopathology that certain self and environment constellations allow maintenance of adaptive development even in the face of adversity (e.g., Garmezy, 1991).

Multiple arguments can be presented to understand this discrepancy between an age-related increase in risks and stability in self-related indicators of well-being (Staudinger, 2000). First and foremost, the self applies various protective mechanisms to reinterpret or transform reality in the interest of maintaining or regaining levels of well-being (e.g., M. M. Baltes &

Baltes, 1986; Filipp, 1996; Greve & Wentura, 2003). Second, age is only a rough proxy of increasing risks; not everyone of a given age cohort needs to be concerned by them. Therefore, the negative effects need not necessarily show on a group level. Third, as just argued, the self has a strong interest in continuity and growth. Over a given period of time, the self adapts to even adverse circumstances as if nothing or not much has happened. Thus, for researchers interested in the "self at work," it seems crucial at which point in this adaptive process the assessment takes place. Fourth, the changes due to increasing risks may be chronic rather than acute and therefore might not affect the self suddenly, but gradually. It may be difficult, therefore, for the self to recognize them and reflect them in self-report measures.

In the following, we will illustrate the reserve capacity of the personality system by citing select findings ordered according to the distinction introduced above between (a) form and structure of the personality system and (b) self-regulatory and self-transformational processes. Except for few studies with objective indicators of adaptivity, such as longevity or professional success, in most of the studies adaptivity is measured by self-report indicators of well-being. First, with regard to form or structure we will highlight information on differences in the adaptive fitness of personality and self profiles. Second, we will select evidence on the adaptive value of self-regulatory processes in three domains for further illustration of life span developmental changes: (1) goal seeking and reorganization; (2) self-evaluative comparison processes; and (3) coping. Finally, note that the protective mechanisms described in the following are an inherent part of theories of successful development such as the theory of selective optimization with compensation (P. B. Baltes & Baltes, 1990b).

Evidence for Reserve Capacity in Indicators of Personality Structure

There is longitudinal and cross-sectional evidence that individual differences in largely stable personality characteristics contribute to level of adaptation and sometimes even advances. From a life span perspective, it is important to note that the adaptive patterns differ somewhat depending on the first time of assessment (i.e., adolescence or adulthood) and thus whether short- or long-term predictions are involved. This applies especially to two traits widely assumed to constitute a risk or a protective factor, that is, neuroticism and optimism or cheerfulness (Friedman et al., 1995; Scheier & Carver, 1987). One possible explanation for the contradictory finding with regard to cheerfulness and optimism might be that cheerfulness in adolescence is linked to certain risk behaviors whereas optimism in adulthood is related to higher levels of positive emotions, which have protective effects in the face of stress (e.g., Fredrickson & Levenson, 1998). As very few life time studies are available, our knowledge about the long-term protective personality profile to date is still limited. Nevertheless, it seems safe to say that across a number of studies, positive expressions of the following personality characteristics have been demonstrated to mostly contribute to positive outcomes, thus, can be called general-purpose mechanisms (cf. Friedman et al., 1995; Helson & Wink, 1987; Manners & Durkin, 2000; Peterson, Seligman, Yurko, Martin, & Friedman, 1998): *Conscientiousness, extraversion, openness to experience, behavioral flexibility, ego resilience, ego level, internal control or agency (efficacy) beliefs, and cognitive investment.*

Another strand of research focuses less on trait-based personality characteristics than on the structure and content of self-conceptions. Evidence is accruing that a positive, multifocal and diversified, yet integrated structure of priorities and self-conceptions, or identity projects, makes transactive adaptation to developmental changes easier (e.g., Diehl et al., 2001; Freund, 1995; Riediger et al., 2005).

It is recent work that has shown that understanding the adaptivity of self-definitions is more complex than first thought. Combining dimensions like quantity, richness, positivity, integration, and importance of self-definitions, as well as differentiating real and potential selves in one theoretical framework will be an important step in capturing the adaptive life span dynamics of self-knowledge. Very important also seems a more explicit recognition of contextual factors including issues of collective self-concepts such as among spouses (M. M. Baltes & Carstensen, 1999; Hermans, 1996).

Evidence for Reserve Capacity in Self-Regulatory Processes: The Goal System and Self Evaluation

Selection of Goals and Life Priorities. Life span theory (P. B. Baltes, 1997) emphasizes the critical importance of selection of domains and life priorities for effective regulation of developmental processes such as advancement, maintenance, recovery and regulation of loss. In this sense, personality traits as well as possible selves act as motivational sources, and are linked to goals that are either strived for or avoided.

The evidence on life span development of life priorities and personal life investment patterns reported above indeed points to selection into individual life contexts and the importance of internal and external contexts in defining salient features of the self across the life span (see also Brandtstädter & Rothermund, 1994; Cantor & Fleeson, 1994; Carstensen, 1995; Staudinger & Schindler, 2005). Socioemotional selectivity theory, for instance, argues for systematic and adaptive life span changes in social goals over the life span (e.g., Carstensen et al., 1999). So, temporal constraints like impending end of life may shift the criteria used for selecting social relationships, requiring a corresponding change in the criteria for judging a particular relationship as adaptive (e.g., Carstensen et al., 1999).

Beyond the social realm, the adaptive value of life priorities in general seems to change. For example, older adults find meaning in life predominantly by searching for "contentment," whereas younger adults report searching for "happiness" (Dittmann-Kohli, 1991). Younger people tend to assess their subjective well-being in terms of accomplishments and careers, whereas older people associate well-being with good health and the ability to accept change (Ryff, 1989a). These changes are highly adaptive and illustrate the importance of flexibility—giving up or reducing investment in those roles and commitments that are no longer available, and investing in commitments which fit current conditions of living (e.g., Brim, 1992; Dittmann-Kohli, 1991; Freund & Baltes, 2002b). Flexibility in goals and investments, or priorities, is of course facilitated by a rich variety of self-defining concepts to select from and prioritize. In this sense, a rich variety of interrelated but well-articulated life goals is part of a person's developmental reserve capacity (cf. Staudinger et al., 1995; Riediger et al., 2005).

In addition to the repertoire and selection of goals, other facets of goal pursuit also relate to adaptation. Achieving a goal is usually adaptive, but the meaningfulness of the goal and the degree of commitment to it may enhance or limit that adaptivity (see also Brunstein, 1993; Emmons, 1996). Further, one must act; one study demonstrated that the relationship between people's goals and well-being was primarily mediated through doing more in the selected domain (Holahan, 1988; see also Harlow & Cantor, 1996). Recent evidence suggests that the pursuit of approach goals (or hoped-for selves) is related to greater well-being, while that of avoidance goals (or feared-for selves) relates to less well-being (e.g., Carver & Scheier, 2003; Elliot, Sheldon, & Church, 1997). Most of this research is done with young adults and much less is known about changes over the life span. Due to reduced resources and increased risks, avoidance goals seem to be more prevalent in later life and lose the dysfunctional effect which they evince in young adulthood (Freund & Ebner, in press). In old age it is the maintenance goals that demonstrate the highest adaptive value.

The adaptiveness of goal investment is also altered by life circumstances. Given highly restrictive life circumstances, such as major health constraints, concentration on a few selected goals rather than many helps to sustain levels of subjective well-being (Staudinger & Fleeson, 1996). This finding has been replicated with longitudinal data from the Berlin Aging Study (Schindler & Staudinger, 2005b). When considering a life span sample, it was found that it is during middle adulthood and into old age that the exact composition of the investment pattern (i.e., the selection pattern) contributes significantly to subjective well-being (Staudinger & Schindler, 2005).

The Adaptive Value of Self-Evaluations. In addition to changes in content, ranking, and valence of self-concepts and goals, self-evaluative processes can be considered protective or risk factors. Three motives of self-evaluation (see Fiske & Taylor, 1991) can serve protective functions—self-verification, self-enhancement (e.g., Taylor & Brown, 1988), and self-improvement (e.g., Taylor, Neter, & Wayment, 1995).

General statements such as "positive illusions are adaptive" are simplistic (cf. Taylor & Brown, 1988; Colvin & Block, 1994; Baumeister, 1989). It's important to know when positive illusions are adaptive (e.g., at which point in the action sequence; see e.g., Schwarz & Bohner, 1996). It may, for instance, be adaptive to have positive illusions before the action is completed to maintain motivation. But it may be dysfunctional to maintain positive illusions during implementation and when interpreting outcomes, because this reduces the likelihood of an adequate response (Oettingen, 1997). Consistent with this reasoning, people think more realistically when setting goals than when implementing them (Taylor & Gollwitzer, 1995). The particular content of the illusions is also important. For example, positive expectations about behavior outcomes contrasted with negative fantasies about the same outcome can result in the best behavioral outcome (Oettingen, 1996). Such unresolved recent issues

qualify the existing literature on the adaptivity of self-evaluations, which we address next.

Self-Evaluation: Social Comparisons. Goals shift in any activity during the life span, and those shifts lead to shifts in the selection and weighting of comparative information (Bandura & Cervone, 1983; Frey & Ruble, 1990). Individuals also modify their self-evaluative standards within a given domain in order to adapt to decreases in their behavioral competence or negative changes in their health condition, thus maintaining stability in their self-views (Buunk & Gibbons, 1997; Frey & Ruble, 1990).

Social comparison and other forms of interactive minds (P. B. Baltes & Staudinger, 1996a) are one important mechanism of self-regulation (e.g., Wood, 1996). New reference groups are selected or sometimes even constructed in order to permit a reorganization of personal standards of evaluation (e.g., Buunk, 1994). Downward comparisons, in which individuals compare themselves to people who are worse off in a relevant domain of functioning, may become more important with age, increasing levels of risk, or losses that cannot be remedied through instrumental action (e.g., Filipp & Mayer, 2005; Heckhausen & Krueger, 1993; Heidrich & Ryff, 1993). Of course, little is known about the level of consciousness at which people make such comparisons in everyday life.

The downward comparison story is not as simple as it seems, however (see also Wood, 1996). The operationalization of downward social comparisons varies markedly between studies. Some studies evaluate spontaneous reasons for self-evaluations provided "online," which are later coded for comparison standards. Other studies ask in retrospect for the frequency with which social upward, downward, and lateral comparisons are made and relate this to measures of well-being (e.g., Filipp & Buch-Bartos, 1994). Still other studies have participants rate themselves and a generalized other on certain personality dimensions, and then indirectly infer upward or downward comparisons (e.g., Heckhausen & Krueger, 1993). As suggested above, the most critical issue for adaptivity may be the use of the most functional comparison at the appropriate time during the person-situation transaction, something seldom addressed in these studies.

Self-Evaluation: Lifetime Comparisons. Besides social comparisons, comparisons with oneself at different times in the life span constitute an important resource for the self. As noted earlier, evidence on lifetime trajectories of social and lifetime comparisons remains scarce. In one study, higher frequency of future-oriented comparisons by older participants was related to lower well-being (Fillip & Buch-Bartos, 1994). In contrast, drawing on past successes in difficult situations can produce adaptive outcomes (Aldwin, Sutton, Chiara, & Spiro, 1996; see also Staudinger & Fleeson, 1996). Obviously, it is critical to distinguish between upward and downward temporal comparisons, as past and future comparisons can involve standards of better or worse functioning. It is not the temporal comparison per se that is protective or damaging; rather, depending on the characteristic or domain, and on the point in the self-regulatory process, lifetime comparisons can result in an enhanced self-evaluation or a sense of loss and decline. Selectively attending to positive aspects of the self at different points in the lifetime can support a positive sense of self at the present. The endorsement of selective lifetime comparisons may contribute to the lack of age differences in concurrent self-evaluations.

Longitudinal work has demonstrated that self-perceived personality change may be biased by what one might call "time enhancement" (Woodruff & Birren, 1972). Participants perceive improvement as compared to their own past, whereas the actual ratings collected at the two occasions (25 years apart) did not reveal significant change (see also Ross, 1997). Unfortunately, no interactions with age in this tendency to upgrade the past were tested. Other work on self-perceived personality change shows that discrepancies between ratings of past, present, future, and ideal personality are especially pronounced for young adults and hardly existent for older adults (Ryff, 1991; see also Ross & Bühler, 2001). It seems adaptive—and in line with respective developmental tasks—for young adults to strive for improvement and thus perceiving the past and the future to be of a different category (contrast effect; Schwarz & Strack, 1999). While for older adults, with decreasing resources, it seems adaptive to conceive of the future as being close to the present and the past and perceiving them as belonging to one category (assimilation effect; Schwarz & Strack, 1999). In this vein, a recent study found that in old age perceptions of ourselves in the past and the future have a stronger predictive value for our well-being in the present than in young and middle adulthood, which

may in fact contribute to perceiving fewer changes (Staudinger, Bluck, & Herzberg, 2003).

Persons' current view of themselves may not be meaningful unless we also understand how they believe they once were and will become. Being moderately extraverted in the present when having been very extraverted in the past has different implications for well-being than being moderately extraverted in the present and introverted in the past. Fleeson and Baltes (1998) showed that past and future ratings of personality predicted well-being above and beyond present ratings. When only current personality is assessed, the absence of information about change may mask relationships between personality perceptions and well-being (see also Fleeson & Heckhausen, 1997). Similar cautions apply to goal assessments. Regrets about past, unattained goals predict lower subjective well-being over and above current goal ratings and general tendencies toward negative affect (Lecci, Okun, & Karoly, 1994).

Coping and Control Strategies: Further Evidence for Reserve Capacity Related to Self-Regulatory Processes

In contemporary contextual models of coping (e.g., Brandtstädter & Greve, 1994; Filipp, 1999; Heckhausen & Schulz, 1995; Lazarus, 1996; Staudinger et al., 1995) questions of adaptivity are conditioned on the particular situation, including all its inherent constraints and demands. Whether a coping behavior is adaptive depends entirely on who does it, in response to which stressor, and in which situation the behavior occurs. In this vein, increasing evidence highlights the importance of context. For example, depending on a person's level of physical impairment, different coping styles are related to subjective well-being (Aldwin & Revenson, 1987; Staudinger & Fleeson, 1996). What has been labeled "regressive" and thus dysfunctional coping under "normal" living circumstances (e.g., "I like someone to take over," "denial," "I give up") is functional under conditions of physical impairment. Thus, older adults' "regression" in coping styles may be adaptive, given higher incidences of physical constraints (Staudinger et al., 1999). Of course, even "normally" adaptive behaviors are noneffective if not well executed (e.g., Suls & David, 1996).

Beyond the adaptivity of specific coping behaviors, it is important to have multiple coping options to choose from, while retaining some selectivity. Those old individuals who report selective flexibility in coping, that is endorsing some coping styles very strongly and others not at all, also demonstrate high levels of well-being (Staudinger & Fleeson, 1996). Similar findings are reported for coping with depression in old age. Rather than any particular form of coping, better mental health means being able to choose from several different responses (Forster & Gallagher, 1986). In a similar vein, the integrated multiplicity and selectivity (with regard to importance) of self-definitions has protective value, and social relations with multiple functions are a richer resource than other types of relationships (for an overview, see Staudinger et al., 1995). This evidence suggests that access to, and flexible selection from, a repertoire of regulating functions or characteristics (e.g., coping, self-definitions, functions of a relationship, life investments) may be a key resource used by individuals in proactive adaptation.

People obviously show highly adaptive coping behavior well into old age. In contrast to stereotypical views of the elderly as rigid, the evidence based on social-cognitive processes of self-representation, self-regulation, and self-enhancement, points to a substantial capacity for adjustment to and mastery of life's demands. Of course, this capacity for adaptation may find its limits in extreme situations, such as the challenges of advanced old age (P. B. Baltes & Smith, 2003; J. Smith & Baltes, 1999).

Many facets of coping and control processes remain uninvestigated or poorly understood, however, including the microgenesis of coping processes (e.g., Lazarus, 1996). To outline one example—findings suggest that the critical factors in success at quitting cigarette smoking involve being reflective and thoughtful (e.g., emotion/self-focused) at a planning stage and then problem-focused and behavioral during the actual quitting process (Perz, DiClemente, & Carbonari, 1996). As in the case of self-evaluative cognitions, it is also crucial to focus on the timing of coping. We need to consider which coping behavior is exhibited at which point in the coping process (e.g., Suls, David, & Harvey, 1996). For instance, longitudinal studies in the domain of coping with cancer (e.g., Filipp, 1999) and with death of a close person (e.g., Wortman & Silver, 2001) demonstrated that coping strategies such as "minimizing the threat" and "wish for someone to take over" maintained their adaptive power across a period of 9 months after the critical event. In contrast, the strategy "rumination" only showed positive relations during the first 3 months and turned into being maladaptive thereafter.

Summarizing Foci and Facets of Personality Development across the Life Span

In this section, we brought together theory and research from three different areas of research, that is, trait personality, the self-system, and self-regulatory processes. Each of these areas is characterized by their own foci and methodological approaches. We have argued that a life span perspective on personality development, rather than viewing these three approaches as relatively independent from each other or even mutually exclusive, tries to incorporate and integrate theoretical and empirical evidence from these fields. Dynamic systems theory and similar theoretical perspectives such as models of successful development provide useful theoretical guidance for this endeavor.

1. A central feature of personality development is the emergence of structure and of an associated system of self-regulatory mechanisms that mediate successful transactional adaptation. Beginning in childhood, we obtain solid evidence for structure, a sense of coherence, and some stable modes of adaptive behavior (e.g., Caspi & Bem, 1990). Such a view is represented in dynamic-system models of development (Magnusson, 1996), where principles of structural emergence and self-organization are critical for successful ontogenesis. Structural organization and coherence of personality, self, and self-regulatory mechanisms are a necessary precondition (constraint) for adaptive fitness and further growth. In this sense, the ensemble of features described function as general-purpose mechanisms.

2. Theory and research have advanced beyond the traditional trait versus change contrast. Traits themselves are part of the dynamic personality system. Thus, even stability is developmental in the sense that it is the result of surviving continuous challenge. Indeed, we do change during adulthood and old age but to a degree that does not jeopardize our sense of continuity. Personality development is characterized by a dialectic between trait expressions and self-regulation at work.

3. We have started to explore the fertility of extending the distinction between the biologically driven cognitive mechanics and the culturally driven cognitive pragmatics to also cover the field of personality functioning. The result of this endeavor is a heuristic model that distinguishes between the biologically driven mechanics and the culturally driven pragmatics of life. The two neurophysiological indicators selected to represent the mechanics of life, that is, heart rate activity and cerebral asymmetry, seem to evince less steep increases in the beginning and lesser decreases at the end of life; as well as lower longitudinal stability of interindividual differences when compared with the developmental evidence that is available about the life mechanics of cognition. One source of this difference in trajectories may be that for evolutionary reasons children are already further developed with regard to basic emotional and motivational tendencies than in terms of higher cognitive functions. Consequently, we may speculate that following the law of "first in, last out" these basic indicators of emotional and motivational functioning maintain higher levels of functioning until later in life than indicators of the cognitive mechanics. Such an interpretation would make it understandable why many personality mechanisms are well-preserved into older ages and only demonstrate decline when the oldest-old are considered.

4. There has been no systematic work as of yet on the interaction between the life mechanics and pragmatics of personality. Also our knowledge about the links between the neurophysiological and the behavioral level are still at the beginning. Thus, our insight into the functional relations between the life mechanics and pragmatics in that regard is rather limited. Nevertheless, the limited evidence available foreshadows the rich and complex interactions taking place along the continuum between the life mechanics and pragmatics of personality. The picture is further complicated by the special role of the self in the development of the mechanics and pragmatics of life. The self is not merely a developing element in this system, but also has an orchestrating function, coordinating cognitive, emotional, and motivational development. When it comes to life as a whole, the self can be postulated to play a central role in organizing our actions and thoughts, but we need to recognize that at least the consciously agentic self is but part of organizing behaviors.

5. Against this background, we suggest that in the domain of the personality system, developmental increases and stability dynamics extend over longer time spans than is true for the domain of cognition qua cognition. In fact, we have argued that the losses and stressors of adult life may even result in advances regarding the acquisition and refinement of self-regulatory skills. Still, when studying the resilience of the aging self, we also need to take into consideration

whether the underlying physiological and neurological systems have a debilitating and/or facilitating influence on self and personality functioning. The less positive evidence on personality functioning in the oldest old supports this conjecture.

6. Personality as a dynamic system composed of various components with different properties holds a domain-general potential for the transactional adaptation of the developing organism. We argued and presented evidence that personality serves an executive or orchestrating function with regard to the management of gains and losses during ontogeny. Personality possesses a great ability to negotiate the opportunities and constraints of development that come with age, historical, and idiosyncratic conditions. What we have called general-purpose mechanisms play a central role in this adaptational process. Besides protective personality structure and content, it is primarily the availability of a rich variety of self-regulatory mechanisms, and of an adaptive algorithm which monitors their application, that contribute to the adaptational power of personality. Table 11.6 summarizes these protective features in more detail. This adaptive potential reaches its limits in very old age when, due to biological processes, the functional losses may for more and more persons reach an overwhelming degree or at earlier ages when other extreme life circumstances result in an imbalance of gains and losses.

TABLE 11.6 Summary of Protective and Optimizing Characteristics of Self and Personality

Self and Personality Components	Protective and Optimizing Characteristics (Examples)
Personality	Conscientiousness, extraversion, openness to experience, behavioral flexibility, ego resilience, advanced ego level, and cognitive investment
Self-concept	Interrelated, well-articulated variety of self-conceptions and life priorities
	Positive agency (efficacy) beliefs
Self-regulatory and life-management mechanisms	
–Self-evaluation	Application of a functional type of comparison (up, down, lateral, temporal) at the appropriate time in the adaptational process
–Goal setting and restructuring	Selection and reorganization of life priorities
–Coping styles	Intraindividual variability and flexibility in coping styles and compensatory strategies
	Flexibility in adapting goals to circumstances
–Systemic processes	Selective optimization with compensation (SOC)

7. The systemic and overall developmental theory of selective optimization with compensation introduced in the first part of this chapter serves as a useful theoretical tool when analyzing the adaptive potential of the self and personality (P. B. Baltes & Baltes, 1990b). When orchestrating the optimization of development by processes such as selection and compensation, the appraisal of resources is of central importance. Questions such as how to evolve a goal structure and the associated goal-relevant means and motivational investment strategies, how to deal with selection-related disengagements from other possible goals, when to accept a loss and reorient one's life, and when to still strive harder because current behavior is not yet employed to its fullest capability become crucial in composing life development. Brim has argued, for example, that one criterion for making this decision could be to consider something like a "performance/capacity ratio" (Brim, 1992). According to this ratio, acceptance of a certain loss becomes necessary when the display of the behavior requires a "dysfunctionally" high amount of reserve capacity.

CONCLUDING COMMENTARY

The purpose of this chapter was to present life span developmental psychology as a theoretical orientation to the study of human development. Because the dominant theoretical approaches in developmental psychology have been formed primarily by research on infants, children, and adolescents, we made special efforts to highlight the uniqueness in developmental theory that emanates from a life span developmental framework. An unfortunate by-product of this strategy of presentation may have been the relative inattention paid to important commonalities between age-specialized developmental theories and theoretical efforts in life span work.

There is a larger (and growing) commonality in theoretical approach between more age-specialized developmental theories and life span developmental theory than might appear to be true based on the arguments presented in this chapter. In part, this is true because there are several new sources (only alluded to in this chapter) from which innovative theoretical efforts in various quarters of developmental psychology have emerged and which contain a structure of arguments similar to

those put forward in the short history of life span developmental theory. Work in cultural psychology, dynamic systems theory, and on other forms of self-organization in ontogenesis, are examples of this new theoretical treatment of ontogenesis that is beginning to pervade the developmental field as a whole.

As was true for life span psychology and the benefits it derived from its contact with the biology of aging, these new kinds of theoretical treatments have benefited from transdisciplinary dialogue, especially with modern developmental biologists but also anthropologists. Biologists have perhaps led the way in moving research away from unilinear, organismic, and deterministic models of ontogenesis to a theoretical framework that highlights the contextual, adaptive, probabilistic, and self-organizational dynamic aspects of ontogenesis (P. B. Baltes & Graf, 1996; Magnusson, 1996). Similarly, cultural psychologists and anthropologists (e.g., Cole, 1996; Durham, 1991; Valsiner & Lawrence, 1997) have succeeded equally in convincingly demonstrating that human ontogenesis is not only strongly conditioned by culture, but that the architecture of human development is essentially incomplete as to the culturally engineered pathways and possible endpoints (P. B. Baltes, 1997).

Not the least because of this transdisciplinary dialogue, a new conception has emerged regarding the "nature" (Kagan, 1984) of human development. In the modern context, the nature of human development no longer refers to the fixed-biological (P. B. Baltes, 1991; R. M. Lerner, 1984; Magnusson, 1996). Rather, in modern versions of ontogenesis, its nature is both biological and cultural, and both of these categories are subject to dynamic and interactive changes as well as systemic transformations. Of all developmental specialties, life span development, because of its intimate connection with long-term processes of individual development, cultural evolution, and generational transmission is perhaps the field most dependent on, and committed to, such views (e.g., P. B. Baltes, Reuter-Lorenz, & Rösler, 2006; P. B. Baltes & Smith, 2004; S.-C. Li, 2003). Most recently, the emergence of the concept of biocultural co-constructionsim is another justification of this orientation.

The future of life span developmental theory will depend significantly on the extent to which the metatheoretical perspectives advanced turn out to be useful in the conduct of empirical inquiry. On this score, the 1980s have witnessed impressive growth. In the area of intellectual development (see following), for instance, we now have available a cohort- and age-sequential study that extends over close to 50 years (Schaie, 2005) and demonstrates the varied conditions and outcomes which we can observe when placing adult development into the context of historical change and, in addition, consider processes of individual differentiation. There also have been advances in demonstrating the usefulness of the life span approach for other specialties such as clinical (Staudinger et al., 1995; Vaillant, 1990) and applied psychology (Abraham & Hansson, 1995; B. B. Baltes & Dickson, 2001; Sterns & Dorsett, 1994). In fact, these intersects of the life span approach to the study of human development with other psychological specialties need to be identified and nurtured.

Close to 25 years ago, one of us wrote: "There can be no strong field of life span developmental psychology without a solid foundation in and connection to childhood. By the same token, the study of child development does not exist in a vacuum, but is vitally enriched by considering the aftermath of childhood" (P. B. Baltes, 1979b, p. 1). Since then, there has been much progress in elaborating this reciprocal connection between age-focused developmental specialities and their integration into a life span view of human development, but at the same time, this challenge continues to be with us.

CHAPTER 12

The Life Course and Human Development

GLEN H. ELDER JR. and MICHAEL J. SHANAHAN

The study of the life course and human development flourished during the closing decades of the twentieth century, extending across substantive and theoretical boundaries (Mortimer & Shanahan, 2003), and now appears in many subfields of the behavioral sciences. With this change has come an increasing appreciation for linkages between changing contexts and human development. *Context* refers to the social embedding of individuals and often calls for the study of longitudinal, historical, and spatial variations. *Human development* entails patterns of growth and adaptation that extend from birth to death.

Conceptual breakthroughs associated with the life-course framework, coupled with the dramatic growth of longitudinal studies, have generated more research and knowledge than ever before about behavioral adaptations in real-world settings. We are also increasingly aware of individuals as agents of their own lives. New avenues of research have opened, and the future offers exciting promise for understanding how dynamic views of context and the person—including biological dimensions—interact to influence achievements, physical and psychological well-being, and social involvements.

To grasp the magnitude of this change, consider studies of person and society in the 1960s. In his widely read *The Sociological Imagination,* C. Wright Mills (1959) encouraged "the study of biography, of history, and of the problems of their intersection within social structure" (p. 149). Mills started with the individual and asked what features of society produce such a person. He argued that the seemingly "personal problems" of one's biography are better understood as repercussions of broad social tensions. He had few empirical examples, however, and was not concerned with dynamic views of person and context. Rather, he focused on types of society and adult behavioral patterns, with little recognition of social change, development and aging, or even human diversity. Indeed, longitudinal studies of human lives

We thank Ross Parke, Avshalom Caspi, and Richard Lerner, who provided thoughtful reviews to the first edition of this chapter (Elder, 1998a). The senior author is indebted to the Spencer Foundation for a Senior Scholar Fellowship. The staff of the Carolina Population Center provided valuable assistance in preparing the first and second editions of the chapter. We are particularly indebted to Lilly Shanahan for her thorough review of the second edition.

were an uncommon subject of study, particularly in their social and historical contexts. The concept of the life course had not yet appeared in the scholarly literature and was not addressed in the seminars of leading graduate programs.

The unfolding story of life-course theory up to the present owes much to a set of pathbreaking studies that were launched more than 60 years ago at the Institute of Child Welfare (now Human Development) at the University of California in Berkeley: the Oakland Growth Study (birth years 1920 to 1921) and the Berkeley Growth and Guidance Studies (birth years 1928 to 1929). When these studies began, no one could have imagined what they eventually would mean for the field of human development. The investigators did not envision research that would extend into the adult years of study members, let alone into the later years of old age. There were many reasons for this limited perspective. Except for support from the Laura Spelman Rockefeller Foundation, substantial funds for longitudinal studies were virtually nonexistent. In addition, the idea of adult development had not yet captured the attention of behavioral scientists. A mature field of adult development and aging was still decades away from becoming a reality.

Nonetheless, these considerations did not restrict the studies from continuing into the adult years and middle age. The Institute of Human Development contacted the members of the Oakland Growth Study for interviews in the early and late 1950s, and another follow-up, scheduled in 1972 to 1973, joined the lives of all study members, some parents, and offspring, in an intergenerational framework.

By the 1970s, Jack Block (1971), with the assistance of Norma Haan, had completed a pioneering longitudinal study focused on continuity and change in personality from early adolescence to the middle years in the lives of the Oakland and Berkeley Study members. Also during the 1970s, George Vaillant (1977) followed a panel of Harvard men (students recruited between 1939 and 1942) into the middle years of adulthood, assessing mechanisms of defense and coping. Another study at the Institute of Human Development (Elder, 1974/1999) placed the lives of the Oakland Growth Study members in the Great Depression and traced the influence of hardship on family life, careers, and health up to midlife. To cap off this active decade, investigators at the Berkeley Institute completed a multifaceted study that revealed patterns of continuity and change in social roles, health, and personality, with a distinctive emphasis on life patterns across the middle years (Eichorn, Clausen, Haan, Honzik, & Mussen, 1981). Both historical cohort comparisons and intergenerational connections were part of this project.

At Stanford University, a research team headed by Robert Sears actively followed members of the Lewis Terman sample of talented children into their later years. This was the oldest, active longitudinal study at the time, with birth years extending from 1903 to the 1920s. By the 1990s, the project had assembled 13 waves of data spanning 70 years (Holahan & Sears, 1995), and research had begun to reveal the historical imprint of the times on the study members' lives (Elder, Pavalko, & Hastings, 1991), from the 1920s to the post World War II years and into later adulthood (Crosnoe & Elder, 2004; Shanahan & Elder, 2002).

This extension of the early child samples to the adult years provided initial momentum to the scientific study of adult development and sharpened awareness of the need for a different research paradigm that would give attention to human development beyond childhood and to contexts beyond the family. What social routes to adulthood promoted behavioral continuity or change from the early years of life? Which ones enabled problem children to turn their lives around and become effective adults? Child-based models of development had little to offer because they did not address development and aging in the adult life course and were not concerned with changing social contexts. For the most part, studies of continuity and change from childhood to the adult years were limited to evidence of correlational patterns between measures at time 1 and time 2 (Jones, Bayley, Macfarlane, & Honzik, 1971). The intervening years and their mechanisms remained a "black box." Little, if anything, could be learned about linking events and processes from such analysis.

Kagan and Moss (1962), for example, studied the Fels children from "birth to maturity" by using correlation coefficients to depict behavioral stability across the years, but this approach ignored the diverse paths that youth take into adult life. By age 23, some of the respondents followed a path to college, full-time employment, and marriage, and others entered military service or mixed employment and education. The timing of such transitions was important in determining their meaning and implications. For example, adolescent marriage and parenting are coupled with more social and economic

constraints than the same transitions occurring according to a normative timetable, but late family formation maximizes economic advantages and minimizes the disruptive effect of young children. However, these considerations of context and timing—so richly descriptive of lives—were of little interest. In large part, this inattention reflected the view that continuity of behaviors and psychological dispositions required little explanation aside from the label "stability."

Empirical studies of children into their adult and midlife years revealed major limitations to conventional knowledge of human development, which, in turn, posed major challenges for the future study of behavior:

- To replace child-based, growth-oriented ("ontogenetic") accounts of development with models that apply to development and aging over the life course
- To think about how human lives are organized and evolve over time, exhibiting patterns of constancy and change
- To relate lives to an ever-changing society, with emphasis on the developmental effects of social change and transitions

As a whole, these challenges revealed a view of human development that was advocated by proponents of a contextualized psychology (e.g., Cairns & Cairns, Chapter 3, this *Handbook,* this volume) and many decades earlier by the Chicago school of sociology (Abbott, 1997), especially by William I. Thomas. With the close of the nineteenth century and through the first decades of the twentieth century (a time of massive changes in U.S. society), Thomas made a persuasive case for studying change as "experiments of nature" in the lives of immigrants and children. Inspired by Thomas and Znaniecki's *The Polish Peasant in Europe and America* (1918–1920), researchers began to use life-record data to investigate the impact of social change. Before most of the innovative longitudinal studies had been launched, Thomas urged, in the mid 1920s, that priority be given to the "longitudinal approach to life history" (Volkart, 1951, p. 593). He claimed that studies should investigate "many types of individuals with regard to their experiences and various past periods of life in different situations" and follow "groups of individuals in the future, getting a continuous record of experiences as they occur."

Social transformations of the twentieth century raised many questions about historical variations in family life and contexts beyond the family, including schools and communities. In the classic Middletown studies (Lynd & Lynd, 1929, 1937), findings on families during the 1920s seemed to have little relevance to family life in the Great Depression. Life-course theory emerged in the 1960s in response to these issues and to the challenge of an aging population and the rapid growth of longitudinal studies. In the terminology of this chapter, the *life course* refers most broadly to a theoretical orientation (or paradigm) that encourages the study of changing lives in changing contexts. To use Robert Merton's (1968) distinction, a *theoretical orientation* establishes a common field of inquiry by defining a framework that guides research in terms of problem identification and formulation, variable selection and rationales, and strategies of research design and analysis.

Based in large measure on sociocultural theories of age and social relations (Elder, 1975; Neugarten, 1968; Ryder, 1965), the life course as a *concept* refers to a sequence of socially defined, age-graded events and roles that defines, in large measure, the contours of biography. A sociocultural perspective gives emphasis to the social meanings of age. Birth, puberty, and death are biological facts, but their meanings in the life course are social facts or constructions. Age distinctions are expressed in expectations about the timing and order of a transition, whether early, on time, or late. The life course can be historically linked to specific transitions and to the meanings of cohort status (Riley, Johnson, & Foner, 1972). Birth year locates people in specific birth cohorts and thus according to particular social changes.

The first author encountered such ideas about age and life course in the 1960s, just after arriving at the Institute of Human Development (UC Berkeley, 1962) to work with sociologist John Clausen on the Oakland Growth Study. The dramatic changes of families and individual lives across the 1930s focused his energies on the patterning of lives and links to a changing socioeconomic system. Codes that captured trajectories were needed for people's lives instead of the conventional codes for status at one point in time such as family socioeconomic status (SES) and personal achievement or failure. The link between age and time provided an important step in this direction such as age-patterned events. This perspective on life changes suggested a way of thinking about the social construction of individual lives, along with ideas from the life-history tradition of the early Chicago School of Sociology. Thus, *Children of the Great Depression* (Elder, 1974/1999) represents the

published version of this initial effort to fashion a life-course framework.

Since its inception, life-course studies have expanded their purview beyond historical variations to include dynamic patterns of context in cohorts. These studies reveal remarkable diversity in cohorts with respect to poverty experiences and economic fortunes, residential mobility and the composition of neighborhoods, family structure and household membership, and experiences shaped by diverse stressors, employment patterns, and immigration (Shanahan, Sulloway, & Hofer, 2000). Each life is marked by social change in these respects, and the life-course framework has proved useful in studying how these dynamisms shape lives and how the social aggregate of individual life patterns affect social institutions.

We begin this chapter by viewing the emergence of life-course thinking as a response to some of the challenges we have noted, particularly those that stem from following children into middle and old age. Life-span ideas in developmental psychology, life-cycle theory of role sequences, and concepts of the age-graded life course were prominent in this conceptual enterprise. By the end of the 1970s, a new synthesis, relating theory on relationships and age, achieved a theoretical orientation.

The basic concepts and distinctions of life-course theory are surveyed in the next section, with emphasis on the individual life course, its institutionalized pathways, developmental trajectories, and transitions. In addition, paradigmatic themes of life-course theory are identified and illustrated by research projects. The themes include human agency and choice making in the construction of lives, the timing of lives, linked or interdependent lives, and human lives in historical time and place. This account explores distinctive contributions of life-course theory to studies of children, adolescents, and young adults. The concluding section features newly emerging developments in life-course study, with an emphasis on biological perspectives, and a promise of a theoretical framework that combines biology, social and cultural influences, and psychology.

THE EMERGENCE OF LIFE-COURSE THEORY: A HISTORICAL ACCOUNT

Over the past 30 years, advances in life-course theory and research have come from many quarters across the behavioral and social sciences, identifying important problems and defining approaches from sociology (Elder, 1974/1999, 1975, 1985; Riley et al., 1972), demography (Ryder, 1965), history (Hareven, 1978, 1982; Modell, 1989), anthropology (Kertzer & Keith, 1984), and both ecological (Bronfenbrenner, 1979) and life-span developmental psychology (Baltes & Baltes, 1990). Major examples include:

- Recognition of a life-course perspective on human development, extending from birth to maturity, and the rapid growth of longitudinal studies that link childhood and the adaptations of later life (Phelps, Furstenberg, & Colby, 2002; Young, Savola, & Phelps, 1991).
- Life-history calendars for the collection of retrospective accounts of life events (Caspi et al., 1996; Freedman, Thornton, Camburn, Alwin, & Young-DeMarco, 1988).
- New appreciation for the necessity of longitudinal, contextually rich data (Hofer & Sliwinski, 2002; Little, Bovaird, & Marquis, in press); appropriate statistical techniques; and structural and dynamic, person- and variable-centered approaches (e.g., Bergman, Magnusson, & El-Khouri, 2003; Collins & Sayer, 2001; Little, Schnabel, & Baumert, 2000).
- Cross-disciplinary models of collaboration (Elder, Modell, & Parke, 1993), particularly with psychology and history, but now extending to exciting developments in subfields devoted to the study of physical and emotional well-being (Halfon & Hochstein, 2002; Hertzman & Power, 2003; Kuh, Ben-Shlomo, Lynch, Hallqvist, & Power, 2003). This chapter draws liberally from these sources in exploring the relevance of contemporary progress for studies of child, adolescent, and adult development.
- A growing awareness that, beyond history and the differing experiences of cohorts, social change may refer to dynamic contextual patterns experienced *within* cohorts through diverse life histories (Shanahan et al., 2000). Further, many contextual features are correlated, and their synergistic interactions are critical to understanding time and place.

As is seen, these developments have relevance for the study of the individual life course, its relation to changing social and historical conditions, and its implications for developmental processes. In this respect, life-course theory has much in common with interactionist think-

ing—which emphasizes interactions between person and context (see Magnusson & Stattin, Chapter 8, this *Handbook,* this volume)—but it also attends to the organization and reorganization of social structures and pathways through life. As might be expected, life-course theory shares many objectives and concepts with the ecology of human development (Bronfenbrenner, 1979; Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume), including a multilevel concept of the environment, from micro to macro. Life-course models also share the ambition of life-span developmental psychology in rethinking the nature of human development and aging (Baltes, 1994; Baltes, Lindenberg, & Staudinger, Chapter 11, this *Handbook,* this volume), but with particular attention to links between changing contexts and lifelong development.

The principal traditions that led to life-course theory are illustrated in Figure 12.1: life-span concepts of development, social relations, and age and temporality.

The first strand (life-span concepts of human development) includes references to the pioneering work of Erik Erikson's (1950, 1963) psychosocial stages of development and Paul Baltes's (1997) process of selective optimization with compensation. In addition, Richard Lerner (1982, 1991) has stressed the relative plasticity and agency of the aging organism (see also Schaie, 1965, with emphasis on the later years of aging), the multidirectionality of life-span development, and the lifelong interaction of person and social context. The concept of developmental task, perhaps first delineated by Robert Havighurst (1949), also represents a way of viewing development across life stages. The concept alerts the analyst to the possibility that specific experiences may be highly salient at different points in life, although empirical evidence for distinct psychosocial stages is not compelling. The perceived or defined life course can change with aging through successive life reviews in which the past is assessed in light of the present. Staudinger (1989) has focused on "life review" as a way of studying intellectual development across the life span.

The second strand (social relations) includes the early work of W. I. Thomas on life histories (Thomas & Znaniecki, 1918–1920), G. H. Mead on socialization and the self (1934), Everett Hughes on work and the self (1971), Kurt Lewin on power dependence relations (1948), and L. S. Vygotsky on language, the self, and social relationships (1978; see also Clausen, 1968; Parke, Ornstein, Rieser, & Zahn-Waxler, 1994). The development of social role and self theories belongs in this tradition, and features the writings of sociologist Robert

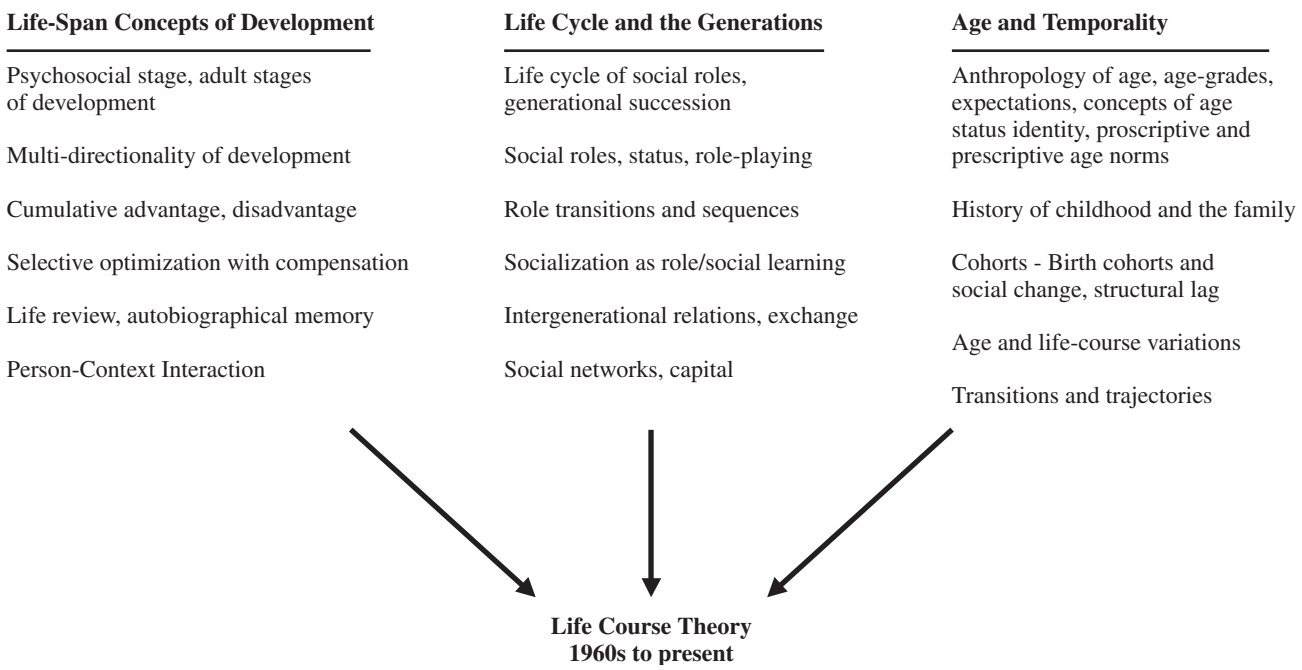

Figure 12.1 The emergence of life-course theory (1960s to present): research traditions and their concepts.

Merton on role sets and reference groups (1968), Morris Rosenberg (1979) on self-esteem, and Urie Bronfenbrenner on socialization (1970), to name a few. The field of intergenerational relations has expanded from two to three and even four generations, with important contributions to an understanding of three generations from Reuben Hill (1970), Vern Bengtson and Laufer (1974), James Jackson (2000) and his three-generation study of African Americans, and Ross Parke (Parke & Ladd, 1992).

A number of topics illustrate distinctive contributions to a third strand (the study of age and temporality in lives). These include the early contributions to age-grading by social and cultural anthropologists and the pioneering analysis of birth cohorts and generational units by Karl Mannheim in the 1920s (Elder, 1975). Also covered is Bernice Neugarten's work on the social psychology of age and the innovative sociological contributions of Matilda Riley and her collaborators. Demographers Uhlenberg (1974) and Hogan (1981) have produced creative analyses of cohort life patterns and age-grading. In social history, Hareven (1978, 1982) and Modell (1989), among others, have made imaginative contributions to a historical understanding of the life course. The study of age expectations and timetables in adolescent development is nicely illustrated by Silbereisen's programmatic study of youth affected by German reunification (e.g., Silbereisen & Schmitt-Rodermund, 1995; Silbereisen & Wiesner, 2000, 2002).

We turn now to a survey of each strand of influence on life-course theory.

Concepts of Human Development across the Life Span

A number of efforts in the psychological sciences were made during the post-World War II years to link child and adult developmental trajectories to social structure and changes in society, though typically from the perspective of a maturing or aging organism. Research questions did not ask about the implications of environmental change for the developing individual. Erik Erikson's (1950, 1963) theory of psychosocial stages was formulated with an eye to cultural variations, but he also largely saw the social system and culture from the vantage point of the developing organism. Likewise, Daniel Levinson's (1978) *The Seasons of a Man's Life* outlined a theory of life structure that ignored variations in social structure and culture over historical time in which psychosocial transitions were affixed to age as if immutable to institutional change, such as the midlife transition between ages 40 and 45. For Erikson, Levinson, and other ontogenetic theorists, the starting point was a sequence of stages through which all persons must pass.

This perspective views the social context as a "scene or setting" through which the person—loaded with his or her "natural predispositions"—must pass. By contrast, the life-course paradigm views the interplay of social context and the organism as the formative process, making people who they are. Individuals do not "develop according to their natures" but, rather, they are continually produced, sustained, and changed by their social context (see Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume). Indeed, Mitterauer (1993) observes that, in many times and places, historians find little evidence of Erikson's stages.

Proponents of life-span developmental psychology (a field of inquiry first identified by name in 1969) addressed the challenges of such a circumscribed view by seeking a concept of development and aging across the life span that emphasizes cultural influences and learned experiences or skills in patterns of aging. In theory, historical and cultural variations emerged as particularly influential sources of adult adaptations and development. As Baltes (1979) observed, "It appears that restricting developmental events to those which have the features of a biological growth concept of development is more of a hindrance than a help" (p. 265).

Paul Baltes (1993, 1994) has been a major figure in the conceptual articulation of life-span development since the 1960s. More than most proponents of this perspective, he has interacted with life-course ideas and distinctions over the decades (see Baltes et al., Chapter 11, this *Handbook,* this volume). The following propositions on life-span development are not new in themselves but they add up to a distinctive perspective:

- Life-span development results from lifelong adaptive processes in which some are cumulative and continuous, and others are discontinuous and innovative, showing little connection to prior events or processes.
- Ontogenetic development is local, specific, and time-bound, so it is never fully adaptive. There is no pure advance or loss in development.
- Age-graded influences are most important in the dependency years, childhood/adolescence and old age,

but history-graded and nonnormative influences are most consequential across the early and middle years of adulthood.

- Changes occur in relation to positive and negative events, gains, and losses, with the likelihood of expected losses increasing. Biological resources decline over the life span, but cultural resources may increase such as the cultivation of wisdom.
- Life-span development entails *selection, optimization,* and *compensation.* These mechanisms seek to maximize gains and minimize losses or declines. Selective optimization with compensation represents a "life-span model of psychological management that describes how individuals can deal with the dual faced nature of human aging and the ubiquitous, age-related shift toward a less positive balance of gains and losses" (Baltes, 1993, p. 590).

The way these mechanisms or strategies work in later life is illustrated by an interview with the concert pianist Arthur Rubenstein. When asked how he remained a successful pianist in his late years, Rubenstein referred to three strategies: "(1) he performed fewer pieces, (2) he now practiced each more frequently, and (3) he introduced more ritardandos in his playing before fast segments, so that the playing sounded faster than it was" (Baltes, 1993, p. 590). The strategy of selection is illustrated by Rubenstein's concentration on fewer pieces, the more frequent practice illustrates the use of optimization, and the increasing reliance on contrast in speed exemplifies a strategy of compensation.

This psychological model of successful aging has relevance for successful development at all ages including childhood and adolescence. Adaptations in adolescence can be viewed through the guidelines of selective optimization in which gains are maximized and risks, losses, or deprivations are minimized. Youth select activities in which they are competent (i.e., athletics, academics, or street life) and optimize benefits through an investment of resources, time, energy, and relationships. Marsiske, Lang, Baltes, and Baltes (1995, pp. 35–36) rightly claim that selective optimization with compensation is best understood as a metamodel for life-span development because it applies broadly to aspects of the "developmental person-context matrix." Life-span developmentalists, such as Baltes, Schaie, and others, have undoubtedly enriched our thinking about development and aging across the life course, and they have given some attention to the role of social, cultural, and historical forces in developmental processes.

However, concepts of life-span development generally fail to apprehend social structure as a constitutive force in development. The problem stems from the life-span framework's conceptualization of context, which refers to age-graded, history-graded, or nonnormative influences: Age-graded influences shape individual development in largely normative ways for all persons, history-graded influences shape development in different ways for different cohorts, and nonnormative influences reflect idiosyncrasies (e.g., losing a leg in an accident). Such a view has been unduly restrictive in two senses. First, within-cohort variability largely reflects nonnormative influences, which are not easily subject to scientific study (Dannefer, 1984). As a result, the social basis for within-cohort differences becomes a residual category. Second, as Mayer (2003) has noted, life-span psychology views historical and nonnormative influences as idiographic (i.e., unique, nonrepeating), leaving only age-graded influences, which are thought to be largely based in biology and age norms.

Because the larger social forces that lead to age norms are of little interest, within-cohort regularities in behavior are explained solely by personal attributes (biology and internalized norms). In the final analysis, the study of contextual influences in cohorts is hampered because it produces largely invariant patterns through such age-graded influences, or it cannot be studied because of its seemingly random nature. Despite these conceptual difficulties, life-span studies are beginning to investigate links between broader social contexts and individual functioning (e.g., Heckhausen, 1999).

The important issue to recognize is that there is not one optimum *point of entry* for studying human development across the life span (see also Shanahan & Porfeli, 2002). Indeed, the multilevel nature of human development invites different points of entry (each with specific research questions) ranging from cultures and social institutions to the human organism. Entry points frequently link or cross adjacent levels in the developmental process. Studies commonly employ different entry points in the same research, although framed by a central question. Thus, a project motivated by the impact of rural change on children's social and emotional development should be framed by an initial focus on some aspect of this social process such as the degree of economic hardship and displacement. Inquiry would explore

the process by which this change makes a difference in children's developmental experience. Parts of this study might also investigate the determinants of specific emotional or social outcomes and relevant protective resources in the family, a point of entry that centers on the developmental status of the child. Still other entry points might begin with the interchange of parents and child or with sibling relationships. Each point could become a framing statement for an independent study.

How Lives Are Socially Organized: Roles, Cycles, and Age

The second column of Figure 12.1 refers to how an individual's life pattern is structured by multiple role sequences and their transitions. These transitions into and out of social roles across the life span entail both social and personal changes in status and identity (Glaser & Strauss, 1971). In their field studies, anthropologists have referred to a patterned role sequence from birth to death as a "life cycle" (Kertzer & Keith, 1984). Changes in major roles, such as from youth to marriage and parenthood, generally represent changes in a social stage across the life cycle.

In concept, the life cycle views life organization through social relationships, particularly kin relationships, and generational succession. A dominant concept of the life span from the early 1900s up to the 1960s, life cycle generally referred to a sequence of social roles among individuals and families. A more precise social meaning of life cycle is a sequence of stages in parenting, from the birth of children through their departure from the home to their own children. The role sequence refers to a reproductive process that always applies to human populations. In a life cycle of generational succession, newborns are socialized to maturity, give birth to the next generation, grow old, and die. The "cycle" is repeated from one generation to the next in a human population (O'Rand & Krecker, 1990).

Life cycles as reproductive cycles vary greatly in the pace of their revolutions. Early childbearing, shortly after menarche, accelerates the cycle and shortens the distance between the generations. When the eldest daughter has a child before the age of 13, her mother may become a grandmother before the age of 30 and a great-grandmother before the age of 50. A sequence of early childbearing across the generations weakens the generational and age basis for family authority and social control. By contrast, late childbearing slows the cycle and minimizes age similarities across adjacent generations. In a rapidly changing world, parents, grandparents, and children share less culture and historical experience.

The life cycle concept incorporates both socialization and social control processes. The predominant roles of a life stage lock people into a set of normative expectations and informal sanctions that provide direction and discipline. Commitments to a line of action arise over time through obligations to significant others (Becker, 1961, 1964). Stable role relationships ensure a measure of personal stability, just as entry into such relationships can stabilize a person's life and minimize involvement in unconventional and dangerous activities. Sampson and Laub (1993) observed, in their sample of men from a low-income urban sample, that adult bonds to conventional figures and lines of activity defined a route of escape from delinquency for a substantial number of men with a childhood history of delinquency and economic disadvantage.

During the familistic post-World War II years, the life cycle became well known as the *family cycle* through the writings of Paul Glick and Reuben Hill; a set of ordered stages of parenthood defined primarily by variations in family composition and size (Elder, 1978). Major transition points included courtship, engagement, marriage, birth of the first and last child, the children's transitions in school, departure of the eldest and youngest child from the home, and marital dissolution through the death of one spouse. Family life in this era provided a better fit to this sequence of roles than it does today. Marriage and parenting have been uncoupled to a considerable extent (Bumpass & Lu, 2000). Children are increasingly born prior to marriage or outside of marriage altogether. In the United States, the prevalence of divorce has led to multiple families in a person's life and to the likelihood that most children will experience a single parent household before they enter adulthood.

The life-cycle concept and its family-cycle version usefully knit together the full array of life stages and generations. They also provide insight into processes of socialization and social control over the life span that link the developing person and his or her career. And yet, the life cycle's focus on reproduction and parenting has limited value as a way of viewing the lives and developmental trajectories of children and adults because it does not apply to never married, nonparent, or divorced persons, all of whom have become increasingly common (e.g., Fussell, 2002). The focus on a single ca-

reer also ignores the realities of multiple careers, and each person generally occupies multiple roles at the same time (whether spouse and parent or spouse and employee), but these concurrent roles are not part of the life cycle's scope. Consequently, the life or family cycle did not orient research to the management or coordination of multiple roles such as marriage and work. By the end of the 1960s, a prime era for life-cycle research, a survey by Young and Willmott (1973) concluded that studies of work and family had proceeded along separate paths with no significant effort to examine their interdependencies. This contrasts rather strikingly today with the flourishing study (with an emphasis on interlocking trajectories) of work and family relations (Blair-Loy, 2003; Crouter, Maguire, Helms-Erikson, & McHale, 1999; Drobnic, Blossfeld, & Rohwer, 1999; Moen, 2003; van der Lippe & van Dijk, 2002).

In addition, the life cycle is insensitive to temporal location and matters of timing. The concept depicts a sequence of social roles and transitions. Social roles are ordered but are not temporally located in a person's life. In the case of the family cycle, for example, each stage of parenting could be arrayed in a sequence but would not be bound by age or the temporal markers that come with a perspective on the age-graded life course. A life-cycle model of a person's life might locate marriage before the first birth, but it would not indicate whether the marriage occurred at 20 or 40 years. Sequence models thus provide only part of the story on life context.

The kinship term of *generation* is part of a life-cycle perspective and shares its blindness to temporality. Members of an ancestral generation do not occupy a common historical location relative to events and long-range trends. A parent generation, for example, may have birth years that span 30 years, a period that could include eras of economic depression, global war, and peace in the twentieth century. The greater the time span, the more diverse the historical experience of the generation. With these points in mind, it is apparent that generational role or position cannot offer a precise way of connecting people's lives to the changes in society. Indeed, intergenerational studies are generally distinguished by their insensitivity to historical time or location; generations are frequently studied in the timeless realm of the abstract.

Temporal limitations of this kind are generally characteristic of models based on role theory. Ebaugh's study of role exits (1988) makes this limitation very clear. The concept of "role exit" involves a change of identity in terms of the new role and its predecessor, but Ebaugh makes no explicit reference to timing across the life span or to historical time. Judging from the analysis, one might conclude that it is not consequential whether an illness and death involves a child or a grandparent, whether family separation occurs in one's 20s or 50s, or whether a lay-off occurs at the beginning or the end of one's productive work life. On the contrary, the evidence suggests that timing matters because social timetables, age norms, and age-graded sanctions influence individuals.

In summary, role sequences and identity change, socialization and social control, the life-cycle perspective, and generations are conceptual elements of a *relationship* view of life patterns and organization that dates back to the nineteenth century. One of the earliest proponents of this view, sociologist W. I. Thomas, used life-record data to study the emigration of Polish peasants to European and U.S. cities around the turn of the century (Thomas & Znaniecki, 1918–1920). In this pioneering work, described as "the greatest single study done thus far by an American sociologist" (Nisbet, 1969, p. 316), the lives of immigrants embodied the discontinuities of the age; they were socialized for a world that had become only a memory. The societies they left and entered—the Old World and the New—presented contrasting *lines of genesis* or primary sequences of social roles for individual adaptation and development. Matters of social and historical time are clearly relevant to this project, and yet, Thomas and Znaniecki were largely insensitive to them.

For many years, the relationship and life-cycle perspective offered a valuable way of thinking about the social patterning and interdependence of lives, although limited in a number of respects. During the 1960s, this approach began to converge with new understandings of age to form life-course models that combined the virtues of both theoretical traditions: linked lives across the life span and generations, and temporality through an age-graded sequence of events and social roles, embedded in a changing world. In addition, these models were informed by life-span concepts of human development that underscored the agency of individuals in the social construction of their lives and life courses.

Age and Life Course

The importance of the 1960s in linking these theoretical traditions had much to do with the appearance of new

thinking about age, including an appreciation for its diverse meanings and consequences (see third column of Figure 12.1). These new thoughts include an emphasis on subjective experiences with the age structures of society and the individual's own construction of a life course, as expressed in the pioneering work of Bernice Neugarten (Neugarten, 1996; Neugarten & Datan, 1973). In the University of Chicago's Committee on Human Development, post-World War II studies, such as the Kansas City project, were more successful than other efforts at the time in linking human development through the adult years to the social structures in which people lived. For example, Neugarten and Peterson (1957) observed a relationship between age-linked concepts of self and life stage by socioeconomic position. Working-class people were older when they entered the self-defined middle years of life, compared to upper-status people. Neugarten contributed to this early work by connecting socioeconomic careers to adult psychology, role transitions, and generations. We return to these important contributions in the context of age-based perspectives on the life course. Through the innovative work of Norman Ryder (1965) and Matilda Riley (Riley et al., 1972), a more developed articulation of the relation between historical time and lives was proposed, as expressed through membership in age cohorts and successive age strata. For the first time, this work joined two relatively independent lines of research on age (Elder, 1975): (1) sociocultural and (2) cohort-historical.

Sociocultural Patterns in Human Experience

The relevance of age for a sociocultural understanding of life organization has evolved over many decades of ethnographic study by anthropologists, as in research on age-grading and age-set societies (Kertzer & Keith, 1984). This work has generally focused on age structures in culture; however, the new inquiry explored individual experiences of age and age-grading, giving fresh insights to the social and psychological variability of people's lives.

Contrary to a structural view of age patterns in cultures (Eisenstadt, 1956; Kertzer & Keith, 1984), studies began to show that people of the same age do not march in concert across major events of the life course; rather, they vary in the pace and sequencing of their transitions and they do so in ways that have real consequences for family pressures, child socialization, and personal well-being. This variation also appears in accounts of differential aging among people who follow different social trajectories.

During the late 1950s and early 1960s, Bernice Neugarten directed a research program that featured a concept of normative timetables and individual deviations from such expectations (Neugarten & Datan, 1973). The timetable of the life course refers to social age, as defined by people's expectations regarding events. In theory, age expectations specify appropriate times for major transitions, and violations of these expectations may lead to punitive responses from others. There is an appropriate time for entering school, leaving home, getting married, having children, and retiring from the labor force. Neugarten, Moore, and Lowe (1965) observed a high degree of consensus on age norms across some 15 age-related characteristics in samples of middle-class adults. The data reveal general agreement among men and women on the appropriate age for a woman to marry and support the hypothesis that informal sanctions are associated with relatively early and late marriage. Moreover, the women were aware if they were on time, late, or early with respect to marriage and other major role transitions.

Although subsequent studies have extended this line of research (Settersten & Mayer, 1997), relatively little is known about age expectations and their boundaries and related sanctions; thus, doubts have been raised about age norms (Marini, 1984). These topics deserve far more attention than they have received to date. Some notions about the proper phasing of the life course take the form of cognitive descriptions or predictions rather than normative accounts, whether prescriptive or proscriptive. However, the process by which these descriptions or age expectations are constructed, transmitted, and learned remains largely unexplored territory.

For many decades, age-grades or categories were inferred as possessing common significance without evidence of their meaning to the individuals involved. At what point do young children take the perspective of a student? When do young adults begin to take an adult standpoint and view themselves accordingly? Is the main transition point for an adult perspective marriage, the birth of a child, or stable employment? Such questions were of interest in Neugarten's research program, and she broke new ground in testing the proposition that life stage is partially a function of one's socioeconomic status and career.

In the mid-1950s, Neugarten found that men in the lower-economic strata were likely to perceive a more rapid passage through the major age divisions of life

than did middle-class men: Maturity, middle age, and old age come earlier at a lower-economic strata, owing perhaps to class-linked occupational demands and stresses (Neugarten & Peterson, 1957). The man who relies on mental skills in a sedentary occupation foresees a relatively long period of productivity, while the man who works with his hands expects a relatively short span of productive activity, followed by retirement. This research is one of the earliest contributions to what is now called a "constructionist perspective on the life course" with its emphasis on human agency and choice making.

Age distinctions order social roles (e.g., the sociocultural perspective of the Neugarten studies), but they also order people through age or birth cohorts. Cohorts have long been common to demographic research on marriage, fertility, and divorce. However, these cohort studies were not carried out with an interest in the life course.

Age Cohorts in Lives

Important theoretical work on the link between life patterns and changes in society began to appear in the 1960s, featuring Ryder's influential essay on "The Cohort as a Concept in the Study of Social Change." The most comprehensive pioneering work was authored by Matilda Riley and her colleagues in *Aging and Society* (Riley et al., 1972). Riley and her colleagues viewed age as a basis of stratification in historical experience and in role sequences across the life course. "Whereas socioeconomic strata are ranked to form a social hierarchy, age strata are typically ordered by time (hence, are more akin to geological strata)" (p. 23). Birth year indicates historical time, and chronological age acquires the meanings of social timing and life stage. Birth cohorts provide a link between historical change and the life course.

Birth year or date of entry into a system (such as school graduation or marriage) locates the individual according to historical time and related social changes: With age peers in the cohort, this person is exposed to a particular segment of historical experience as he or she moves across the sequence of age-graded roles. To grasp the meaning and implications of birth year and cohort membership, the analyst specifies the distinctive historical events and processes at the time, as well as characteristics of the cohort such as its size and composition. These characteristics are themselves a consequence of historical changes in birth and death rates, immigration, and migration.

Adjacent birth cohorts are most sharply differentiated during rapid change, and represent a vehicle of social change when cohort differences arise. As successive cohorts encounter the same historical event, they do so at different stages in their life course. This means that adjacent cohorts bring different life experiences to the change. Consequently, the impact of the event is contingent on the life stage of the cohort at the point of change. Ryder (1965) stressed this "life-stage principle" in his account of cohort differences in the life course. As each cohort encounters a historical event, whether depression or prosperity, it "is distinctively marked by the career stage it occupies" (p. 846). Examples include the differential age of military entry among U.S. veterans who served in World War II. The age range spanned 20 years: Some recruits had just left high school while others were in their mid-30s with families and careers.

From this vantage point, historical influence in life experience can take different forms in cohort studies. One form is expressed as a cohort effect when social change differentiates the life patterns of successive cohorts such as the older and younger "children of the Great Depression" who were born in the 1920s. Consistent with the life-stage principle, younger children, and especially the boys, were most adversely influenced by the economic stresses of the economic collapse (Elder, 1974/1999). Cohort differences were also expressed in the prevalence of a behavior or practice such as life-course reorganization or the proportion exposed to trauma in World War II.

A cohort effect may also be expressed in a changing social mechanism, as expressed in the transition to parenthood across four birth cohorts of White women in upstate New York, United States (Forest, Moen, & Dempster-McClain, 1995): 1907 to 1918, 1919 to 1923, 1924 to 1928, and 1929 to 1933. The first cohort came of age during the Great Depression, the second moved into adulthood during World War II, the third made the transition in the early post-World War II years, and the fourth became parents during the 1950s. The study found employment before marriage to be a primary source of childbearing delay for women in the first two cohorts. However, in the younger cohorts, educational advancement played a significant role in the delay of the first birth, far more than premarital employment. Advanced education was becoming increasingly important in the lives of women, including women's return to school following marriage and

the birth of children, especially in the third and fourth cohorts.

In addition to cohort effects, history takes the form of a period effect when the influence of a historical change is relatively uniform across successive birth cohorts. Rodgers and Thornton (1985) conclude that "most of the changes in marriage rates observed during this century are the consequences of period characteristics" (p. 21) rather than of differences between cohorts. They draw the same conclusion about rates of marital dissolution and instability: "the big picture is one of overwhelming historical effects that influenced all subgroups of the population substantially and surprisingly equally" (p. 29). On divorce, they refer especially to the rising level up to the 1930s, the decline in the Great Depression era, a rapid recovery to the extraordinary peak of divorce in the mid-1940s, and to the upward trend during the 1960s and 1970s. The precise factors in these period variations remain to be determined.

Efforts to disentangle these effects (cohorts and period) and those associated with maturation or aging have not advanced knowledge on historical change in lives. Cohort studies seldom address questions that specify a type of social change or the process that makes a difference. Life-span studies, for example, may assign environmental change to an error term or view cohorts as a test of the generational boundaries of behavioral outcomes, as in cohort sequential designs (Baltes, Cornelius, & Nesselroade, 1979). However, even when history is substantively important for understanding developmental change, this influence is likely to be operationalized as a period or cohort effect that provides no clue as to the precise nature of the process.

Another approach to historical change—the comparison of cohort subgroups—rests on the empirically documented assumption that members of each birth cohort are exposed differentially to trends and events. Not all children who lived through the Great Depression were exposed to severe hardships, and not all veterans of World War II were exposed to heavy combat. In the Great Depression, families did not uniformly experience the economic decline, and family hardship did not affect all subgroups of children in the same way (Elder, 1974/1999). Though variations by subgroups in specific birth cohorts represent a significant advance over cohort comparisons, even more valuable is a focus on exposure to a particular contextual or historical change. This strategy has more to offer in developmental and life-course implications because research is directed to the explication of a specific change process such as family adaptations to migration.

Cohort membership has specific implications for lives when a particular cohort size is paired with available economic opportunities. Richard Easterlin (1980) has pursued this issue in his account of postwar change in the work lives of men. His point of departure was the link between the supply of younger men and their relative economic position, and between changing cohort size relative to options and life chances. Other things being equal, the greater the relative supply of young male workers, the weaker their relative economic status and gains. Before 1960, the relatively small birth cohorts of younger men experienced a wide range of advancement opportunities, and their relative economic position (compared with older men) increased significantly. After 1960, the "baby boom" cohorts began entering the young adult category, producing a labor surplus and restricting economic progress.

The behavior of these birth cohorts was symptomatic of the "relative economic squeeze" they encountered. The economic position of young men has deteriorated relative to that of older men, family formation has been delayed by increasing numbers of young adults, and the employment rate of young women has increased more rapidly than that of older women. Among young adult cohorts during this period, an upward trend in the divorce, suicide, and crime rates is observed, as well as a leveling off in the college enrollment rate, which has climbed steadily since the 1940s. Research inspired by Easterlin has led to mixed results, however, suggesting that the model may be over-simplified (Pampel & Peters, 1995).

In part, this simplification reflects a problem shared by cohort studies as a whole: when theory and research focus on the cohort level, the linking mechanisms between lives and changing times are difficult to pin down. Cohorts can be merely "black boxes" with no information on causal dynamics and linkages. Behavioral differences between cohorts also do not readily yield an understanding of the social or historical factors that account for them. Speculation frequently takes the place of disciplined explication. The problem with cohort studies has much to do with exposure of people in a birth cohort to varied environmental changes. Thus, some grade school children are exposed to the economic stress of a

plant closing, and other children are insulated from such stresses. In response to this social heterogeneity, more studies are investigating specific types of differential social change in birth cohorts.

Before surveying one of these studies conducted by Reuben Hill, we sum up the temporality of age by identifying meanings that have special relevance to human development: the ages of life or lifetime, the diverse meanings of social time, and historical time. *Life time* is indexed by chronological age and refers to the stage or position in the developmental-aging process. From a developmental standpoint, age alerts the investigator to subgroups that are differentially vulnerable to particular types of social change. The lifetime meaning of age requires specification of the variables it represents. *Social time,* such as the age patterned sequence of events, includes "family time" across stages of parenting and the generations. A normative concept of family time indicates an appropriate time for leaving home, for marriage, and for bearing children. Last, *historical time* refers to a person's location in history; membership in a birth cohort indicates this location.

Life Cycle and Life Course

In any period of theoretical transition, both old and new models guide research. We see this mix of old and new in the 1960s. Hill's (1970) three-generation study is a case in point. The grandparent generation married before 1915 and the parent generation between the 1920s and mid-1930s. Hill made significant contributions to the life-cycle model in essays on the family cycle and development, and he launched this multigenerational study to pursue issues of intergenerational continuity and change. However, the dramatic social changes at the time underscored the historical imprecision of generational membership by placing the older and younger members of each generation in different historical epochs. Couples from the parent generation who married in the 1920s had significantly more children than those who married in the depressed 1930s. The two groups were found to be sufficiently different in life course to constitute samples of different populations.

The heterogeneity of generations on historical experience has led some analysts to identify cohorts in each one, and Hill used this modification in his own work. He investigated strategies of family management, which included the timing of marriage and parenthood, the spacing of children, the husband's and wife's entry and reentry into the labor force, and the timing of material acquisitions. Consistent with a life-course model, he noted that in periods of rapid change, "each generational cohort encounters at marriage a unique set of historical constraints and incentives which influence the timing of its crucial life decisions, making for marked generational dissimilarities in life cycle career" (1970, p. 322). The middle generation in Hill's study followed this pattern of cohort differentiation.

In one sense, the generational dimension of life-cycle analysis has helped to contextualize the individual life course by emphasizing the social dynamic of "linked lives"—parents and children, husband and wife, grandparents and grandchildren, siblings and friends. Parents and grandparents are not merely present at a stage in life, but rather appear as lifelong associates. From this vantage point, the life-cycle model made adult development especially relevant to an understanding of child development, an important insight that has not been fully realized in studies of children. Personal or social change in parents has developmental consequences for children; conversely, change in the behavior of children can alter the behavior and psychology of parents (Crouter & Booth, 2003). In concept, children become active agents of their own life course.

This life-cycle contribution to the life-course project appears in a longitudinal study of Californians from the Oakland Growth sample that were born in the early 1920s, passed through adolescence in the depressed 1930s, and were subject to the labor needs of World War II (Elder, 1974/1999). The central question concerned the effects of the Great Depression on the lives and development of the Oakland children. An intergenerational framework seemed entirely appropriate for addressing this question, with an emphasis on the process by which economic hardship made a difference in the lives of children by changing family processes and socialization.

But the dramatic changes of life experience from the 1920s into the late 1930s raised questions that could not be addressed by the perspective. The effect of change depended on many things including their exposure to the event, their age or developmental stage, and the age of their parents. Fast-changing economic and family circumstances called for relating them to the ages of parents and children. These observations made the distinctions of birth cohort and life stage especially relevant:

> At the time of maximum hardship in the early 30s, the Oakland children were well beyond the dependency state of early childhood, with its consequences for intellectual and emotional development, and they reached the age of majority after opportunities had improved through nationwide mobilization for war. Persons born 10 years before the Oakland children would have entered the labor force during the worst phase of the economic collapse, while the welfare of persons in the 1929 cohort would have been entirely dependent on conditions in their families. (Elder, 1974/1999, p. 16)

Family adaptations to economic hardship became a set of linkages between the economic collapse of the 1930s and the developmental experience of children. In place of static concepts of family life, the study turned to notions of the family economy and its multiple actors as a way of thinking about the economic crisis and its implications for children. Through linked relationships and actors, changing economic roles and status shaped the experience of children. Thus, children who acquired paid jobs in the community became more socially independent than other youth.

An appraisal of growing up in the Great Depression required knowledge of life paths to adulthood, such as education, marriage, work-life advancement, and military service. Some youth escaped hardship through early work and military service, others through higher education and marriage. However, some outcomes have more to do with their timing than with mere occurrence: Marriage is an example. Hardship favored early marriage by diminishing the chances of higher education and by making home life unappealing. Likewise, developmental theory suggested that the early work experience of adolescents would accelerate their thinking about work and the timing of their entry into adult work roles.

These and other conceptual issues made theoretical distinctions concerning the age-graded life course especially useful to the study. Consider the sequence of events that link early adolescent work experience and adult work. Family hardship increased the involvement of boys in gainful employment and, through this experience, advanced their social independence and sensitivity to matters of vocation. This sensitivity took the form of an early vocational focus and work commitment that led to work lives, which effectively countered any educational handicap of family hardship, even among the sons of working class parents. In the end, family income losses did not adversely affect the occupational standing of the Oakland men or the status that the Oakland women achieved through marriage.

As noted in this account, *Children of the Great Depression* (Elder, 1974/1999) began with concepts of the life cycle and relationship tradition, such as role sequences and generation, but soon turned to the analytic meanings of age for linking family and individual experience to historical change (especially birth cohort and life stage), and for identifying trajectories across the life course, using a concept of age-graded events and social roles. Both theoretical strands provide essential features of life-course theory on matters of time, context, and process. The life course is age-graded through institutions and social structures and embedded in relationships that constrain and support behavior. In addition, people are located in historical settings through birth cohorts and they are linked across the generations by kinship and friendship. The 25th anniversary edition of *Children of the Great Depression* (Elder, 1974/1999) includes another chapter, which compares the Oakland cohort in life patterns to that of a younger birth cohort, the Berkeley Guidance study members, born in 1928 to 1929. The Berkeley males were more adversely affected by Depression hard times than all other gender/cohort subgroups in the comparison.

Contemporary theory on the life course and its social dimensions thus differs from perspectives of an earlier era by joining the life cycle processes of social relationships with the temporality and contextual aspects of age. For examples of this shift, we need only compare Thomas and Znaniecki's *The Polish Peasant in Europe and America* (1918–1920) with its analysis of generations and lineages in a relatively timeless, abstract realm, to the birth cohort, age-graded life course, and intergenerational themes of *Family Time and Industrial Time* (Hareven, 1982)—a study of successive worker cohorts and their families in a large textile mill with declining economic prospects during the 1920s and 1930s. Though explicitly historical, *The Polish Peasant* does not locate the immigrants according to birth year and historical setting, nor does it describe their life stage at the time of their emigration. Hareven's study provides these markers and uses them to assess the implications of industrial change for worker families (parents and children) in the textile city of Manchester, New Hampshire.

Through the integration of social relationship concepts and age-based distinctions, along with life-span concepts of the person and human organism (see Figure 12.1), the life course became a vital, expanding field of inquiry in the 1970s and 1980s. Both the individual life course and a person's developmental trajectory are inter-

connected with the lives and development of others. Life-course theory thus took issue with life-span studies that viewed human development as an unfolding process, which was not coactive with social and cultural processes in historical time. However, it is responsive to Lerner's (1991, p. 27) call for more attention to contextual variability, and continues to be an emerging perspective on developmental science (Cairns, Elder, & Costello, 1996; see also Ford & Lerner, 1992; Thelen & Smith, Chapter 6, this *Handbook,* this volume) that extends across system levels and disciplines.

The contextual perspective of the life-course framework has much in common with Urie Bronfenbrenner's ecology of human development, now called bio-ecological theory (Bronfenbrenner & Ceci, 1994), but it differs in emphasis on the temporal dimension of historical, family, and life contexts. Bronfenbrenner's *Ecology of Human Development* (1979) proposed a multilevel view of the sociocultural environment, from macro to micro, but it did not include a temporal perspective on individual development across changing environments. In life-course studies, this perspective includes age-graded social trajectories or pathways as well as historical contexts. Some years later, after making a case for the person-process-context model, Bronfenbrenner (1989, p. 201) noted a major lacuna in his work that also applied to Lewin's original thinking—the dimension of time. To correct this limitation, he proposed the general concept of "chronosystem," with its three interacting components over time: (1) the developing person, (2) the changing environment, and (3) their proximal processes. Although this concept has not been widely adopted, the ecological perspective itself has generated many contextual studies of child development (Moen, Elder, & Lüscher, 1995; see also Bronfenbrenner & Morris, Chapter 14, this *Handbook,* this volume).

Human development in life-course theory represents a process of organism-environment transactions over time in which the organism plays an active role in shaping its own development. The developing person is viewed as a dynamic whole, not as separate strands, facets, or domains such as emotion, cognition, and motivation. The course of development is embedded in a dynamic system of social interchanges and interdependencies across and within levels. As noted by Bronfenbrenner (1996), this dynamic in life-course theory is illustrated well by the interlocking lives and developmental trajectories of family members who are influenced differentially by their changing world.

We turn now to some basic concepts and perspectives that center on the individual life course and developmental processes.

BASIC CONCEPTS AND PERSPECTIVES OF THE INDIVIDUAL LIFE COURSE

The individual life course and its relation to developmental trajectories represent a common meeting ground for life-course theory and developmental science, with its "perspective on individual functioning that emphasizes the dynamic interplay among processes that operate across time frames, levels of analysis, and contexts" (Cairns et al., 1996). Building on advances since the 1960s, life-course theory has uniquely forged a conceptual bridge between developmental processes, the life course, and ongoing changes in society based on the premise that age places people in the social structure and in particular birth cohorts.

To understand this conceptual bridge, we turn to elementary concepts. First, we begin with multiple levels of the life course, ranging from institutionalized pathways to cumulative patterns of context that shape the individual life course. Second, other important temporal concepts, such as trajectory, transition, and turning point, are taken up with particular emphasis on the properties of social transitions. Third, we focus on linking mechanisms that have proven highly useful in the study of contextual influences. Beginning with studies of children who were born before the Great Depression, research has revealed a set of mechanisms that link context and the individual life course. These mechanisms help to flesh out the conceptual meaning of more general principles of the life course.

The central role of agency in the shaping of lives was evident in these early studies, and subsequent research has highlighted its connections to social context. While the concept of agency encompasses many phenomena—particularly when viewed through psychological constructs such as motivations, values and aspirations, and personality—its full significance in life-course theory is found in its dynamic interplay with social location (Hitlin & Elder, in press). Finally, we consider issues surrounding selection, which refers to the factors that lead people to contexts and experiences (Caspi, 2004). Every empirical study of lives enters an ongoing system of exchanges between person and context. Selection and related concepts acknowledge this complexity and encourage heightened sensitivity to the challenges that

surround the identification of contextual influences. Paradigmatic themes of life-course theory draw on these elementary concepts in highlighting distinctive conceptual orientations such as the relation between changing times and lives.

Social Pathways, Cumulative Processes, and the Individual Life Course

Social pathways and cumulative patterns represent dynamic views of context. Pathways typically refer to sequences of social positions in and between organizations and institutions. Institutionalized pathways generally have specified time boundaries, what Merton (1982, 1984) has called "socially expected durations." The legislated ages at maturity for voting and marriage can be viewed as marking off an accepted duration of dependency. Social pathways are generally age-graded and thus identify relatively early, on-time, and late transitions. Children who are held back in school become aware of their lagging status on the educational ladder (Alexander, Entwisle, & Dauber, 1994), and company managers talk about the relation between age and grade in prospects for promotion to senior rank (Sofer, 1970, p. 239).

In addition to their age-graded nature, pathways structure the direction that people's lives can take. Pallas (2003, p. 168–169) observes that pathways have distinct features that govern how strongly people's trajectories and behaviors are shaped including, for example, the number of options a pathway leaves open in the future, the extent of mobility that is likely to be experienced, stigma and extrinsic rewards, and the importance of personal choice. Some pathways provide future opportunities and chances for upward mobility based on personal motivation, while others effectively block promising avenues irrespective of one's efforts.

Pathways are also multilevel phenomena reflecting arrangements in place at levels of culture, the nation-state, social institutions and organizations, and locale. To varying degrees, people work out their life course in established or institutionalized pathways. At the macro end of this multilevel system, governments generally establish pathways (Leisering, 2003). At micro levels, institutional sectors (economy, education, etc.) or local communities (school systems, labor markets, and neighborhoods) guide the pathways. Each system level, from macro to micro, socially regulates, in part, the decision and action processes of the life course, producing areas of coordination or discord and contradiction (e.g., marriage, divorce, and adoption laws). At the primary level of the individual actor, some decision pressures and constraints are linked to federal regulation, some to the social regulations of an employer, and some to state and community legislation.

Mayer (1986) had the nation-state in mind when he identified important societal mechanisms, "which impose order and constraints on lives" (pp. 166–167). These include the cumulative effects of delayed transitions, institutional careers, the historical circumstances associated with particular cohorts, and state intervention. Growth of the state in social regulation counters the potentially fragmenting effects of social differentiation. At the individual level, the state "legalizes, defines and standardizes most points of entry and exit: into and out of employment, into and out of marital status, into and out of sickness and disability, into and out of education. In doing so the state turns these transitions into strongly demarcated public events and acts as gatekeeper and sorter" (p. 167). These are what Buchmann (1989, p. 28) properly calls events in "the public life course."

Multilevel accounts of the life course are well illustrated with cross-national studies of the transition to adulthood (Settersten, Furstenberg, & Rumbaut, 2005), particularly in relation to the social pathways from secondary school to work (Kerckhoff, 2003; Marshall, Heinz, Krueger, & Verma, 2001). In Great Britain, secondary school-leavers can follow a path to work that consists of technical training programs or schools that provide credentials for a particular craft. With the freedom to make a wide range of choices, students also miss opportunities and desirable job placements. Far more structure is provided working-class German youth in a secondary-level system that in theory joins industrial training and education in an apprenticeship system. In principle, placement in a skilled craft is assured for youth who complete their apprenticeships. In Japan, occupational recruitment typically occurs in schools from the secondary-level to higher education, and the hiring firm provides specific job training, not the schools or craft institutes. American adolescents encounter the least amount of articulation between schooling and workplace. Vocational training in secondary schools is not closely linked to specific industries, their recruitment, and skill needs. In many less-developed countries, youth are forced to leave school early to support their families; in turn, their lowered educational attainment results in low wages, which forces their children to leave school early as well (Shanahan, Mortimer, & Krueger, 2002). This intergenerational cycle of disadvantage il-

lustrates how pathways from school to work can reproduce across the generations.

In societies, role sequences become established or institutionalized in the culture with the passage of time. With respect to work, for example, Spilerman (1977) has used the term *career lines* to refer to pathways defined by the differentiated and aggregated work trajectories or histories of individuals. In his view, career lines are "shaped by the nature of industry structures (e.g., occupational distribution, mode of recruiting into upper status slots such as promotion from below versus hiring from outside the firm) and by the institutional demography of the labor market" (p. 552). In an expanding market, these career lines extend across company and industry boundaries. Career lines vary in their receptivity to different times of entry: The trades frequently require early entry through a training program in contrast to the less age-graded nature of public school teaching and service occupations. The selection and timing of career entry are major determinants of subsequent earnings and work trajectories.

Prior to entry into work, however, young people encounter educational pathways. Studies of the educational system in the United States reveal that these pathways begin very early in life and that their effects cumulate to produce marked differences among students and workers. Thus, drawing on data from the Beginning School Study in Baltimore, Entwisle, Alexander, and Olson (2003) have documented educational pathways that begin to take form in the first grade. In a school where 88% of the students were on subsidy, every first grade student received a failing mark in reading in the first quarter. In low-SES schools more generally, the average first grade reading score was 1.64 (below a C), in contrast to students in high-SES schools, who averaged 2.15 (above a C). They also report that, even controlling for family background and standardized test scores, Black children received lower first grade reading and math scores, and these racial differences were subsequently magnified.

While students of all races and socioeconomic groups benefited from schooling to the same degree, low-SES students' reading ability decreased during the summer vacation, while high-SES students' reading improved. Given initial differences in reading and math ability and these invidious summer trends, Entwisle et al. (2003) concluded that "the long-term persistence of early rankings means that inequities visible in the first grade translate into deficits all along the line" (p. 239). Indeed, recent studies drawing on this sample show that first grade attributes—including temperamental factors, grades, and standardized test scores—predict educational attainments at age 22 as well as similar factors measured at age 16 (Entwisle, Alexander, & Olson, 2005). Interestingly, parental influence, assessed in high school, greatly underestimates the effects that parents have on their children's attainments because much of it has already been converted into school outcomes.

Kerckhoff's (1993) study of connections between school and work in Great Britain also shows patterns of divergence. Regarding achievements, he nevertheless finds continuity in students' place in the school system over time. Thus, early placement in an elite primary school is associated with the "high road" to the university. A low-status placement is frequently associated with the opposite path for students. At each stage of schooling, differences are magnified, with the transition from junior to secondary school producing the greatest deflection. In young adulthood, at age 23, one's occupational prestige reflects a set of cumulative structural influences that originated early in the life course.

By considering pathways, we understand more completely the choices and actions that shape individual life courses and their developmental implications. According to this perspective, the individual life course is determined over time by the general and specific dictates of social pathways. For the very young child, these pathways often begin, in large measure, with the residential and socioeconomic histories of parents. Small differences cumulate over time and, by young adulthood, result in significant differences in achievements and prospects. As with educational pathways, research is beginning to show how career lines form at a young age and lead to diverging patterns. For example, sociologists have typically viewed the first job for pay after school completion as the onset of one's work career, but studies are now identifying how earlier work experiences, starting at least in high school, bear on future achievements and attainments (Mortimer, 2003).

Ideally, studies of the developmental consequences of life-course change take into account the potential constraints and options associated with particular pathways. However, the realities of research are expressed in a disciplinary division of labor. Sociologists (Mayer, 2004) and historians make use of a multilevel view of the life course in their historical and comparative studies. Both attend to issues of contextual variation. As historian E. P. Thompson once said, "the discipline of history is above all a discipline of context" (Goldthorpe, 1991, p. 212). Developmentalists in psychology may

center on the impact of life-course change (Noack, Hofer, & Youniss, 1995) or simply ignore it altogether, usually the latter. At least up to the 1990s, the typical longitudinal study of social development among children, as published in Child Development, measured the socioeconomic environment only at the beginning of the research (Elder & Pellerin, 1995). Articles still recommend the use of atemporal indicators that provide a snapshot of families and children at a point in time, despite growing evidence that the dynamic features of families often are of consequence for children's well-being and achievements (Shanahan et al., 2000).

Social pathways encompass cumulative processes, which refer to long-term patterns of experiences that sustain behavioral continuity or lead to change. Some cumulative processes reflect social experiences of long duration. The concept of *duration* refers to the span of time between changes in state. The full implications of long and short exposures to a situation depend on the nature of the situation itself. For example, is divorce preceded by a lengthy period of family conflict? Little is known about the qualitative nature of experiences of long and short durations, though a lengthy involvement tends to increase behavioral continuity through acquired obligations, investments, and habits (Becker, 1964). The longer the duration of marriage, for example, the greater the chances for marital permanence (Cherlin, 1993); alternatively, marital happiness is likely to decline at all marital durations, with accelerated declines occurring during the earliest and latest years of marriage (VanLaningham, Johnson, & Amato, 2001). The connection between marital permanence and the length of marriage has much to do with shared material assets (Booth, Johnson, White, & Edwards., 1986), which often prevent divorce in spite of marital unhappiness (White & Booth, 1991). Much more needs to be known about the quality of marriages of differing durations and their development implications (Hetherington, 1999).

Duration of unemployment also increases the risk of permanent unemployment. The latter may involve acquired ties to the unemployed as well as a de-skilling process in developing the incapacity to work. Indeed, many forms of social class and economic hardship endure. In two British birth cohorts, Schoon and her colleagues (2002) found "a stark chaining or continuity of risk factors" such that parental social class powerfully predicts material deprivations through childhood, adolescence, and into young adulthood. Yet, great diversity in socioeconomic experiences has been observed through the life course, producing complex patterns of durations. To adequately understand the covariations between diverse spells and development, we need to know more about duration in interpersonal and developmental processes.

A particularly telling example of the complexity of durations and their potential meaning is found in Mortimer's (2003) St. Paul longitudinal study of adolescent employment. With monthly educational and employment data, Mortimer and her colleagues developed a typology of work patterns through high school based on duration (whether the student worked more than 18 months through the 48 months of high school) and intensity (during periods of employment, whether the student worked, on average, more than 20 hours per week). Mortimer, Staff, and Oesterle (2003) showed that ninth graders with higher educational promise—as indicated by grades and aspirations—opted for less intensive work. Low intensity workers were also more likely to save their earnings for college. In turn, "steady workers" (high duration, low intensity) are more likely to earn a BA degree within 9 years of high school graduation than high duration-high intensity workers. Indeed, among students with low levels of educational promise, those who chose a steady work pattern were more likely to receive their BA than their low promise, high duration-high intensity counterparts. Such findings suggest that work of differing durations and intensity has distinct meanings and consequences and highlight the misleading nature of cross-sectional studies.

The duration of children's exposure to poverty is likewise complex. Although poverty durations in the early life course have been linked to numerous indicators of psychosocial adjustment and achievement—including cognitive development (G. J. Duncan, Brooks-Gunn, & Klebanov, 1994), delinquency (Jarjoura, Triplett, & Brinker, 2002), and, perhaps to a lesser extent, emotional outcomes (Brooks-Gunn & Duncan, 1997)—little is known about the mechanisms that account for such relationships. The challenge of understanding how the duration of poverty coincides with developmental experiences is complicated by the patterns of deprivation observed in national samples.

Between ages 1 and 17, about one-third of American children will spend at least 1 year in poverty (Rank & Hirschl, 1999). Of individuals experiencing poverty, about half of Blacks and one-third of Whites will fall into poverty in 5 or more of the next 10 years (Stevens, 1999). Bane and Ellwood (1986) conclude that "the average poor black child today appears to be in the midst of a poverty spell which will last almost 2 decades"

(p. 21). However, most poverty spells turned out to be comparatively shorter, owing in large measure to markedly improved earnings (Bane & Ellwood, 1986). Slightly more than 40% of poverty spells in the Bane and Ellwood analysis ended within a single year. About 70% were over within a period of 3 years. In addition to the potentially complex patterns of poverty over the life course, the first transition into poverty—particularly if unexpected—may be especially damaging to children's well-being (Oh, 2001).

Besides the duration of poverty, time spent in various social classes may also be important to well-being and achievement but, once again, temporal patterns of social class may be complex. McDonough, Duncan, Williams, and House (1997) showed that low income (i.e., less than $20,000 per household) that persisted 4 to 5 years raised the risk of mortality among adults significantly when compared to households experiencing this income level for a transitory period. Middle-income adults, however, are at increased risk for mortality if their income fluctuates appreciably over a 5-year period. Drawing on the British Birth Cohort of 1958, Power, Manor, and Matthews (1999) show that lifetime patterns of social class (based on father's occupational status at birth, and then one's own occupational status) predict poor health at age 33. The risk of poor health increased for men in the most advantaged (4%) to the least advantaged (19%) lifetime SES groups (see also Mare, 1990).

The duration effects for socioeconomic stressors may be nonlinear, in which case a tipping point is reached before an adverse outcome is observed. Additional time spent in deprivation may lead to a nonlinear increase in distress. For example, Wadsworth, Montgomery, and Bartley (1999) observed that British men who experienced a long period of unemployment (exceeding 3 consecutive years) reported less healthy profiles subsequently, although this effect was not observed for lesser durations.

Durations of poverty, low income, and other forms of socioeconomic disadvantage are likely to be related to a wide range of indicators of adjustment and achievement, although very little is known about the linking mechanisms. One plausible mechanism is exposure to stressors and the availability of supports and coping mechanisms. While material resources undoubtedly shape the stress process (Link & Phelan, 1995), a detailed understanding of how temporal patterns of social class link to stressors, supports, and coping mechanisms remains largely unaddressed. The quality of one's paid work is another plausible candidate linking social class with long-term outcomes.

Characteristics of paid work are known to be associated with psychological and physical functioning, although little research has investigated temporal patterns of work characteristics. A notable exception is Amick and his colleagues (2002), who report that men who spend their work lives in jobs with low levels of control have a 43% increase in chance of death when compared with men who have jobs with high levels of control over their work life. Thus, multiple aspects of social class are likely to matter for well-being, but such relationships depend on the duration of experiences.

Many cumulative processes refer not to the duration of a particular social circumstance but rather to the triggering of chains of interrelated events, which have significant implications for later well-being and attainment (Rutter, 1989). Behavioral continuities across the life course are likely to be found in social interactions that are sustained by their consequences (*cumulative*) and by the tendency of these styles to evoke maintaining responses from the environment (*reciprocal*; Caspi, Bem, & Elder, 1989). In *cumulative continuity,* both individual dispositions and family values are likely to favor the choice of compatible environments, and this reinforces and sustains the match. Thus, antisocial youth tend to affiliate with other problem youth, and their interaction generally accentuates their behavior, producing over time what might be described as *cumulative disadvantages* (Cairns & Cairns, 1994; Sampson & Laub, 1997; Simmons, Burgeson, Carlton-Ford, & Blyth, 1987). Among problem youth from inner-city neighborhoods, those who were most negative toward their life chances lacked the support of close kin and friends, did not have a supportive older sibling, and were most likely to be involved with deviant friends (Furstenberg, Cook, Eccles, Elder, & Sameroff, 1999).

Reciprocal continuity refers to a continuous interchange between person and environment in which reaction forms action and then by another cycle of action and reaction. As with cumulative continuity, the net result of reciprocal continuity is the cumulation of experiences that tend to maintain and promote the same behavioral outcome. Baldwin (1895) refers to such interchanges as "circular functions" in ontogeny. The ill-tempered outburst of an adolescent may provoke a cycle of parental rage and aggression, a widening gulf of irritation, and, finally, parental withdrawal, which reinforces the adolescent's initial aggression (Pepler & Rubin, 1991). Over time, the interactional experiences of aggressive children can establish attitudes that lead them to project interpretations on new social encounters and

relationships, thereby ensuring behavior that affirms the expected behavior. Aggressive children generally expect others to be hostile and thus behave in ways that elicit hostility, confirming their initial suspicions and reinforcing their behavior.

A growing body of evidence points to cumulative processes linking early social experiences—particularly forms of inequality—and later health and well-being (Power & Hertzman, 1997). Drawing on the Dunedin sample, for example, Poulton and his colleagues (2002) show that childhood socioeconomic status (based on occupational categories) is an important predictor of physical health at age 26 even with adult socioeconomic position controlled. Children growing up in households marked by low socioeconomic conditions have poorer health—defined, for example, by the body-mass index and cardio-respiratory fitness—when compared with children who grow up in high socioeconomic households, regardless of their adult socioeconomic status. The cumulative mechanisms that link such early experiences with later physical well-being are not well documented, although plausible mechanisms include health-related behaviors (van de Mheen, Stronks, Looman, & Mackenbach, 1998).

Can cumulating processes that lead to poor outcomes be neutralized by subsequent experiences? The possibility is not often entertained, and the answer is likely to depend on the processes being studied, their temporal properties, and indicators of well-being and achievement at issue. However, the question reflects the interest in dynamic views of context and contingency that life-course analysis promotes. Research shows, for example, that marital transitions involving the loss of a partner are associated with declines in adult health. Can subsequent remarriage improve matters? It likely does (Willitts, Benzeval, & Stansfeld, 2004), but its salutary effects appear to diminish with the number of prior marital transitions (Barrett, 2000).

Similarly, unemployment is thought to diminish adult health and subsequently the family support of children. In what circumstances will reentry into the labor market lead to improvements in well-being? Drawing on a representative sample of English and Welsh working men, Bartley and Plewis (2002) examined the effects of occupational category and unemployment status in 1971, 1981, and 1991—covering most of the men's working lives—on long-term illness. Unemployment in 1971 and 1981 and occupational class at all three time points had independent effects on illness, providing powerful evidence for cumulative effects. By implication, recent employment compensates, at least in part, for prior spells of unemployment, as does improvements in one's occupational status (see Poulton et al., 2002).

Experiences may cumulate because social circumstances are largely stable or lead to "functionally equivalent" relationships with people and involvements with organizations and institutions. In the latter case, chains of interrelated experiences all encourage the same behavioral outcomes.

Trajectories, Transitions, and Turning Points

Social pathways and cumulations of experience present temporally sensitive descriptions of context. Trajectories provide a dynamic view of behavior and achievements, typically over a substantial part of the life span. Transitions refer to a change in state or states such as when youth leave home. A substantial change in the course of a behavioral trajectory, often during transitions, may represent a turning point.

Trajectories and transitions are elements of established pathways, their individual life courses, and developmental patterns. Among individuals, social roles evolve over an extended span of time, as in trajectories of work or family; and they change over a short time span. The latter may be marked by specific events such as children entering school for the first time, completing the first grade successfully, and graduating from high school. Each transition, combining a role exit and entry, is embedded in a trajectory that gives it specific form and meaning. Thus, work transitions are core elements of a work-life trajectory, and births are important markers along a parental trajectory.

Trajectories and transitions refer to processes that are familiar in the study of work careers and life events. The language of careers has a distinguished history in the field of occupations and the professions, and it still represents one of the rare languages that depict a temporal dimension or process. Career lines, as pathways, refer to sequences of positions, while careers, as trajectories, refer to coinciding behaviors and achievements. Work careers have been defined as disorderly and orderly, and achievements have been represented as career advancement, whether early or late, rapid or slow (Wilensky, 1960). The term *career* has also been applied to the trajectories of marriage and parenthood (Hill, 1970). All of these uses fall in the more inclusive definition of a life-

course trajectory. The term does not prejudge the direction, degree, or rate of change in its course.

A developmental trajectory refers to change and constancy in the same behavior or disposition over time, but consistency of measurement may be difficult to achieve in many cases, especially in the measurement of aggression and dependency (Kagan & Moss, 1962). Nevertheless, trajectories of intraindividual change tell a different story from life stories based on cross-section analysis, and this concept is compatible with widely shared views of development (Molenaar, Huizenga, & Nesselroade, in press; Tremblay, 2004). Further, the modeling of trajectories has become increasingly sophisticated, offering the analyst increasing options for thinking about patterns of change (e.g., Collins & Sayer, 2001; T. E. Duncan, Duncan, S. Strycker, Li, & Anthony, 1999; Singer & Willett, 2003).

Developmental trajectories are also integral to life-course theory, especially when they are studied as interdependent with the changing dynamics of social trajectories. In a four-wave study of early adolescents, based on growth-curve models, Ge and his colleagues (Ge, Lorenz, Conger, Elder, & Simons, 1994) found that (a) the trajectories of depressive symptoms increased sharply among White girls, surpassing the symptom level of boys at age 13; (b) the increase for girls was linked to their exposure to an increasing level of negative events; and (c) the initial warmth and supportiveness of a mother minimized the subsequent risk of depressed states and negative events among daughters. Studies such as these have inspired many efforts to interrelate developmental trajectories and context, although frequently neglecting the changing nature of social circumstance.

Increasing attention is being devoted to the study of classes of behavioral trajectories based on the supposition that people may be qualitatively distinct in their developmental patterns (Bauer & Curran, 2004; Nagin, 1999; Nagin & Tremblay, 2001). According to this perspective, the population is heterogeneous with respect to behavioral trajectories; as such, distinct subgroups can be identified, and their covariates examined. For example, Moffitt (1993; see also Moffitt, Caspi, Harrington, & Milne, 2002) hypothesized that aggregate patterns in antisocial behavior conceal two distinct groups: (1) A small percentage of youth engaged in antisocial behavior at every stage of life ("life-course persistent"), and (2) a larger percentage of youth engaged in antisocial behavior during adolescence only ("adolescence-limited"). Indeed, drawing on semiparametric models, researchers have uncovered evidence for unique trajectories of antisocial behavior (e.g., Nagin & Land, 1993). With greater use of such models there has been increasing appreciation for methodological issues (see Bauer & Curran, 2003 and accompanying exchanges; Eggleston, Laub, & Sampson, 2004; Nagin, 2004) and theoretical nuance (Nagin & Paternoster, 2000) that complicate the search for qualitatively distinct types of behavioral trajectories. Nevertheless, this approach raises exciting possibilities for linking behavioral patterns with change and stability in context and experience.

The multiple role trajectories of life patterns describe *strategies of coordination* or *synchronization.* Various demands compete for the individual's or family's scarce resources such as time, energy, and money. Goode (1960) argues that an individual's set of relationships is both "unique and overdemanding," requiring strategies that minimize demands by scheduling and rescheduling transitions where possible. To cope with simultaneous, linked trajectories, the scheduling of events and obligations becomes a basic task in managing resources and pressures. The needs of children and financial requirements, for example, play important roles in determining work and leisure options.

The meaning of a transition has much to do with its *timing* in a trajectory. Consider the case of parenthood: the earlier the event, the greater the risk of social and health disadvantages for mother and child (Furstenberg, Brooks-Gunn, & Morgan, 1987). Early life transitions can have developmental consequences by affecting subsequent transitions, even after many years and decades have passed. They do so through behavioral consequences that set in motion cumulative advantages and disadvantages, with radiating implications for other life domains. A Baltimore study of adolescent mothers who were followed from 1966 to 1984 (Furstenberg et al., 1987), shows that variations in personal resources (e.g., IQ) during adolescence affected their economic success by influencing how they timed and ordered early events from marriage to education or employment. From the vantage point of this study, the quality of transition experiences early in life may foretell the likelihood of successful and unsuccessful adaptation to later transitions across the life course.

Transitions to parenthood during adolescence in the Baltimore panel raise another important general distinction: Life transitions can be thought of as *a succession of mini-transitions or choice points.* The transition from marriage to divorce is not simply a change in state, but

begins with disenchantment and extends across divorce threats, periods of separation, and the filing of divorce papers. Different causal factors may operate at each phase of the process. The "origin" influences that increase the risk of disenchantment are likely to differ from those that sustain the process toward marital dissolution. In like manner, we can think of the transition to motherhood in adolescence as a *multiphasic process* in which each phase is marked by a choice point with options and social constraints.

For example, young women may choose to engage in premarital sex or not, to use contraception or not, to seek an abortion or not, and to marry the father or not. Only a handful of options lead to an illegitimate birth. After the birth of a child, young women face other decisions, such as whether to ask for their mothers' help in child care or to put the child up for adoption, to marry or to remain single, or to pursue educational and employment possibilities or to enter the welfare system. The implications of having an illegitimate birth vary according to the options chosen. Some opportunities blend well in favoring positive outcomes: They represent an adaptive strategy, while others do not.

Figure 12.2 presents a series of transitions that can lead to unwed motherhood, as sketched from the Baltimore study. Each choice point occurs at a different state in a young girl's life and thus could involve varied life-course dynamics and explanations. The process of becoming an adolescent mother requires sexual activity, failure to use, or ineffective use of, contraception, and, once pregnant, the decision to bear and raise the child. Across these stages of the process, an agency "has several possible points at which to target its interventions; at initiation of sexual activity, at contraception use, or, at the resolution of a pregnancy" (Hofferth, 1987, p. 78).

The significance of this formulation becomes apparent when we return to a time when unwed motherhood was viewed simply as one transition, a concept that obscured the strategic points of preventive intervention along the life course. Given their multiphasic nature, many transitions cover relatively long periods. The female pubertal transition, for example, begins before menarche and may last well beyond it. As Dorn and her colleagues (Dorn, Susman, & Ponirakis, 2003) observe, "Although menarche itself is an event (the first bleed), the integration of our findings of pre- and postmenarcheal hormone variability support a conceptualization of menarche as an integral part of a longer-term biological process" (p. 300). Similarly, the transition to adulthood—as indicated by demographic markers—begins when youth complete school, which occurs at age 17 or 18 for most American youth, and ends with family formation, which may take place in the mid-30s, if at all (Fussell & Furstenberg, 2005). Developmentalists tend to view transitions as dis-

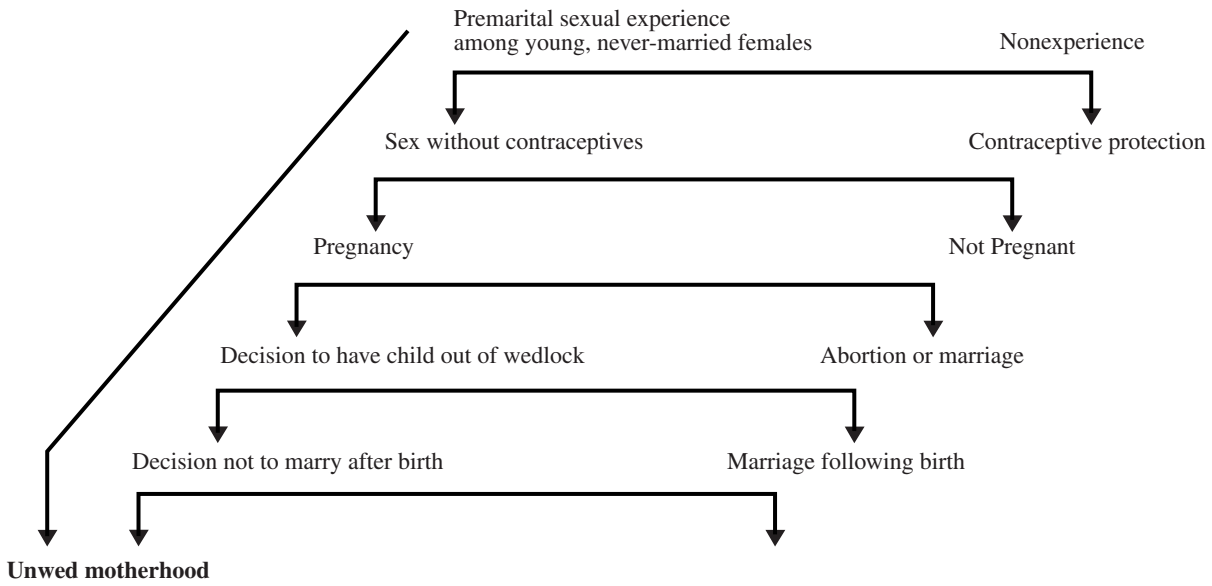

Figure 12.2 The life course of unwed motherhood. As adapted from "Family Transitions, Cycles, and Social Change" (p. 41), by G. H. Elder Jr., in *Family Transitions,* P. A. Cowan and M. Hetherington (Eds.), 1991, Hillsdale, NJ: Erlbaum. Reprinted with permission.

crete events that occur in a relatively short period and, consequently, very little is known about the sequence of minitransitions leading to full transitions.

The two faces of a transition—leaving a state and entering a new state—can have different causal explanations, as when divorce is followed by remarriage. Moreover, "leaving a state" is part of the individual's history that shapes the meaning of the new role or situation (Wheaton, 1990). Leaving a conflicted, violent marriage would cast single status as a stress-relieving status. The meaning and developmental implications of a transition depend on the timing of the change relative to norms and cognitive expectations. Judging from studies conducted to date (McLanahan & Sorensen, 1985; Wortman & Silver, 1990), widowhood is most distressing for young women, a time when the event is least expected or normative. By comparison, job loss during young adulthood is relatively common, and entails less of an emotional risk than in the later years.

The apparent contrast between institutionalized transitions and personal, idiosyncratic "transition experience" can misrepresent reality. In many cases, life transitions are an institutionalized status passage in the life course of birth cohorts and a personalized transition for individuals with a distinctive life and social history. The latter may represent an individual working out of the former. These faces of a transition apply to the normative transitions of life, from birth to school entry, marriage, parenthood, and retirement. Transitions of this kind may seem more predictable and structured than nonnormative events, but all transitions can be sorted according to their structuredness or degree of external regulation, duration, timing, predictability, and novelty.

Life transitions into different environments facilitate this process by representing potential *turning points* in a trajectory for a troubled life course. Such turning points are sometimes referred to as "knifing off" past experiences, which can allow for new opportunities and behavioral patterns. One example of a turning point is the desistance from criminal activity, a "knifing off experience" that involves a transition into new situations that provide monitoring, social supports, growth experiences, and the emergence of a new self-identity (Laub & Sampson, 2003). Military service, gainful employment, and marriage are all new role commitments that provide opportunities for a break from the past and social integration (see also Bouffard & Laub, 2004).

A further example of turning points—this time in an educational trajectory—is found in a study of feeder patterns into high school. In the American school system, pathways between middle school and high school are structured in different ways, affecting the proportion of one's middle school classmates who attend the same high school. Schiller's (1999) study of how differing feeder patterns affect subsequent grades is revealing. Among students receiving mostly Cs in middle school, high school math grades decrease as the proportion of one's classmates in the same high school increases. The reverse is true among students receiving mostly As in middle school: High school math grades increase as the proportion of one's classmates in the same high school increases. As Schiller notes, when middle school students disperse into many high schools, opportunities seem to open up for students at the bottom, as peer networks are disrupted. Consistent with a turning point, the old social world is knifed off and new opportunities for growth and identity change present themselves.

The concept of turning point also applies to the particular way people view their life trajectory—a subjective account of lived experience involves some degree of change in situation, behavior, or meaning. Maruna and his colleagues' (2001) exceptional interview study of desistance among ex-convicts is one of a few research efforts to investigate the changing nature of the self during a turning point. Important themes in the life narratives of desisters include acknowledging past crimes, understanding their genesis, and recasting the self as in control and with newfound purpose. Clausen (1995) has used detailed analyses of life histories to assess the subjective turning points of people who have been part of a longitudinal study for 60 or more years. Based on this work, he concludes that "one's life does not have to take a different direction for a person to feel that a turning point has occurred. But one must have a feeling that new meanings have been acquired, whether or not life experiences are much changed" (p. 371).

The challenge to life-course study is to understand the linkages among changing pathways and transitions, life patterns, and developmental trajectories. A useful first step in this direction leads to mechanisms that link context and the individual life courses. Our next topic of basic concepts and distinctions.

Selection, Endogeneity, and Contextual Effects

Life-course analysis investigates the dynamic features of social contexts and seeks to understand the relevant mechanisms by which time and place shape human

development. Any study of context and behavior must address the complex processes by which people select and otherwise experience specific environments in the first place (Caspi, 2004). Consider life-events, which numerous studies identify as potent stressors. Virtually all research on life-events views them as causes of distress (e.g., depressive symptoms) with very little appreciation that (a) distress can increase the likelihood of encountering life-events, and (b) various circumstances (hypothetically, for example, working conditions, socioeconomic status) may cause both life-events and depressive symptoms. By failing to account for these exogenous processes, the estimated effect of life-events is likely to be biased. Moreover, this task involves important issues of theory as well as methods.

Thoits's (1994) study of life-events and mastery is instructive. Drawing on two measurement occasions, she classified the stress associated with major life-events in the workplace and in one's romantic life as (a) solved, (b) unsolved but attempted to solve, and (c) unsolved and did not try. Scores on a mastery scale at Time 1 were highest at Time 2 for adults who reported no problematic situations. Scores diminished significantly for adults who encountered life-events and solved them but were lowest for people who encountered life-events and did not solve them. Mastery predicted the subsequent experience of life-events and attempts to resolve their attendant distress. Similarly, Shanahan and Bauer (2005) show that low levels of mastery in high school increase the likelihood of life-events after graduation, which in turn diminish mastery in young adulthood. Indeed, growing evidence suggests that internalizing and externalizing symptoms increase the likelihood of encountering stressors (Aseltine, Gore, & Gordon, 2000; Hoffman & Cerbone, 1999; Kim, Conger, Elder, & Lorenz, 2003; Leadbeater, Kuperminc, Blatt, & Herzog, 1999). By implication, failure to account for such initial differences might well overstate the true magnitude of the effect of such stressors on personal well-being.

More generally, the challenge of preexisting differences that lead people to contexts and promote behavioral outcomes is pervasive in the study of human development. Thus, high school students tend to enter college environments that "are consistent" with their personal characteristics (Alwin, Cohen, & Newcomb, 1991), assortative processes create homophily in forming friendships and heterosexual pairs (Caspi & Herbener, 1990), and risk takers in military service are likely to end up in combat units (Gimbel & Booth, 1996). Transitions of this kind generally accentuate the behavioral effect of the selected dispositions, producing greater individual differences and heterogeneity between groups. Cairns and Cairns (1994, p. 117) observe that social selection and accentuation go together in peer group formation. Once a group is formed in terms of selected attributes (e.g., aggressivity), the selected behaviors are accentuated. This process has obvious social implications when unruly behavior is involved and makes identifying "peer effects" particularly difficult.

Much research has examined the effects of paid work during high school on grades, neglecting the possibility that less academically engaged students may choose to work longer hours. Adjusting for such a selection process, the effect of work hours on grades is negligible or insignificant (Schoenhals, Tienda, & Schneider, 1998; Warren, LePore, & Mare, 2000; see also Paternoster, Bushway, Brame, & Apel, 2003, for the case of paid work and antisocial behaviors). The issue can also be viewed in experimental terms: When preexisting differences between people cannot be ruled out by random assignment (e.g., differing levels of school engagement), the "pure effect" of the experimental manipulation (e.g., hours per week of paid work during high school) on the outcome (e.g., grades during high school) cannot be determined with certainty.

In some instances, the problem can be addressed with highly revealing randomized trials. What, for example, are the implications of residential change? Perhaps moving from poor urban areas to more advantaged neighborhoods improves the lives of children. Do they profit from the change? The question is difficult to answer given that certain types of families—those possessing more resources—would be likely to move in the first place. Yet, a randomized study of the question became possible with the Moving to Opportunity (MTO) demonstration project, which has operated in five U.S. cities (Baltimore, Boston, Chicago, Los Angeles, and New York) since 1994 (see Katz, Kling, & Liebman, 2001; Ludwig, Duncan, & Hirschfield, 2001). Families were eligible to participate if they had children and lived in public housing or Section 8 housing with a neighborhood poverty rate of 40% or more. Interested families who applied were randomly assigned to one of three groups: the experimental group (which received rent vouchers for housing in low poverty areas), a Section 8 comparison group (which received unrestricted rent vouchers), and a control group (which did not receive rent vouchers). The design is especially helpful in

learning about how neighborhoods affect well-being because, in normal circumstances, specific types of families live in specific types of neighborhoods, which makes it difficult to disentangle the contributions of families and neighborhoods.

In the typical move to a middle-class, European-American suburb, the African American mothers and their children were involved in radically different worlds with higher behavioral expectations and typically European-American age-mates. If unemployed before the move, African American mothers who moved to the suburbs were more likely to find jobs and to engage in job searches, when compared to the city movers. In the follow-up, the suburban minority students more often followed a college track and attended a 2- or 4-year college. If not in college, they were nearly twice as likely as city movers to be employed full-time with pay greater than the minimum wage and job benefits. The suburban adolescents were also far more likely to be engaged daily in activities with European-American students, despite racial threats and harassment.

Before and after comparisons show that the transition improved life chances, at least for the females. Four to 7 years after baseline, girls' mental health improved, although boys' problem behaviors may have worsened as a result of their families' receiving the MTO offer to move (G. J. Duncan, Clark-Kauffman, & Snell, in press). Girls in the experimental group also reported less risky behavior and better educational outcomes, while males exhibited more risky behaviors and physical health problems (Kling & Liebman, 2004). The lack of advantage for boys in the MTO experimental group is difficult to explain, although Kling and Liebman speculate that boys in the experimental group may have experienced stereotypes, relinquished fewer ties to their old neighborhoods, and settled into peer groups that exerted negative influences. Rabinowitz and Rosenbaum (2000) provide valuable developmental insights on these transition experiences in their account of Chicago's Gautreaux program, with its goal of enabling families to leave public housing for suburbs and city neighborhoods that were better off financially.

In many instances, randomized trials such as the MTO are not possible or offer imperfect solutions themselves (Kaufman, Kaufman, & Poole, 2003). In such cases, statistical models may be helpful in determining unbiased effects of social context. Yet, no statistical solution is without assumptions and drawbacks (e.g., Bound, Jaeger, & Baker, 1995, on instrumental variable estimation). More important, the issue can also be viewed through life-course theory. As George (2003) notes, selection and endogeniety are less a methodological nuisance than another way of describing ideas that have long been central to life-course theory, particularly pathways and agency. In a life course, contextual experiences most likely reflect prior circumstances. Such prior conditions and experiences represent a substantive interest of life-course research, although they can also be viewed as potential threats to identifying the relationship between present circumstances and behavior.

LIFE TRANSITIONS AND HISTORICAL CHANGE

We have identified properties of life transitions that specify a way of thinking about social change and its psychosocial effects. According to this account, social change refers to a broad range of transitional phenomena such as residential change. Additional contributions to this perspective come from mechanisms that link transitions and life patterns to historical change, such as the Great Depression and World War II, and to paradigmatic principles that define the life course as a theoretical orientation. These mechanisms include the notion of life stage and its social roles, the social imperatives of new roles or situations, the cycle of losing and regaining a sense of personal control in changing situations, and the accentuation of individual dispositions in changing environments. Each of these mechanisms involves interdependent lives. The paradigmatic principles draw on these mechanisms in charting the perspective of life-course study—the principles of lifelong development and aging, human agency in making choices, the importance of timing in lives, linked lives, and historical time and place (Elder, 1998b). These principles represent more general theoretical themes that collectively define the analytical scope of life-course theory.

Linking Mechanisms

Linking mechanisms refer to the processes by which social change and behavioral development are interrelated. They were originally documented in *Children of the Great Depression* (Elder, 1974/1999), a study of cohorts born at opposite ends of the 1920s and occupied different life stages when the economy collapsed. The

life-stage principle, noted above, suggests that young people of different ages are likely to be exposed to a different slice of history. Indeed, the Oakland children passed through adolescence during the worst years of the Great Depression, but the Berkeley children became teenagers in World War II. Consequently, job scarcity, financial pressures, and emotional stress represented defining features of the Oakland cohort's transition from childhood to young adulthood. By contrast, members of the Berkeley cohort were exposed to the "empty households" of World War II when parents worked from sun up to sun down in home front industries.

By encountering the Great Depression and other historical events at different times in life, the Oakland and Berkeley cohorts have different stories to tell about their childhood, adolescence, and adulthood. The particular sequence and timing of prosperity, economic depression, and war distinguishes the developmental experiences of the two birth cohorts. The concept "goodness of fit" in the match of person-environment is an important feature of the life-stage principle and its implications for human development (see Eccles & Midgley, 1989, p. 9).

Consider the Berkeley males who entered the Great Depression when they were highly dependent on family nurturance and vulnerable to family instability. Economic hardship came early in their lives and represented a prolonged deprivational experience, from the economic valley of the 1930s to the war years and departure from home. By comparison, the Oakland males were older and more independent when hardship hit their families. They assumed important roles in the household economy and entered adulthood with a more crystallized idea of their occupational goals. Despite some handicaps in education, they managed to end up at midlife with a slightly higher occupational rank. The life stage of the Oakland males represented a better fit in the match between person and environment when compared to the Berkeley males.

The vulnerability of the younger Berkeley boys is consistent with the results of other studies, which show that family stressors are especially pathogenic for males in early childhood (e.g., Rutter & Madge, 1976). How can we explain the accomplishments of the older Oakland males up to middle age? One explanation is that they assumed valuable economic and household roles amid family hardships. Family experience of this kind enhanced their social independence and reduced their exposure to family conflict. Another explanation centers on the military experience of most of these young men. Service in the military made higher education more possible through the GI Bill and frequently led to a supportive marriage.

Another linking mechanism involves *situational imperatives,* the behavioral demands or requirements of a new situation. The more demanding the situation, the more individual behavior is constrained to meet role expectations. In emergency family situations, helpful responses become an imperative for members, as in hard-pressed families during the worst years of the Great Depression. Rachman (1979) refers to these imperatives as "required helpfulness." The Oakland children were old enough in the early 1930s to be called on to meet the increased economic and labor needs of their family, and a large number managed to earn money on paid jobs and to help in the household. This money was often used to cover traditional family concerns such as school expenses.

In deprived families, girls generally specialized in household chores, while boys were more often involved in paid jobs. This gender difference made girls more dependent on the family and generally fostered greater autonomy among boys. Adolescent jobs in the 1930s typically included what might be regarded as odd jobs in the adult world, from waiting on tables and clerking to delivering newspapers and running errands. Employment of this kind may seem developmentally insignificant, though it carried the important implication that people counted on them—they mattered. Indeed, staff observers rated the working boys as more energetic and efficacious than other boys on a set of scales. The flow of influence was no doubt reciprocal. The more industrious were likely to find jobs and success in work that would reinforce their ambition. With additional chores at home, working boys experienced something like the obligations of adult status. To observers who knew them, they appeared to be more adult-oriented in values, interests, and activities when compared to other youth.

Boys who managed both household chores and paid jobs were most likely to think about the future and especially about a career. In adulthood, these youth were more apt to have achieved a measure of clarity and self-assurance in their work career when compared to other males. They also settled more quickly on a stable line of work and displayed less floundering during their 20s. Apart from level of education, this work life has much to do with the occupational success and work ethic of men who grew up in deprived families during the 1930s. The response of these young people to Depression imperatives had enduring consequences for their lives and values.

The developmental significance of adaptations to the imperatives of new and challenging situations is expressed across the life course and in other cultures.

Consider the reunification of West and East Germany, which produced dramatically new worlds, "almost from one day to the next, new laws, new institutions, and a new economic system governed the lives of the people of East Germany" (Pinquart & Silbereisen, 2004, p. 290). For the young, the school system changed almost overnight and students soon faced a dramatically different economy as well. Silbereisen launched a project to study these changes and their developmental effects soon after the collapse of East Germany—a cohort of East and West Germans from age 13 to 29 in 1991, followed up by a 1996 survey. Adaptations to the unification process were slow in coming among respondents in the study, and especially among those from former East Germany such as young women of lower status. They reported later family transitions and financial self-support in 1996, when compared to the West Germans.

Situational imperatives are elements of new situations that characterize *control cycles,* which, as described by W. I. Thomas (see Elder & Caspi, 1988), refer to changing relations between expectations and resources that affect a sense of personal control. A loss of control stems from a process in which resources fall below expectations. This change motivates efforts to restore control by adjusting expectations, resources, or both in terms of their relation. During the Great Depression, heavy income loss tended to affect children, sometimes adversely, through family adaptations to such deprivation in the Great Depression. These include the reduction of family expenditures, the employment of more family members, and the lowering of living standards (Elder, 1974/1999). Equilibrium in these financially strained families was achieved when expectations matched resources. The psychology of this cyclical process is well described by what Brehm and Brehm call "reactance" (1982). Feelings of reactance occur whenever one or more freedoms or expectations are eliminated or threatened. Such emotions spur efforts to regain or preserve control. "It is the threat to control (which one had) that motivates an attempt to deal with the environment" (p. 375). Once control is achieved, expectations may be raised, thereby setting in motion another round of equilibrating initiatives.

The final mechanism, known as the *accentuation dynamic,* relates transition experiences to the individual's life history of past events, acquired dispositions, and meanings. When a transition heightens a prominent attribute that people bring to the new role or situation, we refer to the change as an accentuation effect. Entry into new roles or situations is frequently selective, and the accentuation dynamic tends to amplify selection behaviors. From this perspective, early transitional experiences become prologues for adult transitions that increase heterogeneity over the life course. We see this development in longitudinal studies of divorce and their increasing attention to the behavioral changes initiated by it across the life course and the generations (Amato, 2000; Amato & Cheadle, 2005). In children, as well as adults, the divorce transition appears to accentuate dispositions that were present well before the event itself. For example, boys with behavior problems after a divorce were frequently engaged in problem behavior before the divorce.

Selection and social causation processes are interwoven in this accentuation process. Quinton and associates (Quinton, Pickles, Maughan, & Rutter, 1993) show this process in the history of a conduct disordered boy. Conduct disorder is associated with conflicted, dysfunctional parenting. Children in these environments were most at risk of choosing deviant friends when parents were in conflict. A harmonious family sharply reduced this risk. The next step involved the selection of a deviant partner, a process that occurred through a deviant peer network. For girls, and especially those not inclined to plan, early pregnancy resulted from a deviant boyfriend. More future-oriented youth managed to avoid this outcome and were better able to establish stable relations with nondeviant mates.

As a whole, these linking mechanisms—life stage, situational imperatives, control cycle, and the accentuation dynamic—represent different understandings of the connections among individual lives, developmental trajectories, and the changing social world. They are embedded in a theoretical framework defined by paradigmatic principles of the life course where they specify the dynamics at work. Consider, for example, the first principle on human development and aging as lifelong processes. New transitions along the life course establish different life stages and tend to accentuate the dispositions people bring to the situation with its social imperatives in shaping behavior. A life transition also entails some loss of personal control and motivates efforts to regain it.

Paradigmatic Principles of Life-Course Theory

The following principles emerged from studies of *Children of the Great Depression* (Elder, 1974/1999), subsequent research, and the complex interplay of intellectual and social forces at the time that stressed the importance of placing human development in a lifelong context (Elder, Johnson, & Crosnoe, 2003). Collectively,

they define the life course as a theoretical orientation that provides a framework for studying phenomena at the nexus of social change, social pathways, and developmental trajectories. We begin with the principle of life-span development.

The Principle of Life-Span Development: Human Development and Aging Are Lifelong Processes

Over the years, the life span has been represented as a sequence of life stages, from infancy and early childhood to old age. Each stage became an age-specific domain for specialized study. However, we recognize now that developmental and aging processes are most fully understood from a lifelong perspective (Kuh, Power, Blane, & Bartley, 1997). Behavior patterns at midlife are not only influenced by current circumstances and by the anticipation of the future, but also by prenatal and early childhood experiences. The biomarkers of predisease pathways extend back to the early years (Singer & Ryff, 2001) and, perhaps, even reflect intrauterine experiences shaped by the mother's context and experiences. Long-term studies are documenting the relationship between late-life adaptation and the formative years of life-span development. These include the national longitudinal studies of birth cohorts in Great Britain, marked by birthdates of 1946, 1958, 1970, and 2000. They are all scheduled to be followed into the later years of life (Ferri, Bynner, & Wadsworth, 2002). Such long-term longitudinal studies are still rare.

This temporal frame poses major challenges as well as exciting opportunities. The longer a life is studied, the greater the risk of exposure to social change. The lives of people in their 80s or 90s are thus most likely to reflect the particular contours of a changing society. Longitudinal data archives generally lack adequate information on change in social relationships, social organizations, and residential ecologies. However, the availability of geographic codes with coordinates that map households for users of large data sets now enable investigators to assess contextual changes and their effects on lives.

Another challenge posed by the principle of lifelong development and aging centers on the question of why some behavioral patterns persist while others fade. What influences play a role in this change? We are just beginning to identify mechanisms that drive patterns of continuity and change. For example, Caspi and Bem (1990) identify three modes of interaction between person and situation that have relevance to individual continuity and change: (1) evocative, (2) reactive, and (3) proactive interactions. Evocative interactions refer to the process by which an individual's appearance, behavior, or personality elicits distinctive responses from others. Reactive interactions refer to people who encounter the same situation but interpret and respond to it differently. Examples include academic failure and the separation of parents, and their variable meaning at different life stages. Proactive interactions refer to the selection of environments such as friendships.

Transitional experiences across the life course involve individual initiatives, situational constraints and opportunities, the dispositions and prior experiences that people bring to new situations, and the influence of others. Though many factors influence lives, young people play an important role in constructing their own lives though the choices they make.

The Principle of Human Agency: Individuals Construct Their Own Life Course through Choices and Actions They Take within the Opportunities and Constraints of History and Social Circumstance

Elements of human agency have been prominent in studies of lives (see Haidt & Rodin, 1999; Thomas & Znaniecki, 1918–1920) and are central to studies that relate lives to broader social contexts. People make choices in constrained situations that enable them to exert a measure of control over their life course. These choices ensure a degree of *loose coupling* between social transitions and life stages. Even during the economic turmoil and distress of the 1930s, mothers found jobs amid scarce options, while many of their children carried responsibilities in the home and community. When deprived parents moved their residence to cheaper quarters and sought alternative forms of income, they were involved in a process of "building a new life course." One part of this process appears in the response of young people to needs in the family economy. As noted earlier, they were called on to meet the increased economic and labor needs of deprived households, and a large number managed tasks in the family and earned money on paid jobs.

The initiative of Depression youth from financially strained families is much the same among contemporary youth in an Iowa longitudinal study of rural hardship (Elder & Conger, 2000). This pioneering study began in the late 1980s with 451 farm and small town adolescents and their families in the north central region of Iowa, United States. The adolescents are now in their late 20s.

Children of deprived rural families in this region assumed more responsibilities such as unpaid chores and work on the farm. Boys and girls also sought paid work when faced by the time and labor pressures of both large households and economically distressed farm families. Whether living on a farm or not, working adolescents tended to describe themselves as industrious and efficacious, more so than other youth. Many of these young people would eventually have to seek their fortunes in other communities, and we know that the movers were among the more capable members of the younger rural generation. Youth with migration intentions had done well in school, but they perceived dismal life chances in their local region.

Choice making in migration is vividly expressed in Hagan's (2001) account of American war resisters during the Vietnam War, and their troubled decision to take the "northern passage" to Toronto, Canada, a legal sanctuary from the American selective service system. Nearly 10,000 men chose to defy the military draft and the counsel of their families, and some made this journey with female friends. A majority continued their protest of the war along the way and in their northern community. Though many years removed from the Vietnam crisis, former war resisters (a majority of whom still reside in Canada) remembered the emotional complexity and discord of their decision process. War resisters made their decision to settle in Canada after countless appeals and protests, knowing the moral stigma of their action in the American public. Interviews recall this traumatic time and the process by which "each decision against service in the war" constructed a deviant path from the perspective of American society. This was a different path from that followed by siblings. They were more likely to be employed in human service and artistic professions, and they ended up with lower earnings, but this inequality stemmed more from their prolonged involvement in war protests and the world of activism, which also altered their sense of self and relationships with family and friends.

Does "planfulness" make a difference in the quality of life choices and agency? In *American Lives* (1993), John Clausen focused on this question, with emphasis on the formative adolescent years of Californians who were members of the Oakland and Berkeley Guidance Studies. He hypothesized that competent adolescents who think about the future with a sense of personal efficacy are more effective in making sound choices and in implementing them during the transition to adulthood. These more "planful decisions" lead to greater success in work and family through adulthood. Planful competence was defined by three dimensions: (1) self-confidence, (2) dependability, and (3) intellectual investment. A competent adolescent is equipped with the self-discipline to pursue chosen goals and has the ability to evaluate personal efforts accurately as well as the intentions and actions of others, using an informed knowledge of self, others, and plausible options. Clausen found that the highly competent males in adolescence were most likely to achieve a successful start through education, occupational careers, and family, apart from the influence of IQ and class background. Moreover, this beginning anticipated achievements across the life course, even into the 60s. The young men with a planful competence were more likely to have stable marriages and careers and tended to find satisfaction and fulfillment during their final decades. The planfully competent also ranked highest on the stability of their personality across the years.

Do these findings reflect the special circumstances of the study members' early adult years—the beginning of World War II and an unparalleled era of prosperity? Postwar benefits for veterans encouraged them to obtain a college education, but what if we stepped back a decade of two so that both a Great Depression and global war loomed ahead? To do this, we turned to the Lewis Terman data archive (Holahan & Sears, 1995), a longitudinal study of the brightest Californians. This study of talented children was launched in the 1920s, a time when California's economy seemed to offer unlimited opportunity. Half of the children were born before 1911, the other half by the early 1920s. By selecting only the most able of California's children for the study, Terman could direct his attention to great promise and the expected rise of talent to positions of accomplishment and leadership.

But history changed this trajectory (Shanahan & Elder, 2002; Shanahan, Elder, & Miech, 1997). The older cohort had completed most of its post-high school education by the stock market crash and looked ahead to a stagnant and declining labor market, while the younger men faced the prospects of going to college in the later years of the Depression decade. Lacking good job prospects, a substantial number of the older men stayed in graduate school, extending their list of degrees. By contrast, World War II reduced significantly the educational opportunities of the younger men, while having no impact on the education of the older men who were well past the college years.

With these different historical paths in mind, it is not surprising that planful competence in adolescence had much greater relevance for the future of the younger men, when compared to the older cohort. The planfulness of the older men in adolescence had no effect on their chances for advanced education and career achievement. In large part, this outcome reflects the process of "warehousing" in which the young prolong their stay in school during economically troubled times. School persistence had less to do with personal motivation than with a way of getting out of hardship situations. Life constraints and the timing of careers shape the choices of human agency.

The Principle of Timing: The Developmental Antecedents and Consequences of Life Transitions, Events, and Behavior Patterns Vary according to Timing in a Life Course

Lifelong processes of human development and human agency underscore ways of thinking about the timing of lives and their social contexts. As Bernice Neugarten (1968) has shown in her pioneering work, people do not march through life in concert. They tend to vary by the age at which they pass through life transitions—when they begin and complete their schooling, enter a first job, establish an independent domicile, share a household with a friend, marry, have children, see children leave home, and lose their first parent. They also vary in when they perceive themselves as young, middle age, and old.

In *Children of the Great Depression* (Elder, 1974/1999), some members of their cohort entered marriage before their twentieth birthday, while others were still unmarried a decade later. Early marriage tended to produce life disadvantages, from socioeconomic hardship to the loss of education. Early childbearing had similar consequences. All of these age variations or differences can make a difference by setting in motion a dynamic of cumulative events and processes. To illustrate this point, we turn to the ages at which children experience the breakup of their family and engage in behaviors that initiate a sequence of disadvantage.

No time is a good time for a child's loss of a parent through separation or divorce, but the child's age when such change occurs can make an important difference in its consequences. To address the impact of a single-parent household, Krein and Beller (1988) matched mother-daughter and mother-son samples from the National Longitudinal Surveys to investigate three relevant hypotheses: (1) the transition to single-parent status is most damaging during the early preschool years, owing to heavy time demands; (2) duration of residence lessens the educational achievement of offspring by diminishing social resources; and (3) boys are likely to be more impaired by the change than girls, owing to modeling processes (see also McLanahan & Sandefur, 1994). Although Krein and Beller designed precise measures of the age and length of time a child lived in a single-parent household, the reports of family structure are retrospective because the mothers were interviewed between the ages of 30 and 44. The offspring were interviewed when they were 14 to 24 years. However, such retrospective reports are reasonably accurate.

The study found that timing mattered, along with duration and gender: (a) the adverse effect on education was much greater for the preschool versus the later years, (b) the adverse effect increased with the number of years a child spent in a single-parent household, and (c) the adverse effect was more negative for males than for females. The strongest and most consistent timing and duration effects were obtained among White males, with family income controlled. Black females and men were next in line on effects, followed at some distance by White females. Whether family income was controlled, the timing and duration of living in a single-parent household mattered least for White females. The meaning of this result was not pursued in the study, although these young daughters of single-parent mothers may be protected by maternal support and the model of a self-sufficient woman. Little is known about the actual life history of family structure and the timing of a child's exposure to different phases.

Social disadvantage though family dissolution, erratic parenting, and low socioeconomic status plays an important role in channeling youth toward involvement in antisocial behavior (Sampson & Laub, 1993). The early timing of this involvement increases the risk of a persistent pattern of such behavior. Thirty-five years ago Lee Robins (1966) found that antisocial boys were likely to enter unskilled jobs and experience spells of unemployment, short work weeks, and an unstable marriage. More recently, a study of ill-tempered boys in the Berkeley Guidance Study found them to be at risk for the very same kind of disorganized life course (Caspi, Elder, & Bem, 1987). They were not able to maintain social relationships or jobs. Sequences of adverse events are part of a cumulative process of life disadvantage. Just how this process unfolds is a subject of much theorizing and research. Patterson (1996) views the process

as a cascade of secondary problems such as school failure, depressed mood, and parent rejection. An early history of antisocial behavior is linked to late adolescent conduct through such processes.

From this research and studies into the adult years, three markers along a disadvantaged life course emerge: (1) age at first arrest, (2) incarceration or jail time, and (3) unemployment. In combination, they underscore the importance of "onset timing for deviant activities." The earlier the age at first arrest the greater the likelihood of a criminal career (Farrington et al., 1990). Age at first arrest is a reliable predictor of this future because it sharply increases the likelihood of chronic, violent, and adult offending and the risk of incarceration. Though incarceration is a popular response to the crime problem, jail time appears to be a large part of the problem itself, owing to its role in expanding the disadvantaged population. Using both nationwide and local samples, Freeman (cited by Sampson & Laub, 1996) reports that in all analyses "having been in jail is the single most important deterrent to employment." This finding held up even with adjustments for individual differences that account for unemployment.

An early onset trajectory is defined as a rule by a first arrest before the age of 14. Studies to date link early onset with an earlier onset of antisocial behavior (Patterson & Yoerger, 1996). Perhaps as early as age 6 or 7, a breakdown in parenting processes increases coercive actions (e.g., talking back, explosive behavior, or hitting). The resulting interchange leads to fighting, stealing, and truancy. Antisocial actions that are prototypic of delinquent acts, such as stealing from parents and hitting them, increase the risk of delinquency through the medium of deviant friends. The later onset of deviant behavior includes more conventional youth who are or might be seen as "transitory delinquents." They are more antisocial than uninvolved youth, but not as antisocial as the early onset youth. Patterson and Yoerger conclude that the most intriguing thing about the late-onset boys is that they tend to be more deficient in social skills than are the early onset boys. They regard this as key to predicting which boys will persist in adult crime and which boys will not.

The profound life-course implications of early involvement in antisocial behavior continue to focus empirical work on the dual pathways hypothesis (Farrington & West, 1990; Moffitt, 1993; Moffitt, Caspi, Dickson, Silva, & Stanton, 1996; Nagin, Farrington, & Moffitt, 1995). In the Dunedin longitudinal study, Moffitt (1993) defined two groups with scales and interviews: childhood and adolescent onset of antisocial behavior. With associates, she has followed the males up to their 26th year (Moffitt et al., 2002), a time that is still prior to the median age at first marriage for males in New Zealand. At this age, the childhood group shows the most elevated pattern of psychopathic personality traits, problems of mental health, violent and drug-related crime, substance dependence, and financial-work problems. Adolescent-onset delinquents were less extreme on these measures. Neither group of young people reveal turning points in behavior, perhaps owing to their continuing status in the maturity gap before an established adulthood. Entry into quality jobs and marriages may still produce such turning points, as Laub and Sampson (2003) have shown in their long-term study of delinquent youth and their divergent adult lives.

In life-course theory, age at onset of antisocial behavior is most appropriately expressed as a continuous, time-dependent process. From research to date, one would expect causal factors during the early years to feature neurological and social skill deficits as well as impaired family processes and indications of extreme distress. In the later years, other factors, such as deviant peer activities, would come to the fore; but when they become prominent may depend on the particular ecology, whether the high-risk environment of the inner city or the network closure of small rural communities. By employing this analytic model, empirical research and not decisions based on potentially different criteria are likely to determine whether and when a break occurs between types of causal influences.

Across the life course, the onset of antisocial behavior or its timing is generally viewed in a matrix of social relationships or linked lives. Indeed, change from a life of crime to a conventional lifestyle typically involves change in a young person's best friends, as prompted by marriage or military service (Laub & Sampson, 2003).

The Principle of Linked Lives: Lives Are Lived Interdependently and Social-Historical Influences Are Expressed through This Network of Shared Relationships

The principles of timing and linked lives address in complementary ways the temporality, process, and context of lives and human development. Interdependent lives highlight the role of significant others in regulating and shaping the timing of life trajectories through a network of informal control. This network can be

thought of as a "developmental context" (Hartup & Laursen, 1991) and as a "convoy" of significant others through life (Antonucci & Akiyama, 1995). Whatever the plans of an individual, these "significant others" initiate or experience life transitions that produce transitions in his or her own life. As Becker once observed (1964), the expectations and informal sanctions of these "others" channel behavior and the life course in certain directions.

Linked lives are expressed in *Children of the Great Depression* (Elder, 1974/1999) across the generations, in the parental marriage, and in the relationship of parents and siblings. Older and younger siblings influence each other directly through their encounters, whether nurturant, competitive, or conflictual (Brody, 1996). In an African American sample, Brody and associates (2003) found a significant link between the antisocial behavior of older and younger siblings, but it was strongest in disadvantaged neighborhoods that provided abundant opportunities for the younger sibling to express this behavior, when compared to siblings in affluent residential areas. Examples of an indirect path include the experience of parents with the eldest child that undermines or strengthens their sense of competence in parenting. A third potential sibling link involves the differential treatment of siblings by parents, relatives, or teachers. Little is known about continuity and change in sibling relations from childhood into the adult years.

Marriage and the mutual regulatory influence of each partner illustrate both the process of timing through the synchronization of lives and of the embeddedness of each family member's life. For example, Caspi and Herbener (1990) investigated the influence of marital relations on the developmental trajectories of husbands and wives. In "choosing situations that are compatible with their dispositions and by affiliating with similar others, individuals may set in motion processes of social interchange that sustain their dispositions across time and circumstance" (p. 250). Among marriages with strong ties, they observed trajectories of parallel development over 20 years. Husbands and wives did not change toward greater resemblance in developmental trajectory, but they did show a parallel course of development. When marriages dissolved, the former partners tended to follow less parallel trajectories. A late-life follow-up of Bennington College graduates from the 1930s came to similar conclusions (Alwin et al., 1991). Women were likely to select a college that matched their political beliefs, and they married men with similar beliefs, which sustained their own beliefs into the later years.

Family changes are especially relevant to the principle of linked lives and its implications. Hernandez (1993) refers to a number of revolutionary family changes in the lives of children and adults, including the decline in family size, migration off the land, the growth of women's employment, divorce, and single parenting. Contemporary farm families in the Midwestern region of the United States are characterized by strong community and intergenerational ties, which are weaker for families of farm-reared parents in urban settings. A longitudinal study of families in the north central region of Iowa documents this contrast and the greater social resources of young people with families who have ties to the land (Elder & Conger, 2000). These young people were among the most competent and resourceful adolescents in the study and their accomplishments in school and social leadership had much to do with their social ties to family, church, and community. They were also more engaged in joint activities with their parents and reported stronger relationships with grandparents and teachers. Their social responsibilities fostered a sense of "mattering" to others, a feeling of significance because other people counted on them. In this social world, linked lives regulated and empowered personal development, a social control that could also take the form of barriers to residential change and access to new opportunities in other places.

The experiences and attributes of one generation, such as parental work values, are passed on to the young through relationships between the generations. For example, drawing on the Youth Development Study, Ryu and Mortimer (1996) found parental work experiences and values to be correlated with the work values of children. Mothers' extrinsic work values (such as on money, security) fostered similar values in the lives of their teenage and young adult daughters, and mothers with strong intrinsic values (including work autonomy and interest in job) were least likely to have daughters who valued extrinsic rewards such as high income and status. For sons, the supportiveness of parents mattered more than parents' actual work values and occupational experience. The more supportive the father and mother, the stronger the son's intrinsic values. Intergenerational relations are an important medium for the transmission of work values.

Interdependent lives also extend beyond the family to friends, teachers, and neighbors. Theories of resilience

commonly assume that positive influences can offset negative influences (Luthar, 2003; Werner & Smith, 2001). A positive school environment of classmates and teachers might compensate for a child's punitive family environment or a drug-infested neighborhood. Relevant to these issues is a short-term longitudinal study of adolescents in Prince George's County in the Washington, DC, area (Cook, Herman, Phillips, & Settersten, 2002). The influence of nuclear families, friendship groups, schools, and neighborhoods was assessed in the lives of mainly African American and European-American students in the seventh and eighth grades during the early 1990s. The quality of all four contexts had independent and additive influences on adult success, defined by a composite of school performance, social behavior, and mental health indicators. No reliable interaction effects were observed among the four contexts. The effect of any one context was not large, but the total contextual effect proved to be substantial.

Conventional approaches to the study of peers or friends, as linked lives, have viewed the relationship only from the perspective of the child or adolescent. The perspective of the "other" has seldom been assessed. Studies have also ignored the developmental history of friendship and peer experiences. Bearman and Brückner (1999) address both of these deficiencies in their investigation of girl's friendship and peer group as contributing factors to sexual experiences in adolescence. Their study, based on the National Longitudinal Study of Adolescent Health, provides evidence of the positive influence of peers at multiple levels. Both adolescent girls and their friends were classified as high risk or low risk by school orientation and success as well as by evidence of health-risk behavior such as drinking, skipping school, and fighting. A girl's own risk was less important for her first sexual intercourse and pregnancy than the risk of her male and female friends. Moreover, the age of a girl's friends tended to be more important than her own age. Girls with older friends were more likely to engage in sexual intercourse. Moreover, a girl's circle of close friends and her wider peer network mattered more than her best friends. These effects were predominantly protective. Girls who had low-risk friends among their close circle of friends or in their peer group were less likely to have sex or experience a pregnancy.

A young girl's pregnancy can have consequences that fundamentally change the lives of her mother and grandmother, among others. When a 13-year-old has a child, her 28-year-old mother becomes a grandmother, and her grandmother becomes a great-grandmother. Using data on 41 female lineages from urban multigenerational African American families in Los Angeles, Burton (1985; Burton & Bengtson, 1985) has creatively explored the ripple effects of teenage pregnancy across the generations. The age ranges of respondents in the early lineages were 11 to 18 for the young mothers, 25 to 38 for the grandmothers, and 46 to 57 for the great-grandmothers. The other lineage units were judged on time in transitions. The age ranges for mothers, grandmothers, and great-grandmothers were 21 to 26, 42 to 57, and 60 to 73, respectively.

Role transitions that were "on time" were generally welcomed. One 22-year-old mother commented that she had become a mother " 'at the right time': I was ready, my husband was ready, my mother was ready, my father was ready, my grandmother couldn't wait." By comparison, early transitions multiplied social strains and deprivations in the family system, all reflecting the violation of expectations. With few exceptions, the young mothers expected their own mothers to help care for their child. However, this expectation never materialized in four-fifths of the cases, in part because the mothers felt that they were too young to become a grandmother. As one woman put it, "I can't be a young momma and grand momma at the same time. Something seems funny about that, don't you think?" A good many of the mothers resisted the grandparent identity because it conflicted with their availability as dating and sex partners.

The refusal of mothers to become grandmothers, with their normative child care expectations, led most of the young mothers to shift these duties to their grandmothers, now the baby's great-grandmother. Some of these women felt that the change made their life go by too fast. In the words of a woman beset by too many claims, "I ain't got no time for myself. I takes care of babies, grown children, and old people. I work too . . ." Some of these newly promoted great-grandmothers felt they had to put their lives on hold until "the older generation died or the three younger generations grew up." The repercussions of this ill-timed pregnancy across the generations underscore the price of interdependent lives and the support they may provide.

The Principle of Historical Time and Place: Individual Life Course Is Embedded in and Shaped by Historical Times and Places over a Lifetime

Children of the Great Depression (Elder, 1974/1999) is based on children who were born and reared in a specific

historical time and place, defined by culture, social institutions, and diversity of people—the 1920s, the San Francisco East Bay, California. The book also describes a very different Depression experience in Great Britain, Germany, and Japan. Even in the United States, conditions during the Great Depression varied among cities, East and West, and between rural and urban places. In view of this variation, the study's generalizations are uncertain. Also uncertain are generalizations across historical time such as periods of economic depression and recession.

One of the best examples of both historical and spatial variations in the life course and human development comes from studies of lives during military times. The immediate years after World War II, for example, were hard times in many parts of Europe and Asia, unlike the prosperity experienced in the United States. American children who grew up in financially strained families during the Great Depression frequently saw military service as a "bridge to greater opportunity." However, the age at which they entered the service made a difference in how it affected their lives. When appraised in terms of costs and benefits, military service for Americans has favored the recruit who entered shortly after completing secondary school. This time of recruitment comes well before commitments to higher education, a marriage partner, children, and a line of work.

By contrast, later recruitment tends to disrupt all of these activities. Empirical research (Clipp & Elder, 1996; Elder, 1986, 1987; Elder, Shanahan, & Clipp, 1994; Sampson & Laub, 1993, 1996) has documented the life-course advantages of early mobilization and the disadvantages of relatively late entry, quite apart from the mental health and mortality effects of wartime combat. The disadvantages include family disruption, prolonged father absence (Stolz, 1954), family discord, and divorce (Clipp & Elder, 1996), but these are not due to the mental and physical wounds of wartime combat. Exposure to heavy combat markedly increased the likelihood of emotional and behavioral problems after leaving the service, but such problems were not concentrated among the late entrants. Before getting into the details of selected studies, we note some basic features of the transition to military service, in eras of World War II, the Korean conflict, and the Vietnam War.

First, military service tended to pull young people from their past, however privileged or unsavory, and in doing so it created new beginnings for developmental life changes. Basic training defined a recruit's past as irrelevant. This definition encouraged independence and responsibility, separated recruits from the influence of their home community and family, and allowed a degree of social autonomy in establishing new ties. Basic training also promoted equality and comradeship among unit members, made prior identities irrelevant, required uniform dress and appearance, minimized privacy, and rewarded performance based on group achievement.

A second distinctive feature involves "a clear-cut break from the age-graded career," a time-out in which to sort out matters and make a new beginning. Military duty legitimized a time-out from education, work, and family, and liberated the recruit from all conventional expectations for an age-graded career, such as expectations regarding progress and life decisions.

Just being in the armed forces released the recruit from probing life-decision questions from parents (e.g., Have you decided on a job or career? When will you be promoted or get married?). As Samuel Stouffer and his associates in the American Soldier study (1949, Vol. 2, p. 572) noted, for many soldiers in World War II, "perhaps for a majority, the break caused by Army service [meant] a chance to evaluate where they had gotten and to reconsider where they were going." This time-out would be far less timely for men and women who were mobilized in the midst of family and career responsibilities.

A third feature of mobilization offered a broadened range of developmental experiences and knowledge, including exposure to in-service skill training and educational programs, as well as exposure to new interactional and cultural experiences through service itineraries that extended across the country and overseas. Out of such experiences came a greater range of interpersonal contacts, social models, and vocational skills. Horizons were broadened and aspirations elevated. A veteran interviewed just after World War II (Havighurst, Baughman, Burgess, & Eaton, 1951, p. 188) commented about the remarkable diversity of his acquaintances in the service and their influence on his views. As he put it, the experience "sort of opens up your horizons. . . . You start thinking in broader terms than you did before." Post-World War II veteran benefits, particularly the GI Bill, gave significant support for these new aspirations.

The creation of new beginnings, a time-out or moratorium to rethink and rework one's future, and a broader range of skills, interpersonal contacts, and cultural experiences do not exhaust important features of military experience for new entrants, but in combination they define a bridge to greater life opportunity and a potential

turning point, especially for disadvantaged youth. As a total institution that presses from all angles, the military is uniquely suited to recasting life trajectories. Indeed, many years ago, Mattick (1960) found that young men paroled to the army had a much lower recidivism rate than civil parolees. Features of basic training and the transition to military service have been adopted over the years by social interventions, most especially by the Civil Conservation Corps in the 1930s.

Early entry into the military tends to minimize life disruption and maximize such life-course benefits as vocational education, skill training, and the GI Bill of support for veterans' education and housing. In both the Oakland Growth and Berkeley samples (1986, 1987), with birthdates in the 1920s, young men with disadvantages of one kind or another were likely to join up as soon as they could. Three types of disadvantage were especially consequential: (1) membership in an economically deprived family, (2) poor high school grades, and (3) feelings of personal inadequacy during adolescence. In combination, these factors predicted early entry into military service and its pathway to personal growth and greater opportunity. Early entrants show greater life benefits of the service up to the middle years than did later entrants.

Military service offered greater life development among the early entrants in two ways. One route involved situational changes that made these recruits more ambitious, assertive, and self-directed by midlife (Elder, 1986). The second route involved extensive use of government educational and housing benefits through the GI Bill. This important legislation, which has been likened to a Marshall Plan for America, was available to recruits up through the age of 25. Early recruits in the Oakland and Berkeley cohorts were most likely to take advantage of these benefits for training and a college education (Elder, 1986, 1987).

Though initially more disadvantaged, the early entrants at least matched the occupational standing of the nonveterans at midlife, and the Berkeley males from deprived families showed greater developmental gains up to the age of 40. Using Q-sort ratings of personality in adolescence and at midlife (Elder, 1986), the study found that the early entrants displayed greater change toward self-direction and confidence than the later entrants. The mental health risks of combat exposure did not alter this effect of life stage and timing in the two cohorts.

Involvement in the military helped to account for why men from financially strained families in the 1930s have fared well in their adult years, matching if not exceeding the occupational accomplishments of adults from more privileged backgrounds. However, the military experience itself has remained largely a "black box" and a subject of informed speculation. What were the mechanisms of developmental change? Sampson and Laub (1996) provide some answers to this question in a compelling test of the early entry hypothesis. They use life-record data on a sample of approximately 1,000 men who grew up in poverty areas of Boston (birth years, 1925 to 1930), and more than 70% of the men served in the military. Sheldon and Eleanor Glueck (1968) originally designed the longitudinal study of delinquency with a matched control sample—500 delinquents and 500 controls.

The delinquent sample of White males, ages 10 to 17, was drawn from a population of youth who were committed to one of two correctional schools in Massachusetts. The matched controls (on age, IQ, race-ethnicity, and neighborhood deprivation) included 500 White males from the Boston public schools, also ages 10 to 17. The two samples are treated in all analyses as independent. From 1940 to 1965, the Gluecks collected a rich body of life-history information on the study members. With a particular eye to experiences in the military, they assembled unparalleled details on the men's service experience—their in-service training programs, special schools, exposure to the military justice system, and arrests. The life-record data on the sample of delinquents have also been coded by Sampson and Laub.

Men in the delinquent and control samples typically entered the service at the age of 18 or 19 years, and most served over 2 years (more than 60% overseas). Consistent with their history, men from the delinquent sample were far more involved in antisocial conduct during their service time than the controls (official misconduct, number of arrests, dishonorable discharge), and they were less likely to experience in-service training and benefits from the GI Bill. Nevertheless, men from the delinquent sample were more likely to benefit from the service over their life course, when compared to the controls, and this was especially true for men who entered the service at an early age. In-service schooling, overseas duty, and use of the GI Bill significantly enhanced job stability, economic well-being, and occupational status, independent of childhood differences and socioeconomic origins. However, benefits of the GI Bill were larger for veterans with a delinquent past, especially when they entered the military at an early age. The significant

benefits of the GI Bill and overseas duty on socioeconomic position were observed across the adult years up to the age of 47.

In combination, these findings provide consistent support for the life-course advantages of early entry into World War II, and one study suggests that it applies as well to the Korean War (Elder, 1986). However, ecological context matters, as one might expect. The timing of military service had very different effects in countries that lost World War II, specifically Japan and Germany. West German males, born between 1915 and 1925 were drawn very heavily into military action (up to 97% of an age cohort—Mayer, 1988, p. 234). These cohorts of veterans lost as many as 9 years of their occupational career in the war, suffered a high rate of imprisonment during and after the war, and experienced a mortality rate of 25%. German children born around 1930 were also hard hit by the war years, according to data from the German Life History Project (Mayer & Huinink, 1990, p. 220). The war disrupted their families and education and they entered the labor market in a war-devastated economy. Work placements were often poor, mixed with spells of joblessness, and advancement was unpredictable. Even the economic boom after the deprivational years of recovery did not fully compensate this younger cohort for its wartime losses in occupational achievement. A similar story is told by these two birth cohorts (circa 1920 and 1930) in Japan (Elder & Meguro, 1987), except that the younger group was mobilized as students for work in the fields and factories. A large number reported bomb-damaged homes and a forced evacuation to the countryside.

Today, military service occurs in a very different life course, marked by a later entry to adulthood for the college-oriented (Settersten et al., 2005). The nature of this service has also changed in many places, from obligation to voluntary. The aging of human societies has extended the transition to young adulthood, from family origins in adolescence to the establishment of a family in the early 30s or even later. In the United States, young people are entering adulthood at a time of rising educational requirements and later family formation for the middle class especially. This contrasts with an accelerated timetable for the working class and families in poverty—their transition events tend to occur much earlier.

We have used military service to illustrate the role of historical time and place in lives. Military service functioned as a trajectory out of disadvantage in the lives of Depression youth who survived World War II, but this escape was conditional on historical time and place: Opportunities and life itself were lost by countless youth in Europe and Asia.

Contributions of Life-Course Theory to the Study of Human Development

In combination, these paradigmatic themes of life-course theory identify its core features and potential contributions to the study of human development. First, this perspective places the field of study in a lifelong framework. Human development and aging are lifelong processes, expressed in continuity and change, and biological, social, and psychological terms. The early years of child development have formative implications for subsequent trajectories and healthy adaptations in later life. In the course of aging, individuals change their environment and social pathways by differentially interpreting, selecting, and assigning meaning to situations and personal experiences. This process is expressed by the principle of human agency—life-course choices are made in structured situations. Across the life course, pathways also shape the behavior of individuals through social demands and challenging options. Contexts and individuals thus become correlated. Transactional processes of this kind are established early in life and contribute significantly to life-course continuity. Life changes tend to occur when situational demands change and pressures increase to alter one's life course (e.g., marriage and military induction).

Few conceptual distinctions are more relevant to an understanding of developmental change and the lives of children than the link between age and timing. Thus, the full negative impact of a lengthy dependence on welfare for the educational progress of African American children appears after the third grade (Guo, Brooks-Gunn, & Harris, 1996). Cumulative dependence on welfare markedly tends to increase the risk of grade retention from the third to the ninth grades. Age and timing distinctions also enable studies to relate children to the life course of significant people in their lives. Middle-aged parents and their biographical experiences are an integral part of the adolescence of their children, and the experiences of youth figure prominently in the social world of their parents. In social meaning or function, parents remain parents for as long as they and their children live. Likewise, the significant relationship of grandchildren and grandparents can have much to do with the quality and pattern of their own lives. Lives

and developmental trajectories are thus embedded in a moving system of intergenerational relationships.

As a theoretical orientation or framework, the life course provides a conceptualization of the maturing individual's changing environment and its developmental relevance. This formulation locates children and their families in historical time and place. Cultural scripts and social structure play an important role in organizing human lives as life courses, along with the actions of people and the internal forces of self-regulation. In theory, macrochanges influence developmental processes by altering the individual life course through multilevel processes and social structures. For children growing up in the Great Depression, hard times shaped their life course by changing their family's experience and trajectory. Historical influences were filtered by their cohort membership and social class in 1929 and by their actual exposure to severe income loss as expressed in family adaptations. Place also made a difference because the economic collapse hit the eastern half of the United States before the western coast.

INTEGRATING BIOLOGICAL MODELS WITH THE LIFE COURSE: A PROMISING FRONTIER

New developments in the study of behavior and biography offer exciting possibilities for life-course studies. Research on neighborhoods and communities (Morenoff, 2003; Sampson, Morenoff, & Gannon-Rowley, 2002), autobiographical memory (e.g., Fivush & Haden, 2003), and subjective understandings of the self (Macmillan, Hitlin, & Elder, in press) have become increasingly sophisticated. Substantial progress has also been made toward integrating the stress paradigm with life-course principles (Elder, George, & Shanahan, 1996; Wheaton & Clarke, 2003). Advances such as these depend not only on novel data collection efforts but also on theory that directs attention to behavioral patterns as they vary by place, time, and age.

The study of biological processes and behavior illustrates this need for integral models that encompass social settings and development. As explosive as interest may be in biological studies of behavior, this work—encompassing evolutionary processes, metabolic processes associated with the endocrine and immune systems, genetics, and neuroscience—has not fully appreciated the importance of context and its dynamic features, the core insight of life-course theory. If behavioral development reflects ongoing exchanges between person and context, then its fully informed study necessarily involves longitudinal views of both biological and social processes. Thus, integration of the life course with biological models of behavior represents an emerging and highly promising area of study.

Such integration is facilitated by two considerations. First, many topics of interest to life-course studies are linked in significant ways to biological processes. These topics include, for example, trajectories of physical and mental health, the stress process, patterns of aggression and deviance, sexual behavior, fertility, parenting, and manifold dimensions of aging and mortality. Second, other topics are also likely to be associated with biological processes, albeit less conspicuously, including educational and occupational careers, patterns of close interpersonal relationships both within and beyond the family, and one's involvement and status in organizations.

Further, biological models of behavior have undergone nothing short of a paradigm shift in the past few decades, moving from biological determinism to the widespread assumption that "nature and nurture" interact in complex ways. This new view is consistent with propositions of systems theory (Lerner, Chapter 1, this *Handbook,* this volume), several of which are especially relevant to a discussion of biology and the life course. First, human behavior is the product of multiple levels of analysis, including, for example, levels characteristically associated with sociology, psychology, biology, and anthropology. By extension, there is no *a priori* reason to believe that any one level will have special explanatory value. For example, genes do not simply cause behavior (see Gottlieb et al., Chapter 5, this *Handbook,* this volume) and, at the same time, behavior is not purely a result of social forces.

Second, all levels of analysis are characterized by plasticity, which refers to the range of possibilities (Lerner, 1984). Thus, each person's behavior represents one set of possibilities from among a finite range of possibilities; similarly, every social order represents one form of organization out of a range of possible social orders. Third, although each level is likely to operate according to its own laws, the levels interact to produce behavior (Cairns, McGuire, & Gariepy, 1993). That is, systems theory assumes that many factors at multiple levels interact to form sets of "correlated constraints" that include the behaviors of interest and their covariates.

These behaviors and their covariates represent organized systems, and ongoing reciprocal interactions among their levels explain continuity and provide a map of opportunities for change.

When viewed jointly, these principles define a central theme of genetic, metabolic, and evolutionary approaches to behavior: Social and biological forces interact in complex and dynamic ways to define ranges of likely behaviors. By itself, this theme acknowledges the importance of context and its interplay with biology. Yet, a second overarching theme links biological models of behavior to the life course more directly: Behavior reflects a lifetime of reciprocal exchanges between person (including biological makeup) and context. This theme acknowledges that behavior cannot be fully understood without reference to prior experience. To explore these themes, we focus here on behavioral genetics and the life course (for discussion of the life course and evolutionary and endocrinological processes, see Shanahan, Hofer, & Shanahan, 2003).

Virtually all research on the life course has proceeded without considering the influence of genes on behavior, and, at the same time, behavioral genetics has proceeded without regard to the sophisticated models of social context that often characterize life-course research. Many lines of research have now established, however, that genotypes do not produce behaviors in a simple way (see Gottlieb et al., Chapter 5, this *Handbook,* this volume). Rather, phenotypes are likely to reflect the cumulative history of the individual's genotype (i.e., the genetic make-up of the organism), phenotype (i.e., any observable feature of an organism, including its behavior), and context. Indeed, there is widespread appreciation among behavioral geneticists that the links between genotypes and phenotypes are often heavily conditioned by social location and personal experiences. What is insufficiently appreciated is that the dynamic features of context often determine its meaning for the person. Put differently, the significance of social context for genetic expression will often depend on processes occurring in the life course as revealed by, for example, pathways, trajectories, transitions, turning points, and durations. One of the forefronts of behavioral genetics—gene-environment interactions—provides a useful example of this principle.

Mechanisms of Gene-Environment Interaction

Gene-environment (GE) interactions occur when genes alter the organism's sensitivity to specific environmental features or environmental features exert differential control over genetic effects (Kendler & Eaves, 1986). That is, genes may or may not be expressed depending on the context, or the effect of context may depend on the genotype. Many students of human behavior, development, and aging believe that the study of GE interactions will promote a better understanding of complex human behaviors (e.g., McClearn, Vogler, & Hofer, 2001; McGue, 1999; Rowe, 2001; Rutter & Silberg, 2002; Sawa & Snyder, 2002; van Os & Marcelis, 1998; Wahlsten, 1999). Yet, few empirical examples of GE interactions have been identified in the study of behavioral phenotypes in humans, and failures to find such interactions have been noted (e.g., Heath et al., 2002; McGue & Bouchard, 1998, p. 12).

Part of this discrepancy between the presumed commonality of GE interactions and the infrequency of their detection undoubtedly reflects methodological difficulties (e.g., power issues, levels of measurement, over-reliance on cross-sectional designs), or over-simplified conceptualization and measurement of social context. What is it about social context that would interact with the genotype to produce behavior? To date, four social processes have been identified (Shanahan & Hofer, 2005).

First, social stressors may *trigger a genetic diathesis,* as is found, for example, in numerous studies of life-events that trigger various forms of depression among people at high genetic risk for internalizing problems (e.g., Kendler & Kessler, 1995; Silberg & Rutter, 2001). Second, social context may *compensate for a genetic diathesis,* which means that the absence of notable stressors or the provision of an enriched environment may prevent the expression of a genetic risk. For example, people at genetic risk for depression but not experiencing life-events typically do not exhibit depression. Studies of mice show that enriched settings can completely compensate for genetic risks for cognitive tasks that are necessary to negotiate a maze (Rampon, Tang, Goodhouse, Shimuzu, & Tsien, 2000; Rampon & Tsien, 2000).

Third, social context may also *prevent the expression of a genetic risk through social control processes.* Numerous studies show that sources of social control—for example, religion, monitoring, anonymity, cultural values and norms—lead to lowered levels of alcohol consumption despite a genetic propensity or, conversely, high levels of consumption in the absence of genetic inhibitors to drinking (e.g., Dick & Rose, 2001; Higuchi et al., 1994; Koopmans & Slutske, 1999). Finally, Bron-

fenbrenner and Ceci's (1994) bio-ecological model suggests that *proximal processes encourage the actualization of genetic potential:* As proximal processes—enduring forms of social interactions characterized by progressive complexity—improve, the genetic potential for positive development is increasingly actualized. For example, Rowe and Jacobson (1999) showed that the heritability of verbal intelligence is significantly greater among high-education households than low. Their results suggest that the genetic potential for verbal intelligence is more fully realized in homes of better-educated parents, which are assumed to provide enriched proximal processes (e.g., Guo & Stearns, 2002).

Gene-Environment Interactions in the Life Course

What is notable about all of these processes is that they occur in the life course or are age-graded experiences that form trajectories or pathways. How can the life course inform the study of genetic expression? First, triggering, compensatory, social control, and proximal processes are all mechanisms that occur over considerable periods, and thus must be studied with life-course distinctions in mind. Second, the nature of these processes is multifaceted and will vary through the phases of life: For example, the factors that constitute social control in childhood differ significantly from social control mechanisms in adolescence, which, in turn, differ from control in young adulthood. The importance of these themes—the dynamic and multidimensional nature of context—can be appreciated when considering existing approaches to context in behavioral genetic research.

Dynamic Patterns of Context

The case of GE triggering interactions involving life-events and depression illustrates the importance of conceptualizing and measuring context through time. As noted, many studies show that life-events are significant stressors that trigger depression in people with a genetic susceptibility for that disorder. Such studies typically ask people to indicate from a list of the life-events that have occurred over a specified period. The total number of life-events experienced is then associated with depression.

Yet, the magnitude of the relationship between life-events and indicators of distress like depression or depressive symptoms is often modest (Turner, Wheaton, & Lloyd, 1995), and the cumulative evidence shows that these modest associations are observed because, in part, the invidious nature of stressors is contingent on the prior, contemporaneous, and subsequent experiences of the person (Elder et al., 1996). In effect, life-events—like all potential sources of stress, compensation, enhancement, and control—can only be understood in the context of the life-course trajectories that embed them.

Indeed, while the vast majority of studies examine the negative implications of life-events for well-being, or the conditions in which such negative effects are attenuated, life-events can actually have *positive* effects on well-being, depending on prior circumstances. For example, Wheaton (1990) shows that severe life-events have a positive effect on psychological well-being if they resolve an antecedent source of chronic distress. Thus, among adults who have lost a spouse, persons with high levels of prior marital problems report significantly less distress than with low levels of prior marital problems. Similar patterns are observed for earlier divorce, premarital breakup, and a child moving out, with qualified evidence for recent divorce, job loss, retirement, and getting married. Wheaton concludes that role histories often determine the meaning of a life-event (for other examples of the positive effects of life-events, see also, Amato, Loomis, & Booth, 1995; Sweeney & Horwitz, 2001).

Furthermore, the experiences of early traumas (including life-events) on later well-being are likely to be contingent on complex patterns of cumulative stressors. Turner and Lloyd (1995) report that the number of cumulative lifetime traumas significantly predicts onset of disorder (major depression or substance abuse) but not relapses of disorders. The number of traumas experienced since the first onset, however, significantly predicts relapses. Controlling recent life-events, the authors find that the number of post-onset traumas and chronic stressors increases major depression and substance use, while the number of pre-onset traumas *decreases* the risk of major depression. The authors conclude that the effects of life-events on distress will be significantly underestimated if life-time patterns of both traumas and episodes of disorder are not taken into account (for the independent effects of earlier and later stressors, see also, e.g., Ensel & Lin, 2000; Hayward & Gorman, 2004; Poulton et al., 2002).

With respect to experiences subsequent to the life-event, research shows that the effects of life-events are often contingent on their implications for later life patterns. For example, in their overview of research on childhood adversity and its effects on adult adjustment,

McLeod and Almazan (2003) note that much of the effect of parental loss (other than by parental separation) is mediated by subsequent experiences. Studies suggest that the provision of good child care, integration into and achievements at school, good peer relations, and supportive, intimate relationships can all act to break the link between parental loss in childhood and poor psychosocial outcomes in adulthood (e.g., Quinton & Rutter, 1988; Rutter, 1989). In adulthood, the effects of life-events are often contingent on how the events are resolved.

While our review of the life-events literature is not meant to be comprehensive, it underscores that the cross-sectional measurement of exposure to life-events represents a crude proxy for increases in stress load that could actually trigger a genetic diathesis for psychosocial distress. Likewise, variables that represent other forms of stressors—as well as potential sources of social compensation, control, and enhancement—are likely to acquire their meaning and impact only when viewed as part of a life-course trajectory. In an effort to enhance the accuracy and validity of their models, behavioral geneticists are beginning to assess behavior in developmental terms. A similarly dynamic orientation is necessary to capture the full significance of social context.

In addition to the dynamic features of experiences, the life course directs attention to the changing nature of social processes through the phases of life. Social context is part of a "cascade of associations" (Johnston & Edwards, 2002) or mediating mechanisms that makes certain behaviors more likely than others. As Rutter and Pickles (1991) observe, a GE interaction is not an explanation but rather something to be explained. For example, Link and Phelan (1995) suggest that socioeconomic status is a "fundamental cause" of well-being, meaning that, as a rule, high socioeconomic status is associated with good health. Nevertheless, the mechanism by which high socioeconomic status has these salutary effects varies considerably depending on the time and place. Socioeconomic status may promote manifold dimensions of well-being and health through, for example, preventative behaviors, monitoring and treatment, the amelioration of stressors, and/or the provision of stimulating, healthy environments. Perhaps all of these mechanisms are at work, or perhaps their importance differs at different points in life.

Sampson and Laub's research (1993) on informal social control illustrates the multifaceted nature of this mechanism. In childhood, informal control refers to a complex range of parenting behaviors, peer relationships, and connections to school and religious institutions. Through adolescence, the importance of these sources may wane to some degree, and close interpersonal relationships and the workplace may increase in importance. Informal social control in young adulthood is often indicated by attachments to the labor force, marriage, parenthood, military service, and religious and civic involvements. Across the phases of life, these sources of control tend to be positively interrelated, although, according to Sampson and Laub, youth experiencing low informal control may have experienced an increase in control during the transition to adulthood. Thus, social control refers to numerous, changing, and interrelated processes through the early life course. For example, it would be a mistake to suppose that measuring parenting before age 5 could capture these complexities.

The Multidimensional Nature of Context

Empirical studies that demonstrate GE interactions almost invariably involve the interplay between an indicator of genetic risk and a dimension of social experience. For example, depression is thought to be responsive to stressors, but research typically examines only one dimension of stressors (such as life-events). A focus on one dimension of context is likely to underestimate the effect of contextual factors, which often operate as "correlated constraints," or groups of variables that co-occur and work interactively. The multidimensionality of context raises two possible sources of complexity.

First, high levels of interaction may characterize indicators of triggering, compensation, control, and enhancement. Highly stressful circumstances (capable of producing GE triggering interactions), constraining circumstances (capable of producing GE social control interactions), and enhanced circumstances (capable of producing GE enhancement or compensation interactions) are likely to reflect manifold aspects of context that exert their influence on the person as a set of variables, not individually. For example, Rutter (1990) suggests that the presence of three or more risk factors predicts maladjustment in an interactive fashion. Likewise, the developmental challenges posed by neighborhoods marked by concentrated disadvantage are numerous, intercorrelated, and likely to exert their negative influences in nonadditive ways. Indeed, in their overview of research on childhood adversities and their implications for adulthood, McLeod and Almazan (2003) observe that:

> attempts to disaggregate the effects of clustered adversities may offer relatively little insight into processes of risk

> and resilience. The different clusters of events that children experience have different meanings that are lost when those events are studied in isolation. (p. 401)

While behavioral geneticists have understandably been interested in gene-gene (GG) and gene-environment (GE) interactions, environmental factors may create *environment-environment (EE) interactions,* whereby groups of contextual factors have nonadditive effects on behavior. Particularly, if only extreme settings will moderate genetic expression (Scarr, 1992), then such environments are likely to involve EE interactions. Regardless of the presence of EE interactions, the high associations observed between contextual variables warrants caution when interpreting bivariate studies that interrelate one genotype and one contextual factor (e.g., Caspi & Sugden, 2003). This point is clear in a study of sexual behavior among adolescents and their peers.

The case of virginity pledges among adolescents illustrates the highly interactive nature of a form of social control in delaying age of first sexual intercourse. Drawing on data from Add Health, Bearman and Brückner (2001) observe that the risk of sexual initiation is 34% lower among youth who took a virginity pledge than among nonpledgers. The effect of pledging is contingent, however, on other contextual features that, taken as a whole, establish controlling circumstances. The others found the pledging effect to be stronger in early and middle adolescence, but it did not prevent sexual intercourse until marriage. In addition, the effect of pledging varied according to the type of school that the student attends, and the percent of pledgers in the school. In "socially open schools"—where many of the students report friendships and romantic relationships with students from other schools—pledging has no effect if no other pledgers are present. In such schools, for every 1% additional same-sex pledgers, the rate of the transition to first intercourse is delayed by 2%. In socially closed schools—where friendships and romantic relationships are contained in the school—the opposite is observed: with no other pledgers present, pledgers are much less likely to experience their sexual debut. When other pledgers are present, the pledgers' transition rate is higher than that of pledgers in schools with few pledgers. For adolescents in schools with more than 30% pledgers, a threshold is reached whereby pledging has no effect. That is, by itself, pledging status tells little of the story of how sexual behavior is controlled. When this form of social control is viewed as a constellation of variables that create EE interactions—encompassing status, type of school, and percent of pledgers in the school—the controlling nature of the context can be more fully appreciated.

Second, the principles of equifinality and multifinality (which states the end phenotype may be the product of multiple, distinct causal pathways and single causes may lead to multiple, distinct phenotypic expressions) are relevant to links between social context and gene expression. For example, Kendler, Gardner, and Prescott (2002) examined the interrelationships among 18 risk factors over the life course (some of which were retrospectively recalled) and depressive episodes. The best-fitting, most parsimonious model included 64 paths among risk factors and the occurrence of major depression, a simple but dramatic example of how multifaceted mediational pathways can be. Distress is known to reflect many different types of stressors, which can, in turn, take on many different forms. Similarly, many specific forms of social control that inhibit antisocial behavior have been identified, including warm and nurturant parenting, positive connections with schools and nonrelated adults, intimate interpersonal relations, marriage, parenthood, and meaningful ties to the labor market (e.g., Sampson & Laub, 1993). These considerations suggest that causal pathways involving social context and biological substrates may involve complex combinations of different factors that lead to the same outcome.

Future Directions for the Life Course and Behavioral Genetics

Taken together, these themes heighten sensitivity to the dynamic, highly contingent, and multidimensional nature of social processes that are likely to be integral to genetic expression. The study of such themes would transform how research typically proceeds in behavioral genetics (Coll, Bearer, & Lerner, 2004). Behavioral genetic research typically views social context in unidimensional, static terms, although life-course research shows that formative social processes exhibit patterns of change and constancy across the phases of life, and these dynamic patterns determine the salience of context for behavior. Integrating life-course models of social processes with behavioral genetic studies thus presents exciting new opportunities for understanding behavioral development in increasingly precise terms.

Ideally, such integrative efforts will capitalize on a long-standing interest of life-course research or the comparison of people across differing social contexts. Such an interest may involve the study of social change,

which involves the transformation of context in people's lives, migration, or cross-national patterns. All of these types of studies provide an advantage in the study of development by creating notable variability in context and behavior. The utility of these approaches is suggested by behavioral genetic studies of alcoholism. For example, Higuchi et al. (1994) show that while the suppressive effect of the *ALDH2*2* genotype (i.e., homozygous for the null allele) inhibits alcoholism among the Japanese, the suppressive effect of the heterozygous genotype (i.e., one null and one normal allele) has waned with successive cohorts. The authors speculate that social controls on drunkenness have loosened in Japanese society through the twentieth century.

The functional polymorphism *ADH2*2* also protects against alcoholism, but its effects may be contingent on context. The fact that Jews drink less than other Caucasians is thought to reflect the fact that *ADH2*2* is more prevalent in the former group. Among Jews, however, the inhibitory effect of *ADH2*2* may be contingent on environmental factors. Although drawing on a small sample, Hasin et al. (2002) report that the effect of *ADH2*2* in suppressing alcohol consumption was less among Russian Jews who had been exposed to an environment of heavy drinking prior to immigration than among Israeli Ashkenazi and Sephardic Jews who had not been exposed to such an environment. This research illustrates how social change and the life course can be strategic in the study of genetic expression because they create "experiments of nature" that dramatically alter the contextual forces thought to alter genetic expression.

CONCLUSIONS

The emergence of life-course theory and its elaboration over the past 30 years can be viewed through prominent challenges to developmental studies that questioned traditional forms of thought and empirical work. They include:

1. The necessity for concepts of development and personality that have relevance beyond childhood and even adolescence
2. The need for a way of thinking about the social patterning and dynamic of lives over time, as they relate to developmental processes
3. The increasing recognition that lives and developmental trajectories may be transformed by a changing society

Each challenge was posed by the early longitudinal studies, as they continued well into the adult and late life years, and the mounting realization that much of the story of child development is written across the adult years. In addition, the challenges had much to do with the demographic and political pressures of an aging society.

Social theories of relationships and age converged in the 1960s with emerging concepts of life-span development to produce a theoretical orientation to the life course. More than any other theoretical initiative, life-span developmental psychology has responded to the first challenge by advancing a conceptual orientation on human development and personality across the life span. One result is a concept of ontogenetic development in which social structures and cultures merely establish behavioral settings. By contrast, life-course theory views human development as a coactive process in which sociocultural, biological, and psychological forces interact over time. Social structures and cultures are constituent elements in the developmental process. People play an important role in shaping their life course and development, although choices and initiatives are always constrained by social forces and biological limitations.

In concept, and as discussed in this chapter, the individual life course provides a response to the second challenge, a way of thinking about life patterns or organization. Lives over time do not merely follow a sequence of situations or person-situation interactions. Instead, the life course is conceived as an age-graded sequence of socially defined roles and events that are enacted and even recast over time. It consists of multiple, interlocking trajectories, such as work and family, with their transitions or changes in states. People generally work out their life course in relation to established, institutionalized pathways and their regulatory constraints such as the curricula or tracks of a school, the age-graded expectations of a family, and the work careers of a firm or culture.

The individual life course, developmental trajectories and transitions (as psychobiological continuities and change), and established pathways are important elements in the life-course study of human development. Any change in the life course of individuals has consequences for their developmental trajectory, and historical change may alter both by recasting established pathways. Thus, adultlike expectations for productive work in World War II communities were lowered toward childhood to enable young people to fill needed

roles. By placing people in historical locations, life-course theory has oriented research to the third challenge, to understand the process by which societal changes make a difference in the primary world and development of children.

This chapter on life-course theory represents the beginning stage of a long journey toward understanding human development in ways that extend across individual lives, the generations, and historical time. Just as the major themes of developmental psychology from a century ago seem to be regaining prominence in contemporary studies (Parke et al., 1994), including a renewed interest in genetic influences, emotional regulation, and the study of hormones, life-course theory can be viewed through renewed priorities (e.g., social context and change, life histories) that were once dominant in the past, particularly in the early Chicago School of Sociology. These observed continuities, however, pale in relation to the novel integrations and new directions of contemporary theory. Building on a wider net of cross-disciplinary scholarship in developmental science, distinctions of time, context, and process have become central to a life-course theory of child, adolescent, and adult development. The integration of biological models with the life course represents a promising interdisciplinary frontier for this field of study.

CHAPTER 13

The Cultural Psychology of Development: One Mind, Many Mentalities

RICHARD A. SHWEDER, JACQUELINE J. GOODNOW, GIYOO HATANO, ROBERT A. LeVINE, HAZEL R. MARKUS, and PEGGY J. MILLER

Cultural psychology, no longer a new field, may be more accurately depicted as a *renewed* field (Jahoda, 1990, 1992), approaching the study of mind from deep historical antecedents in the work of eighteenth- and nineteenth-century scholars such as Johann Gottfried von Herder, Giovanni Vico, Wilhelm Dilthey, and Wilhelm Wundt. Herder and Vico pioneered comparative research with the aim of identifying the distinctive characteristics of particular folk and historical traditions. Dilthey raised

This chapter is a revision and update of a manuscript that was originally prepared when the coauthors were members of the

questions about the contrast between the natural science approach and the spiritual or moral science approach to human understanding and the explanation of behavior. Wundt, who is often heralded as the father of modern scientific psychology, also thought deeply about the limits of psychology as an experimental discipline and about its possibilities as an investigation of folk psychologies. Herder's premise that "to be a member of a group is to think and act in a certain way, in the light of particular goals, values, pictures of the world; and to think and act so is to belong to a group" (Berlin, 1976, p. 195) presents a starting point for the contemporary discipline of cultural psychology.

Cultural psychology aims to document historical and cross-cultural diversity in the processes and products of the human mind. The psychological side of cultural psychology is the study of how individual persons think and act in the light of their particular goals, values, and pictures of the world. This is a genre of psychological study based on a definition of the psychological (or of the mental) as consisting of what individual persons want, feel, think, know, and value. The cultural side of cultural psychology is the examination of socially assisted processes of learning and schema activation associated with becoming a member of a particular group. The discipline of cultural psychology gives special attention to the particular wants, feelings, knowledge, reasoning, and values required for normative or competent participation in the local customary practices of some historically identifiable community, especially (although not exclusively) cultural communities that have a capacity to recruit new members through processes of kinship and marriage and wish to perpetuate a particular way of life.

Cultural psychology has been experiencing a major revival since the early 1980s, owed in some significant measure to developmentalists from several fields (e.g., Bruner, 1990a, 1990b; Cole, 1990, 1996; Goodnow, 1990a; A. Gottlieb, 2004; Greenfield, 1997; Greenfield, Keller, Fuligni, & Maynard, 2003; Haidt, Koller, & Dias 1993; Lave, 1990; R. A. LeVine, 1989, 2004; Levy, 1973, 1984; Markus & Kitayama, 1991b; Menon, 2002; J. G. Miller, 1984, 1994b; P. J. Miller & Hoogstra, 1992; Much, 1992, 1993; Rogoff, 1990; Ross, Medin, Coley, & Atran, 2003; Rozin & Nemeroff, 1990; Shweder, 1990a, 1991, 1996a, 1996b, 2003a, 2003b; Shweder & Haidt, 2000; Shweder & LeVine, 1984; Stigler, Shweder, & Herdt, 1990; Super & Harkness, 1997; Weisner, 1984, 1987, 2001; Weisner & Lowe, in press; Wertsch, 1985, 1992). The term *cultural psychology* has also become increasingly popular among European "activity theorists" (Boesch, 1991; Eckensberger, 1990, 1995; see also Brandtstädter, Chapter 10, this *Handbook,* this volume), contextual psychologists of the sociohistorical school (Cole, 1995; Rogoff, 1990; Wertsch, 1991; see also Cole, Chapter 15, this *Handbook,* Volume 2; Elder & Shanahan, Chapter 12, this *Handbook,* this volume), anthropologists interested in the relationship of symbols and meanings to population-based differences in psychological functioning (D'Andrade, 1995; Howard, 1985; R. A. LeVine, 1990a, 1990b; Levy, 1984; Lutz & White, 1986; Shore, 1996; Shweder & LeVine, 1984; G. M. White & Kirkpatrick, 1985), and among developmental, social, and cognitive psychologists in search of a unit of scientific analysis that is larger rather than smaller than the individual person (Bruner, 1986, 1990a, 1990b; Cole, 1988,

Social Science Research Council Planning Committee on Culture, Health and Human Development. We were able to develop and undertake this cooperative project, involving an intellectual division of labor and writing, as a result of our colloquies at SSRC. We are grateful to Diana Colbert of SSRC and Katia Mitova of the University of Chicago who contributed in innumerable and invaluable ways to the completion of this manuscript in its original form. We express our heartfelt gratitude to Frank Kessel, our Program Officer at SSRC, for his collegial contributions not only to this chapter project but also to the various activities of the Committee on Culture, Health, and Human Development over the years of its existence. The skill, balance, and good cheer with which he shepherded the Committee's activities are deeply appreciated. The Planning Committee was supported by grants from the Health Program of the John D. and Catherine T. MacArthur Foundation and the W. T. Grant Foundation. The Center for Advanced Study in the Behavioral Sciences (where Shweder and Markus were Fellows during the 1995/1996 academic year) and the MacArthur Foundation Research Network on Successful Midlife Development (MIDMAC) provided intellectual and material assistance in the preparation of the original review. The current updated revision of the chapter took place during the 2003/2004 academic year. Richard A. Shweder, a Carnegie Scholar (2002), wishes to express his gratitude to the Carnegie Foundation for its generous support. The authors wish to express their great thanks as well to Michele Wittels, who skillfully contributed to the coordination and processing of this revised and updated edition of the chapter.

This chapter is dedicated to our friend and colleague Giyoo Hatano, in honor of his personality, his life, and his work. Even while his sudden and recent death deeply saddens us, the memory of our kind, dedicated and elegant friend and imaginative colleague makes us smile and warms our hearts.

1992; Goodnow, Miller, & Kessel, 1995; Kitayama & Markus, 1994; Medin, 1989; P. J. Miller & Hoogstra, 1992; Nisbett, 2003; Nisbett & Cohen, 1996; Rogoff, 1990; Yang, 1997).

Research in cultural psychology is now featured in several journals, most notably *Culture, Mind and Activity, Culture, Medicine and Psychiatry, Culture and Psychology, Ethos: Journal of the Society for Psychological Anthropology, Psychological Review, The Journal of Personality and Social Psychology,* and *Child Development.* Impressive collections of theoretical, methodological, and empirical papers have appeared (Goodnow et al., 1995; Holland & Quinn, 1987; Jessor, Colby, & Shweder, 1996; Kitayama & Markus, 1994; Rosenberger, 1992; Schwartz, White, & Lutz, 1992; Shweder, 1991, 2003a, 2003b; Shweder & LeVine, 1984; Stigler et al., 1990; G. M. White & Kirkpatrick, 1985). Important monographs and empirical studies have been published (D'Andrade, 1995; Fiske, 1991; Kakar, 1982; Kripal, 1995; Levy, 1973; Lucy, 1992a; Lutz, 1988; Menon & Shweder, 1994; J. G. Miller, 1984; P. J. Miller, 1982; Parish, 1991; Seymour, 1999; Shimizu & LeVine, 2001; Shwalb & Shwalb, 1996). A number of generative proposals have been put forward for comparative research on culture and cognition (Cole, 1990; D'Andrade, 1995; Lave, 1990; Lucy, 1992a, 1992b; Shore, 1996), culture and emotion (Kitayama & Markus, 1994; Mesquita & Frijda, 1992; Russell, 1991; Shweder, 1991, 2003a, 2003b, 2004; Shweder & Haidt, 2000; Wierzbicka, 1992, 1993), culture and morality (Haidt et al., 1993; Jensen, 2005; J. G. Miller, 1994a; Shweder, Mahapatra, & Miller, 1990; Shweder, Much, Mahapatra, & Park, 1997), and culture and the self (Doi, 1981; Herdt, 1981, 1990; Kurtz, 1992; Lebra, 1992; Markus & Kitayama, 1991a, 1991b, 2003; J. G. Miller, 1994b, 1997a; Shweder & Sullivan, 1990). The field has been conceptualized, reconceptualized, and reviewed from many perspectives: in a book-length history (Jahoda, 1992), in a book-length program for a cultural psychology rooted in sociohistorical theory (Cole, 1996), in *Handbook* chapters (Greenfield, 1997; Greenfield et al., 2003; Markus, Kitayama, & Heiman, 1996; J. G. Miller, 1997b), in the *Annual Review of Psychology* (Shweder & Sullivan, 1993; Greenfield et al., 2003), in the Minnesota Symposia on Child Psychology (Masten, 1999), and in the Nebraska Symposium on Motivation (Markus & Kitayama, 2003).

Moreover, the publication of this chapter, which has been updated and revised after its initial publication in the last edition of the *Handbook,* itself signals a continuing appreciation of the value and relevance of cultural psychology to developmental studies. The last edition was the first time that the *Handbook of Child Psychology* included a chapter under the name cultural psychology. It should be acknowledged, however, that this chapter continues a broader conversation about culture and individual development that began in previous editions of the *Handbook,* beginning with Margaret Mead's contribution to the first edition, published in 1931. The section of this chapter on the interpersonal worlds of childhood provides an update of Robert LeVine's chapter in the third (1970) edition of the *Handbook.* And, the Laboratory of Comparative Human Cognition's (LCHC) chapter on culture and cognitive development in the fourth (1983) edition of the *Handbook* is an important predecessor to this chapter, especially the section on cognitive development. We carry forward LCHC's emphasis on the semiotic mediation of experience and on a unit of analysis that does not abstract the individual from his or her social and cultural context or focus exclusively on what is "inside the skin" or "inside the head."

In this chapter, we selectively discuss the cultural psychology of individual development, with special attention to the way in which culture and psyche "make each other up" in the domains of self-organization, thinking, knowing, feeling, wanting, and valuing. The chapter is organized into five sections: an introduction, which lays out major conceptual issues, followed by four topical areas—the cultural organization of early experience, language and socialization, self-development, and cognitive development—although issues concerning moral development and the value-laden nature of mental functioning are addressed throughout the chapter.

We see these topical areas as paradigmatic in the cultural psychology of development, yet we are also keenly aware that several topics of vital interest receive only passing and scattered attention—gender, play, feelings and emotions, spirituality, and physical development. Without any pretense of representing all relevant research agendas or conceptions of the field, we characterize some of the things cultural psychologists have learned about the interpersonal, ideational, and social communicative dimensions of psychological development. In keeping with cultural psychology's commitment to comparative inquiry within and across cultures, we make a special effort to draw from the empirical record in a way that represents the range of

cultural variety in psychological functioning across human groups.

CULTURAL PSYCHOLOGY: HOW IT DIFFERS FROM OTHER APPROACHES TO CULTURE AND PSYCHOLOGY

The main wager of cultural psychology is that relatively few components of the human mental equipment are so inherently constrained, hardwired, or fundamental that their developmental pathway is fixed in advance and cannot be transformed or altered through cultural participation. The bet is that much of human mental functioning is an emergent property that results from symbolically mediated experiences with the behavioral practices and historically accumulated ideas and understandings (meanings) of particular cultural communities. This was the bet of Herder and Vico in the eighteenth century, of Wundt and Dilthey in the nineteenth century, and of Ruth Benedict, Margaret Mead, Edward Sapir, and many other psychological anthropologists in the first half of the twentieth century. It is a bet that the renewed discipline of cultural psychology, informed by contemporary research from several disciplines, is still prepared to make today.

Orienting Definitions

At least since the time of Herder and Vico in the eighteenth century, *cultural psychology* has been a label for the reciprocal investigation of both the psychological foundations of cultural communities and the cultural foundations of mind. It has been a designation for the study of how culture and psyche make each other up. Alternatively stated, cultural psychology is the study of all the things members of different communities mentally experience (know, think, want, feel, value), and hence do, by virtue of being the kinds of beings who are the beneficiaries, guardians, and active perpetuators of a particular cultural tradition.

As a first approximation, we shall define *culture* as a *symbolic and behavioral inheritance* received from out of the historical/ancestral past that provides a community with a framework for other-directed vicarious learning and for collective deliberations about what is true, beautiful, good, and normal. Although it is important to distinguish between the symbolic and the behavioral inheritances of a cultural community (understandings and behaviors are not always fully coordinated from either a socialization or developmental point of view, and actions do sometimes speak much louder than words), given the complexity and richness of culture, any genuine cultural community is always the beneficiary of both symbolic and behavioral inheritances (Shweder, 2003b).

In analyzing the concept of culture, most definitions extant in the literature have tended to be either purely symbolic in emphasis (culture as the beliefs and doctrines that make it possible for a people to rationalize and make sense of the life they lead) or purely behavioral in emphasis (culture as patterns of behavior that are learned and passed on from generation to generation). In our view, the most useful definitions of culture try to honor both inheritances. Such definitions focus on units of analysis that are simultaneously symbolic and behavioral (e.g., Robert Redfield's 1941 definition of culture as "conventional understandings, manifest in act and artifact, that characterize societies," p. 132). Later in this chapter, we discuss in detail a two-sided unit of analysis for cultural psychology called the *custom complex* (J. W. M. Whiting & Child, 1953), and we try to acknowledge and honor both the symbolic and behavioral inheritances of any cultural community.

The *symbolic inheritance* of a cultural community consists of its received ideas and understandings, both implicit and explicit, about persons, society, nature, and the metaphysical realm of the divines. To illustrate, ideas and understandings that are part of the symbolic inheritance of many enlightened secular folk in the European American cultural region include:

- The understanding that infants are born innocent, naive, and free of any prior sins or inherited evils
- The idea that individual wants, preferences, and tastes matter and should be openly expressed and accommodated
- The belief that the main justification for rules, regulations, and any other forms of authority is to promote social justice and enable individuals to pursue their self-interest free of harm and to have the things they want
- The conviction that, other than human nature, the material world is devoid of intentionality and has no will of its own

- The doctrine that God and divinity are archaic notions that should be displaced in the contemporary era
- The related idea that the era in which we live is the most advanced, enlightened, and exceptional in human history and should be classified and heralded as an age of reason

The *behavioral inheritance* of a cultural community consists of its routine or institutionalized family life, social, economic, and political practices. To illustrate, a few of the routine or institutionalized family life practices that are popular among many rural folk in the South-Asian Hindu cultural region include:

- Joint family living (adult brothers co-reside in the same family compound or dwelling space with their living parents and their wives marry in)
- Co-sleeping arrangements of children with their parents
- Separate eating arrangements for husband and wife (no family meal)
- Sexual division of household tasks
- Time-out and seclusion for females during their menstrual period
- Parental hand-to-mouth feeding of children long past infancy and well into middle childhood
- Prohibitions on premarital dating and sexuality
- Physical punishment for unruly or bad behavior
- Arranged marriage between young men and women of similar social status (primarily based on caste, local region, and relative wealth)

Of special import for the cultural psychology of individual development is that human beings are the kinds of beings who benefit from and carry forward a cultural tradition. They try to promote, promulgate, and share their understandings and practices with their children, their relatives, and their community at large. They are active agents in the perpetuation of their symbolic inheritance, largely because (among other motives) the ideas and values that they inherit from the past seem to them to be right-minded, true, dignifying, useful, or at least worthy of respect.

They are also active agents in the perpetuation of their behavioral inheritance. They try to uphold, enforce, and require of each other some degree of compliance with the practices of their community, largely because (among other motives) those practices seem to them to be moral, healthy, natural, rational, benefit promoting, or at least normal.

A noteworthy example of the combination of symbolic and behavioral approaches in cultural psychology is Alma Gottlieb's recent book (2004) about reincarnation beliefs in West Africa and their role in the patterning of infant development. Among the Beng people of Cote d'Ivoire, newborn children are comprehended and perceived as old souls—spiritually powerful, psychologically complex, socially sophisticated, and retaining a memory of previous lives and halcyon times spent dwelling in the abode of the spirits. They do not enter the world naive, at least not according to the Beng. Gottlieb's *The Afterlife Is Where We Come From* offers an eye-opening interpretation of the local cultural meanings of developmental milestones such as the transition from crawling to walking (which is actively discouraged by Beng parents) and the child's early articulation of intelligible speech (which is greeted with anxiety). Her study of Beng infant development and its connection to local beliefs about reincarnation provides an expose of the dangers of presumptively universalizing culture-specific ideals for human development, as she argues that infant development is not, and perhaps ought not to be, the same wherever you go.

From the viewpoint of cultural psychology, the most satisfactory definition of culture presupposes the existence of an active mental agent who not only is the recipient and guardian of a cultural tradition but also is motivated and engaged in some specific way of life. Thus, our definition of culture emphasizes both symbols and behavior. Such an approach also means that a major prerequisite for conducting research in cultural psychology is an imaginative capacity to suspend our disbelief (e.g., one's disbelief that the animating force in the body of an infant is an old soul) and a willingness to set aside (at least temporarily) our own negative moral and emotional reactions (e.g., of anxiety, disapproval, indignation, or disgust) to other people's understandings and practices. To practice cultural psychology, we must be willing and able to enter into other peoples' conceptions of what is right-minded, normal, beautiful, and true (Shweder, 1996b), and we must at least try (we may fail, but that is itself an informative outcome of the methodological effort) to translate their goals, values, and pictures of the world into an intelligible (and perhaps even rationally defensible) account of their behavior.

Thus, cultural psychology is the study of the mental life of individuals in relation to the symbolic and behav-

ioral inheritances of particular cultural communities. It is the study of the way culture, community, and the psyche instantiate one another and are mutually sustaining, and, thus, how they become coordinated and make each other possible. A cultural tradition dies (it exists only in a canonical text or in an ethnographic book on a library shelf) if there is no community that lives its doctrines, makes manifest its shared understandings, or inhabits its way of life. Similarly, some designated category of persons (e.g., Latinos, non-Hispanic Whites; residents of the Pacific Islands; citizens of the United States) is not a cultural community unless its members actively inhabit, think about, and hold each other accountable to some symbolic and behavioral inheritance from out of some historical/ancestral past that they identify with as a people, and claim as their own.

WHY CULTURAL PSYCHOLOGY IS NOT CROSS-CULTURAL PSYCHOLOGY

Many proponents of *cultural psychology* distinguish it from *cross-cultural psychology.* This is what a few of those authors have to say about the aims of a renewed cultural psychology, and the ways in which it differs from the discipline or research enterprise known as cross-cultural psychology.

Shweder and Sullivan (1993; also Shweder, 1990a) identify the aim of cultural psychology as the study of ethnic and cultural sources of psychological diversity in self-organization, cognitive processing, emotional functioning, and moral evaluation. They describe cultural psychology as a "project designed to reassess the uniformitarian principle of psychic unity [which they associate with cross-cultural psychology] and aimed at the development of a credible theory of psychological pluralism." They argue that performance or response differences between populations arise from differences in the normal meaning of stimulus situations and materials across populations (the problem of "partial translation" or "limited commensurability"). They suggest that a special feature of cultural psychology is its recognition that "through the methodical investigation of specific sources of incommensurability in particular stimulus situations (so-called thick description) a culture's distinctive psychology [the way people think and act in the light of particular goals, values, and pictures of the world] may be revealed." For example, Shweder et al. (1997; also see Jensen, 2005; Shweder et al., 1990) describe the different moral developmental pathways and patterns of moral judgment for children in societies privileging an "ethics of autonomy" (where individualism, having the things you want, and harm, rights, and justice concepts predominate) in contrast to societies privileging an "ethics of community" (where notions of duty, sacrifice, loyalty, and hierarchical interdependence and other social roles based on communitarian moral concepts predominate) or societies privileging an "ethics of divinity" (where notions of sanctity, purity, pollution, and the connection between the sacred order and the natural order predominate).

A similar point is made by Greenfield (1997) who notes, "It is the human capacity to create shared meaning that produces the distinctive methodological contribution of cultural psychology." She goes on to argue that it is a mistake of modern psychology in general and modern cross-cultural psychology in particular to treat perspective (the shared meanings of a group is a type of perspective) as a form of bias that should be eliminated from research procedures. She contrasts the methodology of cultural psychology with that of modern cross-cultural psychology as follows:

> The methodological ideal of the paradigmatic cross-cultural psychologist is to carry a procedure established in one culture, with known psychometric properties, to one or more other cultures, in order to make a cross-cultural comparison (Berry, Poortinga, Segall, & Dasen, 1992). In contrast, the methodological ideal of the paradigmatic cultural psychologist is to derive procedures for each culture from the lifeways and modes of communication of that culture.
>
> This ideal explains why interpretive methods, especially ethnographic methods, have been so important to many cultural psychologists. Ethnographic approaches were devised originally by cultural anthropologists as a means of understanding other cultures on their own terms—not as projections of the researcher's own ethnocentric assumptions (Malinowski, 1922). The goal is to understand what people say and do from the perspective of insiders to the culture, to render them intelligible within their own collectively shared interpretive frameworks. From this standpoint, comparisons within and across cultures make sense only when they are grounded in descriptions of the local meanings of the people being studied. At the same time, these approaches carry with them the reflexive recognition that researchers too are members of particular communities and cultures; that they may come to see their own local meanings in a new light by way of studying people who construe the world differently.

For further discussion of interpretive and ethnographic methods as applied to the study of children, see C. D. Clark (2003); Corsaro and Miller (1992); Erickson (1986); Jessor et al. (1996); P. J. Miller, Hengst, and Wang (2003).

One useful metalanguage or theoretical framework for the nonethnocentric identification and comparative translation of culture-specific aspects of mental functioning has been developed by the anthropological linguists Anna Wierzbicka and Cliff Goddard (Goddard, 1997, 2001; Goddard & Wiezbicka, 1994; Wierzbicka, 1986, 1990, 1993, 1999; see also Shweder 2003a, 2004). Wierzbicka and Goddard have identified a core set of semantically simple, intuitively obvious, universal folk concepts (such as good, true, want, feel, do) that can then be used to elucidate the particular ways the mental states of members of different cultural groups vary. For example, in the domain of feelings and emotions those authors have effectively made the provocative point that the contemporary American notion of "sadness" has several cultural specific features (not even shared by various Northern European subcultures), and they have proposed that the very idea of an emotion (in contrast to the idea of a feeling) is not a semantically simple, intuitively obvious, or universal folk concept.

To return to Greenfield, one powerful (and somewhat ironic) implication of her analysis would seem to be that the genuine existence of different cultural realities is incompatible with the methodological assumptions of cross-cultural psychology. More specifically, if your research procedures and instruments travel readily and well (e.g., they are easy to administer and they display the same psychometric properties from one test population to another) then you probably have not traveled far enough into a truly alternative cultural world.

This may explain why long- and short-term fieldwork, language learning, naturalistic observation, detailed ethnography, and the analysis of the semantics and pragmatics of everyday discourse and communication are central to the study of cultural psychology, yet have played a minimal role in cross-cultural psychology. It may explain why much of the evidence in cross-cultural psychology (yet relatively little of the evidence in cultural psychology) is derived from observations in university laboratories, or from inventory or test procedures administered primarily to relatively cosmopolitan university students in other lands.

The Western institution of the university carries with it many features of an elite cosmopolitan culture wherever it has diffused around the world. University students in Tokyo, Nairobi, New Delhi, and New York may be far more like one another (and like the Western researcher) than they are like members of their respective societies whose life ways are embedded in less familiar indigenous understandings, institutions, and practices. Even if you have traveled 10,000 miles to get there, a university setting in another land may be much closer than you think.

Much (1995) drives home this point with the following observation:

> It is especially important to be clear about one distinction. Cultural psychology is not the same as "cross-cultural psychology," which is a branch of experimental social, cognitive and personality psychology. The chief distinction is that most of what has been known as "cross-cultural psychology" has presupposed the categories and models that have been available to participate in experiments or even to fill out questionnaires. . . . The argument often assumed to justify the tactic of studying mostly student behavior is based upon a sweeping and gratuitous universalist assumption—since we are all human, we are all fundamentally alike in significant psychological functions and cultural (or social) contexts of diversity do not affect the important "deep" or "hard wired" structures of the mind. There are several problems with this position. One is that there have been few if any satisfactory identifications of deep, hard wired and invariant mental structures which operate independently of the context or content of their functioning; the "method variance" problem in experimental psychology is related to this fact. Another problem is that even though there may be certain biologically based psychological foundations . . . this does not necessarily mean (1) that they are invariant across individuals or populations or (2) that culture does not affect their development as psychological structures and functions.

Whereas Greenfield and Much draw some methodological contrasts between cultural versus cross-cultural psychology, J. G. Miller (1997b) envisions the difference between cultural psychology and cross-cultural psychology in theoretical terms (although a similar theoretical point can be found in Greenfield and Much). She suggests, "The dominant stance within cultural psychology is to view culture and psychology as mutually constitutive phenomena which cannot be reduced to each other." She adds that such a stance "contrasts with the tendency in cross-cultural psychology for culture to be conceptualized as an independent variable that impacts on the dependent variable of individual psychology."

Markus et al. (1996) carry forward this point. With an intent to simultaneously study the cultural origins of mind and the mental side of culture, they argue that "culture and psychology, regardless of the level at which they are analyzed, are interdependent and mutually active." Markus et al. suggest:

> The communities, societies, and cultural contexts within which people participate provide the interpretive frameworks—including the images, concepts, and narratives, as well as the means, practices and patterns of behavior—by which people make sense (i.e., lend meaning, coherence and structure to their ongoing experience) and organize their actions. Although experienced as such, those organizing frameworks (also called cultural schemas, models, designs for living, modes of being) are not fully private and personal; they are shared.

Markus et al. go on to say:

> Importantly, the contention here is that these group-based meanings and practices are not separate from observed behavior. They are not applied as interpretive frameworks after "behavior" has occurred. Instead they are fully active in the constitution of this behavior; they are the means by which people behave and experience, and thus should be taken into account in an analysis of this behavior. The claim is that with respect to the psychological, the individual level often cannot be separated from the cultural level. Many psychological processes are completely interdependent with the meanings and practices of their relevant sociocultural contexts and this will result in systematic diversity in psychological functioning. It follows from this perspective that there may be multiple, diverse psychologies rather than a single psychology.

MULTIPLE, DIVERSE PSYCHOLOGIES

Perhaps, the central claim of cultural psychology (in contrast to other approaches to the study of consciousness and mental life) is that "there may be multiple, diverse psychologies rather than a single psychology," and perhaps the central problematic of the field is to make sense of that provocative claim. Does such a claim entail the denial of universals? If not, what universals of mind are entailed by cultural psychology? How are those universals to be reconciled with the existence of diverse psychologies across human populations without trivializing that diversity or treating it as mere content?

Currently, there is no single answer that all cultural psychologists would endorse. One type of answer, with a pedigree stretching back to Vico (Berlin, 1976), suggests that "the nature of [human beings] is not, as has long been supposed, static and unalterable or even unaltered; that it does not so much as contain even a central kernel or essence, which remains identical through change; that the effort of [human beings] to understand the world in which they find themselves and to adapt it to their needs, physical and spiritual, continuously transforms their worlds and themselves" (p. xvi).

A second type of answer to those questions, to be developed in this chapter, starts from the premise that any human nature that we are in a position to understand and render intelligible must have "a central kernel or essence," but it is rarely a strong constraint. According to this answer, the central kernel or essence of human nature consists of a heterogeneous collection of mutually contradictory structures and inclinations, which are differentially and selectively activated, brought "online," and given character and substance in the course of the historical experience of different cultural communities. The motto "One mind, many mentalities: universalism without the uniformity" is the rallying cry for the interpretation of the claim that there may be multiple, diverse psychologies rather than a single psychology.

This motto advertises a discipline founded on the principle that the abstract potentialities and specific heterogeneous inclinations of the human mind are universal but only gain character, substance, definition, and motivational force (i.e., assume the shape of a functioning mentality) as they are translated and transformed into and through the concrete actualities of some particular practice, activity setting, or way of life (Cole, 1990; D'Andrade, 1995; Goodnow et al., 1995; Greenfield, 1997; Greenfield et al., 2003; Lave, 1990; Markus et al., 1996; Much, 1992; Nisbett & Cohen, 1995; Rogoff, 1990; Shweder, 1991; Shweder & LeVine, 1984). The slogan connects current researchers in cultural psychology with the intellectual ancestors of the field (Vico, Herder, and others; Berlin, 1976) who, Kant- and Hegel-like, believed "Form without content is empty, content without form meaningless."

For at least 200 years, a distinctive tenet of cultural psychology has been the claim that the formal universals of mind and the content-rich particulars of any sustainable mentality or way of life are interdependent, interactive, and give each other life. Scholars, such as Herder, Vico, and Wundt, scoured the historical record for successful (cohesive, shared, stable) fusions of form and content in which the human imagination has, of necessity, gone beyond the relatively meaning-barren

constraints of logic and mere sense perception to construct an imaginative (and culture-specific) picture of the underlying nature of the world and it values, resulting in a *mentality* (the Homeric mentality, the Hindu mentality, the Christian fundamentalist mentality) supportive of a way of life.

They took as their data the great symbolic formations produced by human beings: myths, folk tales, language patterns, naming systems, ethnoscientific doctrines, and ethical, social, and religious philosophies. They also took as their data the great behavioral formations produced by human beings, including customary practices of various kinds: subsistence activities, games, rituals, food taboos, gender roles, the division of labor, and marriage rules. They interpreted those symbolic and behavioral formations as alternative manifestations, substantializations, or instantiations of the disparate abstract potentialities of the universal mind, which they believed was the business of cultural psychology to characterize and to explain.

THE MEANING OF MEANING AND A CONTEXT FOR CONTEXT IN CULTURAL PSYCHOLOGY

In contemporary cultural psychology, the translation and transformation of one mind into many mentalities is typically conceptualized as a process by which contexts and meanings become essential, active components inside as well as outside the psychological system of individuals. In cultural psychology, this process is sometimes described as the process by which culture and psyche make each other up.

This insistence in cultural psychology that contexts and meanings are to be theoretically represented as part of the psychological system and not simply as influences, factors, or conditions external to the psychological system distinguishes cultural psychology from other forms of psychology, which also think of themselves as contextual (or situated). The aim in cultural psychology is not first to separate the psychological system from its nonpsychological context and then to invoke some type of external setting effect or outside situational influence on psychological functioning. The aim and the challenge are rather to recast or soften the contrast between person and context (inside versus outside, subjective perspective versus external reality) so that the very idea of a context effect will take on new meaning because our theoretical language for psychological description will be contextual from the start. In part, cultural psychology involves the study of real things that do not exist independently of some collectively shared point of view. Later in this chapter, we address in some detail this issue, of dichotomies that need to be softened or recast (see also Overton, Chapter 2, this *Handbook,* this volume).

The distinction between cultural psychology and other contextual approaches in psychology is subtle, important, and easy to overlook because all approaches to psychology that emphasize context share much in common, especially their opposition to the idea that the science of psychology is primarily the study of fixed, universal, abstract processes or forms. Thus, cultural psychology shares with other contextual psychologies the assumption that the mind of human beings (knowing, wanting, feeling, valuing, etc.) can only be realized through some situated or local process of "minding," which is always bounded, conditional, or relative to something—shared meanings, goals, stimulus domain, available resources, local artifacts, cognitive assistants, and so on. Beyond that general point of similarity, cultural psychology should be understood as a rather special type of contextual approach.

In the conception of cultural psychology developed in this chapter, the relevant contexts for the realization of mind are the customs, traditions, practices, and shared meanings and perspectives of some self-monitoring and self-perpetuating group. The primary emphasis is on contexts thought to be relevant for the realization of mind in the sense that such contexts are the means for transforming a universal mind into a distinctively functioning mentality, a distinctive way that "people think and act in the light of particular goals, values and pictures of the world" (Berlin, 1976). In this approach, cultural psychology is not coextensive with contextual psychology (more on this in a moment). More important, the contrast between inside and outside, person and context, and subjective perspective and external reality is reconceptualized in cultural psychology as a process by which culture and psyche are constantly and continuously making each other up.

THE UNIT OF ANALYSIS PROBLEM

Just as the general field of psychology seems unsure whether its proper subject matter should be the study of

behavior or the study of consciousness or the study of the mental life (which is a broader subject than the study of consciousness because it includes states of mind that are not in awareness), so too cultural psychologists do not always seem to agree on their proper unit of analysis. Practitioners of cultural psychology study mentalities, folk models, practices, activity settings, situated cognitions, and ways of life. It is not clear whether these units of analysis mentioned in the literature are different ways of speaking about the same intellectual object or whether it is possible to combine them into a single unit of analysis.

For the sake of clarity in this review, we adopt a proposal for a common unit of analysis for cultural psychology put forward more than a generation ago (J. W. M. Whiting & Child, 1953) in an exemplary collaboration between an anthropologist and a psychologist. Whiting and Child suggest combining mentalities and practices (the symbolic and behavioral inheritances of a cultural community) into a single unit of analysis called *the custom complex,* which "consists of a customary practice and of the beliefs, values, sanctions, rules, motives and satisfactions associated with it" (p. 27). If we adopt this proposal, cultural psychology can be defined as the study of the custom complex.

Although J. W. M. Whiting and Child introduced the idea of a custom complex in 1953, its theoretical implications were not widely or fully appreciated at the time. Curiously, the idea was not taken up or carried forward by psychological anthropologists working in the classical tradition of the 1950s. It was not until the 1980s and 1990s, with the rebirth of a two-handed cultural psychology focused on the way culture and psyche make each other up, and with the return of an interest in "activity settings" (Cole, 1992, 1995; Weisner, 1984, 1996, 2001, 2002) and a "practice approach" to developmental studies (Goodnow et al., 1995), that J. W. M. Whiting and Child's conception gained currency and appeal.

If a custom complex "consists of a customary practice and of beliefs, values, sanctions, rules, motives and satisfactions associated with it," then the idea bears some resemblance to the social psychologist's idea of a personal "life space" (Lewin, 1943), to the sociologist's idea of a societal "habitus" (Bourdieu, 1972, 1990), and to the historian's idea of an epochal "mentality."

Using the custom complex as a unit of analysis makes it possible to conceptualize cultural psychology as the study of the way culture and psyche are socially produced and reproduced, resulting in an intimate association between a mentality and a practice and a partial fusion of person/context, inside/outside, or subjective perspective/external reality.

Examples of a custom complex are so commonplace they are easy to overlook. They include the mentalities associated with nursing on demand, co-sleeping in a family bed, the family meal, enforcing strict Christian discipline, performing the ritual of "what did you do in school today," or practicing ways to bolster self-esteem.

A Custom Complex Example: Who Sleeps by Whom in the Family

The mentality (what people know, think, feel, want, value, and hence choose to do) intimately associated with the practice of "who sleeps by whom" in the family provides a paradigmatic example of a custom complex. Who sleeps by whom in a family is a customary practice invested with socially acquired meanings and with implications for a person's standing (as moral, rational, or competent) in some consensus-sensitive and norm-enforcing cultural community.

Research on family life customs in different communities in the United States (Abbott, 1992; Okami & Weisner, in press; Okami, Weisner, & Olmstead, 2002; Weisner, Bausano, & Kornfein, 1983) and around the world (Caudill & Plath, 1966; LeVine, 1989, 1990a, 1990b; McKenna et al., 1993; Morelli, Rogoff, Oppenheimer, & Goldsmith, 1992; Shweder, Balle-Jensen, & Goldstein, 1995; J. W. M. Whiting, 1964, 1981) confirms the existence on a worldwide scale of several divergent custom complexes in this domain, each consisting of a network of interwoven and mutually supportive practices, beliefs, values, sanctions, rules, motives, and satisfactions. Indeed, on a worldwide scale, the European American who-sleeps-by-whom custom complex is not the one that communities most typically produce, reproduce, and enforce with the various formal and informal powers (e.g., legal interventions, gossip, and effects on reputation) at their disposal.

The middle-class European American custom complex includes the ritualized isolation of children during the night, the institution of bedtime, and the protection of the privacy of the sacred couple upheld by a cultural norm mandating the exclusive co-sleeping of the husband and wife. This European American custom complex is typically associated with something like the following propositional attitudes, where knowing,

thinking, feeling, wanting, and valuing define the set of potential attitudes, and thus can be stated in propositional form:

> I value autonomy and independence; I want my children to become autonomous and independent adults; I know that I can promote autonomy and independence in infants and young children by having them sleep alone; I value sexual intimacy with my spouse; I know that a sleeping space is the most suitable site for sexual intimacy with my spouse; I know that it will not be possible to have sexual intimacy with my spouse if the privacy of the spousal sleeping space is violated; I know that children have erotic impulses and a sexual fantasy life that should not be aroused or titillated by adults for the sake of the mental health of the child; I don't want to damage the mental health of my children or make them unhappy and neurotic about sex or touching; I feel anxious about touching and having prolonged skin-to-skin contact with a young child; therefore, infants and young children should be trained, encouraged, and if necessary, forced, to sleep alone.

This custom complex is sanctioned, glorified, rationalized, and enforced in innumerable ways in the European American culture area, although nearly every one of those propositional attitudes is thought to be wrong, bizarre, or beside the point by adults and children in many parts of Asia, Africa, and Central America, where children routinely and habitually co-sleep with one or more of their parents and/or siblings and prefer to do so even when more than ample sleeping space is available for separate sleeping arrangements (Abbott, 1992; Brazelton, 1990; Caudill & Plath, 1966; Shweder et al., 1995).

In the early 1960s, Caudill and Plath (1966) discovered that (a) urban Japanese parents felt morally obliged to provide their children with a parental sleeping partner, (b) husbands and wives were willing to separate from each other to do so, and (c) approximately 50% of 11- to 15-year-old urban Japanese boys and girls slept in the same room as their mother or father or both. In another example, Shweder et al. (1995) discovered from a record of single-night sleeping arrangements in 160 high-caste households in Orissa, India, that only 12% of the cases matched the European American custom complex in which husband and wife sleep together and separate from their children.

The cluster of propositional attitudes that lend authority to co-sleeping still need to be worked out for the different culture regions of the world (although see Morelli et al., 1992). The Japanese custom complex includes the propositional attitudes:

> I value and want to promote interdependency and feelings of closeness and solidarity among members of the family; I know that co-sleeping will help children overcome feelings of distance and separation from members of the family who are older or of a different sex.

The Oriya Hindu custom complex includes the propositional attitudes:

> I highly value children as members of the family; I know that children are fragile, vulnerable, and needy and therefore should not be left alone and unprotected during the night.

Chastity anxiety and the chaperoning of adolescent females also play a part in the Oriya custom complex (Shweder et al., 1995).

Examples of the way local experts (pediatricians, advice columnists, or social workers) rationalize, uphold, and lend authority to the European American custom complex can be found in the responses of "Dear Abby" and "Ann Landers" to the many letters they receive about the perceived problem of parent-child co-sleeping. The following, published May 26, 1994, in the Chicago Tribune, is a typical exchange between concerned adults in the European American cultural zone:

> Dear Abby: My niece—I'll call her Carol—is a single mother with a 4-year-old son. (I'll call him Johnny.) Carol just turned 40. Since the day Johnny was born, he has slept with his mother in a single bed. They go to bed between 8 and 10 o'clock every night and always have snacks and drinks in bed. They watch TV and cuddle until Johnny falls asleep in his mother's arms. Abby, this child has never fallen asleep alone. Carol lives with her parents, and there is no shortage of beds in their home. Recently, Carol and Johnny visited me in my country home, and I gave them the bedroom with twin beds. The following morning, I discovered that Carol had pushed the beds together so she and Johnny wouldn't be separated. I think Carol's emotional needs are taking precedence over what is best for her son. He has no father, and his grandparents have no say in his upbringing. I would appreciate your as-

sessment of this situation. No city, please, and sign me, Concerned Aunt.

Dear Concerned: You have good reason to be concerned, You hit the nail on the head—Johnny doesn't need to sleep with his mother nearly as much as she needs to sleep with him. You would be doing Carol an enormous favor if you advised her to get counseling in the rearing of her son. With all her good intentions, she is "(s)mothering" her son. Johnny's pediatrician will be able to recommend the best counselor for Carol and Johnny. It is desperately needed.

Surprisingly little is known about the long-term effects of nighttime isolation or separation versus co-sleeping in any part of the world, which is a major lacuna in the history of research in cultural psychology. Nevertheless, with the publication of an important longitudinal study by Okami et al. (2002; see also Okami & Weisner, in press) there is now some empirical grounds for being suspicious about any strong or generalized claims about the long-term effects on children of sleeping alone versus co-sleeping with one or more parents.

More on the Custom Complex: The Intimate Association between a Mentality and a Practice Supported by a Cultural Community

The concept of a custom complex presupposes an intimate association between a mentality and a practice that is supported, enforced, defended, and rationalized by members of some cultural community. When such an association is in place, it will be the case that other members of the cultural community will judge the mentality associated with the practice to be normal and reasonable, while any actual participant in the practice will experience the mentality associated with the practice to be under the skin, close to the heart, and self-relevant; the mentality will have become habitual, automatic, and can be activated without deliberation or conscious calculation—it will have become internalized. This intimate (some might say experience-near) connection or partial fusion of a mentality and a practice does not, however, prohibit us from drawing an analytic distinction between the mentality and the practice that instantiates it. It does not keep us from characterizing the custom complex as two things intimately connected or partially fused.

The study of a custom complex calls for the analysis of a two-sided thing—the intimate connection between a mentality (the symbolic inheritance of a cultural community) and one or more specific practices (the behavioral inheritance of a cultural community). This analysis begins with the systematic identification, through observation and interviews, of the routine or habitual family life and social practices engaged in by members of some self-monitoring and self-regulating group. Some of these practices may surprise, disgust, or enrage an outside observer, although to the jaded eyes of the group members their own practices are likely to seem ordinary, decent, and reasonable or at least "normal."

Each of the following practices, for example, is a commonplace way of being, at least for the members of the particular cultural communities that uphold them. In one cultural world, a 2-year-old child gets in bed with his or her mother, unbuttons his or her mother's blouse, suckles at her breast, and sleeps by her side throughout the night. In another cultural world, each child in the family sleeps in a private sleeping space separated from the sleeping space of all adults. In one cultural world, a woman brings food home from the market and cooks it, and then she and her husband consume the food together. In another cultural world, a man brings food home from the market, his wife cooks it at home, and he consumes the food alone and his wife eats separately and later. In one cultural world, children are fostered by their parents to more prosperous families in their society who subject these children to ordeals of hardship, physical punishment, and demanding tests of loyalty, requiring them to work as family servants until they endure the ordeals and pass the tests (Bledsoe, 1990). Then the children are adopted and supported by those families and patronized and provided for throughout life. In another cultural world, however, parents get upset (even incensed) if another adult touches their child, reprimands or scolds their child, makes strenuous demands of their child, or causes their child to suffer abuse in any way.

As noted earlier, the analysis of a custom complex ends when one is able to spell out as comprehensively as possible the things that the members of some group (tacitly or explicitly, consciously or unconsciously) know, think, feel, want, and value that explain and make intelligible the things that they do. Thus, the analysis begins with the identification of practices and it ends with the specification of a distinctive mentality.

This interest in the distinctive mentality associated with the practices of a cultural community distinguishes cultural psychology from other approaches to the study of practice domains in which it is assumed that human activities come in natural domains or universal kinds (e.g., religion, economics, family life, schooling, or politics) and

that members of different cultural communities think and behave more or less alike because of the strong constraints of each species of activity, regardless of community. The idea of a custom complex invites a very different approach in which it is assumed that members of various cultural communities have distinctive mentalities associated with each of their practice domains (e.g., a Taiwanese mentality of family life versus a New England mentality of family life), leading members of those cultural communities to engage in divergent patterns of behavior in ostensibly similar domains.

The idea of a custom complex also invites cultural psychologists to address the question of whether a particular cultural community has a characteristic mentality (e.g., the Protestant mentality), which leaves its generalized mark on many domains in that community, thereby making, for example, Protestant economics, Protestant religion, and Protestant family life more like each other than like a parallel natural domain in another cultural community.

We emphasize, however, that cultural psychology does not presume the existence of global consistency or thematic integration across all practice domains in a culture. Even Ruth Benedict (1934) was quite aware that many cultures are not patterned after some simple mold (Dionysian, Apollonian) or fundamentally integrated by a single theme (e.g., the work ethic). She knew, as we know, that the degree to which a small set of core beliefs, goals, or motives can account for the meaning and behavior of a people across the many domains of their life (family, work, and politics) is entirely an open empirical issue.

There is no way to know in advance of years of research in some particular cultural community whether their many practice domains all draw on the same mentality. Nevertheless, even if a particular cultural community is not thematically integrated (one small set of core meanings revealed in many practice domains), the custom complex is still a natural theoretical frame of analysis for cultural psychology. The idea defines a parameter space for conceptualizing and modeling the ways that culture and psyche make each other up, resulting, on a worldwide scale, in multiple instances of a relatively stable or equilibrated condition in which a mentality and a practice are mutually sustaining and reciprocally confirmatory. Not all custom complexes are integrated in the same way or cohere to the same degree. Nevertheless, the idea makes it possible for us to ask about the ways and degrees to which a relatively stable equilibrium (the intimate association of a local mentality and a cultural practice) has actually been achieved.

THE CLASSIFICATION OF PRACTICES

To conduct a relatively complete and systematic empirical study of a community's cultural psychology, it is necessary to identify the members' practices and categorize them into domains. Practices can be categorized in many ways, because any scheme of classification will depend largely on the investigator's theory of human needs (physical, social, psychological, and spiritual) and the research issues at hand.

One of the several ways practices can be classified into domains is from an ontogenetic perspective, with special reference to the development of mastery or expertise in some domain of psychological functioning (knowing, thinking, feeling, wanting, or valuing). Thus, practices might be identified and classified by reference to the particular substantive type of competence they promote (e.g., practices promoting social sensitivity, practices promoting moral development, practices promoting cognitive development). For example, a recent study (Munroe, in press) of 3- to 9-year-olds in four cultures (the Logoli of Kenya, Newars of Nepal, Black Carib of Belize, and American Samoans) produced the counter-intuitive and provocative finding that children are more willing to engage in opposite gender sex role play and seem less threatened by sex role confusions in societies that have institutionalized adult patriarchal or patricentric practices such as male dominance, gender segregation, and a strict sexual division of labor. Although one can only speculate based on the data presented in Munroe's study, one might entertain the hypothesis that where gender is culturally sanctioned as a basis for social organization the interest and capacity to imaginatively take the perspective of the other across the gender division is more highly developed.

Or a developmentalist might classify practices not so much according to the substantive competence (e.g., taking the perspective of others) acquired but rather according to types of processes of acquisition. Werker (1989; also G. Gottlieb, 1991), has generated a short list of hypothetical ways that experience (read exposure to or active participation in a cultural practice) can affect the development of any mental skill or ability. She imagines five kinds of processes:

1. Maturation (the practice made no difference; the ability would have developed without it).

2. Facilitation (because of the practice, the ability was attained more quickly than otherwise would have been the case).
3. Induction (without the practice, there would have been no ability at all in this domain).
4. Attunement (because of the practice, a higher level of ability was attained than otherwise would have been the case).
5. Maintenance/loss (the ability was preexisting but would have been lost or deactivated if it had not been kept online through participation in the practice).

At this early stage in the evolution of a cultural psychology of individual development, we can only look forward with excitement to the time when we will have in hand the research designs, methodologies, and systematically collected bodies of evidence that will allow us to classify practices in this way. We look forward to the time when we will be able to distinguish between each of those five interpretations of the effects of participation in a cultural practice on the growth of a mental state or ability.

Cultural psychology is, however, not committed to a blank-slate learning theory (the blank-slate stance is a straw person, and not even John Locke posited an entirely empty organism prior to learning from childhood experience) nor does it presuppose an induction theory of mental development. Quite the contrary, much of the current research in cultural psychology is quite compatible with (and may even presuppose) either an attunement or a maintenance/loss account of the differential emergence, activation, or selective maintenance of particular mental states. Our conception of cultural learning is discussed later, especially in relationship to innate ideas.

In this chapter, we can seldom choose between different interpretations (maturation, attunement, maintenance/loss, etc.) of how participation in a cultural practice affects the activation of a mental state or the emergence of a mental skill. What we can do, however, as an intermediary step in building a full-blown cultural psychology of individual development, is point to some of the research and scholarship in cultural psychology that tries to describe and explain the differential ontogenetic emergence, activation, and selective maintenance of what the "I's" in different groups know, think, feel, want, value, and hence choose to do, including research about the "self." Later in this chapter, we examine one important line of cultural psychological research on the development of an *interdependent* (sociocentric, collective) versus *independent* (autonomous, individualistic) self, but the cultural psychology project has general implications for claims about mental development that are quite independent of any particular findings in any particular domain.

For example, comparative research by Ross et al. (2003) has suggested that cognitive developmental theories presumptively positing a universal anthropocentric stage in the development of children's folk biological knowledge (the idea that young children everywhere initially project a naive human psychology onto nonhuman species) are more accurately viewed as local descriptions of the course of mental development for urban majority children who grow up with an impoverished experience of nonhuman nature. Native American Menominee children and rural children from mainstream populations in the United States, whose involvement with plants and nonhuman animals is positively structured and mediated by cultural beliefs and practices of various sorts, do not display the predicted universal developmental pattern and exhibit competences in ecological reasoning that are absent from the mentality of the urban, mainstream kids in the United States.

There are many other ways to classify cultural practices into domains. From the point of view of personal and social identity, cultural practices might be identified and classified by the existential problems they address. In any society, there are many existential questions, which must be answered for the sake of both individual mental health and social coordination:

- *Self practices* answer: "What's me or mine, and what's not me or mine?"
- *Gender practices* answer: "What's male, and what's female?"
- Disciplinary practices answer: "How are norms and rules to be enforced?"
- *Distributional practices* answer: "How should burdens and benefits be distributed?" (Shweder, 1982)

A closely related approach has been proposed by Fiske (1991, 1992), who argues that social life is comprised of four social relationships: communal sharing, authority ranking, equality matching, and market pricing. Fiske's scheme could readily be adapted and used in the classification of practices (practices promoting a sense of commonality, the importance and legitimacy of hierarchy, etc.). Some researchers may prefer to identify and classify practices by the institutions in which they are embedded (e.g., family-life practices, school-life practices). Other researchers, with different intellectual

aims and inclinations, may prefer to classify practices according to the biological needs or physical survival functions they serve (e.g., eating practices, health practices, or sexual practices).

Still others may want to proceed emically (Pike, 1967), which involves letting the classification of practice domains go hand in hand with the specification of the mentality of a cultural community, in the anticipation of some counterintuitive and astonishing results. In some cultural communities, for example, among devout Brahmans in India, there is a highly elaborated practice domain that might be labeled oblations, sacrifices, and sacramental offerings. It encompasses the daily preparation and consumption of food and includes in the same general practice domain other activities (e.g., prayer and animal sacrifice) that would never naturally go together in the mentality of a Western researcher. Among Hindu Brahmans in India, food is not a personal preference system. Given the local culturally elaborated idea that eating is a sacramental offering to a divinity (the self is conceptualized as a piece of divinity) residing in a temple (the human body), what you eat, how and by whom it has been prepared, and the conditions under which you eat is a mark of your moral standing and social status in the world.

THE ANALYSIS OF MENTALITIES

Mentalities are the other side of the custom complex. They can be investigated in the following ways: (a) by analyzing the idea of a mentality into its component parts: knowing, thinking, feeling, wanting, and valuing; (b) by modeling what some ideal or prototypical "I" (subject, agent, individual, or self) who might be engaged in this or that practice might know, think, feel, want, and value; (c) by empirically determining the degree of specificity or generality of those components of a mentality for actual agents across practice domains in a cultural community (and perhaps across cultural communities for a particular practice domain); and (d) by pointing to broad patterns of generality for mentalities when and where they exist.

For example, there is good empirical reason to believe that the mentality dubbed *interdependency, sociocentrism,* or *collectivism* supports and maintains a whole array of practices both in and across domains for some populations in Japan, while the mentality dubbed *independence, autonomy,* or *individualism* supports and maintains a disparate array of practices both in and across domains for some groups in the United States (Markus & Kitayama, 1991a, 1991b; Triandis, 1989, 1990).

Thus, although cultural psychology is, in one major sense, the study of the way culture and psyche make each other up; in another closely related sense, it is also the study of the origin, structure, function, operation, and social reproduction of that intimate association between a mentality and a practice known as the custom complex.

THE TWO SIDES OF CULTURAL PSYCHOLOGY

Cultural psychology is the study of the way culture and psyche make each other up, resulting in the formation of the custom complex, which is a unit of analysis for characterizing the way multiple, diverse psychologies emerge out of the abstract potentialities of a universal mind. Psychological pluralism emerges, at least in part, because peoples think and act in the light of particular goals, values, and pictures of the world. Those factors are rarely the same across cultural communities.

The cultural side of cultural psychology is the study of the mentality-laden practices (including the symbolic forms, communicative exchanges, rituals, mores, folkways, and institutions) developed, promoted, promulgated, enacted, and enforced (and hence judged to be customary, normal, legal, moral, or reasonable) by the "I's" (the subjects, agents, individuals, or selves) of particular groups.

The psychological side of cultural psychology is the study of practice-related mental states, the things that the "I's" (subjects, agents, individuals, selves) of particular groups know, think, feel, want, value, and hence choose or decide to do to carry forward the normal practices of their society.

Based on those two sides of cultural psychology, which are fused in the idea of a custom complex, the aim of the discipline is to investigate precisely those cases where the following three conditions hold:

1. A "practice" displays significant variation across groups and differential patterning of within-group variations (e.g., there is a far greater probability of children and adults co-sleeping in a family bed in South Asia and Africa than in Europe and the United States and the correlation between social status and co-sleeping is not the same in South Asia and in the United States).

2. The components of a mentality (knowing, thinking, feeling, wanting, and valuing), such as feelings of closeness, pleasure, and serenity versus feelings of anxiety or agitation associated with skin-to-skin contact between parent and child, display significant variation across groups and differential patterning of within-group variation (e.g., European American males, in comparison to South Asian males, are more likely to feel anxiety associated with skin-to-skin contact between parent and child and feelings of closeness, pleasure, and serenity produced by skin-to-skin contact between parent and child may be correlated with gender in the United States, but not in South Asia).
3. The distribution of the practice appears to be related to the distribution of the mentality, and vice versa.

Thus, through the idea of a custom complex, cultural psychology joins the study of individual mental states to the study of cultural practices. On the one hand, investigators explore those features of what individuals know, think, feel, want, value, and hence choose to do that are primed by, traceable to, or derivable from participation in the symbolic forms, communicative exchanges, rituals, mores, folkways, and institutions of some consensus-sensitive or norm-enforcing group.

On the other hand, investigators look at the way in which the mentality-laden practices (the custom complexes) of particular groups gain their credibility, reasonableness, and motivational force from the very psychological states that they have helped activate and to which they have given life. Cultural psychology is therefore the study of reciprocal connections between culture and psyche and of the various patterns or forms of coherency (custom complexes) that have arisen out of their interactions.

CULTURAL PSYCHOLOGY'S THEORY OF MIND

On a worldwide scale, there is well-documented diversity in the developmentally relevant cultural practices that promote, sustain, and confirm what the "I's" of particular groups know, think, feel, want, value, and hence choose to do. Consequently, cultural psychology is concerned not only with the inherent, mandatory, or fundamental aspects of the human mind but also, indeed especially, with those parts of what people know, think, feel, want, value, and hence decide to do that are conditional, optional, or discretionary and are primed and activated through participation in the symbolic and behavioral inheritance of particular groups. In effect, cultural psychology is a discipline committed to the study of patterns of psychological difference across groups or subgroups and to the investigation of the emergence (and dissolution) of stable, relatively coherent, and intimate interconnections between cultural practices and individual mental states.

Any study of difference, however, presupposes many commonalities, likenesses, or universals by which attributions of difference become intelligible. A notable feature of our conception of cultural psychology is that it presupposes certain universal truths about what is (and what is not) inherent in human psychological functioning. At a minimum, we are committed to a theory of mind in which everywhere in the world human beings are the kind of beings who have a mental life (who know, think, and use language and other symbolic forms) and who feel, want, and value certain things, which is one way to explain what they do (Donagan, 1987).

Even more deeply, we are committed to the view that psyche consists of certain mental powers. Most notable of these are (a) the representational power to form beliefs about other persons, society, nature, the divine, and about means-ends connections of all sorts; and (b) the intentional power to affect an imagined future state of affairs by means of acts of the will, which is the human capacity to have a causal influence on the world through acts of decision making and choice.

If the power of representation is an essential feature of the human psyche, then the human psyche can be studied, at least in part, as a knowledge structure. If the power of intentionality is an essential feature of the human psyche, then the human psyche can be studied, at least in part, as inherently ends-sensitive, which is minimally what it means to be agentic or to have a free will.

This view of the inherent powers of the psyche accords reasonably well with William James's (1950) description of the marks of the "mental." According to James:

> The pursuance of future ends and the choice of means for their attainment are thus the mark and criterion of the presence of mentality in a phenomenon. We all use this test to distinguish between an intelligent and a mechanical performance. We impute no mentality to sticks and stones because they never seem to move for the sake of anything, but always when pushed and then indifferently and with no sign of choice. So we unhesitatingly call them senseless. . . . No

> actions but such as are done for an end, and show a choice of means, can be indubitable expressions of Mind. (p. 1)

As noted earlier the anthropological linguists Anna Wierzbicka (1986, 1991) and Cliff Goddard (1997, 2001) have shown that the notion of a mental subject or agent ("I") and mental state concepts such as to know, think, feel, want, and value (as good or bad) are lexicalized in all languages of the world and universally used in folk psychology to explain what people do. And it has been argued by Collingwood (1961, pp. 303, 306; see also Shweder et al., 1997), among many others, that at least one basic sense of the folk psychology concept of a "cause" is the idea of "a free and deliberate act of a conscious and responsible agent" that is best understood through the ends the agent is trying to achieve and the means the agent believes are available for achieving them. With respect to its picture of the component parts of a mentality, folk psychology and cultural psychology presuppose pretty much the same picture of the universal and inherent features of the human psyche. Those marks of the mental include representation, intentionality, knowing, thinking, feeling, wanting, valuing, and hence deciding to do something.

Although cultural psychology is primarily concerned with the emergence and development of psychic pluralism, it makes use of a restricted set of mental state concepts as a universal framework for understanding the organization of psychological differences between the "I's" of different groups. The nature and organization of such differences and the manner of their development are discussed in the following section.

CULTURAL PSYCHOLOGY'S SPECIAL USE OF MENTAL STATE CONCEPTS

In cultural psychology, mental state concepts are used to refer to the causal powers inherent in the mental nature of human beings. Such concepts are not necessarily meant to be descriptions of bits of human consciousness or of deliberative awareness.

One can use a mental state concept to explain what people do without necessarily assuming that the mental events in question are events in consciousness. What a person knows, thinks, wants, values is not always in front of that individual as a piece of awareness, even as it plays a causal role in how the person acts. How that causal process operates and produces its effects is a mystery that is at the heart of the unresolved (and perhaps irresolvable) mind-body or mind-brain problem. Not all types of explanation of human behavior assume that mind matters, in the sense of having causal effects on the body. Cultural psychology makes the assumption that mental states are real, not epiphenomenal.

This suggests one additional power inherent in the human psyche—the ability to translate or transform a self-conscious deliberative process into a routine, automatic, unconscious, or habitual process. This power to turn a slow calculative process into a rapid response process prepares the individual to respond skillfully, smoothly, and not self-consciously (indeed almost mindlessly) in particular ways in particular circumstances. When this translation or transformation is fully accomplished, the associated mentality comes to be intimate and seems to be implicit in the practice.

As J. W. M. Whiting and Child (1953) pointed out long ago, with respect to the beliefs implicit in a practice: "The performer of a practice does not necessarily consciously rehearse the belief to himself at each performance. [For example, a typical middle-class European American parent does not necessarily consciously think to herself or himself 'I know that I can promote autonomy and independence in infants and young children by having them sleep alone' every time she or he goes to bed at night.] If asked, however, she or he will generally be able to report immediately at least some of the associated beliefs; in this case one may surmise that rehearsal of the belief was not part of the stimulus pattern for the present performance of the custom but rather a significant part of the stimulus pattern earlier in the development of the custom" (p. 28).

This comment by J. W. M. Whiting and Child is important for two reasons. First, it highlights the developmental process of becoming unconscious, whereas most developmental theorists, from Vygotsky to Piaget to Kohlberg, privilege the developmental process of becoming conscious or reflective. Whiting's and Child's implication that much of social behavior is habitual and automatic and that social life would not be possible if this were not so accords well with the views of Bourdieu (1972, 1990, 1991), Packer (1987), and others who are concerned with the difference between participating in the world and consciously deliberating about it.

Bourdieu argues that as practices are repeated again and again, they come to be seen as part of a natural order, and their original explicit reasons for occurrence may be difficult to resurrect. Packer makes the point that development typically involves becoming more fluent at some activity and that this is not necessarily the

same as becoming more reflective about that activity (as any serious athlete surely knows; see also Keil, Chapter 14, this *Handbook,* Volume II).

The idea of the custom complex and the return of research interest to the study of routine or habitual practice is an invitation to rethink some basic and classical ideas about the nature of development (on the intellectual history of the idea of "habit" see Charles Camic, 1986). More needs to be said about the misguided idea that one can define progressive development as some standard formal criterion such as the shift from intuition to reflection or from context-boundedness to context-independence (Kessen, 1990).

One can add to the classical image of progressive directional change an indefinitely large series of other dichotomies. Somewhere or other in the vast literature on cognitive development, someone or other has argued that the fully developed mind is complex (versus simple), complete (versus incomplete), explicit (versus tacit), impersonal (versus personal), taxonomic (versus associative), elaborated (versus restricted), concept-driven (versus percept-driven), detached (versus affect-laden), consistent (versus inconsistent), and so on. As should be apparent from our discussion of the custom complex and the developmental advantages of tacit understandings, habits, and unreflective but fluent skills, cultural psychology is deeply suspicious of any attempt to define progressive development by universal (decontextualized) formal criteria. In some cases, cognitive development is the process of becoming less reflective not more reflective. Again, at times, the accumulation of tacit understanding is what intellectual growth is all about. It all depends.

The second reason for the importance of J. W. M. Whiting's and Child's (1953) comment is that it underscores the point that any adequate investigation into the cultural psychology of a person or a people—any description of a custom complex—must characterize the level of consciousness of the mentality that is associated with a particular cultural practice. Are the relevant beliefs, values, motives, and satisfactions active without deliberation, active because of deliberation, reportable reflections, unavailable to reflection, and so on? When it comes to participation in the custom complexes of any particular cultural community, to what extent is the course of development from the deliberate to the automatic, from the self-conscious to the fluent, or from the explicated to the tacitly understood? At the very least, the cultural psychology of development into the customary practices of any cultural community is likely to be the story of the progressive shift from deliberation and self-consciousness to mindless or intuitive fluency. It is a developmental story that has rarely been acknowledged in child development studies, except perhaps by those interested in the acquisition of physical skills such as walking down stairs, typing a letter, or hitting a golf ball.

SOCIAL DEVELOPMENT IN THE DIVERGENT INTERPERSONAL WORLDS OF CHILDHOOD

From the perspective of cultural psychology, the local world of the child—especially in those dimensions likely to affect behavioral and psychological development—is largely mediated through culture-specific mentalities and practices of child rearing. In documenting variations across populations, cultural psychology first considers how responsible caregivers and educators, with special attention to the local ideas and meanings that support their behavior, routinely organize the child's experience. If people think and act in the light of particular goals, values, and pictures of the world, what are the goals, values, and pictures of the world (the mentality) of members of different cultural communities? Are there any generalizations that can be made about how and why differences arise in children's worlds and how they are structured?

As portrayed in the anthropological literature, variations in childhood worlds across human populations can be roughly divided into three categories corresponding to the material, social, and cultural conditions for child development (R. A. LeVine, 1989). First, material conditions include diet, housing, infant holding devices, and forms of protection against disease and other health risks. Second, social conditions include the family, peer groups, and other aspects of the interpersonal environment. Third, cultural conditions refer to the local ideational models, combining beliefs and moral norms that give meaning to all features of the child's world as well as to the child's development.

The focus in this section is on interpersonal aspects of the child's world, as mediated by differing cultures throughout the world. A considerable body of evidence on this subject has accumulated over the past 35 years (since a review of the literature appearing in the third edition of the present work; see R. A. LeVine, 1970, and even more since Margaret Mead's review in the *Handbook's* first edition in 1931), permitting some generalizations about the range of variation in children's worlds and their

meanings. The interpersonal worlds of children from birth to adolescence in different cultural communities vary widely along dimensions that can be described in quantitative and qualitative terms and that indicate divergent pathways for behavioral and psychological development—particularly when analyzed from the perspectives of interactional theories of development.

First, we begin by describing how differing organizational settings, caregiving relationships, parental practices, and age-graded participation in activities provide divergent patterns of socially and symbolically mediated experience for children of different cultures. Second, we turn to the cultural mentalities that not only rationalize and legitimize these social patterns but also motivate parental behavior. Third, we consider to what extent culturally differentiated social experience during childhood affects the psychological development of individuals—their attachments, skills, competence, preferences, relationships, and emotional experience as adults. Finally, we attempt to generalize about universals and variations in social development and their implications for developmental theory and research.

THE SOCIAL ORGANIZATION OF CHILDHOOD EXPERIENCE

In this section we discuss the character and composition of domestic groups and variations in their function, size, density, boundedness.

Organizational Settings

For the first few years of life and often much longer, children in most societies are raised in domestic groups (the normal residential homes of the adults who care for them). The functions of these groups, and their size, composition, social density, and boundedness—all variable across cultures—influence the quantity and quality of social experience possible for a child in a given society. Many of these features, and the sociospatial arrangement of the family as a domestic group as a whole, are often not matters of personal choice but are standardized in local practice according to the dominant mode of economic production and prevailing ideas of morality.

The Function of Domestic Groups

In societies with domestic agricultural or craft production, where every family engages in productive work at home, children are raised in local settings designed for economic activities as well as for family residence. In urban-industrial societies like the United States, in which only 2% of adults engage in food production, children are more likely to be raised in home settings specifically designed for child care and segregated from adult economic activity.

This difference between cultural worlds in which work and family have been merged versus cultural worlds in which work and family have been separated (in some cases, as in the upper middle-class European American cultural area, with the family functioning more or less like a Montessori School) makes a great deal of difference for children. Where home is the setting for food or craft production, the attention of mothers is more often divided between child care and other demanding tasks. The family is then more likely to operate as a command hierarchy, with children at the bottom, and children are more likely to be spectators of a wide range of adult activities and to participate in them from an early age (Rogoff, Mistry, Göncü, & Mosier, 1993). A family that functions as an economic production unit, like that of many Third World people today and preindustrial Europe and North America, constitutes a distinctive world of childhood in which child labor is expected and children's play and education must be accommodated to the workplaces and routines of the home.

The actual amount of children's labor contributions in such families varies from one agricultural people to another (Nag, White, & Peet, 1978). Among those with low-level technology, like the peoples of sub-Saharan Africa, children may have to work a great deal at tasks they can do such as fetching water, herding animals, caring for babies, and assisting in cultivation. This permits the adults to concentrate on the heavier or more skilled tasks of hoeing, planting, weeding, harvesting, and food processing. Among peoples with a higher level of agricultural technology including irrigation, draft animals, and plows (e.g., rural villagers of India), the need for domestic labor is less and children may be indulged and have more free time. The actual utility of child labor in a particular setting, however, depends on the specific crops cultivated, their seasonal cycles, the availability of resources, such as water, and whether children can be hired outside the family. When new technology is introduced, the situation changes, and children may be freed from labor, unless they are drafted into craft production at home or sent elsewhere as hired hands.

In foraging (i.e., hunting-gathering) and fishing communities and among pastoral nomads, children also participate in productive activities at early ages (by the

standards of contemporary industrialized societies), but the degree to which they are confined or free to play in the course of the day and the year varies with the rhythm of the work cycle. Similar to agricultural communities, domestic economic production largely determines the functional world of children's social lives.

The Size of Domestic Groups

The number of persons coresiding in domestic units is extremely variable among human societies, and although some of this variation depends on the definition of the unit, it is certain that the nuclear family household of Europe and North America is among the smallest in the world. Anthropologists have reported large domestic groups (up to and more than a hundred) under a single roof or surrounded by a single wall in places as diverse as New Guinea, lowland South America, West Africa, and indigenous North America: Although such groups have internal social boundaries, they certainly provide a child of any age with opportunities for interacting with many and diverse persons most of the time.

This is also true, in a more limited way, of societies with extended or joint family structures in which the domestic unit encompasses two or more nuclear families of two or more generations. B. B. Whiting and Whiting (1975) pointed out that when adult women share cooking facilities and yard space, they are more likely to interact with each other's children and cooperate in child care. The joint families of India are an example, as are the large compounds of the Yoruba of southwestern Nigeria, the smaller compounds of the Giriama of coastal Kenya (Wenger, 1989), and the Hausa of northwestern Nigeria (R. A. LeVine, LeVine, Iwanaga, & Marvin, 1970; Marvin, VanDevender, Iwanaga, LeVine, & LeVine, 1977). In all these environments, the sheer size of the domestic group guarantees that the child will interact with a large number of women and children from infancy onward.

The Composition of Domestic Groups

In contemporary urban-industrial societies, the domestic group is coterminous with the household, and composition of households with children can usually be classified by whether one or both parents reside there and whether there are other adults such as grandparents. It is more complicated among agrarian and other nonindustrial societies in which households as physical structures can be situated in larger domestic units usually referred to as compounds or homesteads by anthropologists.

Among the Gusii of southwestern Kenya, a married woman and her younger children live in a house by themselves, but it is a unit embedded in a homestead owned by her husband or father-in-law, along with the (nearby) houses of her parents-in-law, brothers-in-law, and co-wives. If her husband is a polygamist, he may live in the houses of his other wives all or part of the time or even in a hut of his own separate from all of them, though near enough for children to bring him hot food from their houses.

Furthermore, as the children get older, they leave the mother's house to sleep in the house of an older brother (for boys) or a grandmother (for girls), all within the homestead. The Gusii mother-child household is the elementary unit of family residence, but the homestead is the basic unit of domestic social life from the viewpoint of adults, and its male members form the nucleus of a local patrilineage (R. A. LeVine et al., 1994; R. A. LeVine & LeVine, 1966). This complex composition of domestic groups is common to many nonindustrial societies and often means that the child grows up in a more complex residential environment than that of the average American child.

The Social Density of Domestic Groups

The interactive settings in which children spend their early lives—including those of eating, sleeping, work, and play—vary widely in social density across cultures regardless of the size and compositional complexity of domestic groups. Gusii children may grow up in a homestead with as many as 58 inhabitants but spend all their hours in and around their mother's house, interacting only with mother and older siblings during the preschool years.

In contrast, Hausa children, in a much smaller compound, may experience greater social density because the sharing of cooking facilities and yard space among the Hausa women in a walled compound creates more crowded settings for daily interaction involving children. The social density a child experiences, especially during the less mobile early years of life, depends not only on the wealth or resources of the family but also on the rules that govern family interaction. It seems hard for Americans and Europeans to believe that people in other cultures may enjoy, indeed prefer, crowded settings in which to eat, sleep, work, play, and even breastfeed babies (Tronick, Morelli, & Winn, 1987), but such preferences are widespread among the world's peoples, even when they have enough domestic space in which to carry on these activities in isolation.

The Boundedness of Domestic Groups

Interactive patterns in the child's world are constrained by the social boundaries recognized by adults. Boundaries can be physical in form, like the mud walls of a Yoruba or Hausa compound or the cultivated fields that divide the mother-child households of a Gusii homestead from each other. Boundaries can also be invisible or conceptual barriers, as in the local traditions of interhousehold visiting, greeting, and hospitality that limit the interaction of children and adults in many Western and Japanese urban neighborhoods.

In urban India, by contrast, there are middle-class apartment dwellings occupied by kin-related families whose children wander in and out of each other's homes without such restriction. From the children's perspective, the permeability of the household and other domestic units in the immediate environment provides the basis of a cognitive map of their social world.

Care-Giving Relationships

Mothers are the primary caregivers of their children for at least the first 2 years of life in most human societies, but there are significant exceptions, and there is even greater variation in the array of supplementary caregivers who assist mothers and form relationships with young children. The ethnographic record as a whole does not suggest that there is a single system for human child care but rather a range of parental patterns flexible enough to respond to and enable varying economic, demographic, and technological conditions with diverse care-giving arrangements that affect the interpersonal experience of the growing child.

When women have a heavy workload due to a primary role in food production, then the resultant scarcity of female labor may create a demand for supplementary caregiving arrangements. When children are scarce relative to adult women (due to high rates of infertility, infant and child mortality, or contraception), adult women who are infertile or postmenopausal may be eager to take care of young children born to others. When wet nurses or synthetic milk formulas become available, maternal breast-feeding may decline. Thus, variations in caregiving practices and relationships are generated by the differing conditions to which human populations adapt.

There are some human populations in which a majority of children under 2 years of age live with and are cared for by someone other than their mothers. These fostering and adoption practices have been documented in Micronesia (Carroll, 1970) and West Africa (Bledsoe, 1989). In these cases, young children are distributed among kin, often to mothers and sisters of the women who gave birth to them, after a period of breast-feeding by the mother. There is usually no effort to disguise the original relationship, and children often go back to their mothers after a period of years. Although some mothers do this because they feel obliged to meet the demands of their own mothers or sisters, they usually also feel that the child will benefit from additional sponsorship, as Goody (1982) has described for the fostering of older children among the Gonja of Ghana. All these practices are infused with the assumptions of a kinship ideology in which children are seen as belonging to, and as potential beneficiaries of, a descent group wider than the biological parents. Mothers who do not care for their own children are not viewed as irresponsible or neglectful in these cultural communities.

In a much larger range of societies, children are raised by their mothers, though often with help from others such as sibling caregivers, grandmothers and other related adult women, and fathers or other men.

Sibling care of infants is widespread not only in sub-Saharan Africa (where it is ubiquitous) but also in Oceania, Okinawa, and parts of Southeast Asia (Weisner, 1982, 1987, 1989a, 1989b; Weisner & Gallimore, 1977). It is more frequent where mothers have extensive responsibility for agriculture.

The practice of sibling caretaking raises the question of whether leaving infants in the care of 5- to 10-year-old children, which would be considered criminal neglect in the United States, harms babies when it has achieved the status of a custom complex and is the routine practice of an entire population.

From the available evidence, the answer to this question is: No, babies are not harmed by this practice. For several reasons, first, 5-year-old children can be, and are, trained to be responsibly protective, if not necessarily sensitive, caregivers, particularly for babies carried on the back. Second, child care is largely conducted in the open air during the day, and neighbors are within earshot in case anything goes wrong. Third, the child nurse is not expected to substitute for the mother in a general sense, but simply to complement her care by protecting and feeding the baby for a few hours at a time. The mother breast-feeds during the day and sleeps with the baby at night, and infants raised under these conditions become attached to their mothers.

Finally, and in light of the foregoing, it seems that the American or European American concern about psychological harm is probably exaggerated. Babies can accommodate comfortably to sibling care, and back-carrying as well as other widespread forms of tactile stimulation promote both physical growth and psychosocial attachment during the 1st year (R. A. LeVine et al., 1994, pp. 257–258).

Furthermore, sibling care can initiate a strong lifelong relationship between an older sister and younger brother, which some cultures selectively promote. Among the Hausa, the marriage of a sister's son to the daughter of the brother she cared for as an infant is a preferred form of cross-cousin marriage. Even in the short run, the relationship of the toddler to his sibling caregiver often introduces the child to a larger group of children who become salient nonparental figures in his life.

Grandmothers and other adult women often play an important supplementary role in infant care, especially where children are raised in large domestic groups. From West Africa to India and China, grandmothers are not only caregivers in the early years but also, as the child grows older, complements to the mother's disciplinary role with their unconditional nurturance and emotional support. Children can, and often do, form intense and long-lasting relationships with other resident women in extended family situations.

Fathers and other men are more rarely observed as caregivers for young children, but there is variation across human populations. Hewlett (1992) has provided substantial data from diverse peoples. He distinguishes between the father's investment in the child, which may be indirect and consist of providing resources through the mother, and involvement with the child, which refers to interaction.

Although paternal interaction with young children is rare relative to that of the mother and other females, and it is unusual cross-culturally for males to be constant and responsible caregivers (as opposed to occasional playmates) for infants or toddlers, the range is quite considerable. Among the Dinka of the Sudan, for example, the exclusion of men from attending the delivery of a child is extended through the early years of a child's life, and the father only interacts with his older children (Deng, 1972). Aka pygmy fathers in Cameroon, however, participate substantially in the care of young children (Hewlett, 1991), and among high-caste Hindu farmers of the Katmandu Valley in Nepal, various men in the extended family take care of infants and toddlers for periods of time during the day (S. LeVine, n.d.). As Harkness and Super (1992) point out, fathers can be in the presence of young children without interacting with them, and it is only when cultural practices and mentalities favor it, that fathers and other men will assume responsibility for the care of children or engage them in interaction. Infants become attached to their father and other men who interact with them, as they do to their mother, siblings, grandmothers, and other adult women (Ainsworth, 1967).

Parental Practices

An important and culturally variable part of the child's social environment is constituted by the customary activities that parents and others arrange for them. Observational investigators of human and other primate offspring have created a number of dichotomous categories to describe these activities: Child-centered communications versus those that do not include the child, distal (often verbal) versus proximal (usually physical) stimulations, reciprocal or contingent vocalization versus unilateral speech to a child, positive versus negative emotional arousal, soothing versus stimulation, and sensitive versus insensitive response to infant signals.

These dichotomies are behaviorally specified to be unequivocally observable in differing contexts of primate behavior, but they nevertheless seem to reflect European American middle-class preferences for child-centered, distal, verbal, reciprocal, emotionally positive, stimulating, and sensitive patterns of parent-child interaction. Studies using these categories cross-culturally usually show that parents in other cultures exhibit some or all of these behaviors less frequently than middle-class European Americans (R. A. LeVine et al., 1994; Richman et al., 1988; Richman, Miller, & LeVine, 1992).

However valid these findings of difference in frequencies may be, they are only part of the story. Taking European American custom complexes as the reference point for comparison almost inevitably means overlooking activities and dimensions that are salient only in the other cultures. Without a complementary account of the mentality and point of view of the other culture, this is grossly uninformative, like an African account that might describe the American family as lacking cattle and agriculture.

The findings may indicate that parents in the other culture are not committed to the same custom complex

in their observable practices and do not share the European American mentality, but the findings do not describe what custom complex they are committed to and what goals, values, and pictures of the world they are in fact and in practice following. To make sense of observable differences in parents' practices, it is necessary to describe the parents' cultural models of social relations. It is necessary to describe the mentalities that guide and give meaning to their practices and to a child's social participation. Some illustrations are provided in the next section.

Age-Graded Activities

In all societies, the social interaction of children is altered by their age-related participation in activities at home or school. The institution of schooling creates an extreme form of age-grading. In most schools children, from the ages of 5- to 8-years-old onward, tend to be rigidly segregated by age from those older and younger for many of their daytime activities.

The peer groups that result are neither natural nor universal. In societies without schools, children's relationships with each other are formed among siblings or other multiage groups of juveniles (Konner, 1975). In these multiage groups, participants are much more sharply differentiated by authority and knowledge than in school-based peer groups. In such groups, relationships among older and younger children may facilitate the learning of skills by the younger, who observe mature practice performed by someone old enough to be more skilled but close enough in age to be easily imitated (Dunn, 1983).

Sibling relations may also promote interpersonal responsibility, cooperation, and sensitivity to the vulnerability of others on the part of the elder children (Schieffelin, 1990; Weisner, 1982, 1987, 1989b; B. B. Whiting & Edwards, 1988). Schools, alternatively, may foster interpersonal comparison and competition among peers and, by obstructing the child's observational access to mature practice, make learning more problematic and hence more self-conscious (Lave, 1990; R. A. LeVine, 1978; Scribner & Cole, 1973). Cultural variability in age-graded social activities is widened further by specific combinations of siblings, school and work in the local environments of children, and culture-specific norms that elaborate or diminish age ranking.

CULTURAL MENTALITIES CONCERNING CHILDHOOD SOCIAL RELATIONS

Parents do not always try to control the interpersonal environments of their children in detail, particularly after the first 2 or 3 years, and when they try to, they are often far from successful. Nevertheless, parents care about and can usually influence the settings in which their children interact with others, their caregivers and companions, and the kinds of interactions that take place (B. B. Whiting & Edwards, 1988; B. B. Whiting & Whiting, 1975). Thus, it matters what parents think and feel about such things, and socially inherited beliefs, values, and pictures of the world frame what they think and feel. Parents are culture bearers, and their models of childhood social relations are as variable as their culture's conceptions of the good life and how to live it (Harkness & Super, 1996; R. A. LeVine et al., 1994; R. A. LeVine, Miller, & West, 1988).

Parental Models and Strategies

Parental behavior is symbolic action in Geertz's (1973b) sense of the term and reflects a local mentality about what parenthood and child development are and ought to be, as formulated in the symbols of a particular culture. The local cultural mentality gives meaning to the actions of parents and children and motivates parents to promote certain behaviors and dampen others. A cultural mentality of child care has three components: (1) moral direction, (2) a pragmatic design, and (3) customary scripts for interaction (R. A. LeVine et al., 1994).

Moral Direction

Cultural mentalities of child care are goal driven; they are formulated by cultural concepts of virtue toward which a child's behavioral development should move. The vernacular words (e.g., independence, autonomy, and self-reliance for the European American middle class) and the images associated with them that represent virtuous goals of development help provide parents' rationales for their observable child-care practices.

Research on comparative ethics and development, however, has revealed that the humanly recognizable virtues or moral ends of life can be culturally organized in ways that do not privilege an "ethics of autonomy" (Haidt et al., 1993; Jensen, 1996, 2005; Shweder, 1990b;

Shweder et al., 1990, 1997) and that in some societies an "ethics of community" and/or an "ethics of divinity" leads to an emphasis on alternative virtues and goals of development such as duty, respect, hierarchical interdependency, purity, and sanctity.

Furthermore, each type of ethics highlights a particular view of the self. Shweder et al. (1997) argue that (a) the ethics of autonomy is associated with a conception of the self as an individual preference structure, where the point of moral evaluation is to increase choice and personal liberty; (b) the ethics of community is associated with a conception of the self as an office holder in which a person's role or station in life is intrinsic to their identity; and (c) the ethics of divinity is associated with a conception of the self as a spiritual entity connected to some sacred order of things and as the bearer of a legacy that is elevated and pure. The meaning of child-care practices in any particular community, from disciplinary practices to sleeping arrangements to the practice of circumcision, is often most understandable with reference to the particular moral ends that justify and rationalize those practices in the minds of parents in that local cultural world (on initiation and circumcision see, e.g., Kratz, 1994, pp. 341–347).

Pragmatic Design

Cultural mentalities of child care embody strategies not only for facilitating the child's behavioral development in a morally virtuous direction but also for achieving other ends (e.g., survival, health, and economic returns) and for overcoming obstacles to the attainment of all these ends. This utilitarian aspect of child-care mentalities provides a practical value and convinces parents that they are doing what is necessary and right.

Customary Scripts for Interaction

The moral and pragmatic aspects of a child-care mentality may or may not be explicitly formulated in general terms, but they are always represented in the social customs that guide the interaction of parents and other caregivers with young and older children. At this level of specificity in social interaction, for example, the script for responding to a baby's cry among the Gusii of Kenya is an immediate soothing response. This response is seen as promoting the calmness and compliance of a young child (the moral direction) as well as the child's health and survival in the early months (part of the pragmatic design). However, it is so customary that allowing a baby to cry more than a few seconds is experienced by Gusii adults as an intolerable breach of caregiving norms.

THE EFFECTS OF EARLY INTERPERSONAL EXPERIENCE

What effects do cultural variations in interpersonal environments and symbolically mediated experience have on the behavioral and psychosocial development of the child? A cultural community or population-level approach provides a clearer picture of the effects of early experience than a focus on the psychology of individual differences (R. A. LeVine, 1990a). For example, children who grow up in China obviously learn to speak Chinese, just as those who grow up in Turkey learn Turkish. Less obvious, but well established by sociolinguistic investigators of child language, is that as young children acquire a first language they also master the communicative practices regulating interpersonal behavior in their communities (Ochs & Schieffelin, 1984; Schieffelin & Ochs, 1986a, 1986b).

The symbolic mediation of experience and communicative practices are discussed in a following section. The main point of emphasis here is a very simple one: For young children the development of communicative competence reflects their early experience in a particular language environment and constitutes an important part of their early enculturation.

By age 3, children have culture-specific capacities for and expectations of emotionally salient interpersonal behavior, embedded in speech routines and other customs of face-to-face interaction, in the context of specific relationships (Schieffelin, 1990). Their behavioral development has taken a culturally distinctive character and direction, diverging from that of other cultures.

Relatively little research has been done on the behavioral consequences of cultural variations in early social experience, but there is some evidence of measurable effects. Social behaviors shown to differ across culturally varying samples of children include infant-mother attachment (Grossmann & Grossmann, 1981, 1991; Grossmann, Grossmann, Spangler, Suess, & Unzner, 1985), attention-seeking (R. A. LeVine et al., 1994; B. B. Whiting & Whiting, 1975), dependence (Caudill & Schooler, 1973), cooperation (Thomas, 1978), and gender orientation (B. B. Whiting & Edwards, 1988). In each of these cases, the evidence of

behavioral difference has been interpreted by the investigators to reflect the impact of the children's prior experience in divergent cultural environments, although it is probably not possible at this time to choose between different interpretations of this impact (e.g., facilitation, attunement, or maintenance/loss, as discussed earlier; Werker, 1989).

An example from infancy research is the Grossmanns' (1981, 1991; Grossmann et al., 1985) study of infant-mother attachment in Bielefeld, North Germany. This German replication of Mary Ainsworth's Baltimore study (Ainsworth, Blehar, Waters, & Wall, 1978) found that the majority of a nonclinical sample of 12-month-olds was classifiable on the basis of the videotaped Strange Situation as "insecurely" attached to their mothers. Forty-nine percent of the sample was classified in the "A" category or "anxious-avoidant," almost twice as large a proportion as in American samples. The Grossmanns related this departure from American norms to the German mothers' custom complex—their mentality and practices. German mothers, in this region of Germany, prefer a greater physical and interpersonal distance from their infants than Americans, leaving them alone more often and sometimes pushing them away. They would consider American infants rated as "optimal" by attachment researchers to be spoiled.

According to the Grossmanns' interpretation, the culture-specific preferences of the German mothers was based on a broader cultural mentality, even ideology, emphasizing an ideal of pure independence that is even more exaggerated than the European American ethics of autonomy. For these mothers, this cultural ideology was translated into maternal practices that affected not only their infants' routine expectations for social interaction and comforting but also their response to separation and reunion in the Strange Situation. Their interpretation of their findings implies, though the Grossmanns do not say so, that the profile of attachment ratings of American infants in the Strange Situation can be seen as reflecting the culturally influenced parental practices of European Americans rather than a universal norm for all human populations (LeVine & Norman, 2001).

If this is so, then claims of species-typical universality for attachment as observed in the Strange Situation should be considered premature. Infant reactions to reunion with their mother after a brief separation at 12 months of age can be reinterpreted as indicators of early enculturation to a cultural standard of interpersonal distance mediated through parental practices of infant care.

The German evidence provides the starting point for a cultural critique of the Bowlby-Ainsworth model of attachment, especially its claims to have discovered the evolutionary origins of human social relationships and the biological basis for judgments of optimality, normality, and pathology in early development. As more detailed and culturally informed evidence on behavioral development in diverse cultures accumulates, a cultural critique of developmental models may serve a useful purpose, particularly if the models themselves continue to ignore cultural variation in early social experience.

At this point, it may not be possible to launch robust generalizations about the psychological effects of early interpersonal experience based on population-level comparisons across cultures. However, as the concepts and techniques for observing and recording infant care and early communicative exchanges involving children have improved, and as comparative evidence has grown, so have the grounds for believing human behavioral development to be culturally divergent from the early years of childhood onward.

THE SYMBOLIC MEDIATION OF EXPERIENCE: LANGUAGE AND COMMUNICATIVE CUSTOMS IN CULTURAL PSYCHOLOGY

It is a major assumption of cultural psychology that one mind is transformed into many mentalities through the symbolic mediation of experience and that the human conceptual capacities that support culture also support language use, which is the primary means by which the symbolic and behavioral inheritances of a cultural tradition are passed on to the next generation. It is primarily by means of language that human beings negotiate divergent points of view and construct shared cultural realities. In this section, we selectively discuss the role of certain pragmatic forms of linguistic analysis in research on the cultural psychology of development.

As children learn language, they gain entry to existing meaning systems and access to the tools for recreating and transforming those systems. In a wide-ranging review of the literature, Nelson (1996) concludes "language and the surrounding culture take over the human mind" (p. 325), profoundly changing the nature of cognition and communication during the time from 2 to 6 years of age. Language is fundamental not only to meaning construction but to identity. Through its association

with particular contexts, language comes to symbolize and belong to particular groups. Quite simply, there can be no cultural psychology without language.

This premise is traceable to many intellectual forebears of contemporary cultural psychology. These include the eighteenth-century European philosophers who laid the groundwork for cultural psychology (Jahoda, 1992), Wilhelm Wundt and other nineteenth-century proponents of a "second" psychology (Cahan & White, 1992), and Edward Sapir (Mandelbaum, 1951) the anthropological linguist whose works on language in social life and on culture and personality anticipated many topics of current interest to cultural psychologists.

We begin this section of the chapter by discussing the conception of language that is most compatible with the aims of cultural psychology and by identifying resources from allied fields of study that hold promise for deepening our understanding of language in cultural life. We turn next to socialization, one of the fundamental problems of cultural psychology, and review studies that have yielded important insights into the actual process of socialization by examining the forms and functions of everyday discourse. We then single out oral narrative as a paradigm case of everyday discourse, organizing the discussion around issues of diversity. Throughout this section, the primary focus is on research with young children. In keeping with the comparative commitment of cultural psychology, examples of variation within and across cultures are included wherever possible.

LANGUAGE AS PRACTICE

The centrality of language to cultural psychology stems not only from historical precedent but also from the duality of language. Unlike other domains, language is both a tool and an object of inquiry. On the one hand, the use of language as an instrument of inquiry is pervasive; every study of human development depends on verbal communication in one way or another. Children are questioned about the reasons for their moral judgments. Parents are interviewed about their child-rearing beliefs. Verbal behaviors are incorporated into observational coding schemes. Experimental tasks have to be explained to participants. On the other hand, language serves as the object of inquiry in many studies that seek to understand the nature and development of the linguistic system itself, including its various subsystems (e.g., syntax, morphology).

This distinction between language as tool and object of inquiry serves the interests of cultural psychology by promoting critical examination of the ways in which researchers use language in conducting their research and by acknowledging the continued importance of understanding the referential function of language. At the same time, this distinction is limiting because it does not readily encompass a third, rapidly growing set of studies of particular interest to cultural psychology.

These studies focus on talk but they are not concerned with language development itself. Instead, they examine how talk contributes to constituting children's experience in other developmental domains (Garvey, 1992) such as social development (e.g., Dunn, 1993), self construction (e.g., Bruner, 1990a, 1990b), and peer culture (e.g., Corsaro, 1992, 1997). These studies take talk seriously as a "substantive, structured, and structuring activity with intrinsic developmental significance" (Packer, 1987, p. 253). An important implication of this perspective is that a particular social phenomenon may be constituted in qualitatively different ways within and across cultures and that these differences are created partly through talk.

Recent research on play deserves to be singled out because it illustrates this point especially well and because it represents some of the most richly contextualized research in developmental cultural psychology. Children use verbal and nonverbal means to frame their play as nonliteral, to enact pretend roles, and to negotiate pretend transformations with their play partners (e.g., Garvey & Kramer, 1989; Sawyer, 1997). However, local customs and belief systems vary dramatically along many dimensions, including who children play with and how they communicate with one another (e.g., C. D. Clark, 2003; Göncü, 1999; Göncü, Patt, & Kouba, 2002; Haight, Wang, Fung, Williams, & Mintz, 1999; Lancy, 1996; Schwartzman, 1978). For example, when a child has long conversations with an invisible other, middle-class American parents are likely to assume that she is talking to an imaginary companion; Hindu parents that she is talking to a real spiritual being (M. Taylor & Carlson, 2000). In contrast to middle-class European American children, whose mothers induct them into pretense by prompting, elaborating, and modeling (Haight & Miller, 1993), Yucatec Mayan parents do not play with young children (Gaskins, 1999). When Mayan children engage in social pretense, they do so exclusively with other children. Similarly, Indonesian and Mexican children are socialized into play by older siblings

(Farver, 1999). Although children in all these groups engage in pretend play, they do so according to local social and communicative conventions. As a result, play assumes different forms, takes on different significances, and likely makes different contributions to their overall development.

Implicit in these studies is a conception of language that privileges the situated use of language and recognizes that speaking is inherently polysemous when extracted from context (Bauman & Sherzer, 1989; Duranti & Goodwin, 1992; Hanks, 1996). This conception contrasts with the narrowly referential conception of language that holds sway in most research on human development and cross-cultural psychology. The view of language that is most compatible with the aims of cultural psychology does not reduce language to a representational system or repository of knowledge. Rather, it goes beyond grammatical and lexical meaning to include processes of indexical meaning that anchor utterances to their linguistic and nonlinguistic contexts and to unspoken background assumptions.

Hanks (1996) describes speech as "a form of engagement in the world. . . .To speak is to occupy the world, not only to represent it, and this occupancy entails various modes of expression, of which propositional meaning is only one" (p. 236). To speak is to create social realities—to play, tease, instruct, dominate, transform oneself, and so on. Just as language cannot be sealed off from social life, words cannot be sealed off from silence or from gaze, posture, gesture, facial expression, and other practices of the body. From this perspective, speaking consists of practices that are organized beyond the sentence level into dialogues, genres, and multichanneled performances. These larger communicative events, while serving as units of analysis, are themselves multiply embedded in larger sociocultural contexts and networks of cultural practices. In contrast to approaches that take the disembodied word, sentence, or text as the unit of analysis, this approach permits a deeper cultural analysis, for it recognizes that cultural principles are expressed not just in the content of talk but in the way that discourse is organized internally and in relation to larger events and sequences of talk.

Among the many intellectual currents that have fed into practiced-centered views of language is sociohistorical theory, with its focus on semiotically mediated activity (Cole, 1996; Wertsch, 1985) and linguistic anthropology, especially the fields of ethnography of communication (e.g., Bauman & Sherzer, 1989; Hymes, 1974) and language socialization (which is discussed more fully later). These fields have been centrally concerned with cross-cultural comparisons and hence are especially germane to the comparative mission of cultural psychology. Resting on the assumption that everyday talk is a pervasive, orderly, and culturally organized feature of social life in every culture, they seek to understand the diversity of language use in the conduct and constitution of social life.

These fields provide a rich set of conceptual, methodological, and empirical resources that cultural psychologists should exploit more fully. These include procedures for grounding interpretations of communicative practices in the public cues that participants systematically deploy in interaction and critiques of our own social scientific methods as communicative practices whose meaning may not be shared by the people we study. For example, C. Briggs' (1986) analysis of interviewing as a social and cultural practice is still timely and demonstrates the critical importance of customizing interviewing to local metacommunicative practices (see also P. J. Miller et al., 2003, for an application of this approach).

Another important insight from these fields pertains to the issue of context. The focus on naturally occurring discursive practices has led to a much more dynamic conception of context and practice than is usually assumed in developmental studies. Contexts are treated not as static givens, dictated by the social and physical environment, but as ongoing accomplishments negotiated by participants. This shift from static to dynamic is signaled by the term *contextualization,* which focuses attention on the interpretive processes participants themselves use to determine which aspects of the ongoing activity are relevant (e.g., Bauman & Briggs, 1990; Duranti & Goodwin, 1992). This conceptual innovation offers a holistic conception of individual and context as an interlocking system in which the language practice changes along with the person (see Goodnow et al., 1995, for further discussion of this point).

SOCIALIZATION THROUGH LANGUAGE

The growing literature on language socialization deserves further consideration because it arises from an intellectual project that is basic to cultural psychology. Cultural psychology recognizes that child development is inextricably bound to the process of socialization—of orienting oneself in systems of meaning—and seeks to understand the nature of this process as it is actually en-

acted by living, experiencing human beings. Cultural psychology is uniquely positioned, by virtue of its interdisciplinary character and commitment to meaning, to claim socialization fully as its own—something that none of the social sciences has succeeded in doing. Because of the way in which human action has been partitioned for study, socialization has remained marginal to the intellectual agenda of any discipline. As a result, it has been difficult to devise an integrated conception of socialization that slights neither culture nor children.

The field of language socialization provides an important model of how to proceed with this task. Inspired by Edward Sapir's famous words, "Language is a great force of socialization, probably the greatest that exists" (Mandelbaum, 1951, p. 15), this field rests on the premise that children are not only socialized through language but are socialized to use language (Ochs & Schieffelin, 1984). Another touchstone is the Vygotskian idea that sociocultural meanings are created by using language for particular purposes in socially defined activities (Vygotsky, 1934/1987; Wertsch, 1985). If language not only reflects meaning but also constitutes meaning, then an adequate theory of socialization must incorporate talk in a principled way.

Such a theory confers three advantages. First, the actual processes of socialization are rendered accessible through analysis of the forms and functions of everyday discourse. Second, in keeping with a basic insight of modern developmental psychology, the child is accorded an active role through a focus on child and caregivers' mutual, negotiated participation in discourse practices (Brandtstädter, Chapter 10, this *Handbook,* this volume; Rogoff, 1990). Third, the fact that language practices systematically index social statuses and ideologies helps to explain the varied affective stances—eager acceptance, resistance, playfulness—that children assume as they attempt to invest cultural resources with meaning (Watson-Gegeo & Gegeo, 1999). Both the nonneutral, ideologically charged nature of the socializing environment and the necessarily evaluative responses of the child-in-context are taken into account (Goodnow, 1990a).

Beginning in the 1970s, led by the pioneering work of Ochs and Schieffelin (1984), researchers began to translate these ideas into a particular kind of empirical work designed to link macro- and microlevels of analysis. In an attempt to discover how communities structure children's entry into meaning, they combined ethnographic fieldwork with the meticulous documentation of interactions between members and novices as they unfold in everyday life. Although the process of language socialization was assumed to be lifelong, most research focused on the early years. In contrast to many domains of human development, some of the best documented cases were non-Western cultures (e.g., Ochs, 1988; Schieffelin, 1990; Watson-Gegeo & Gegeo, 1990, 1999) and working-class and minority groups in the United States (e.g., Heath, 1983; P. J. Miller, 1982).

Research on language socialization has been the subject of numerous reviews (e.g., P. J. Miller & Hoogstra, 1992; Schieffelin & Ochs, 1986a) and collections (e.g., Bayley & Schecter, 2003; Corsaro & Miller, 1992; Schieffelin & Ochs, 1986b). An important conclusion emerging from this body of work is that there is enormous diversity in the cultural organization of caregiving and language learning and that the pattern of sustained dyadic conversation and mutual negotiation of meaning so familiar to many middle-class European Americans is but one variant among many. As noted earlier, groups differ in the physical and social ecology of child care, in language ideologies and folk theories about the nature of children and development, in the practices used to encourage mature speech, and in the principles that organize interaction.

For example, Kaluli mothers of Papua, New Guinea, believe that infants do not understand and thus cannot be conversational partners (Schieffelin, 1990). They do not talk *to* infants; instead they face babies outwards so that they can be part of the social flow. When older siblings greet the baby, the mother speaks *for* the baby, using language that is appropriate to the older child. Mothers do not interpret or paraphrase infants' vocalizations, a practice that reflects a dispreference for talking about another person's thoughts or feelings. In the working-class African American community described by Heath (1983), multiparty talk is the norm and children are almost never alone. Talk around the child, rather than talk directly to the child, is the primary linguistic resource for novice learners. In a Mayan community in southern Mexico, both dyadic and "eavesdropper" models of language learning are practiced, and nonverbal interaction plays an important role in organizing infants' participation (de León, 2000).

Coexisting with these and other differences are important similarities. For example, many groups socialize children into elaborate forms of teasing and oppositional language (e.g., Briggs, 1998; Corsaro, Molinari, & Rosier, 2002; de León, 2000; Eisenberg, 1986). Even more widespread is the use of explicit instruction to socialize young children into valued ways of acting, feeling,

and speaking (P. J. Miller & Hoogstra, 1992). This is one of the reasons we could suggest (in our initial discussion of the custom complex) that the course of progressive development is sometimes from the reflective to the unreflective, from the explicit to the tacit. For example, Watson-Gegeo and Gegeo (1990), found that Kwara'ae (Solomon Islands) parents used a symbolically powerful and emotionally intense discourse, called "shaping the mind," to pass on traditional knowledge and encourage children to practice reasoning and argumentation.

Research on language socialization also has revealed that many of the most powerful socializing messages are implicit and unintended. They are conveyed through tacit routine organizations of time and space, with their associated routines and distributions of social actors, and through contrastive distributions of language forms and functions that index meaning. The implication is that research that depends exclusively on asking caregivers about their socializing goals is likely to miss some of the deepest and most subtle dimensions of socialization—those pervasive and fundamental cultural orderings that feel most deeply natural to participants and are least likely to be reflected on. For example, Western Samoan children begin to learn about the social stratification that pervades their society not only by participating in interactions in which higher status caregivers direct lower status caregivers to care for them but also by observing how caregivers of different rank distribute themselves in domestic spaces (Ochs, 1988).

In addition to establishing that there are diverse pathways to communicative competence, studies of language socialization also demonstrate that children come to embody diverse ways of being in the world. Particularly relevant to cultural psychology are studies that focus on the socialization of affect. Like earlier work (e.g., P. J. Miller & Sperry, 1987; Schieffelin & Ochs, 1986a, 1986b), recent studies show that children are able to express affect through customary communicative means from an early age and that they deploy a wide variety of communicative resources, not just emotion state terms (e.g., Clancy, 1999). Some studies focus on caregivers' styles of affective socialization (e.g., Cervantes, 2002). Others show how culturally salient affective experience—for example, shame for Taiwanese children (Fung, 1999), interpersonal danger for Inuit children (J. Briggs, 1998)—is constituted through children's habitual participation in recurring patterns of discourse.

Welcome as such evidence is for developmental cultural psychology, the project of mapping a landscape of cultural distinctiveness carries with it certain risks. One of the unintended consequences of the first phase of research on language socialization was to essentialize differences across cultures, minimizing variation within culture and across time (Ochs, 1999). Fortunately, an emerging trend in recent research on language socialization is a focus on bilingual and multilingual communities and other situations in which languages and cultures come into contact (Bayley & Schecter, 2003; Garrett & Baquedano-López, 2002). Kulick's (1992) study of language shift and language socialization in Gapun, Papua, New Guinea is a landmark in this respect. Adults in this small-scale society traditionally spoke the vernacular language as well as one or more other languages. However, under the influence of modernization, Gapuners began to valorize the local Creole language. Kulick found that adults unwittingly interacted with children in ways that systematically denied them access to the vernacular language, resulting in its rapid decline. This study not only linked two trajectories of change (historical change and childhood socialization) but also showed that language ideologies linking gender, affect, and language played a critical role in imperiling the vernacular language.

As scholars turn their attention to language socialization in heterogeneous situations, such as changing language policy in nation states, transnational migration, postcolonial settings, and linguistically diverse institutions (e.g., Fader, 2001; González, 2001; He, 2001; Sandel, 2003), they have begun to problematize important ideas. Garrett and Baquedano-López (2002) point out that such studies reveal that the boundaries of language communities are fuzzy, permeable, and shifting; community can no longer be defined as "geography, language(s) spoken, or broad presupposed social categories such as race or ethnicity, but in terms of mutual social and interactive engagement" (p. 347). Such studies underscore the need to know more about how children navigate and interweave multiple languages, meaning systems, and genres, a process that is also gaining attention in studies of narrative.

Narrative: Getting Those Stories Straight

Narrative is a cultural universal, and one of the most powerful interpretive tools that human beings possess for organizing experience in time and for interpreting and valuing human action. The literature on narrative is vast, and the list of topics relevant to cultural psychology is long. These include the relationship between nar-

rative and memory (e.g., Neisser & Fivush, 1994), the role of narrative in the construction of selves and identities (e.g., Bruner, 1990a, 1990b; Gergen, 1991; Holland, Lachicotte, Skinner, & Cain, 1998; Wortham, 2001), narrative as a therapeutic technique in psychotherapy and psychoanalysis (e.g., Polkinghorne, 1988; Spence, 1982), and narrative in family life (Pratt & Fiese, 2004). Children's narratives have been of keen interest to scholars for the light that they shed on linguistic development (Berman & Slobin, 1994), peer culture (Corsaro, 1997; Goodwin, 1990), literacy (e.g., Michaels, 1991; Wolf & Heath, 1992), and classroom life (Dyson & Genishi, 1994; Nicolopoulou, 1997). Faced with this embarrassment of riches, we have chosen, to focus on a single issue: the role of oral narrative in early socialization. This focus maintains continuity with the previous discussion of socialization through discursive practices while allowing exploration of cultural diversity in greater depth.

Varieties of Oral Narrative

Keith Basso (1996) begins his classic paper on Western Apache oral narratives with an interpretive puzzle. What did Western Apache elders mean when they made the following statements:

> Our children are losing the land. It doesn't go to work on them anymore. They don't know the stories about what happened at these places. That's why some get into trouble. (p. 38)
>
> . . . . I recall stories of how it once was at that mountain. The stories told to me were like arrows. Elsewhere, hearing that mountain's name, I see it. Its name is like a picture. Stories go to work on you like arrows. Stories make you live right. Stories make you replace yourself. (p. 38)

Basso's (1996) attempts to understand the significance of these statements yielded one of the most comprehensive accounts available of a group's shared understanding of how oral narrative functions in their lives. Working in collaboration with informants whom he had known for many years, Basso discovered that Western Apache storytelling exploited two symbolic resources—land and narrative—for maintaining the moral order.

Western Apache use stories about the early history of the group to establish enduring ties between individuals and features of the natural landscape. Because of these bonds, people who have behaved improperly are moved to reflect on and correct their misconduct. At times, a member of the community might find it necessary to "aim" a story at an offender. If taken to heart, the story and the place with which it is associated will "stalk" the offender and promote beneficial change.

Basso's study illustrates three issues of plurality that apply to the study of oral narrative as a socializing medium. First, the most obvious is the issue of narrative diversity across sociocultural groups. Basso describes a distinctive cultural case that is sufficiently detailed to allow precise comparison and contrast with other cultural cases. Second, although the study focuses primarily on one type of oral narrative—historical tales—it situates them in the full range of native narrative categories, including myths, sagas, and gossip. The plurality of oral narrative types in the culture is thus established. Third, access to and ownership of narrative genres is socially distributed, introducing another source of intracultural variation.

Storytelling Begins Early

A question left unanswered by Basso's account is how Western Apache narrative practices intersect with children. For example, when do Western Apache begin to aim historical tales at errant children? An exciting trend in recent developmental research is the strong interest in young children's narratives. There is a growing body of evidence that children from many cultural backgrounds within and beyond the United States begin to tell stories in conversation during the second or 3rd year of life (e.g., Eisenberg, 1985; Engel, 1995; McCabe & Peterson, 1991; Meng, 1992; Ochs & Capps, 2001). At this early age, children step into the narrative practices of family and community, thereby laying claim to an important cultural resource for creating their own socialization (Bruner, 1990a, 1990b). Even linguistically isolated deaf children, whose parents choose not to expose them to a conventional sign system, were able to create gestured narratives (Van Deusen-Phillips, Goldin-Meadow, & Miller, 2001). These stories carried echoes of culture-specific meaning, suggesting that conversational narrative is a remarkably robust medium of socialization.

Personal storytelling not only emerges early in life but it also occurs habitually in a wide variety of communities, occurring especially frequently in working-class communities. For example, stories involving 2½-year-olds occurred at average rates of 3 to 4 per hour in both middle-class Taiwanese and middle-class European American families (P. J. Miller, Wiley, Fung, & Liang, 1997; Wiley, Rose, Burger, & Miller, 1998). Narratives accounted for one-quarter of 2-year-olds naturally

occurring talk in working-class African American families in the Black Belt of Alabama (Sperry & Sperry, 1995, 1996). In working-class European American families in Chicago, 3-year-olds participated in co-narrations at the remarkable rate of 6 times per hour (Burger & Miller, 1999). When personal storytelling occurs so abundantly, it gets woven, densely but almost invisibly, into the fabric of young children's social experience.

Moreover, regardless of where they occur, these small, mundane stories are saturated with value and replete with culturally patterned messages. Stories vary within and across cultures along a host of parameters that encompass how the genre is defined and practiced (P. J. Miller & Moore, 1989). For example, in her classic ethnography of neighboring working-class communities in the Piedmont Carolinas, Heath (1983) found that the European American residents of Roadville adhered to a criterion of literal truth when narrating their personal experiences. This contrasted with the African American community of Trackton, who strongly favored fictional embellishment. Trackton and Roadville also enacted opposing norms toward and away from self-aggrandizement. Trackton children not only created bold and triumphant self-protagonists but also asserted their rights to tell stories by adroitly working their way into adult talk, commanding the floor, and receiving approbation for their verbal artistry.

In their study of an African American community in rural Alabama, Sperry and Sperry (1995, 1996) found that 2-year-olds produced more fantasy stories than factual stories of past experience. "Both caregivers and children enjoyed telling stories of escaping from 'Nicoudini,' the 'Boogabear,' 'Werewolf', or the spectral deer who entered their home one misty evening. Families told such stories easily and frequently, and children gathered around to be thrilled by the imagined terror and to practice creating it themselves" (p. 462; Sperry & Sperry, 1996). Boys' efforts to tell fantasy stories received much more support than girls', a finding that may help to explain how men in this community get to be so good at "tall-bragging."

P. J. Miller, Fung, and their colleagues compared middle-class Taiwanese families in Taipei and middle-class European American families in Chicago and found that in both cases narrators interpreted young children's past experiences in interpersonal terms, situating the child in relationship to other people (P. J. Miller et al., 1997; P. J. Miller, Fung, & Mintz, 1996). At the same time, personal storytelling differed dramatically: Taiwanese families were much more likely than their European American counterparts to tell stories in which they cast the child protagonist as a transgressor. In keeping with local beliefs that parents should take every opportunity to correct young children, many of these stories occurred immediately after the focal child had committed a misdeed in the here and now. Families repeatedly invoked moral and social rules, structured their stories to establish the child's misdeed as the point of the story, and concluded their stories with didactic codas. By contrast, the European American families enacted a self-favorability bias, erasing or downplaying children's misdeeds. These differences were also evident in parents' beliefs about storytelling (P. J. Miller, Sandel, Liang, & Fung, 2001) and in pretend play (Haight et al., 1999).

Wang, Leightman, and colleagues compared stories elicited from Chinese and European American children and reported similar findings. Chinese mothers from Beijing showed a greater concern with moral rules and behavioral standards when co-narrating stories with their 3-year-olds (Han, Leichtman, & Wang, 1998; Wang, Leichtman, & Davies, 2000), and 6-year-olds told stories exhibited a parallel concern with moral correctness (Wang & Leichtman, 2000).

Thus, although personal storytelling is a rich purveyor of values for European American children, the version of personal storytelling practiced by the Taipei and Beijing children leans more strongly in a didactic direction, reflecting and reinforcing larger systems of meaning that privilege moral education. Fung, Miller, and Lin (2004) link this didactic bias to Confucian discourses that valorize teaching, listening, and self-improvement, discourses that continue to circulate in the complex mix of local and global influences that are reshaping childrearing and education in contemporary Taiwan. Li (2002) found that Chinese college students viewed learning as a moral process, imbued with purpose, undertaken according to the virtues of diligence, persistence, and humility, and encompassed by the larger project of self-perfection, but American college students saw learning as a neutral, mental process of knowledge acquisition. The stories told by the Beijing children and their mothers share a similar moral cast.

In sum, studies of children's early storytelling in families and communities demonstrate that this narrative genre is culturally differentiated from the beginning. Wherever personal storytelling is practiced with young children, it takes on local color, absorbing values, affective stances, and moral orientations. As children

participate routinely in personal storytelling, they begin to carve out different versions of personal experience. Personal storytelling thus highlights—and is implicated in—an early developmental moment in the co-creation of person and culture. Particular frameworks of evaluation and interpretation, linked to larger currents of cultural meaning, operate again and again in oral stories, while narrators and listeners create and respond to here-and-now social contingencies. Each co-narrated story, each story aimed at or told around the child provides another opportunity for the child to hear which experiences are reportable and how these experiences should be assessed. In this way, interpretive frameworks are not only reproduced but also repeatedly instantiated in personally relevant terms. To return to the comparisons between European Americans, on the one hand, and Taiwanese or Chinese, on the other, we catch a glimpse of how culturally distinct selves might originate. A need for positive self-regard may be rooted, in part, in storytelling that is systematically biased toward self-favorability, whereas an inclination to self-improvement may be rooted, in part, in the narration of misdeeds and the explicit invocation of moral standards (see the following section: "The Development of Self").

Although comparative studies, informed by local practices and understandings, are necessary for identifying these kinds of divergent developmental pathways, again we emphasize that it is important not to dichotomize such differences, erasing similarities across groups and variations within groups. Evidence is accumulating, for example, that personal storytelling is especially rich in gendered meanings (Nicolopoulou, 1997; Ochs & Taylor, 1995). Again, this differentiation is apparent early in development. Fivush and her colleagues found that middle-class European American children's oral narratives are gendered in numerous ways during the preschool years and beyond. For example, when asked to elicit stories from their young children about specific emotions experienced in the past, mothers co-constructed more elaborate stories about sadness with their daughters than with their sons (Fivush, 1993). Similar findings emerged when fathers served as co-narrators. Even when parents were asked to talk with their children about novel past events (without being asked to elicit talk of specific emotions), mothers and fathers narrated more emotion events with their 3-year-old daughters, compared with their sons, and this contrast was especially marked for sad events (Kuebli & Fivush, 1992). From these and other studies, Fivush and Buckner (2000) conclude that by the end of the preschool years, girls talk much more about sadness than do boys, and that such talk occurs both with parents and friends, possibly contributing to girls' vulnerability to depression.

Variability and Heterogeneity

In addition to these ways in which early narrative varies in and across cultures, a practice approach to narrative reveals even more sources and dimensions of variability. Ochs and Capps (2001) developed a dimensional approach to conversational stories of personal experience, arguing that personal narrative oscillates between the narrators' desire for coherence and their desire for authenticity, but that research has tended to privilege the former. The "default" story involves one active teller, crafting a linearly sequenced, coherent account of a highly tellable event. Such stories are framed by a constant moral stance and are easily detached from surrounding discourse. Researchers should not assume that this default version of storytelling is the only adult model or endpoint of development. Ochs and Capps propose that development proceeds along two lines. Children become able to report norm violations and to produce temporally ordered, coherent narratives; at the same time they learn to use stories in a nonlinear manner to puzzle over events and weigh alternatives.

Ochs and Capps (2001) draw attention to a variety of overlooked or understudied aspects of storytelling that could enrich cultural psychologists' understanding of narrative as a socializing medium. How do children use narratives for problem solving; expressing, negotiating, or failing to negotiate divergent points of view; grappling with moral dilemmas; pondering hypothetical scenarios; envisioning the future? How are children's stories embedded in surrounding discourse and activity? What participant roles are available to children?

Much of the developmental research on preschoolers' stories has focused on children as co-narrators, producing stories about their experiences in collaboration with parents or other family members. Less is known about children as listeners, recipients, overhearers, and eavesdroppers. By way of illustrating the importance of these other participant roles, consider two examples. In the working-class community of South Baltimore, adults and older children told a great many stories of personal experience to one another (P. J. Miller, 1994). Young children were present as bystanders to these stories, free to tune in or not. Many of these stories fell toward the

default end of the continuum highlighted by Ochs and Capps (2001) and were highly performed, riveting accounts, ranging from the hilarious (e.g., the bathtub fell through the floor with Aunt Sharon in it) to the harrowing (e.g., violent encounters in school or on the street). This activity not only modeled narrative virtuosity but also provided curious youngsters with a constantly updated source of information about the lives of significant others, including their mothers' experiences of school, workplace, and male-female relations.

Whereas this study illustrates what a rich and varied socializing medium stories around the child can be, C. E. Taylor (1995) offers a rare, penetrating analysis of how keenly children listen to stories told around them. In one case study of a middle-class family, the 5-year-old sister and 8-year-old brother were initially silent when their parents engaged in narrative conflict at the dinner table. Eventually, the sister protested that the parents were fighting, a concern that they dismissed and rationalized as the conversation continued to unfold. This study not only shows how carefully children monitor adult discourse but also serves as a powerful reminder of two other important points: family narrative is sometimes unfriendly and threatening, exacerbating rather than solving problems, and children are socialized as much by the relationships that participants enact—in this case, parental conflict—as they are by the content of stories.

In her analysis, C. E. Taylor (1995), like several of the scholars mentioned in this section of the chapter, borrowed ideas from Mikhail Bakhtin, the Russian literary scholar and philosopher of language. His vision of language as culturally shaped and socially situated is compatible with the conception of language described earlier (Bakhtin, 1981; Wertsch, 1991). Bakhtin (1986) stressed that speech is organized into genres associated with particular speech situations. He argued that speech is never free of generic constraints but that speakers can achieve individuality of expression by creatively appropriating, combining, and reaccenting existing genres. As researchers apply Bakhtinian constructs to the analysis of children's discourse, it is becoming clear that narrative sense-making involves juxtaposing and interweaving multiple, even conflicting voices and ideological perspectives and that every community affords such heterogeneity (e.g., Cazden, 1993; Dyson, 1993; Hicks, 1994; Tobin, 2000; Wertsch, 1991; Wortham, 2001).

This perspective not only underscores the importance of studying children's narrative repertories (e.g., Preece, 1987; Sperry & Sperry, 1995) but also draws attention to the many ways in which stories are embedded in, are blended with, or otherwise keep company with other stories, other genres, and other activities. For example, ethnographic studies have shown that oppositional talk is an important means by which working-class African American children of various ages construct identities, form friendships, and sustain peer culture and that narratives are often incorporated into oppositional talk as a way of instigating disputes and projecting conflicting points of view (e.g., Goodwin, 1990; Shuman, 1986). The preschooler studied by Corsaro et al. (2002) was already adept at this kind of talk and collaborated with her Head Start peers in producing pretend scenarios that drew on both oppositional and narrative elements. Fung and Chen's (2001) study of the socialization of shame in Taiwanese families revealed that naturally occurring events of shame included multiple episodes and traversed multiple temporal and spatial worlds. Young children were led to relive and reflect on present and past transgressions and to prepare for a better self in the future. Both of these studies suggest that stories do not necessarily come neatly packaged and clearly bounded in children's everyday experience. Rather, stories are embedded in and overlap with other genres in heterogeneous and shifting configurations that illuminate again and again particular threads of meaning for young participants.

The Dynamics of Narrative Practices

Thus, when narratives are treated as situated practices, rather than disembodied texts, it becomes apparent that storytelling is a dynamic process, emerging from particular circumstances, shaped by the interests of narrating participants, recurring in different combinations, and affording children a range of participant roles. Children engage repeatedly in networks of narrative practices, characterized by systematic variability and cross-cutting redundancies. As argued earlier, this is one of the means by which persons and cultures are cocreated. However, narrative is also a means by which individuals affect change and transform identities (Holland et al., 1998; Wortham, 2001).

The dynamic nature of narrative practices is especially apparent when narrators tell the same story repeatedly. Such stories can play a critical role in the lifelong process of socialization. Adults may be haunted, baffled, or sustained for decades by stories from their own or others' lives (e.g., Coles, 1989; Fung,

2003; Gone, 1999; Hudley, Haight, & Miller, 2003; Steedman, 1986). As the person tells the story repeatedly to self and other, it accrues layer on layer of meaning and may be used to reinforce favored interpretations or to construct new interpretations. Repeated tellings and reinterpretations of personal experience are institutionalized in psychotherapy, Alcoholics Anonymous, and religious conversion (Holland et al., 1998; Stromberg, 1993). Children as young as 2 years of age develop intense attachments to particular stories, revisiting them again and again for weeks, months, and even years (e.g., Alexander, Miller, & Hengst, 2001; P. J. Miller, Hoogstra, Mintz, Fung, & Williams, 1993; Nelson, 1989; Wolf & Heath, 1992). The middle-class European American children in these studies treated their special stories as resources for discussion and pretense and used them to ponder problems and manage emotions, activities that were supported by parents. These studies suggest that from the time young children enter into narrative sense-making, they have the capacity to respond differentially to the ordinary narrative flow, seizing certain stories for especially active and intense engagement.

Studies that trace the natural history of stories in children's lives are rare. This is unfortunate for cultural psychology because the process of retelling and revising stories goes to the heart of the socialization process. It is assumed to be transformative in theories ranging from psychoanalysis to the Western Apache model of historical narrative. We need especially to know more about how stories operate over the long term in children's lives.

Again, the Western Apache provide a compelling example. Basso (1996) relates an incident in which an adolescent girl arrived at a ceremonial in hair curlers, a violation of community standards. Some weeks later, when the girl was attending a party at her grandmother's house, the grandmother narrated a historical story about an Apache policeman who suffered dire consequences because he had acted too much like a white man. At the conclusion to the story, the girl left the party. When questioned by Basso, the grandmother explained her granddaughter's sudden departure by saying that she had shot her with an "arrow." Two years later, the young woman told Basso that she threw her curlers away after reflecting on her grandmother's story. Referring to the place where the Apache policeman had lived, she said, "I know that place. It stalks me everyday" (Basso, 1996, p. 57).

THE DEVELOPMENT OF SELF

As noted earlier, the psychological side of cultural psychology is the study of the things that the "I's" (the subjects, agents, or selves) of particular cultural communities know, think, feel, want, and value, including what they know, think, feel, want, and value about the self as a mental being capable of subjective experiences and of participation as an agent in a cultural community. A powerful way in which culture and psyche constitute each other and come to influence individual behavior, we believe, is through our way of being a subject or agent in a social world—what is often called *self-functioning*.

Indeed, the self can be conceptualized as a primary locus of culture-psyche interaction and culture-specific being (see Baltes, Lindenberger, & Staudinger, Chapter 11, this *Handbook,* this volume). It is where the individual, a biological entity, becomes a meaningful entity—a person, a participant in social worlds (P. J. Miller, 1994; Rogoff, Radziszewska, & Masiello, 1995; Weigert, Teitge, & Teitge, 1990). Developing a sense of self as an agentic, continuous entity with intentional powers may appear to arise from highly personal idiosyncratic experiences: A European American self is indeed defined to be individualized and distinct from other selves. Studies highlight, however, that although the experience, structures, and processes of self appear to be primarily individual creations, they are also cultural and historical constructions (Markus & Kitayama, 2003; J. G. Miller, 2003; Oyserman & Markus, 1993).

Before discussing the cultural psychology of the self, we must acknowledge some of the issues and controversies arising in this area. Several trends in philosophy, the social sciences, and world affairs have converged on self and identity as popular topics for research. Perhaps most obviously, as the headlines of any newspaper confirm, nationalism and a concern for maintaining and asserting ethnic or cultural identity are now emerging as a powerful focus in Eastern Europe, the Middle East, Africa, and Asia. In this climate of heightened ethnic identification and conflict, we can no longer afford to ignore the role of cultural practices and mentalities as sources of personal and social identity or the role of self-management and self-regard in all aspects of social life, particularly social conflict (e.g., Crocker, Major, & Steele, 1998; Kakar, 1996).

Perhaps less obviously, certain eternal disputes about the character and causal role of personal identity

in psychological functioning have resurfaced. Several quite disparate currents of thought, including skeptical postmodernism, connectionist-parallel distributed process models in artificial intelligence, and Buddhist philosophical thought (Elster, 1987; Gergen, 1991; Sass, 1992; Varela, Thompson, & Rosch, 1993) have concluded that the self is illusory or epiphenomenal and plays no causal role in mental functioning, whereas other have argued that the self is "multiple" or "protean" (Lifton, 1993).

We will not debate here whether the Buddhists are right that the self is an illusion or whether the Hindus are right that the self is the real component of pure being. We will simply note that the very existence of human social and moral life seems intimately tied up with the evolution of a species whose central psychological makeup is defined by the existence of a causally active and somewhat unitary self ("One self per customer," to use the philosopher Daniel Dennett's phrase; Flanagan, 1992): A self that is free, willful, self-regulating, morally responsible, and conscious; that is the initiator of action, author of texts, holder of rights; and that is the subject of evaluation and social scrutiny when questions about rationality, responsibility, normality, and pathology arise.

Putting aside "epiphenomenalism" (the self as unreal), the choice between "mechanistic" and "vitalistic" conceptions of self seems uninviting (see Kapstein, 1989). Contemporary mechanistic approaches to personal identity argue that our sense of self (e.g., our sense of continuity over time) results merely from the continuity of our memory for discrete mental states (perceptions, pleasure, and pain). Contemporary vitalistic approaches argue that our sense of self is prewired into the human brain. Neither view leaves much room for social, interpersonal, or cultural processes in the construction and maintenance of personal identity.

Perhaps versions of these approaches can be made compatible with cultural psychology, which asserts that the self is not fully reducible to either memory or brain processes. A cultural psychology approach to personal identity examines the part of our sense of self that develops through membership in some local cultural community and symbolically mediated experiences with its practices. This approach examines the effects of labeling and stereotyping, dialogue and narrative, as well as moral agency and social practice on self-functions such as self-regard, self-confidence, and self-definition. It looks at how the self is described, responded to, evaluated, and often regulated by others. Although cultural psychologists acknowledge that the "I" (the subject) is never fully determined by groups' hegemonic ideologies or interpersonal forces alone, they aim to clarify the ways cultural mentalities and practices (including ideologies of the self and symbolic products such as biographies of community exemplars) can powerfully constitute an individual's sense of self.

A cultural psychology perspective furthers our understanding of a self's development by emphasizing that particular ways of representing and being a self, both as object and subject of experience, are grounded in normative understandings and behavioral routines of selfhood in a given sociocultural and historical context (Benson, 2001; Murphy-Berman & Berman, 2003; Oyserman & Kemmelmeier, 1995; Oyserman & Markus, 1993).

From the perspective of cultural psychology, the self is grounded in the mentalities and practices (the custom complex) associated with being an "I" (a subject) in a particular community. Revisiting the insights of some of the field's early theorists (e.g., Dewey, 1938; Erikson, 1968) reveals that culture does not merely surround or cover the "universal" child but rather that culture completes the child (Bruner, 1990a, 1990b; Tomasello, 1999). Culture provides the scripts for "how to be" and how to participate as a member in good standing in the cultural community and particular social contexts. Simultaneously, cultural psychologists recognize that children and adults actively constitute their own cultures, initiating changes in their relations with others and thus in their immediate cultural settings (see Brandtstädter, Chapter 10; Rathunde & Csikszentmihalyi, Chapter 9, this *Handbook,* this volume).

DEFINING AND LOCATING THE SELF AS DYNAMIC, MULTILEVEL, AND MULTIFACETED

The self can be defined as a multifaceted, dynamic system that regulates and mediates behavior (Banaji & Prentice, 1994; Markus & Wurf, 1986). Neisser (1988, 1991) explicitly constructs the self as a multileveled entity, defining five types of self-knowledge: (1) ecological, (2) private, (3) interpersonal, (4) conceptual, and (5) what he labels "extended" (i.e., knowledge of the self over time). Neisser contends that regardless of differing locations or beliefs, people are active, embodied

agents in the natural and social environments, and thus show evidence of ecological and interpersonal selves (Neisser & Jopling, 1997).

This multileveled self is believed to be broadly consequential for individual experience: It provides the blueprint, frame, and foundation for the psyche. Whatever cultural form it assumes, a subject's way of being a person affords and constrains what he or she feels, values, assumes responsibility for, perceives and thinks about, as well as how he or she organizes, understands, and gives meaning to any experience.

The past decade has seen rapidly increasing interest in the nature, functioning, and development of self, and much noteworthy theoretical activity. Several themes can be identified that raise challenging questions about what a self is, how to determine who has one, as well as how and when the self emerges, functions, and develops. Many researchers advocate analyzing the self as not only an object of knowledge but also the subject of experience. Attention to the embodied self, to the role of intersubjectivity in constructing the self, to the situation, context, or niche in which the self participates and to the self as socially engaged rather than isolated or decontextualized is needed (Cole, 1999; Crook, 2003; Harter, 1996; Higgins & Parsons, 1983; Stern, 1985; Tomasello, Kruger, & Ratner, 1993). Cultural psychology research forcefully underscores such issues' importance and raises many complementary concerns (e.g., Greenfield & Cocking, 1994; Valsiner, 1988).

The Conceptual Self

The self has been variously defined as the insider's grasp on the person, as the answer to the "who am I" question, and as a theory or set of schemas that provides the individual with a sense of continuity. The focus has been on the self as object of knowledge (Allport, 1937; Eder & Mangelsdorf, 1997; Epstein, 1973; Kihlstrom & Cantor, 1984; Sullivan, 1940). Historically, despite many theoretical statements to the contrary, the tendency has been to reify the self and regard it as a thing, as exemplified in thousands of studies on *the* self-concept, *the* self, or self-esteem.

Research on the development of self has tended to concentrate on what Neisser labels "the conceptual self." Given the general European American tendency to imagine the mind as the source of experience and thus equate selves with minds, the emphasis on how children think about and represent the self is perhaps obvious. From this theoretical perspective, the self becomes an object of knowledge and it becomes natural to imagine that the self as represented or the *self-concept* is the most significant aspect of individual experience.

In research on development of the self-concept, the critical indicator of the self has been visual self-recognition as assessed by mirrors and photographs. Summarizing the work in this paradigm, Bullock and Lütkenhaus (1990) conclude that self-recognition begins between the ages of 9 and 16 months and by 2 years of age, most children recognize themselves in the mirror and photographs. Some (e.g., M. Lewis, Sullivan, Stanger, & Weiss, 1989) have argued that self-awareness requires such self-recognition. Other studies have examined speech for cognitive representations of self. During their 2nd and 3rd years, children begin to use their name, the pronouns "I" and "me," and possessively claim objects as theirs (L. E. LeVine, 1983; Van der Meulen, 1986).

The idea that thinking about the self is the main element of self is also underscored by a large collection of studies that have explicitly tied the development of self to advancing cognitive capacities (Leadbeter & Dionne, 1981; Leahy & Shirk, 1985; Montemayor & Eisen, 1977; Rosenberg, 1986). Many studies based on the Piagetian model of cognitive development have shown that as a child advances from preoperational thought to formal operations, the focus of self-definition shifts from concrete, objective, and visible characteristics to abstract, private features of the psychological interior. A widely cited review by Harter (1983) notes:

> Young children focus on concrete, observable aspects of self such as physical attributes and behaviors, whereas older children increasingly couch their self-descriptions in terms of traits. With adolescence, there is a further shift toward the use of abstractions and psychological processes such as thoughts, attitudes, and emotions in defining the self. (p. 305)

Still other studies have shown a link between the level of cognitive development and characteristics of the self-concept such as hierarchical organization, integration of opposing conceptions of the self, and the stability of self-conceptions across time and context (see Harter, 1990; Rosenberg, 1986, for reviews).

Indeed, studies with people living in European American contexts demonstrate that such self-concepts exist. These self-concepts include images and conceptions of the person in the present but also in the past and

in the future—narratives of what could have been and what might be (Higgins, 1990; Markus & Nurius, 1986; Oosterwegel & Oppenheimer, 1993). This self-concept is also functional: It mediates behavior and is implicated in all aspects of behavior from strong academic and athletic performance to general well-being and life satisfaction. A negative self-concept of this type is related to delinquency, drug use, and depression (for a review see Bracken, 1996).

The Cultural Self

A cultural psychology approach emphasizes the need to analyze more extensively the experience and understanding of self and to examine critically the cultural presuppositions implicit in much research on the development of self. As stated earlier, the cultural psychology approach to development is skeptical of most attempts to universally define progressive development using abstract criteria, for instance, from behavior to traits or from context-dependent to context-free.

In studies of selves in non-European American cultural contexts, one quickly confronts selves that are not easily characterized by complex mental representation of traits, attributes, preferences, or possessions. It becomes evident that studies on the development of self have proceeded primarily from one cultural viewpoint and drawn on a set of invisible and untested assumptions about the self as an idea or as an objectified and cognitively represented entity.

Comparative research in other cultural communities suggests that selves are not primarily more-or-less stable concepts at all but rather a set of processes or ways of being. Moreover, in some groups, a description of self or others in terms of internal, decontextualized attributes or qualities simply does not occur (Fajans, 1985; Hart, Fegley, Hung Chan, Mulvey, & Fischer, 1993; Lillard, 1996; J. G. Miller, 1984; Ochs, 1988; Rosen, 1995; Shweder & Bourne, 1984). Hart and Edelstein (1992) describe a study conducted with adolescents in Iceland in which one student struggled mightily to answer the "who am I" question and finally in despair looked up from his blank questionnaire and asked, "Are people meant to have these kinds of thoughts about themselves?" In many cultural communities, the nature of self is referenced not to an internal self but instead to a particular social context and characterizing a self outside that context is unnatural and irrelevant.

Goodnow (1990a, 1990b) has argued that cognitive development involves learning the community's definition of being intelligent. Similarly, developing a self requires incorporating the community's definitions of being a self. Once self-development is considered in cultural context, it is almost immediately apparent that what a self is and what it means to be an acceptable or good self can vary dramatically from one cultural place to another (Markus & Kitayama, 1991b; Shweder & Bourne, 1984). As C. Taylor (1989) has argued:

> My self-definition is understood as an answer to the question Who am I. And this question finds its original sense in the interchange of speakers. I define who I am by defining where I speak from, in the family tree, in social space, in the geography of social status and functions. We first learn our languages of moral and spiritual discernment by being brought into an ongoing conversation by those who bring us up. The meanings that the key words first had for me are the meanings they have for us, for me and my conversation partners together. So I can only learn what anger, love, anxiety, the aspiration to wholeness, and so on are through my and others' experience for us in some common place. (p. 35)

THE ONTOLOGICAL BASIS OF SELF

The study of self in psychology, as with many aspects of child development, has incorporated the European American definition of being a person and has been firmly rooted in the ontology of individualism (Greenfield & Cocking, 1994; Ho, 1993; Markus & Kitayama, 1994a; Sampson, 1988). This ontology is extensively incorporated in most child-care practices and the main societal institutions such as schools.

The Person as an Individual

The Latin word "individual" means indivisible and whole, and the central tenet of individualism is the epistemological priority accorded to the separate, essentially nonsocial, individual. The person is assumed to exist independently and to enter into social relations based on need and by mutual consent with other individuals. The focus is on the individual rather than on the social unit of which the individual is a part. The person is cast as an entity whose behavior is determined by some amalgam of internal attributes apart from the external situation.

Individualism is typically analyzed as the critical element of Western society (e.g., Baumeister, 1987; Car-

rithers, Collins, & Lukes, 1987; Guisinger & Blatt, 1994; Sampson, 1985; Triandis, Bontempo, & Villareal, 1988), and many analysts argue that the Enlightenment gave birth to the notion of the Kantian individual and the importance of individual reason and free will. Others suggest that individualism shows the stamp of late industrial capitalism or results from a Cartesian categorization system that draws a sharp distinction between the self and others (Lebra, 1992).

In the framework of individualism, it seems natural to assume that selves are objects and should be unified and integrated, reflecting but not focusing on the concerns of others. Thus, a child's central task is to progressively realize that he or she is separate from others and autonomous, efficacious, in control of his or her actions. The idea of a bounded individual separate from and not unduly influenced by others also leads to a consistency ethic in which a good or authentic self is the same, unchanging self across different situations. (See Fiske, Kitayama, Markus, & Nisbett, 1998; Gergen, 1968; Johnson, 1985; Markus & Kitayama, 1994b; Morris, 1994; Shweder & Bourne, 1984, for a more elaborate discussion.)

The literature on the development of self is also replete with unexamined presuppositions that reflect individualism interwoven with other cultural and historical assumptions. In this literature, interest persists in being a true rather than a false self, which probably echoes Victorian concerns with secret or hidden parts of the self (Baumeister, 1987; Harter, 1986). Currently, there is also pervasive attention to raising children who feel good about themselves and have high self-esteem, aims that derive from societal appropriation of expressing rather than inhibiting feelings, actualizing the self, and fulfilling our potential (Maslow, 1954). The literature on self development also incorporates presuppositions about what type of parenting practices produce these proper or good selves. Thus, the child with high self-esteem is believed to be a product of accepting and approving parenting that highlights a child's successes rather than failures (e.g., Coopersmith, 1967; Heine, Lehman, Markus, & Kitayama, 1999).

The Person as Relational

The individualist model of self that provides the infrastructure for the field's understanding of self is an obvious, natural model for European American researchers. This model is rooted in a set of Western philosophical positions about human nature and in layers upon layers of practice and institutions that give it an objective reality. This model is indeed powerful and practical for characterizing selves in European American contexts, but it is not the only model of how to be. Other ontologies and ideologies of human nature exist that are as yet unrepresented in the literature on the development of self. Analyzing the self in cultural context brings these other ontologies and ideologies of self to light.

Another model of self contrasts significantly with individualism and is pervasive throughout Japan, China, Korea, Southeast Asia as well as much of South America and Africa (Triandis, 1989). According to this perspective, the self is not and cannot be separate from others or the surrounding social context, but is experienced as *interdependent* with the social context: the self-in-relation-to-other(s) is focal in individual experience (Markus, Mullally, & Kitayama, 1997; Triandis, 1989, 1990). According to Kondo (1990), the self is fundamentally interdependent with others from a Japanese perspective, and understanding this Japanese sense of self requires dissolving the self-other or self-society boundary that forms such an obvious starting point in European American formulations.

An important imperative in this alternative way of being is to avoid becoming separate and autonomous from others and, instead, to fit in with others, to fulfill and create obligations and, in general, to become part of various interpersonal relationships. Individuals are naturally understood to exist interdependently with others. Sharing, interweaving, or intersubjectivity is the established cultural rule, not a mystical or magical project (Ames, Dissanayake, & Kasulis, 1994). From this perspective, the individual is an open, communicating center of relationships and thus is intimately connected with other selves. From a Confucian perspective, groups are not separate from individuals. The nature of individuals is to work through others, and to reveal themselves, they must be parts of groups such as families, communities, and nations (Tu, 1994). Moreover, sources of action are found in a person's pattern of involvements with others, rather than internal mental states or processes.

An interdependent view of self does not, as might be imagined from a European American perspective, result in a merging of self and other, nor does it imply that people lack a sense of themselves as agents originating their own actions. This interdependent view requires a high degree of self-control, self-discipline, and agency to effectively adjust oneself to various interpersonal contingencies. Control, however, is directed primarily to

personal desires, goals, and emotions that can disturb the harmonious equilibrium of interpersonal transaction.

This understanding of self stands in contrast to a European American notion of control that entails asserting our desires, goals, and emotions, and attempting to change features of the social situation. Hamaguchi (1985) for example, reports that for Japanese the "straightforward claim of the naked ego" (p. 303) is experienced as childish. Self-assertion is viewed as a sign not of authenticity, but instead of immaturity. This point is echoed in M. I. White and LeVine's (1986) description of the meaning of *sunao,* a term Japanese parents use to characterize what they value in children:

> A child that is sunao has not yielded his or her personal autonomy for the sake of cooperation: Cooperation does not suggest giving up the self, as it may in the West: It implies that working with others is the appropriate way of expressing and enhancing the self. Engagement and harmony with others is, then, a positively valued goal and the bridge—to open-hearted cooperation. (p. 58)

Being responsive to or influenced by others does not indicate inconsistency or false selves at work; rather, it reflects tolerance, self-control, flexibility, and maturity. In many Asian perspectives, children are assumed to be both naturally good and capable of developing the needed sensitivity to and empathy for others through encouragement and example. The good child is believed to be a product of highly responsive parenting practices attuned to the child.

Nevertheless, good parenting does not ignore a child's failures, shortcomings, or transgressions. In Japan, children are encouraged to engage in self-reflection and self-criticism as necessary steps to self-improvement and mastery (e.g., C. C. Lewis, 1995). Similarly, Chinese parents often use an explicitly evaluative, self-critical framework with their children as opposed to an overtly self-affirming one (P. J. Miller et al., 1996). Chinese caretakers claim that shaming as a caretaking practice keeps children from falling into disgrace or losing their all-important connection to others.

Much more could and must be said about these apparently startling differences in ontological assumptions, to which we are alerted when we conduct research in other cultural communities. A comprehensive investigation would not merely contrast "individualism" and "interdependency," but also draw on other ontologies that must exist on a worldwide scale. Nor should we imply a lack of variability in Japanese, Chinese, or Korean populations. We simply underscore that comparative research reveals divergent views of what the self is and should be on a worldwide scale, and that these views critically underpin self-relevant experiences.

If the self functions as an interpretive, integrative, or orienting framework for individual behavior, then whether one has a self shaped by prevalent European American or Asian ontological traditions can matter greatly for individual psychological processing. Comparing behavior constructed in a European American individualistic frame to behavior constructed in other cultural frames may illuminate how cultural processes are implicated in the etiology, nature, and functioning of psychological systems, and how "multiple, diverse psychologies" arise.

CULTURAL DIVERSITY IN WAYS OF BEING

Much of the rapidly expanding literature relevant to cultural variation in the development of self does not focus directly on the nature and functioning of the psychological self system as it has been operationalized in American and European studies. Nevertheless, such comparative literature is pertinent to research on the origins of culture-specific selves.

In examining the culture-specific nature of selves, Markus et al. (1997) have described the custom complexes associated with being a person. They suggest that cultural and social groups in every historical period are associated with characteristic patterns of sociocultural participation or, more specifically, with characteristic ways of being a person in the world, which they call *selfways.* Selfways are patterns or orientations, including ways of thinking, feeling, wanting, and doing, that arise from living one's life in a particular sociocultural context structured by certain meanings, practices, and institutions. People do not live generally or in the abstract: They always live according to some specific, substantive set of cultural understandings (goals, values, pictures of the world). Selfways thus include important cultural ideas, values, and understandings of what it means to be a self and how to be a good self. Selfways, however, are not just matters of belief, doctrine, or ideology, but are also manifest in everyday behavior, language practices, patterns of caretaking, schooling, religion, work, the media, and social episodes, both formal and informal.

The notion of selfways implies that every sense of self will be grounded in some shared meanings and customary practices and will necessarily bear some meaningful resemblance to similarly grounded selves. From

this perspective, to act, live, or function well in a given culture means practicing the underlying cultural views of how to be. Thus, although any two American selves will obviously differ in countless ways, as will any two Japanese selves, cultural participation in either current American or Japanese practices and institutions will produce some critical similarities.

Speaking probabilistically and in central tendencies, culturally acceptable European American selves are likely to be (a) separate, bounded, stable, and consistent; (b) attribute-based (e.g., based in traits, preferences, goals); (c) clear, confident, articulated, elaborated; (d) in control; (e) different from others and uniqueness-oriented; (f) particularly sensitive to positive regard, self-enhancing; (g) success-oriented; and (h) expressive and enthusiastic. Culturally acceptable East Asian selves are likely to be (a) connected; (b) context-based; (c) relational, flexible, malleable, responsive to others' expectations, preferences, and feelings; (d) similar to others and concerned with fitting in; (e) particularly sensitive to potential inadequacy, self-critical; (f) improvement- and mastery-oriented; (g) open, receptive; and (h) fully engaged.

From the moment of birth (and even earlier in some cultural contexts), individuals are given meaning and engaged as persons. Through this cultural participation, they become selves. An infant's mentality or way of being in the world is thus patterned according to the meanings and practices of a given cultural community, and the communities, in turn, are maintained by these mentalities. A continuous cycle of mutual attunement and coordination connects psychological tendencies with the social realities on which these tendencies are brought to bear. From our perspective, features of the cultural system, such as the characteristic ways in which one is led to focus on and attend to others, can become directly incorporated into individual systems of experiencing and organizing the world. They become selfways. As Ingold (1986, 1991) characterizes it:

> Like organisms, selves become, and they do so within a matrix of relations with others. The unfolding of these relations in the process of social life is also their enfolding within the selves that are constituted within this process, in their specific structures of awareness and response—structures which are, at the same time, embodiments of personal identity. (p. 367)

In the following section, we briefly review studies relevant to how selfways develop through cultural participation in the custom complexes characterizing European American and East Asian cultural contexts. We aim to highlight the diverse selfways that develop from such participation. Most of the recent research has focused on a contrast between patterns of cultural participation that construe the person as an independent, autonomous entity and those that construe the person as an interdependent part of a larger social unit. Some researchers suggest that variations on the interdependent pattern characterize about 70% of the world's population (Greenfield & Cocking, 1994; Triandis, 1989).

Selfways in Some European American Contexts

Speaking generally and probabilistically, the European American middle-class cultural region is characterized by selfways that promote independence of the self. Being a European American person requires the individualizing of experience. A person's subjectivity is sensed as a more-or-less integrated whole, configured by attributes and values distinct from others' or society's (see Geertz, 1984). The self is experienced as the individual's meaningful center and is understood to be rooted in a set of internal attributes such as abilities, talents, personality traits, preferences, subjective feeling states, and attitudes. A major cultural task often mutually pursued by caretakers, friends, and teachers is to continually, progressively individualize the child. As researchers become aware that conceptualizing the self as an object and describing one's self in abstract psychological terms are culture-specific tendencies rather than consequences of general cognitive development, they can investigate practices that afford these tendencies.

Despite an explicit cultural emphasis on being nice and caring and helpful (Bellah, Madsen, Sullivan, Swidler, & Tipton, 1985; Deci & Ryan, 1990), development in the European American style is almost synonymous with individualizing and decontextualizing the self. Even as people seek and maintain interdependence with others—social tasks that must be accomplished everywhere—they will maintain a sense of boundedness, relatively greater separation from others, and being in control. Caring, connecting, and relationality will likely assume a more individually agentic form. Many cultural practices that contribute to a sense of agency are so much a part of everyday, domestic life that they are, for all practical purposes, invisible.

In many English-speaking cultural communities, language use itself helps create the decontextualized, agentic

"I." Ikegama (1991) notes that English is a language "which focuses on the human being and which gives linguistic prominence to this notion, while Japanese is a language which tends to suppress the notion of the human being, even if such a being is involved in the event" (p. 301). In characterizing an event, English focuses on the particular person involved, but Japanese emphasizes the event as a whole, submerging the individual in it. Because the human subject is foregrounded in English, one might say "I have a temperature," but in Japanese, one would say roughly "As for me, there is a temperature" or "A temperature goes with me." The English phrase "John ran out of money" might become "As for John, money became null" in Japanese.

Along with foregrounding the subject (the "I") in English, American English speakers tend to be direct and assume that a speaker must make him- or herself clear to listeners. This tendency begins early. Compared to Japanese mothers, American mothers talk more, and more directly, to their children (Azuma, Kashiwagi, & Hess, 1981; Caudill & Weinstein, 1969). In a study of mother-infant interaction patterns, Morikawa, Shand, and Kosawa (1988) compared American and Japanese mothers interacting with their 3-month-old infants. Americans mothers elicited more vocalizations and exhibited more expressions of positive affect, and vocalizations occurred while mothers looked at the baby and the baby was happy and alert. This pattern contrasts with the Japanese studied who more often expressed negative affect and did so while the baby was looking away.

Direct, explicit verbal instruction characterizes teacher-child interactions in the American cultural context (Tobin, Wu, & Davidson, 1989; Wu, 1994). In such interactions, the child's distinctive attributes are identified, then persistently noted and affirmed. Personal attributes and abilities are assumed to define the self—to sustain one's uniqueness and drive one's current, past, and possible actions. The explicit goal is the development of individuals' potential. American institutions may realize the idea of defining attributes by grouping and tracking children according to ability (Stevenson & Stigler, 1992). When resources permit, the curriculum is often individualized on the assumption that each child has a unique learning style and pace.

The American schoolchild is objectified, made to feel special, praised, encouraged, and complimented. In many schools, children may be a VIP or star for a day or a week, celebrate their birthdays, and be honored (Markus & Kitayama, 1994a). Writing projects often involve autobiographies and personal narratives, and art projects focus on self-representation. Many middle-class American children are thus continually encouraged and given chances to express themselves and present their ideas in speech and writing. A common elementary practice in school is show-and-tell: Children bring items then stand before the class and tell a story about their object. All these everyday practices foster an objectification of self and a sense of self as a source of action (Heine et al., 1999).

Moreover, children are encouraged individually and collectively to think of themselves positively as stars, winners, above average, and the repositories of special qualities. It has become routine for every child who plays on a soccer or basketball team to receive a trophy. This practice may discourage competition or invidious comparison among team members, but it underscores the importance, not of the group, but of each individual. Even as many current educators worry that they may have used praise too liberally in the past and try to focus on the learning process rather than on evaluating the child (Damon, 1984, 1995; Damon & Hart, 1988), teachers are persistently urged to find some unique aspect of each child's product.

American children are also encouraged to be independent, autonomous, and self-determining (Bellah et al., 1985). Families in European American middle class contexts often give infants their own beds and bedrooms to foster autonomy (Shweder et al., 1995). Similarly, most developmental markers center on autonomous activity—rolling over, sitting up, walking, and eating by *oneself*.

Additionally, American children are socialized to have distinct preferences. Long before the child is old enough to answer, caretakers pose questions like "Do you want the blue cup or red cup?" Caretakers' questions signal to children that the capacity for independent choice is a necessary, desirable attribute (Markus & Kitayama, 1994a), and thereby instantiate an "ethics of autonomy" that prevails in certain cultural communities but not others (Haidt et al., 1993; Shweder et al., 1997). Moreover, the availability of choice necessitates preferences by which to make choices. Preschool settings are arranged such that children have an extensive choice of activities and need not conform to the group except during limited parts of the day (C. C. Lewis, 1995). Presumably, such efforts to incorporate self-determination into the school day are designed to safeguard the child's intrinsic motivation.

This is an instance of culture and psyche making each other up. Particular kinds of psychological processes (e.g., construing the self as a positive, unique entity) emerge through years of socialization and enculturation as an individual receives then perpetuates social practices and meanings recurrent in a given cultural community (Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997). These psychological processes, in turn, reproduce those same cultural patterns. Becoming a self (a meaningful cultural participant) in a European American context thus involves maintaining an autonomous self separate from other selves and the social context. Those with such independent selves may be more attuned to positive characteristics of the self, and may be especially motivated to discover them, express them in public, and confirm them in private. They often develop processes to buoy their own self-esteem.

The data on European American selves in middle-class contexts support these generalizations. Examining earliest childhood memories and self-reports, Wang (2001a) found that Americans described themselves using individual attributes and reported lengthy, specific, self-focused, and emotionally elaborate memories. Chinese self-reports were briefer and respondents described themselves by roles. Their memories centered on collective activities, general routines, and emotionally neutral events.

In a series of studies with young children, Hart and his colleagues (Hart, 1988; Hart & Edelstein, 1992) asked American children to imagine a "person machine" that makes the original person (respondent) disappear but at the same time manufactures other people (copies of the original) who receive some, but not all, of the original person's characteristics. The respondent's task is to judge whether the new manufactured person with the same physical attributes (looks like respondent), with the same social attributes (has same family and friends), or with the same psychological attributes (same thoughts and feelings) will be most like the original person. They have found that by the ninth grade most respondents believe the copy with the original's psychological characteristics is most like the original.

Consistent with a number of earlier studies of the development of the self-concept (e.g., Harter, 1983), Stein, Markus, and Moeser (1996) have found that 11- to 14-year-old European Americans asked to describe themselves depict a consensual self whose attributes include being caring, friendly, nice, and worried. Moreover, the self-descriptions of adolescents with high rather than low self-esteem matched the consensual self more closely. Such findings suggest that adolescents' tendency to characterize themselves in abstract terms stems from a particular collective idea of "how to be" rather than from increased cognitive ability. These findings are consistent with several other studies on cultural variation in self-categorization (Cousins, 1989; Harter, 1983; Triandis, 1990), which suggest that internal features of the self—the traits, attributes, and attitudes—are privileged and regarded as critical to self-definition.

Furthermore, in a study comparing the self-efficacy levels of children from Los Angeles, East and West Berlin, and Moscow, researchers (Little, Oettingen, Stetsenko, & Baltes, 1995) found that children from Los Angeles had the most optimistic self-efficacy beliefs, while children from East Berlin had the most pessimistic beliefs about personal efficacy. The authors argued that the higher self-efficacy ratings of the Los Angeles elementary school students reflect the high levels of individualism and the low power distance between students and teachers.

Oettingen (1995) argues that efficacy depends largely not only on one's own evaluations in individualist cultures but also on evaluation by in-group members in collectivist cultures. In cultures with a large power disparity between members, children will tend to treat parents and teachers as clear superiors. Children in cultures with a lesser power disparity will have more opportunities to see themselves as "origins" of their own actions. It would be interesting to know how those children of Bielefeld, North Germany, who were reared to be hyper-independent and unspoiled (Grossmann & Grossmann, 1981, 1991; Grossmann et al., 1985; and see earlier discussion of culture-specific presuppositions in attachment research) would have fared on a self-efficacy index.

As researchers develop methods of assessing the selves of ever-younger children, they have found that apprehending and experiencing the world through bounded selfways begins quite early in individualistic cultural communities. European American children appear to have some sense of who they are and which attributes characterize them by 3 years of age (Eder & Mangelsdorf, 1997), and by 4 years of age they show psychological tendencies that reflect the cultural emphasis on individualization and separation from others. They describe themselves as better than their peers in all domains, and studies with adults suggest that this type of self-serving bias or false uniqueness correlates

positively with self-esteem (Josephs, Markus, & Tarafode, 1992). In a cultural system organized around promoting the individuality and uniqueness of the self, a general proclivity to positive self-regard has positive social and psychological consequences.

Selfways in Some East Asian Cultural Contexts

A rapidly expanding literature in psychology, anthropology, and philosophy now provides an increasingly nuanced understanding of the cultural form of Japanese, Chinese, and Korean selves. Systematic analyses of Japanese settings reveal a pervasive concern with and attention to the relational side of social life and to individual position in the social structure (Bachnik, 1994; Lebra, 1993; Peak, 1987; Rosenberger, 1992). Markus and Kitayama (1991a, 1991b) suggest that Asian selfways emphasize the fundamental relatedness of individuals to each other and that the relationship rather than the individual may be a functional unit of consciousness, and claim:

> Experiencing interdependence entails seeing oneself as part of an encompassing social relationship and recognizing that one's behavior is determined by, contingent on, and to a large extent, organized by what the actor perceived to be the thoughts, feelings and actions of others in the relationship. (p. 227)

Lebra (1994) argues that among the Japanese, empathy is a psychological mainstay and must be understood if one is to comprehend almost any aspect of Japanese behavior. Empathy (*omoiyari*) "refers to the ability and willingness to feel what others are feeling, to vicariously experience the pleasure or pain that they are undergoing, and to help them satisfy their wishes" (Lebra, 1976, p. 38). Lebra sees this focus as diametrically opposed to the self-focus common in many European American practices.

This emphasis on empathy implies that Japanese selves should not be conceptualized as lacking individuality or a separate identity or that autonomy is unimportant in Japan (Greenfield & Cocking, 1994; Kim, 1987; Oerter, Oerter, Agostiani, Kim, & Wibowo, 1996). It does imply, however, that such empathic ways of being a self, which explicitly highlight the state of being-in-relation, are different from selfways that emphasize and reify the individual. In this particular Japanese mode of being, subjectivity is sensed as interdependence with a larger whole that includes both the person and others and is configured by constantly referencing the self to the situational setting or context.

Throughout much of the world, the task of child rearing is not the European American one of making a dependent baby into an independent adult, but instead one of cultivating an unruly asocial baby into a civilized social being (Caudill & Weinstein, 1969). The need to uphold interpersonal obligations as well as to maintain connection and harmony with others is highly elaborated in every sphere of social life. Caudill and Weinstein (1986) find that Japanese mothers hold their 3- to 4-month-old infants more and have more body communication with them than mothers in the United States. Furthermore, as noted earlier, co-sleeping and co-bathing are common. Sleeping babies are rarely left alone in Japan. The close, fully interdependent mother-child dyad is particularly idealized in Japan, and many other relationships (e.g., between boss and subordinate) are organized around this familial model. Greenfield and Cocking (1994) characterize interdependent and independent developmental scripts as sharply contrasting, intertwined but never fully balanced. From an East Asian cultural perspective, a self European American style—distinct, positive, and attribute-based—is not a mature, fully civilized form of human agency. A strongly held, clear sense of self signals childishness because it entails failure to take full account of and show sufficient regard for the relationships of which the self is a part. Agency Japanese style results from (a) the sense that the self is afforded and appreciated through the relationships in which it participates, and (b) the sense that the self must flexibly maintain and further the welfare of those relationships.

Such a sense of agency does not mean that the self is passive or just going with the flow. Inter-individual harmony requires active attention. Mulder (1992), in describing Indonesian harmony (*rukun*), notes that it "does not come as a gift but is the result of the active orientation toward mutual respect and adjustment to each other." From this orientation, one must be empathic and flexible to avoid hurting or embarrassing others by one's action. Oerter et al. (1996), in characterizing a Japanese perspective on human nature, quotes a respondent as claiming that "adulthood" means "good understanding, being flexible and following the general rules set by society. The more you grow as an adult, the smaller your own private fantasy world becomes. . . . You become softer-minded, better fitted to the society, but you also become less sensitive" (p. 41).

Interdependence characterizes many different aspects of Japanese life. As noted previously, the Japanese language minimizes the person as an agent. Self-reference in Japanese is accomplished with an elaborated set of communicative customs based on individual status in each particular relationship. The Japanese word for self (*jibun*) means "my share of the shared space between us." Japanese-style interdependence emphasizes living correctly and self-improvement.

Even maternal practices toward infants in Japan seem to involve communicating correct and expected ways to be. Caudill and Schooler (1973) noted that Japanese mothers' speech is apparently aimed to shape directly their infants' physical and emotional states in normative directions. They seem especially concerned with preventing infants' crying and with calming babies whose serenity has been disturbed (Morikawa et al., 1988). Compared to European American mothers, Japanese mothers appear especially alert to infant vocalizations, which they often interpret as signs of distress to which they must respond (Bornstein, Azuma, Tamis-LeMonda, & Ogino, 1990). American mothers, by contrast, seem to talk more to their infants, without trying to directly influence their infants' behavior. Bornstein and colleagues cite a Japanese mother saying to her 3-month-old baby who was looking away ("What is wrong with you?" and "Look at me"). Apparently, to reestablish a dyadic connection when the infants were gazing away from them, Japanese mothers were more likely than Americans to express negative affect, try to establish mutual gaze, or seek information (see also Rothbaum, Pott, & Azuma, 2000; Rothbaum, Weisz, & Pott, 2000; Shimizu & LeVine, 2001).

Such East Asian parenting and teaching practices encourage interdependence through interaction and mutual engagement. When American mothers and toddlers interact with a new toy, American mothers typically focus on the object and draw the child's attention to it. Japanese mothers use the toy to engage the child in a relational or interactive game and do much less talking, explaining, and questioning (Bornstein et al., 1990; Fernald & Morikawa, 1993). According to Lewis's (1995) survey of over 50 Japanese preschools, the focus is on developing children's connections to one another and engaging them in the pleasures of group life. Instead of celebrating individual success, special events recognize the whole group. Children routinely produce group pictures or storyboards, and no child may go to the playground until all are ready. Attention to others is among the primary aims of Japanese education and is fostered in many routine practices. Classroom walls are adorned with group goals, such as "let's cooperate" or "let's pool our strength" (C. C. Lewis, 1995).

Similarly, Chinese parents and teachers consider developing a sense of connectedness to be essential for children's socialization. Child-rearing practices focus on obedience, reliability, proper behavior, social obligation, and group achievement (P. J. Miller et al., 1997; Mullen & Yi, 1995; Wu, 1996). In a study that content-analyzed children's stories and early memories, Wang and Leichtman (2000) found that compared to American children, Chinese children showed greater orientation toward social engagement, a greater concern with moral correctness, greater concern with authority, a less autonomous orientation, more expressions of emotion, and more situational details. To illustrate these differences, Wang and Leichtman provided the following examples from 6-year-olds:

> Memory 1 (American boy): When I didn't get to get a toy. I like to get lots of Legos and there was an underwater one, and it was a little big. It was a medium one and it had one of the things I've been waiting for. But I forget what it was.
>
> Memory 2 (Chinese boy): One day, my mom bought many flower seeds. They were alive. She planted them there. I stepped on them by accident. Then my mom scolded me and spanked me twice. So I cried. I felt a little angry that she spanked me.

Differences by cultural context are especially evident with respect to emotions (Mesquita, 2001; Tsai, Simenova, & Watanabe, 1999). In many middle-class European American contexts, emotions constitute an important aspect of the self and should be emphasized and explained as one develops individuality. In Chinese contexts, emotions result from the child's relations with significant others and serve to both encourage proper behavior in the child and reinforce a sense of connectedness (Wang, 2001b).

Studies of East Asian child-rearing and schooling practices also suggest an emphasis on knowing one's place, role, station, and duties in the social order, particularly in Chinese cultural contexts that explicitly value self-improvement, order, and hierarchy. In a study of Chinese American and European American mothers' beliefs about what matters for raising children, Chao (1992) found that Chinese American mothers stressed sensitivity to other's expectations and the situation, while European American mothers emphasized nurturing the child's

sense of self. Here the former were primarily concerned with the hierarchical, interdependent relationship between self and others and the integrity that derives from doing your duty, but the latter were primarily concerned with furthering their children's independence and encouraging a strong, positive, even assertive, self-regard.

Chao (1993a, 1993b) found an emphasis on order and respect for hierarchy among Chinese American mothers. They scored higher on scales of parental control, authoritarianism, and what Chao calls "Chinese child-rearing ideologies" than their European American counterparts. These Chinese American mothers were more likely to endorse items such as "I have strict, well-established rules for my child," "I do not allow my child to question my decisions," "I make sure I know where my child is and what he is doing at all times," "I teach my child that in one way or another punishment will find him when he is bad," "Mothers can teach children by pointing [out] good behavior in other children," "When children continue to disobey you, they deserve a spanking," and "Children should be in the constant care of their mothers or family members."

Similarly, Rohner and colleagues found that, in contrast to Americans, Korean adolescents perceived parental control as manifesting not hostility and mistrust but love and concern (Rohner, 1984; Rohner & Pettengill, 1985). Notably, strictly controlling parental practices that aim to create a morally dutiful, disciplined sense of agency are also found in some European American contexts and merit further study.

Differences in selfways also come across in play practices. Farver, Kim, and Lee (1995) found that in free play among European American and Korean American preschoolers, European American children primarily described their own actions, rejected their partners' suggestions, and used directives (e.g., "I am your king! Do not obey the bad king! I'll save you!"). Korean American children described their partners' actions, used tag questions, semantic ties, statements of agreement, and polite requests (e.g., "He is a king, isn't he? He's the bad guy, isn't he? The good guy caught him, right?").

Overall, in many East Asian contexts, personal sense of well-being is tied less to meeting an individual's goals (the ethics of autonomy) and more to doing what is required in a given situation, or doing something the right or appropriate way (ethics of community; for more on the ethics of autonomy and community see Shweder et al., 1997). Already in the first months of preschool, Japanese children are required to perform complicated activities, such as arranging their lunch boxes or putting on their clothes for outside activities, in the required way (Peak, 2001). As a child, being part of a family or a school group often means thinking about the social unit and your place in it, and then doing what is proper for this situation. It involves considerations such as "What do my parents or my peers want me to do?" or "Did I do what they wanted me to do?" In a Japanese cultural context, a sense of self is developed by being finely attuned to the expectations of others, by not being left out of their sympathy, and by making sure you are part of the social process. Perceptually, cognitively, emotionally, and motivationally, others—the encompassing social unit, the group and its standards of excellence—are important. Thus, the most useful kind of information about the self concerns your shortcomings, problems, or negative features. Self-criticism is encouraged in all societal settings from the classroom to the boardroom. Cultural participation entails discovering what may be lacking in your behavior and then closing the gap between the actual and expected behavior (Kitayama et al., 1997; Markus & Kitayama, 1994a, 1994b).

In Japan, a constant focus on social expectations and meeting them appears to go hand in hand with a simultaneous focus on self-improvement and self-criticism. In studies comparing self-improving and self-enhancing motivations (Heine et al., 1999, 2001), Japanese participants who failed on an initial task persisted more on a follow-up task than those who succeeded. In contrast, North Americans who failed persisted less on a follow-up task. In Japanese contexts, failures are important and diagnostic and thus serve to highlight where corrective efforts are needed. The emphasis on self-improvement as a virtue can be seen everywhere in Japanese life. An advertisement urging Japanese workers to take vacations exhorted, "Let's become masters at refreshing ourselves" (*New York Times,* May 1995).

The desire for self-improvement has cognitive consequences: Many Japanese tend to focus on areas needing improvement while discounting positive aspects of their performance. This tendency to discount the positive is often misinterpreted by European Americans as self-depreciation, but in Japan it works very well to establish the person as a community member in good standing. Humility might better describe this culturally valued disposition. In contrast to European Americans, who often focus on a self's positive features and equate self-improvement with individual achievement,

Japanese are more sensitive to a self's negative features in a given context.

Further, Japanese practices are often framed in terms of *hitonami* (average as a person). Difficult as it may be for European Americans to believe, many Japanese feel relieved to know that they are average because being different entails the risk of being insensitive to and not belonging in your community. From an interdependent perspective, the self seems best described as a process of self-improvement that requires being sensitive to the expectations of others and not disrupting harmony or equipoise.

Studies of self in Asian contexts all point to self-criticism as integral to the self. Chinese respondents answer the Twenty Statements Test using fewer positive statements about themselves than Americans do (Bond & Cheung, 1983; Karasawa, 1998). Ryff, Lee, and Na (1995) also found that Korean respondents were more likely to endorse negative than positive statements about themselves; European American respondents showed the reverse pattern. Stigler, Smith, and Mao (1985) found similar results among Chinese and United States elementary school students' perceptions of competence: Chinese students rated their competence lower in cognitive, physical, and general domains than did European Americans.

These studies suggest that members in good standing in Asian cultural contexts avoid calling attention to the self, deemphasize their own specialness, and adjust to the immediate situations in which they participate. Even the universally necessary social tasks of individuation, independence, and maintaining autonomy are grounded in an appreciation of interdependence.

These orientations exist at odds with the very practice of personal self-description and thus with commonly exported social science methods requiring people to evaluate and categorize the self. Interdependent (or sociocentric) and individualistic (or independent or egocentric) mentalities and practices are distinct and may require different methods of study. Considered in their respective cultural contexts, notably, these two selfways are equally normal, reasonable, or viable ways of being, although they are associated with patterned or systematic diversity in psychological functioning.

Both types—individualistic and interdependent selfways—involve the participation and support of others and are saturated with cultural meanings. The instantiation and realization of individualism is then a type of interdependence and a socially endorsed and constructed cultural practice. As Vygotsky (1987) suggests, "Every function in the child's development appears twice; first on the social level, and after on the individual level, first between people (interpsychological) and then inside the child (intrapsychological)" (p. 57).

Selfways in Still Other Cultural Contexts

We have focused on the comparison *between* European American and East Asian children to highlight divergent selfways. Nevertheless, important variations in selfways can also be found *within* cultural groups and are increasingly a focus of attention (Strickland, 2000). For example, Harwood and colleagues (Harwood & Miller, 1991; Harwood, Schoelmerich, Ventura-Cook, Schultz, & Wilson, 1996) compared Anglo and Puerto Rican mothers in the United States. They found that relative to Puerto Rican mothers, both middle- and lower-class Anglo mothers placed significantly greater value on self-confidence and independence and significantly less value on obedience, the capacity for relatedness, and proper demeanor. Miller, Potts, Fung, Hoogstra, and Mintz, 1990; Miller and Hoogstra, 1992; Miller, Mintz, Fung, Hoogstra, and Potts, 1992, report that autonomy is important in both working-class and middle-class U.S. communities, but is fostered differently according to social class. In a study of the co-narration of mothers and toddlers in two Midwestern communities, they found that middle-class mothers accorded children speech and author privileges in creating stories about past events, and were less likely than working-class mothers to challenge the toddlers' versions of reality. Working-class mothers also granted children speaker rights—and involved children in longer co-narratives than middle-class children—but challenged children more often to tell the "correct" version rather than their own story. Similarly, recent ethnographic accounts of selves in working-class contexts find less focus on self-confidence, self-expression, and developing potential and more emphasis on stability, integrity, and resilience (Harwood, Miller, & Irizarary, 1995; Kusserow, 1999; Snibbe & Markus, 2004).

A study by Rogoff et al. (1993) comparing U.S. middle-class and Guatemalan Mayan toddlers finds that autonomy also matters in the socialization of Mayan children, particularly among toddlers who are accorded special privileges and not expected to conform to the same rules as older siblings. In contrast to the American children, however, older Mayan siblings cooperated

interdependently with the toddlers without caregiver intervention, suggesting that among the Mayans developing autonomy is associated with understanding that one is an interdependent member of the community and is not as completely autonomous as infants are allowed to be.

Only recently have investigators began to describe how contexts other than European American and East Asian ones influence the constitution of self. For example, a review of parenting among U.S. Latino families finds that despite considerable within-group heterogeneity, Latino parents tend to emphasize the main cultural values of *respeto* and *familismo* (Harwood, Leyendecker, Carlson, Asencio, & Miller, 2002). *Respeto* refers to maintaining proper demeanor, which involves knowing the proper decorum required in a given situation with people of a particular age, sex, and social status. *Familismo* refers to a belief system linking loyalty, reciprocity, and solidarity toward members of the family, which is seen as an extension of the self (Cortés, 1995).

African American parenting, according to a review by McAdoo (2002), must often address persistent issues that African American children confront, such as devaluation of their own worth and future potential, inadequate financial resources, and the challenge of teaching children about race. Moreover, in African American contexts maintaining communal family traditions is essential. Coresidential extended families and their support systems are common and regarded as an important survival system for African American families (Hatchett, Cochran, & Jackson, 1991).

Research in cultural psychology challenges some generalizations about self and self-development and significantly strengthens others. In the next decade, these shifts will likely result in new paradigms for studying the self. Recent theoretical debates and discussions in psychology and anthropology aim to clarify and elaborate the general propositions that the self is (a) constituted in interaction with others, (b) collectively constructed through sociocultural participation, and (c) a product of history (see Elder & Shanahan, Chapter 12, this *Handbook,* this volume). Each of these propositions reflects a central claim of cultural psychology, namely, that processes of self-functioning encompass not only a single psychology but also multiple psychologies.

The Self Is Constituted in Interaction with Others

It is an old idea that one cannot be a self by one's self. Although life in the middle-class European American cultural region has highlighted the conceptual self, studies of self in other cultural locations underscore the importance of what Neisser (1988, 1991) terms the *interpersonal self.* Selves are constituted and develop in interaction with specific others (J. M. Baldwin, 1911; M. W. Baldwin & Holmes, 1987; Cooley, 1902; Hallowell, 1955; Ingold, 1991; Rosaldo, 1984; Shweder & LeVine, 1984). Echoing Mead (1934) and the early symbolic interactionists, the self literature includes a growing appreciation of the dynamic, socially constructed nature of self. This idea has the appeal of potentially bridging the gap between focusing primarily on the individual as a cultural learner (Tomasello et al., 1993) versus on the cultural collective of which the individual is an interdependent part (Cole, 1995). This synthesis promises to get the person back in the practice and the practice back in the person.

Efforts to understand the mutual constitution of self and other in the development of self, or just how it is that selves and others make each other up, are ongoing. Outside of middle-class European American cultural communities many people prefer crowded living conditions and regard the physical presence of others, especially family members, as essential to mental health and well-being. Peak (1987), writing about Japan, claims that becoming a person involves learning to appreciate the pleasures of group life and living in human society. Similarly, Ochs (1988) reports that Samoans are self-conscious about their need for others to acknowledge and sympathize with them. Menon's (1995) interviews with Oriya Hindu women living in extended joint family households reveal that in local moral worlds steeped in an ethics of community the idea of living alone while sane and happy is almost a contradiction in terms (see also Kakar, 1978).

In much European American research on the development of self, others become relevant when selves learn to take the perspectives of these others and get inside their heads (Flavell, Green, & Flavell, 1995), or as specific relationships are forged with particular others. It is increasingly evident, however, that others have a pervasive impact on any person's psychological development throughout life in all cultural contexts. Even prior to birth, individuals are immersed in social relations and activities. Human infants only become selves through their engagement in particular, culturally organized settings (Markus et al., 1997; Weisner, 1982, 1984, 1987). Ever more investigators now assume that mutual involvement of self and others is so fundamental to human functioning that others are automatically perceived as relevant to one's sense of self. Gopnik (1993) refers to an innate bridge or intersubjectivity between self and

others. Infants are responsive to others' affective expressions, and thus others are immediately expected, implicated, and involved in one's becoming a self (see also Ingold, 1991).

The Self Develops through Sociocultural Participation

A cultural psychology perspective places considerable emphasis on what Kitayama and colleagues (Kitayama, Markus, Matsumoto, & Norasakkunkit, 1995; Markus et al., 1997) term the *collective construction of self*. The concept is that selves develop in a dynamic, recursive process in which sociocultural participation in a given cultural system of meanings, practices, and institutions affords characteristic tendencies of the self that further serve to integrate the person into the meanings and practices of a given cultural community (see also Bourdieu, 1972; Giddens, 1984; Martin, Nelson, & Tobach, 1995). This perspective emphasizes that from their earliest moments, selves arise from being a person in particular worlds. From a child's earliest days, partial, incomplete, rudimentary gestures and vocalizations are "infused with specific meanings and significances crucial to enabling the child to become a progressively more competent partner" (Bruner, 1993, p. 532). Children are immediately engaged in the settings of daily life and are subject to the specific normative expectations and the institutional entailments of what Super and Harkness (1986) label a "developmental niche." People always live in culture-specific ways. To live otherwise is impossible.

Super and Harkness's theorizing is one of many attempts to resolve the tension between psychology's excesses in viewing development as natural growth or an unfolding of abilities in stages and anthropology's excesses in viewing development as cultural molding or conditioning. Super and Harkness claim that a child's developmental experience is regulated by (a) the settings—physical and social—in which the child lives; (b) the customs of child care and child rearing; and (c) the mentality of the caretakers. These three mutually interactive subsystems function together with other elements of the large culture and environment to constitute a culture-specific child.

Cultural psychology's approach to the study of self does not deny the individuality, idiosyncrasy, and uniqueness of the self observable in even the most tightknit and coherent collectives. Children do not become general people; they become particular persons or selves. One of the most significant facts about us, writes Geertz (1973a), "may finally be that we all begin with the natural equipment to live a thousand kinds of life but end in the end having lived only one" (p. 45). Every person participates in combinations of significant cultural settings or niches, which in contemporary American society could include specific groups, such as the family or workplace, as well as contexts defined by ethnicity, religion, profession, social class, gender, birth cohort, and sexual orientation. Some of the remarkable variation among people arises at least in part because people are unlikely to participate in identical configurations of group memberships. Even those living in similar configurations of cultural contexts will diverge in the specifics of their everyday, symbolically mediated experiences and due to prior, innate, received, or temperamental differences in their sense of self will differentially attend to, seek out, elaborate, or reflect some features of these experiences and not others. Moreover, participation or engagement in the activities of a given cultural setting can assume divergent forms. Cultural participation can be straightforward and unquestioning, resistant, or ironic. Consequently, there is little danger that people of the same sociocultural and historical niches will be clones of one another. Between-group differences do not imply within-group homogeneity.

The Self as a Historical Product

A cultural psychology approach to the development of self has led researchers to appreciate Bourdieu's idea that processes of self are "history turned into nature" (1991, p. 7). Many Western researchers focusing on the self have participated in their discipline long enough now to have observed historical change in the European American cultural zone in the natural and normative self. In the late 1960s and early 1970s, there was a need to discover the true self and feelings. Currently, there is the need to say no not yes to experience and to create the proper self. Many current self researchers were themselves raised according to the dictates of Dr. Spock but as parents find his prescriptions rigid and inappropriate. Similarly, American educators note that requiring children to be happy and feel good about themselves has produced a generation of children with high self-esteem and no basic skills. Programs under development aim to raise the educational expectations for American children and to replace an emphasis on positive self-evaluation with an emphasis on building specific skills (Damon, 1995).

General societal imperatives of "the way to be" promulgated by the advertising industry and media have

a strong effect on nurturing practices and on both lay and scientific conceptions of self. In a comprehensive historical overview of the American self, Cushman (1995, p. 24) argues that to understand the formation of the American self one must understand the interplay between this nation and what it means to be American, between what it means to be an American and what it means to be human, and between the construction of the self and the construction of the country. It is of no small significance to the renewed field of cultural psychology that self researchers are beginning to heed Kessen's claim (1983):

> The study of children is not exclusively or even mainly a scientific enterprise in the narrow sense but stretches out toward philosophy and history and demography. If we were to recognize such an expanded definition of child study, we might anticipate a new (science) whose object of study is not the true child or a piece of the true child but the changing diversity of children. (pp. 37–38; see also Bronfenbrenner, 1979; Bronfenbrenner, Kessel, Kessen, & White, 1985; Kessel & Siegel, 1983; Lerner, Chapter 1, this *Handbook,* this volume)

CULTURAL PSYCHOLOGY AND COGNITIVE DEVELOPMENT

In the previous sections, we have been considering some selected content areas, using these to bring out features of cultural psychology and to demonstrate how these alter our understanding and analysis of development, influencing concepts, methods, and research questions. Those content areas have had to do with interpersonal relations during childhood, language and communication practices, and the development of self. The fourth and last area chosen is that known as cognitive development. Terms with a cognitive cast to them—*mind, mentality, meanings, understandings, competencies*—have already appeared throughout the chapter. The area of cognitive development, however, gives them a particular place and deepens their analysis.

The material is necessarily selective. We have given preference, however, to proposals and issues that alter our views not only of cognitive development but also of development in general, and that focus on concepts, researchable questions, and possible methods. Structurally, the section is in three sections, each concerned with ways of moving beyond constraining divisions.

The opening material—on separations between thought and action—focuses on links between ways of thinking and ways of acting, on the nature of activities or practices, and on the concept of participation. The section that follows—reexamining separations between hearts and minds—links ways of thinking to feelings, values, and identities. To the analysis of cognitive development, the argument runs, we need to bring the study of accompanying feeling states. We need also to add the recognition that areas of competence and ways of learning differ in the extent to which they are seen as important by the individual or by others, and in the extent to which they are seen as appropriate to a person's current self or possible selves.

For the third large concern—moving beyond traditional separations between persons and contexts—the material is in two parts. Both stem from the challenge of giving specific shape to the general recognition that persons and contexts make each other up. The first starts by considering changes in approaches to the specification of contexts, asking how these fit with views of cognitive development. Here we give special attention to accounts of contexts as both exerting pressure and allowing innovation, as changing rather than static, as heterogenous rather than monolithic and as composed of contested or competing positions, with room for individuals to negotiate what is to be learned or what may be questioned. The later part starts by considering changes in accounts of cognition and cognitive development, asking how context enters into these. Here we give special attention to accounts of cognition in contrasting domains (domains where biological predispositions are major and domains where the bases is more one of gaining expertise), to the nature of expertise, and to the specific role of language and communication in an area—the area known as "theory of mind"—where age-related changes have been seen as biologically based, with little impact from sociocultural experience.

The brief final comments then bring together some comments on the methods highlighted by a cultural psychological perspective: Methods applicable to all aspects of development but particularly illustrated by studies of cognitive development.

Reexamining Thought and Action

The conventional assumption is that the mind comes first. Thought precedes action, at least as an ideal in development. We then find it reasonable to account for

what people do in cognitive terms. To take an example from law, we find it reasonable to ask if children are old enough to know the difference between right and wrong and, given that knowledge, whether they can be held responsible for what they do. We also see it as appropriate, in studies of development, to place our emphasis on changes and variations in the way people think rather than on changes and variations in what they do.

That conventional assumption has been questioned on several grounds. Noted especially in the previous edition were two alternative proposals. The first is that we reverse the usual order, with the flow now from actions to thought. To take a well-known example, we begin by "doing gender." We use, and see others use, different names, games, clothes, spaces, and tasks for males and females. Those everyday practices provide the bedrock for the category of gender. They lead us also to think of gender distinctions as fixed and natural, and they move development in the direction of less reflection rather than more.

The second proposal is that we specify both contexts and the course of development in activities, practices, and the nature of participation. In one society, for example, the main activities for children may be strongly age-graded, with each school group or playgroup made up of children much the same age, and children usually distanced from adult activities. In another society, school-based activities may play a minor role, younger and older children may be more often part of the same group, and children may be present while adults work, talk, or play.

The main directions seen as prompted by those proposals took the form of closer looks at (a) links between particular ways of thinking and particular ways of acting and (b) ways of specifying the nature of activities, practices, and forms of participation. We now take up those directions, asking what has been added since the previous edition, and highlighting some particular gaps that remain.

Examining links between ways of thinking and ways of acting. A view of actions and ideas as intrinsically interwoven is a core part of the concept of custom complex. The challenge lies in finding ways to bring out the forms of that interweaving. Two ways of doing so may be distinguished. One starts from particular forms of activity and asks about associated ways of thinking. The other starts from ways of thinking and asks what practices or activities might establish or maintain them.

For the first method—starting from particular forms of activity—this chapter has already provided a major example. It takes the form of working from language and communicative practices, asking for example how these are associated with particular divisions between truth and fiction, particular distinctions among relationships or events, and particular ways of perceiving or representing the self. That direction is also very much evident in analysis of the extent to which an understanding of "mind" and of what others know or believe is shaped by the presence of lexical terms such as thoughts or beliefs, by adults' questions to children, and by games such as I Spy or 20 Questions. In acquiring adults' language, the argument runs, children also acquire their theory of mind (e.g., Vinden, 1996; Vinden & Astington, 2000).

For a further example involving language, we turn to a study that is especially relevant to the under-explored question: What ways of acting can substitute for one another? We surely learn to distinguish among relationships, for example, by more than one route, by involvement in or exposure to more than one kind of practice. The nature of interchangeability, however, is so far poorly understood. The content area in the study singled out has to do with narrative development. It compares hearing children whose parents are deaf with other children. Narrative development turns out to be the same for both (Van Deusen-Phillips et. al., 2001). The narrative practices of people other than parents, it appears, are sufficient to model the expected structures.

Spoken language and communicative practices are by no means the only practices to attract continuing attention in the study of cognitive development. Anthropology and cultural psychology draw attention to a variety of other tools, ranging from sticks to written scripts, number systems, or maps: Tools that bring out the nature of both cultural variations and historical changes. There are by now many analyses of how various tools come to be available, used, or altered and to shape the way thinking or problem solving proceeds. Several of these are contained in the papers brought together by Cole, Engeström, and Vasquéz (2000). A set of chapters edited by Hatano and Wertsch (2001) provides several further examples, ranging from the use of a globe in learning about astronomy (Schoultz, Säljö, & Wyndhamn, 2001) to the use of models or diagrams in planning constructions (Gauvain, 2001).

From these several sources, we abstract two points that may well be extended to the analysis of many practices. The first is that with extended use we are likely to learn more than how to use a particular kind of tool. We may also develop an understanding of it, a mental model

of how it works, and its possibilities (Oura & Hatano, 2001, describing a particular aspect of development in the course of learning to play the piano). The other is a strong reminder that all such understanding is socially shaped. What is written and used as a basis and purpose for reading, for example, may in some groups cover a wide range of material and of situations. In others, materials and purposes may be strictly limited to writing certain kinds of letters, keeping certain kinds of accounts, or developing religious commitment (Scribner & Cole, 1981).

For the second method—starting from a way of thinking and asking about its possible background—we single out, as a particular case, thinking that involves the emergence of change or innovation.

There are, for example, clearly occasions when people develop ways of being original or creative rather than being only technically and reproductively expert. That kind of development appears to be influenced by the ways in which forms of teaching and definitions of skill allow some individuality of expression rather than only the strict following of prescriptive directions. Cooking and the performance of music, for example, often allow for some individuality of expression—at least at some levels of competence more readily than do areas such as the feeding of animals or plants (Hatano & Inagaki, 1992; Oura & Hatano, 2001).

There are also clearly occasions when reflection, questioning, or resistance occurs rather than the simple acceptance of a customary way of thinking or acting. Most analyses of practice lead us away from exploring that aspect of development. They emphasize instead the extent to which the routine, everyday quality of practices diminishes the likelihood that they will be reflected on, questioned, or resisted. That emphasis has offered a powerful contrast to accounts of cognitive development that emphasize people as making sense of the world in optimal scientific fashion: asking questions, being quickly alert to discrepancies, and investing effort in resolving ambiguities. It leaves open questions about shifts in conventional views and practices, both across generations and in an individual's lifetime.

For the circumstances that encourage questioning or resistance, we have so far little developmental evidence. One relevant circumstance, however, seems likely to be what children learn about the fate or status of questioners. They may be pointed out as odd people, as godless or lost souls whose afterlife is not what one would aspire to. "Curiosity killed the cat," it is said (more often than the rejoinder "Information brought it back").

A further possible circumstance has to do with repetitions of the same message. Repetition in itself, however, is a concept still in need of unpacking. It may take the form of everyone delivering the same message. There are, for example, experimental studies showing that consensus—especially consensus about the affective significance of a particular view—tends to limit the degree of monitoring for exceptions (Frijda & Mesquita, 1994). Repetition may also take the form of the same message emerging from several practices. Involvement in Western-style schooling, for example, is low among Samoan children. Both adults outside school and the nature of school practices in Samoa, however, all convey the same message: the irrelevance of school for the children's current or future ways of living (Watson-Gegeo, 1993).

In specifying activities and forms of participation or nonparticipation, any approach to development that emphasizes the importance of activities needs to move toward distinctions among them. Activities have been distinguished by, for example, where they take place, the people who are present, and the psychology of the people present (e.g., their views of how development takes place; e.g., Super & Harkness, 1986). They have also been distinguished by the tools or artifacts that are available or used (e.g., Gauvain, 2001), the patterns of accompanying talk (Gutiérrez, 2002), and the forms and impacts of repetition (e.g., Hatano & Inagaki, 1992). Practices, for example, are activities where repetition, by oneself or others, gives rise to the sense of the natural or proper ways to act (e.g., Goodnow et al., 1995; P. J. Miller & Goodnow, 1995).

Activities may differ also in the extent to which they allow various forms of participation. We draw particular attention to this aspect. One reason for doing so is that changes in participation have been proposed as promising ways of characterizing the forms that development takes. They may then characterize both the shape and the bases of development. Another is that descriptions of participation build on descriptions of activities as joint and on distinctions among them as how two or more people contribute to a task.

Currently, the most familiar form of attention to changes in participation revolves around teacher-learner or expert-novice relationships. Prompted, especially by Vygotskian theory, the course of development is often seen as one in which the expert provides guidance and structures the task in ways that allow the novice to take over more and more responsibility for the task.

That description of a shift is a rich starting point, but it needs, several expansions that involve (a) the kinds of

relationships considered, (b) the steps or processes involved, and (c) the nature of nonparticipation.

On the first score (the nature of relationships), we need to continue questioning the benign and cooperative quality presented as typical of teacher-learner relationships. Teachers or experts are not always eager to give up their control and novices are not always eager to learn or to take on responsibility (Goodnow, 1990b). Teacher-learner relationships are also not the only forms of relationship that can apply. In some situations, for example, people function or are expected to function more as a team. In still others, one person (e.g., a concert pianist) may seem to take the only active part. Even here, however, the audience listens with expectations about what will be played and how pieces will be played. The performer will take those expectations into account and also try to persuade the audience that the choice of pieces or of interpretation is a reasonable or exciting one (Oura & Hatano, 2001).

For expansions on the second score (specifying steps or processes in participation), we turn to proposals from Rogoff and from H. Clark. Rogoff (2003) describes participation as involving two processes. In one, people seek to achieve some mutual understanding: for example, some mutual understanding of what each knows, what each seeks, what each understands the task to be. In the other, they seek to structure what each will do. They offer choices, invite some actions rather than others, or shape events so that some actions become more likely than others. In effect, they engage in some "mutual structuring of participation" (Rogoff, 2003, p. 287).

H. Clark's (1996) analysis starts from conversation or "language in use" as a prime example of "joint activity." His analysis is not developmentally oriented; however, it does suggest several new directions for developmental research. In any joint activity, Clark (1996) argues, we should ask what each person contributes and is expected to contribute, what they regard as their shared task, how they go about that task, and when some perceived limit to what they can do is reached. In a conversation between a telephone operator and a caller, for example, one person seeks information and the other provides it. Each person checks from time to time that the other has heard what was said, has heard accurately, that the information provided is what was sought and has been understood (in essence, "are you with me?"). Moves toward establishing mutual understanding (Rogoff, 2003) are not only a way of describing what people do but also an indication of a particular competence whose acquisition we might well seek to trace.

In any joint activity, to take a second part of H. Clark's (1996) argument, we should specify the rules, regulations, and etiquette that apply. In any team game, for example, people may be present as players, referees, coaches, fans, or observers. Each is expected to act within certain limits. Acting in violation of these limits incurs penalties. For any game also, the number of people and the rules for participation define the game. People can play football with fewer than the number of required players, for example, but then the game is no longer an official game. Varying the rules as to what each piece may do in a game of chess is also possible but the game is then no longer chess.

In any area, that kind of description suggests, the acquisition of skill may lie in learning both the rules of the game and the limits to which they can be pushed. We learn, for example, that some departures from the expected rules or procedures rule one out of the game while others are tolerated. We learn also that failing to observe the expected patterns (e.g., the patterns for conversations) may not rule one out of the game but is likely to result in fewer invitations to join in on later occasions.

Learning the collaborative rules (Goodnow, 1996b) seems likely to apply to many situations, from turn taking to story telling, school tasks, or teamwork of any kind. How children learn such rules, however, is still far from clear. An intriguing beginning is Martini's (1994) observation that young children who spend a great deal of time with older children (the older children are often their minders) learn quickly that their presence is tolerated as long as they do not interrupt the older children's games. Household tasks bring out a similar aspect of development. They also bring out the extent to which what needs to be learned or negotiated are the reasons for participating, the expected styles for doing so, and the limits to variations in what can be contributed (e.g., variations in what can be delayed, downsized, delegated, swapped, substituted, or taken over; Fuligni, 2001; Goodnow, 1996c, 2004b).

The third and last needed expansion that we single out has to do with the occurrence and the nature of nonparticipation. Most analyses of participation assume that participation always occurs, even at times—as in the example of a concert pianist's audience—when participation is not highly visible. What needs to be accounted for then are the timing and the shape of changes in the way people participate. Nonparticipation, however, can also occur, and may be encouraged in some areas, with attempts at participation regarded as forms of interference (Goodow, 1996a). Where it is encouraged, learning how

not to do so, in acceptable ways, may be a major part of developmental skill (Goodnow, 2004a).

At this point, before we go further in attempts to track down sources, the major need appears to be one of differentiating among forms of nonparticipation. People may, for example, be physically absent. They may stay away or drop out. More subtly, they may be present but unengaged in what occurs. Children may, for instance, participate in the sense that they stay in the classroom (they do not drop out physically). They are, however, uninvolved, uninvested, or not engaged (behaviorally, cognitively, or emotionally) in the formal work of the classroom. Increasingly, that kind of nonparticipation is attracting both attention and proposals to the effect that the difficulty may lie more in the nature of social and classroom contexts than in characteristics of the nonparticipants (e.g., Blumenfeld et al., in press). Delineating forms of nonparticipation, establishing how they come about, and finding ways to change them seems to be one of the next challenges to rise to in analyses of how thought and action are related to one another.

Hearts and Minds

Cultural anthropology has long contained an awareness that matters of the mind cannot be separated from matters of the heart. Feeling cannot be regarded as a separate state from thinking or treated simply as a force that provokes thought (Shweder, 1992). Forms of competence need to be regarded as the skills that communities value (D'Andrade, 1981). Development needs always to be framed by the social group into which one moves: for example, "Becoming a Kwoma" (J. W. M. Whiting, 1941). At issue, to take a statement that has moved into popular discourse, is the battle for hearts and minds.

Cognitive psychology has tended to cover a somewhat different set of concerns. A set of chapters on "affective minds," edited by Hatano, Okada, and Tanabe (2001), illustrates two recurring lines of approach. One focuses on the ways in which emotions influence the nature of processing, with effects ranging from what is attended to or given processing priority to how far information is sought. The other focuses on the ways in which aspects of cognition prompt various emotions, ranging from fear in the face of perceived threat to the way pride, shame, or embarrassment rest on some sense of self and of standards.

What does our cultural psychology perspective add to such analyses of hearts and minds? To consider that question, we take up the place of feelings, values, and identities, again summarizing very briefly the points made in the previous edition and asking what might now be added.

Feelings

The only point covered in the previous edition was the widespread recognition of the need to avoid a two-box approach to thinking and feeling. We now expand on that point in three ways.

One is the use of feeling states as a way of differentiating among shared points of view (D'Andrade, 1992). All members of a cultural group, for example, may hold the view that "everyone should help the poor" or that "each of us can be whatever we want, provided we work hard enough." For some members of the group, however, that idea may be held at the level of a cliché. For others, the idea may be held with a conviction that guides action when a choice arises. For still others, the idea may be held at a level that initiates action: We seek ways to implement it. How some ideas come to be held with various levels of commitment is clearly a question about development that still needs to be explored.

The second expansion has to do with occasions when some ways of thinking or problem solving give rise to strong negative emotions. These ways strike us as terribly wrong, as violating some basic principles, as—to borrow from others—unthinkable, heretical, or taboo (Fiske & Tetlock, 1997; Tetlock, Kristel, Elson, Green, & Lerner, 2000). These feelings may well be an important part of our sense of a major difference between cultures. They also suggest that people may be regarded not only as "intuitive scientists" but also as "intuitive theologians"(Tetlock, McGraw, & Kristel, 2004). That kind of proposal is not only an interesting challenge to any "cool scientist" view of cognition but also nicely linked to a useful method: presenting people with errors of various kinds (essentially variations of expected patterns) and exploring both judgments of seriousness and the kinds of emotions reported.

The third and last expansion to the place of feelings attracts attention because it also challenges conventional concepts and some particular methods. It has to do with variations in the level of attention paid to feeling states as part of understanding others. A study of attention to two aspects of words provides an example. Adult speakers of English and Japanese were presented with words that were pleasant or unpleasant in meaning, and spoken with either a smooth, round tone or a harsh, constricted tone. They were then asked to ignore vocal tone and judge whether the words are pleasant or un-

pleasant in meaning, or to ignore meaning and judge whether the tone was pleasant or unpleasant. Japanese speakers found the first task more difficult than English speakers did. English speakers found the second task more difficult than Japanese speakers did (Ishii & Kitayama, 2001). The course of development for that kind of difference would now be of interest to establish, with one possibility being that English speakers grow out of an initial sensitivity to tone and into a preoccupation with the lexical meaning of words.

Values

At first glance, it may seem strange to use the term *values* in relation to cognition. Values surely belong to accounts of social or moral development. Cognitive values are ubiquitous: embodied in distinctions between what we call basics and frills, significant problems and trivial pursuits, elegant and pedestrian approaches to a problem, original and regurgitated pieces of writing, and proper and odd ways of adding up numbers.

In the previous edition, we noted the ubiquity of cognitive values and raised the question: How are these acquired? What is the nature of such cognitive socialization (Goodnow, 1990a)? We can now offer three expansions: one related to where values occur, a second to how values are acquired, and a third to the range of value tags or value judgments that are made.

For the areas where values are salient, we focused in the previous edition on the nature of the end product: on what is to be learned, what is said, understood, written, or worked on. Values are also attached to particular ways of proceeding or learning. In many cultures, for example, learning by watching is valued over learning by doing (Rogoff, 2003). In any culture, teachers and students may also vary in the value they attach to various ways of learning. Teachers in many Western societies, for example, often favor a process of learning by exploring differences of opinion—by argument or by attempts at resolving different views. Pupils, however, often devalue that procedure and avoid it on the grounds that it may jeopardize their relationships with one another (Lampert, Rittenhouse, & Crumbaugh, 1996). The values attached to play and to formal or academic learning provide a further example. Chinese parents of preschoolers place far less value on play as a source of cognitive development than European Americans. Moreover, their preschoolers themselves also place high value on learning in ways that suggest an "awareness of the unity of learning and morality" (Li, 2004, p. 126) that is slower to develop among European American children. The difference is seen as reflecting—for the Chinese preschoolers—a cultural model of learning in which a combination of "heart and mind for wanting to learn" is central (Li, 2002, p. 246).

For the acquisition of cognitive values, we turned in the previous edition to accounts that are essentially borrowed from theories of social learning. The emphasis was on what happens in dyadic interactions: on the way, for example, that what is said is responded to, built on, ignored, scorned, or actively corrected. We drew especially from accounts by Wertsch (1991) of how children even in the early years of school learn to use "the voice of science": sprinkling their stories or arguments with references to numbers, citing "evidence," and talking about the physical properties of objects rather their personal meaning for the speaker. Noted also were several closely observed accounts of what happens when children bring to school ways of speaking and story telling that are not in a teacher's preferred style. They are quickly made aware that their stories and their ways of story telling are not good, and teachers actively seek to dismantle (Michaels, 1991) the children's styles.

The ways in which we acquire cognitive values, however, need not be limited to such direct interpersonal interactions. Values are also embodied in practices. Take, for example, a school timetable or a school curriculum. In a timetable, some school subjects are allotted the prime times of day, taught every day, and seldom rescheduled. Others are given lower priorities: inevitably dropped or cut short whenever class juggling needs to take place. In the material used for teaching, there may be no references to a child's country of origin, no images of people from a child's identity group, or no stories that are part of a child's heritage. It may not even occur to kindergarten teachers that there is something absurd about using stories such as Red Riding Hood in Samoan classrooms (Watson-Gegeo, 1993). School subjects may also acquire various status tags: Some are thought of a must-be-taken course, some are only for the brightest (Latin and Greek once had this status), and some are best for the less bright (typing once had this status). Still others seem to exist on sufferance: In most secular Western schools, for instance, religion or scripture—if taught at all—is usually an option, and it is often taught by someone who is not part of the regular school staff. In many ways, its position parallels the low degree of attention given in most current analyses of development to religious ways of viewing events and people (Hudley et al., 2003). It is small wonder then that many of us are unprepared for the significance of religious thought in many other parts of the world.

Direct social learning and embedding in the teaching and linguistic practices of a group are then two lines of cognitive socialization. To these, a third needs to be added. It has been considered so far in terms only of judgments about the work of adults, yet is extendable to children. It also points to a way in which practices may be linked to one another: a recurring concern in this chapter. This core proposal is part of Bourdieu's (1979) analysis of intellectual values—of "taste" or "distinction": An analysis that brings out the extent to which some of the same criteria for judging value may apply in several situations. For example, we bring many of the same dimensions to judgments about intellectual productions that, we use for judgments about food, distinguishing between rich and thin, refined or rough, and well or poorly presented. The essence of taste for the European middle-class, Bourdieu (1979) comments, may well lie in the values it attaches to various forms of presentation, for both material and intellectual productions. That proposal not only helps illuminate an area of difference among social groups but also raises developmental questions about the extent to which a common presence makes values easier to pick up or more difficult to set aside in successive situations.

The third and last expansion in the area of values has to do with the range of value judgments. We have so far described various kinds of thinking, learning, or problem solving only as being more versus less valued, more versus less privileged. That is surely an incomplete description. At the least, we might extend the range by adding a term *dispreferred* from Ochs (1990, p. 299), which covers what is actively discouraged. We might extend it also by describing values as what is regarded as ideal, what is tolerated, what is discouraged, and what is regarded as out of the question, impossible, intolerable (Goodnow, 1995, 1996a), heretical, or unthinkable (Fiske & Tetlock, 1997; Tetlock et al., 2000).

We have a great deal to learn about what are regarded as the most serious violations of expected ways of thinking. Building on Fiske's (1991) account of social orientations, Tetlock and his colleagues propose that the underlying base is a violation of "spheres of exchange." With one example being the violation of a distinction between what can be treated as a commodity (traded, sold, or discarded) and what cannot. All cultures, for example, draw distinctions between what can be sold and what cannot. They may differ in their views of what can be sold (e.g., people, sex, loyalties), but the distinction is always deeply felt. We have as well a great deal to learn about the developmental background to such distinctions and the feelings associated with them. At the least, however, these judgments at the far end of a scale of values point to the need for expanding the range of value tags or value judgments among ways of thinking beyond any simple sorting into the more versus the less valued.

Identities

In the previous edition, we divided the argument for the need to link analyses of cognitive development to issues of identity into three ways, which break the line often drawn between analyses of cognitive development.

The first noted that certain ways of thinking, problem solving, or expressing oneself mark one as a schooled or educated person, promoting the choice of some ways of proceeding even when others are available (Nunes, 1995), and often provide the motivation needed to acquire a difficult skill (Hatano, 1995). The second was that changes in competence can lead to some changes in the identity that others assign to us. A person may now, for example, be recognized as a legitimate member of some community of practitioners (Lave & Wenger, 1991): a change in status noted as not always occurring. The third was that the acquisition of competence covers only part of the story. Not acquiring certain forms of competence can also be a way of signaling identity (e.g., an identity as one of "the lads"; Willis, 1977) or a way of protecting one's identity, one's sense of an essentially capable self (e.g., Cole & Traupmann, 1981). The critical skill may also lie in managing to maintain a double identity: for example, an official identity, for teachers, as a reasonable child who obeys the rules and, for one's peers, an identity as one who appears to stay in the letter of the rules but subtly bends or flouts them (Corsaro, 1992).

We have still a great deal to learn, as we noted in the previous edition, about the strategic presentation of identity in the course of development and about what is seen as in keeping with an assigned identity (e.g., the identity of child or beginner). Not in keeping with some definitions of a *child,* for example, is a precocious knowledge of sex or of money values. Not in keeping with some concepts of a *beginner* is the open and nondeferential display of skill or ease.

What might now be added? The expansions seen as especially needed have to do with (a) the nature of membership, (b) asking which members of a group matter, and (c) the implications of moves toward recognizing social and personal identity, multiple identities, and both a current self and possible selves.

On the first score (membership), developmentalists are now familiar with the argument that increasing competence needs to be seen as involving not only a change in the individual but also in the individual's coming to be an accepted, recognized member of a group. One needed expansion on that argument consists of noting that this second shift may not always happen. In a less-than-ideal world, acceptance may still be withheld. The official qualifications may never be enough. More finely, we now need to take a closer look at the meanings of terms such as *community* and *membership.*

Rogoff (2003) provides one example of that move, distinguishing participation from membership. She describes herself, for example, as having "participated for several decades in a Mayan community in Guatemala, but people from that community (and I) do not regard myself as a member of that community" (p. 83). We may, she continues, do better to focus on "the more dynamic concept of participation, rather than the categorical concept of membership" (p. 83). We may also need to think more about the defining features of a community. Communities need not, for example, be "limited to people who are in face-to-face contact or living in geographic proximity" (p. 81). They should, however, "be defined as groups of people who have some common and continuing organization, values, understanding, history, and practices. . . . A community involves people trying to accomplish some things together, with some stability of involvement. . . . A community involves generations that move through it, with customary ways of handling the transitions of generations" (pp. 80–81). Moreover, "participants in a community often continue to regard their involvement and their continuing relationships as central to their lives, whether this is expressed in affection or loyalty or efforts to avoid community ways" (p. 81). How people acquire these understandings of community and these feelings of belonging are questions still to be pursued.

On the second score (some people in a group matter more than others), we take as an example some proposals by Minsky (2000, 2001). Those proposals start by considering people as equipped by nature with "detectors" for praise or censure. The impact of praise or censure, however, depends on the extent to which there is an attachment or close relationship between the person making judgments and the person receiving them. The remarks of a stranger, for example, generate less shame than do the remarks of a parent to whom the child feels attached. The experience of emotions such as pride and shame, and the development of the standards, rules, and goals that M. Lewis (1993) sees as their basis, depend then on the development of attachments and, presumably, the range of people that in any culture are regarded as sources of praise or censure that should "cut to the quick."

The last expansion (closer analyses of identity) takes several forms. Each suggests a different facet of what develops and, in some cases, of conditions that shape cognitive development.

One is a distinction between social identity and personal identity. Personal identity is identity captured by asking whether people see themselves as competent or creative or as being the same person now that they were at an earlier age. Social identity refers to the social categories in which we place ourselves or others place us. We may, for example, describe ourselves as Asian American, Chinese, or Cantonese, or as first-, second-, or third-generation. Others may assign a person to a looser category, using a term such as *Asian* to cover everything from India to Japan. Interest in social identities and social categories has a considerable history, especially since the work of Tajfel (1981). Much of that work, however, has stayed in the realm of social psychology and in references to the life of adults. Increasingly, it shows signs of a much-needed move into analyses of development.

Seen as a mark of cognitive development, for example, is an increasing skill in the description of oneself in ways that fit what is required in various situations and with varied audiences (e.g., Banarjee, 2002). There are age changes, for example, in the appropriateness of children's answers on a task such as the following: "Imagine you are lost in a mall. I'm a detective and it's my job to find you. I've never seen you before and I don't have any pictures of you. Tell me what I would need to know about you to find you." What may also develop with age or experience is skill in shaping a presentation of identities to suit one's own strategic needs. To take an example from observations by Cooper, Garcia Coll, Thorne, and Orellana (in press) two girls in an Oakland school use to good purpose their *mixed* backgrounds (mixed is the term used in the school and the playground). For one, the mother is described in this report as Chinese-American, the father as Jewish. For the other, the mother is described as white, the father as Egyptian. Both girls were noted as using their mixed backgrounds as ways "to avoid fights (mixed meant not on either side of ethnically charged conflicts) or avoid the slight stigma of being

white and build alliances (I told the Black kids that I'm Egyptian and that's in Africa)."

A second expanded look at identity distinguishes between personal and collective identity. It is collective identity that is involved in the sense of "we" (Thoits & Virshup, 1997): reminiscent of J. W. M. Whiting's (1941) description of development as "Becoming a Kwoma." As Ruble and her colleagues point out, most of the work on collective social or cultural identity has been with adults. In contrast, most of the work with children has been on the developing sense of gender and gender constancy (Ruble et al., in press). There is some initial work on the extent to which a sense of racial constancy and a sense of gender constancy follow similar lines (Rhee, Cameron, & Ruble, cited by Ruble et al., in press). There is also the beginning of work on whether and when a sense of collective identity in children has similar consequences to those observed in adults (e.g., an effect on what is attended to and how information is processed, or—a point taken up in research with adolescents by Yip and Fuligni, in press—an effect from the strength of collective identity to successful coping with transitions such as changes in school).

A third expansion is the recognition of identities as multiple, especially when an individual occupies more than one social world: Most children occupy more than one world—home, school, and peers, for example. The children of foreign-born parents have been regarded as especially likely to occupy social worlds that differ markedly in their linguistic practices and values, with the inevitable development of a sense of being torn between two worlds. What they—and all children—may instead develop is a set of border-crossing skills that make it possible to negotiate a reasonably comfortable time in more than one place (Phelan, Davidson, & Yu, 1988).

A fourth and last move in analyses of identity is a distinction between a current self and future possible selves. What may matter most for performance or engagement in school, for example, may be not only an image of oneself at present but also an image of what one might become, and an awareness of the steps that need to be taken to achieve those futures. That kind of proposal not only makes intuitive sense but also is well supported by the results of a California program designed to provide the children of immigrant families with both an understanding of the paths they needed to take from one point in school to another (e.g., the particular levels in mathematics that they needed at various points) and a strengthened belief in their ability to move along the "pipeline," in their "identity pathways" (Cooper, Dominguéz, & Rosas, in press).

Much of this work is in its early stages. What is clear, however, is that these directions of research promise to yield a richer understanding of the ways in which issues of identity, along with feelings and values, are part of cognitive development.

Persons and Contexts

Salient in many areas of development is the issue of how to consider contributions from characteristics of both the individual and the social contexts in which they live. Surprisingly, an emphasis on both is still needed because there are still times when an emphasis on instruction or socialization seems to treat the individual as a blank slate or a sponge that needs only to have information provided in absorbable amounts. There are also times when an emphasis on the individual as actively constructing meanings seems to treat the outside world as essentially blank, ignoring the history and the directiveness with which individuals must work or make sense:

> Once both contributions are fully acknowledged, questions arise about how the two are interwoven. The first move has been a recognition of the need to regard "persons" and "contexts" as influencing each other in ways that are not one-directional, static or linear. The second has been toward some ways of specifying interdependence. Persons and contexts have been described, for example, as "creating each other" (Briggs, 1992), "shaping each other" (Cole, 1990), "making each other up" (Shweder, 1990a), or "co-constructing each other" (Valsiner, 1994).

What are the specific meanings of such phrases, especially in relation to cognitive development? To answer that question, we divide a large body of material into two parts, varying in their starting points. The first starts from several descriptions of contexts and asks what do these imply for the shape or course of development? The second starts from several descriptions of cognitive development and asks how do social or cultural contexts enter into these pictures?

Both parts start with the recognition that any description of either term (*context* or *individual development*) carries implications for the nature of the other. Ecological descriptions of context (e.g., the world as a set of nested circles starting from the home and working outwards into parts of society) carry with them the connotation of development as a journey, with the individual discovering routes, acquiring navigational skills, or finding helpful guides. Descriptions of the world as a stage in which we all play roles or learn our place carry

with them the implication that development involves acquiring effective ways of self-presentation or emotional management.

To take the reverse direction, descriptions of development as coming to make sense of events or to discover regularities imply a world that is not immediately comprehensible, a world in which order or structure is hidden beneath a shifting surface appearance. Descriptions of development as coming to make effective use of the symbols or artifacts available imply worlds in which various tools are available, with some probably more accessible or more promoted than others, varying over groups or across time. Descriptions as activities and changing forms of participation imply worlds that vary in the opportunities they offer for participation or for establishing routines in what one does. In effect, one way of mapping part of the person/context universe always suggests a way of mapping the other. Working from such cross-mapping is likely to be more productive than trying to link analyses that use quite separate dimensions for the description of persons and contexts (Goodnow, 2004a, 2004b, in press).

Starting from Descriptions of Contexts

There are by now many descriptions of contexts: a variety especially brought out in a review by Cooper and Denner (1998; see also Cole, Chapter 21, this *Handbook,* Volume 2).

As an opening step, we distinguish between descriptions by content and descriptions by quality. Descriptions of a culture as shared meanings and practices, or as a warehouse of narratives, for example, place their emphases on content. Descriptions of contexts as always changing, or as multiple and contested, place their emphasis on quality.

The descriptions we choose for particular comment are far from exhaustive, and the selection leaves us with a sense of regretted omissions. We would have liked, for example, to give more space to descriptions of contexts that emphasize opportunities for children and families to establish the routine, everyday activities that are seen as so crucial to development (e.g., Gallimore, Weisner, Guthrie, Bernheimer, & Nihira, 1993; Weisner, 2002). The descriptions chosen for closer comment, however, strike us as offering some particular shifts in the way we think about the shape and course of development and as containing some particular gaps.

We start with some examples of context descriptions. The first two are descriptions of cultural contexts as linked practices and warehouses of narratives. For both, and for all other descriptions, we take it for granted that cultures, like people, are always changing.

Contexts as Linked Practices. We noted in the previous edition (p. 913) that "it is always an open empirical question whether a mentality generalizes across many practice domains (the Hindu mentality) or is specific to a particular practice domain (the mentality of Hindu sleeping arrangements)." That question is prominent also in the present chapter. We are still, however, short of proposals that consider the nature of linking among practices. We noted earlier a possible linking by ways of similar dimensions being used for evaluative judgments about what is produced, using as an example Bourdieu's (1979) analysis of "taste" or "distinction" in judgments about food and about intellectual productions. A further example comes from Rogoff's (2003) analysis of the practices that go with the kinds of arrangement usually found in Western schools. Occurring together are age-grading, a concern with readiness in relation to age, the use of praise for a child's interest or achievement, the asking of questions to which answers are known, particular kinds of demands by children for adult attention, and the move of school type conversations into home settings. In another grouping, Rogoff (2003) sees an emphasis on particular kinds of relationships (horizontal or vertical, dyadic or multiparty in type) as related to differences in "sleeping arrangements, discipline, cooperation, gender roles, moral development, and forms of assistance in learning" (p. 9).

We now need further examples of such possible groups, further indications of the occurrence and the extent of linking, and a check on whether—where linked practices occur—this makes a difference to the pattern of development. The indications of linking come so far from the way adults pattern a child's social world. Do children then shift easily from one linked practice to another? Do they, for example, pick up a distinction embodied in one practice more easily when they have already experienced a linked practice rather than one that is not linked?

Contexts as Warehouses for Narratives or Interpretations. This way of viewing cultural contexts picks up the argument that all social contexts need to be seen in historical terms. In essence, the argument is that the past provides a set of texts or narratives. Each generation may then draw from the warehouse, add to it, or rediscover forgotten treasures. Each generation may also bring, to the available set, attitudes ranging from respect

to indifference, disdain, or scorn. Among cultural psychologists, Wertsch (1991) best exemplifies this approach to culture. More broadly, this concept is central to the work of Bakhtin, who noted the ways in which novelists such as Rabelais or Joyce broke the pattern of previous narratives: the one by covering topics previously regarded as not proper topics, the other by changes in structure, even at the level of sentences (Kristeva, 1980, provides a brief and readable account). In time, the argument continues, some ways of breaking up past patterns become taken up by others. They then become part of what Valsiner (1994) has described as a spiral of influence that alters the nature of what is available to draw from or is regarded as a reasonable selection:

> Novels, we would add, are not the only kinds of texts or narratives that have attracted this kind of attention and that raise questions about aspects of selection or transformation. Martin-Barbero (1993), for example, is one scholar who has brought a similar style of analysis to the way cultural expressions in the form of art, music, film, or television spread from one culture to another. It is not the case, he argues, that cultures in areas such as South America are "over-run" or "swamped" by the cultural expressions of the North. What occurs instead is a process of selection, utilization, and adaptation.

What are the implications of that kind of position for the nature of cognitive development? One is that we may now see development as including the acquisition of a stance toward the texts of the past. That stance may be one of respect and a view that the best way to approach a problem or to provide evidence for one's argument is to turn to the past. In contrast, it may be one of regarding the past as having nothing to do with the present, or as inevitably biased (the product, for example, of old people). That stance, for reasons we still need to pin down, may well change over the course of development.

Overall, warehouse accounts of contexts remind us that the central processes are likely to take the form of selection and transformation. Turning those processes into developmental form then becomes the challenge. Children's selections and transformations of narrative, an earlier section of this chapter suggests, are likely to provide an especially productive starting point. They clearly offer a base for asking about the particular narratives or narrative styles that are held out for children as the best or the ones they should take as models. We may explore also the ways in which children come to incorporate the texts they read into what they themselves produce. When a 10-year-old, for example, starts a story with the sentence—The sun rose over both worlds: the world Sven knew and the one he would be transported to—we can readily hazard a guess that the background reading includes some form of science fiction. What parts of a setting, a plot, or a collection of characters are more readily taken over or more quickly transformed than others? What makes them more likely to be treated in some ways rather than others? All told, narrative selection and transformation seems to capture especially well historical and cultural variations in what children encounter as well as processes of selection, rejection, and transformation.

Contexts as Shared Meanings or Practices. These descriptions of contexts are especially prominent in anthropology in the form of emphases on the presence of cultural models (shared ways of viewing events or people), cultural practices (shared ways of proceeding), or custom complexes (an approach that combines both actions and meanings). We have, throughout the chapter, brought out several implications of these positions for the study of development. We now add several others, prompted by a focus on cognitive development and on the quality of ideas or practices as being shared.

In some anthropological work, the quality of sharedness has given rise to questions about the degree to which there is consensus and about the position of people whose views are *modal* for the group as against being out on the edge of the variations that occur (e.g., Romney, Weller, & Batchelder, 1986). That work is with adults but suggests a new way of viewing development. In any content area and at any age, what is the degree of consensus? Are there some areas or some ages when not being part of the consensus—to be out on the margin or to disagree—is to be avoided, virtually seen as the kiss of death? What promotes an interest in coming to share the same understandings or to act in the same ways as others? The usual emphasis is on the wish to understand others and to be understood by them in ways that make easy the communication of meanings. The reasons seem likely to involve also the strategic presentation of self.

The quality of sharedness prompts other questions about what happens when there are clear departures from everyone being of one mind or acting in the one way. How do children deal with such situations? We use the example of a California classroom that served as a base for observing how children dealt with social categories (Cooper, Garcia Coll, et al., in press). In this classroom, children came from several ethnic backgrounds, signaled in some cases by skin color and in oth-

ers by the style of dress, with the most obvious dress signal being that of girls from Islamic families wearing a veil or headscarf. Teased by another child for wearing something so different, the reply by one girl was "It's part of my tradition," a reply taken from the school's orientation—conveyed in many lessons—of respecting others' traditions. The shared meaning, in effect, was used as a way of justifying an unshared practice. The selection of the reply, and its quick effect, illustrate aspects of shared meanings and practices for which other developmental examples might be sought.

Contexts as Multiple and Contested. No society is monolithic. In most industrialized societies, for example, there are usually to be found more than one religion, political party, or form of schooling, more than one class, and more than one country of origin. Some of the alternate forms may be known by adjectives that imply their minority status (e.g., alternative medicine, alternative schooling, or independent film producers). It is not only the presence of variety that matters but also the way in which these several segments compete or negotiate with one another. The people in one group, for example, may regard the people in another as best avoided, kept at arm's distance, or suppressed. Where these actions do not achieve one's purposes, some form of negotiation or takeover needs to occur. Churches may unite, union activists may be pushed into management, or independent film producers may be co-opted into studio affiliations and productions.

This way of viewing cultures is widespread in the area often known as *cultural studies* (the work cited by Martin-Barbero, 1993, is from this field). Part of its attraction for the study of development is that it leads us away from a view of culture or context as a state or thing. The emphasis falls instead on the presence of various cultural groups, on their perceptions of each other, and on their relationships with each other. In addition, recognition of the extent to which encounters with other people or other positions are usually controlled is prompted.

Control over access to knowledge is a long-standing theme in sociological analyses (e.g., Bourdieu & Passeron, 1977; Foucault, 1980). In developmental studies, it is represented by studies comparing the understanding of animal biology that develops when children can vary their approaches to feeding and care against being restricted to the teachers' prescriptive routines (Hatano & Inagaki, 1986). In a more social fashion, it is represented by questions about the nature of children's encounters with other people. Parents may act in cocoon fashion, structuring a child's world so that experience with different others is at least delayed (Goodnow, 1997), or they may engage in more direct preparatory work. When a child is seen as likely to encounter discrimination, for example, parents may encourage pride in the group's own history, or teach specific ways of responding to name-calling or other derogatory actions (Hughes & Chen, 1999). Both kinds of experience should affect the social categories, the stances toward others, and the degree of reflectiveness about differences among people that children develop. We have a great deal yet to learn about the nature of such effects. They are likely to provide, however, some sharp examples of how particular qualities of social/cultural contexts are related to some particular qualities of cognitive development.

Starting from Descriptions of Cognitive Development

In the previous section, we started from descriptions of cultural contexts and asked about links to descriptions of cognitive development, noting any suggested new ways of considering development or new research questions. In a change of method, we now reverse directions. We start from some particular descriptions of cognitive development and ask how cultural contexts enter the picture.

There are many ways of describing cognitive development. In the previous edition, we noted three: (1) a shift from an initially weak or fluid state to one that was better established or more smooth in its execution; (2) a change in the nature of information processing: changes, for example, in what is attended to or rehearsed; and (3) a move toward dividing cognitive development into domains, with proposals for differences in the nature of development by domain.

The third direction is the one to which we gave most attention then and now. The focus reflects the extent to which debates about domain specificity have been prime sites for exploring questions highlighted at the start of this chapter such as whether, in the area of cognitive development, there is a place for social or cultural factors (innate predispositions might offer a sufficient account of development), what that place might be, and how given abilities and cultural circumstances might be brought together.

In essence, the synthesis regards two kinds of domains as varying considerably in the way cognitive development proceeds. A distinction is drawn between core or privileged domains and other domains (Keil, 1984; Siegler & Crowley, 1994; Wellman & Gelman,

1998). First, in privileged domains, humans are genetically prepared to acquire knowledge systems that deal with important aspects of the world. Second, in nonprivileged domains, development relies on general learning mechanisms (Keil, 1984) or module acquisition modules (Sperber, 2002). In these domains, cognitive development is usually conceptualized as the gaining of expertise. In both domains, sociocultural perspectives have something to offer. Because the two kinds of domain have been conceptualized differently, suggestions from cultural psychology vary from one to the other.

Nonprivileged Domains: Cognitive Development as Expertise. Traditionally, expertise means the accumulation of rich and well-structured domain knowledge, consisting of "chunks" that can readily be used (Chi, Glaser, & Farr, 1988). There is also wide agreement among cognitive researchers that gaining expertise requires years of experience in solving problems in the domain, carried out with concentration and often taking the form of deliberate practice (Ericsson, 1996).

What does cultural psychology add to these characterizations? A central addition, as we see it, is the elaboration of what *expertise* consists of and how it is acquired.

We begin with the argument that through repeated participation in culturally organized practices, both children and lay adults acquire the skills and knowledge needed to perform competently in those practices (Goodnow et al., 1995). To this we add, first, what matters is not only the amount of time spent in repetition but also the nature of what is repeated. Studies by Oura and Hatano (2001) with a group of nonprofessional pianists bring out this point especially. All of these pianists had started piano lessons at 6 years of age or younger. Some, however, had reached a junior expert level. Others were still at a more novice level. Oura and Hatano (2001) asked both to practice a short piece of music. Those who had stayed at the novice level tried only to perform accurately and smoothly. Those who had reached the junior expert level checked and refined their performance from the perspective of an audience in mind. In effect, the two differed in the practice in which they had engaged. The less successful students had expected to play for the teacher who would evaluate how smoothly and how accurately they played. In contrast, the successful students had practiced for playing in public, with an eye to ways of creating their own expression.

Second, we add that the process of gaining expertise is assisted by other people and artifacts: Novices are not expected to solve problems all by themselves. A study by Takahashi and Tokoro (2002) of experienced amateur photographers (senior shutterbugs) brings out this point. Most senior shutterbugs explicitly expressed their appreciation of their supporting networks: networks involving peers, the instructor, and family members who provided transport, prepared lunchboxes, and so on. Even when learners' problem solving activities were apparently solo, other people entered the picture in the form of possible competitors or possible buyers of what one produced. The senior shutterbugs, for example, wanted to take at each moment shots that they and others would regard as good. Their skills improved, unlike school learning, almost as a by-product of keeping these audiences in mind.

A third addition, again broadening our understanding of what is acquired in the course of gaining expertise, emphasizes that the acquisition of knowledge and skills is accompanied by socioemotional changes—for example, changes in interest, values, and identity. That position has been stated with particular strength in Lave's (1991) argument that the practices that developing individuals engage in are embedded in a community of practitioners. All practices, it has come to be recognized, involve socioemotional interactions as well as cognitive divisions of labor. The process of gaining expertise is not likely to be an exception. It cannot be purely cognitive. In one example, Japanese students who develop expertise in the use of the abacus do so in a national climate of admired expertise and in the company of others who are also members of abacus clubs or competitive teams (Hatano, 1995). To take another, volunteers serving at a soup kitchen for homeless people became not only skilful at helping them but also, more important, more favorable toward and sympathetic to those people (Youniss & Yates, 1997).

Finally, cultural perspectives help us as well to distinguish among domains in terms of the kind of expertise required and the occurrence of innovation. Some domains of expertise are knowledge lean: Expertise in these domains is reproductive in nature. Other domains are knowledge rich: In these, individuals, after gaining expertise, are most likely to contribute to cultural change. Expert cooks, for example, may invent new dishes by combining a variety of materials and modes of cooking. The invented dishes may then be incorporated into the culture of cooking, if the new productions attract a number of members constituting the community of cooks.

Conceptual Development in Core or Privileged Domains. In these domains, cognitive development is conceptualized quite differently from what happens in nonprivileged domains. The accounts start from the argument that human beings are biologically predisposed, prior to any experience, to attend to some events rather than others and to make some inferences rather than others (e.g., Keil, 1984). Coherent bodies of knowledge about important aspects of the world are then built on these bases, with many researchers assuming that the acquisition of core domains of thought such as naive physics, psychology, and biology is early, easy, and almost universal. The ways in which this construction takes place may be varied. As Karmiloff-Smith (1992) notes, the innate constraints may "potentiate learning by limiting the hypotheses entertained" (p. 11), but they may also place limits on what is readily learnable. One early assumption was that the evidence for predispositions tended to minimize the role of culture in earlier conceptual development, especially in the first few years (e.g., Carey & Spelke, 1994).

How do cultural psychologists challenge views that exclusively emphasize human inheritance from evolution? The domain of naive psychology or theory of mind (TOM) provides a nice illustration, bringing out how cultural-psychological views change the characterization of the course of development as well as the research methodology.

In a large-scale meta-analysis of studies by Wellman, Cross, and Watson (2001), for example, many studies emerged as focused on identifying age-dependent developmental patterns. The overall pattern of results is that younger children fail to, but children a few years older correctly, recognize that people act in accordance with what they believe is the case, whether it corresponds with the reality that the child has come to know. The overall assumption is that experience makes little difference in this sequence.

An increasing number of innovative studies are compatible with, if not influenced by, cultural-psychological views. Some of these studies assume that attention to forms of communication with significant others may yield different perspectives on the development of TOM. Some, as we noted earlier, assign particularly important roles in TOM development to the use of language as a tool representing mental states (Astington & Baird, in press).

In terms of research methods, these studies aim to connect children's sociocultural experiences to their developing understanding of mental states of themselves and others. One such method is to analyze children's everyday conversation in families prior to a check on their understanding of beliefs as determinants of behavior. For example, family differences in explanatory conversations have been found to be associated with children's later development of TOM (e.g., Dunn, Brown, Slomkowski, Tesla, & Youngblade, 1991; Dunn, 2000). Another research strategy is to compare the TOM performances of different populations of children. Convincing evidence for the importance of complex communication with significant others for the TOM development, for example, is given by Peterson and Siegal (1995): Deaf children's development of TOM is delayed when their parents are hearing individuals who had to learn a sign language later in their life but is *not* delayed when the parents are fluent signers. Still another method that can show the causal effect of linguistic interaction in the TOM development consists of training studies. Lohmann and Tomasello (2003), for example, have demonstrated that 3-year-olds' false belief understanding is facilitated both by perspective-shifting discourse and by sentential complement syntax that represents a belief decoupled from reality.

The domain of naive biology also contains both mainstream conventional studies of age-dependent development and innovative sociocultural studies. For example, among the studies reviewed by Inagaki and Hatano (2002), the majority started from a traditional view of development and focused on the ages at which children would acquire "autonomous" biology. A small number of studies, however (harmonious with cultural-psychological views) showed that the age-dependent developmental patterns observed among urban children (typical experimental participants) are not universal. Instead, the pattern varies with particular kinds of experience.

Most studies have shown that young children's naive biology is human-centered: The properties attributed to other animals tend to be generalized from what is known to be the case for humans. This tendency is weaker or nonexistent, however, among children who have had frequent direct contact with nonhuman animals and plants (Atran et al., 2001; Ross et al., 2003). Even among urban children, active and enduring involvement in animal-raising activity mitigates the human-centered nature of biology. Their enriched knowledge about animals they have raised serves as an extra source for the analogical understanding of animals not yet experienced (Inagaki,

1990). Children's understanding can also be influenced by cultural ideas about the categories in which humans, other animals, and plants can be placed (Hatano et al., 1993; Stavy & Wax, 1989). In short, even young children's naive biology is instantiated differently in different sociocultural environments.

Moving beyond specific areas of knowledge are several proposals for the need to take an interactive view of genetic predispositions and sociocultural facilitations or constraints. Gelman (1990), for example, proposes that innate constraints are so skeletal that they always have to be complemented socioculturally. Another possibility is that both types of constraints usually operate in a mutually facilitating or bootstrapping way, with innate constraints becoming less important as rich domain knowledge is acquired through cultural learning. Worth particular note is the argument that, in a few years after birth, children begin to learn in a uniquely human way, exemplified by joint attention and imitation (Tomasello et al., 1993).

Those several proposals go beyond a view of development as shaped only by genetic predispositions or by sociocultural circumstances. People undoubtedly come equipped to make some distinctions—between inside and outside or animate and inanimate objects. Cultures, however, provide usable artifacts that are shared by a majority of people in a community or a subgroup. These artifacts include physical facilities and tools, social institutions and organizations, documented pieces of knowledge, and commonsense beliefs. They also include the behavior of other people, interactions with them, and social contexts created by them. Cognitive development is best seen as interactively constrained by both sociocultural circumstances as well as genetic predispositions (Hatano & Inagaki, 2000).

A Summary Comment on Cognitive Development: Methods

The account just concluded—covering several ways in which people have explored the place of sociocultural experience in cognitive domains often proposed as the province of genetic predispositions—has brought to the surface a variety of methods. Variety in method provides a way of bringing this section on cognitive development to a close and of underlining again some points about method that have been made in earlier sections of the chapter: in particular, the place of shifts in method as one of the prime features of a cultural psychology perspective.

Making comparisons across cultures, although often informative, is not the only method possible. The most informative route may be a concentration on a culture and on some local practices or ways of thinking. Also valuable is working from a local practice and asking what ideas accompany it or, conversely, starting with a stated or inferred belief and asking what practices might be associated with it.

That aspect of methods (across or in cultures) is not only a pragmatic issue. It reflects also, as Cole (2001) has pointed out, the recognition that "all human groups inhabit a world suffused with their predecessors' history . . . culture and cultural mediation are universal features of human life and an integral part of human development. Consequently, the process of cultural mediation can be studied in a broad range of practices within any large, demographic, culturally constituted group" (p. 168).

We hope it has been evident that we see great benefit in borrowing freely from both experimental and ethnographic approaches, with psychologists perhaps benefiting from a fuller knowledge of how a variety of ethnographic methods may be used (P. J. Miller et. al., 2003, is a useful source). Borrowing conceptual analyses from outside psychology is also important. We have drawn on occasion from anthropology, sociology, and—less frequently than we might do—areas often known as cultural or narrative studies. We have regrettably made the least use of history, a deficit that Cole (2001) points out as applying to many psychological analyses of the cultural nature of human development. The historical analysis of how mind, body, and soul or heart have at various times been separated or merged with one another would in itself, for example, round out our steps in this chapter toward moving beyond current dichotomies.

Our hope is that the benefits of cultural psychology for the analysis of cognitive development lie not only in its prompting fresh approaches to questions about what develops and how this takes place but also in enriching the repertoire of methods that we bring to those questions.

CONCLUSION

It is the hope of all those who welcome the return of cultural psychology as a vibrant research enterprise that more and more social scientists from various home disciplines (psychology, anthropology, linguistics, sociology) will become developmental experts on

the psychological functioning of members of particular cultural communities around the world. Only then will the many questions raised in this chapter begin to be answered. Only then will the abstract pluralistic idea of "one mind, many mentalities" become substantial and concrete, and thereby come fully to life. It is when another culture's taken-for-granted categories appear to us to be counter-intuitive, or out of line with what we assume to be present early in life, that we are most likely to experience the need to rethink our sense of what is natural.
