CHAPTER 14

The Bioecological Model of Human Development

URIE BRONFENBRENNER and PAMELA A. MORRIS

The bioecological model, together with its corresponding research designs, is an evolving theoretical system for the scientific study of human development over time (Bronfenbrenner, 2005). In the bioecological model, development is defined as the phenomenon of continuity and change in the biopsychological characteristics of human beings, both as individuals and as groups. The phenomenon extends over the life course, across successive generations, and through historical time, both past and future. The term *future* raises a question: How is it possible to scientifically investigate phenomena that have not yet taken place? This question is hardly new; indeed, it pervades every field of scientific endeavor. However, we are the only species that, over historical time, has developed the capacity to engage successfully in scientific inquiry, and thereby, in many respects, has

We are especially grateful for the thoughtful criticisms of earlier drafts of the manuscript generously provided by the following colleagues: Jay Belsky, Rick Canfield, Nancy Darling, Glen H. Elder Jr., Steven F. Hamilton, Melvin L. Kohn, Kurt Lüscher, Phyllis Moen, Donna Dempster-McLain, Laurence Steinberg, and Sheldon H. White. We owe particular thanks to Professor Susan Crockenberg and her students at the University of Vermont who, in the course of a graduate seminar, carefully reviewed a draft of this chapter, and made many constructive suggestions. We have done our best to meet the high standards that they commendably set. We wish to express gratitude to Richard M. Lerner and William Damon, the editors of the 1998 Volume and of that series as a whole, for their wise advice, encouragement, and patience. Finally, a special thanks goes to our most severe and most constructive critic, Liese Bronfenbrenner.

been able to change the nature of the world in which we live. As a result, within certain limits, we humans have altered the nature and course of our own development as a species (Bronfenbrenner & Evans 2000; Bronfenbrenner & Morris 1998).

To place bioecological theory of human development into a larger context, it is important to recognize that many of the general perspectives advanced and elaborated in this theory are also parts of other related lines of theoretical and empirical inquiry into human development. Examples include life-span psychology (Baltes, Lindenberger, & Staudinger, Chapter 11, this *Handbook,* this volume), cultural psychology (Cole, 1995; Shweder et al., Chapter 13, this *Handbook,* this volume), Magnusson's developmental theory of contextual-interactive holism (Magnusson & Stattin, Chapter 8, this *Handbook,* this volume), and, especially, the work of Robert Cairns (Chapter 3, this *Handbook,* this volume), who through communications and publications extending over 3 decades, has played a major role in the evolution of the four defining properties of the bioecological model: (1) Process, (2) Person, (3) Context, and (4) Time. Cairns is best known as the founder and principal protagonist of developmental science, and there are several excellent examples of his books and articles that have been most relevant to the evolution of the bioecological model (Bergman, Cairns, Nilsson, & Nysted, 2000; Cairns, 1970; Cairns & Cairns, 1994). The specific profile of the bioecological model of human development is its interdisciplinary and integrative focus on the age periods of childhood and adolescence and its explicit interest in applications to policies and programs pertinent to enhancing youth and family development.

In this chapter, we undertake to present the ecological model of human development that has been introduced over the course of the prior two editions of this *Handbook* (Bronfenbrenner & Crouter, 1983; Bronfenbrenner & Morris, 1998). The main focus of the 1983 chapter was on the empirical and theoretical roots of a model already in use, which centered on the role of the environment in shaping development. In contrast, this chapter is oriented toward the future. The present model introduces major theoretical innovations from the 1983 chapter in both form and content. The present formulation makes no claim as a paradigm shift (if there be such a phenomenon); rather, it continues a marked shift in the center of gravity of the model, in which features of earlier versions are first called into question but then recombined, along with new elements, into a more complex and more dynamic structure.

The transition in the form and content of the model actually took place over an extended period of time, an expression that will become all too familiar to the reader (Bronfenbrenner, 2005). The transition from a focus on the environment to a focus on processes was first introduced in the context of Bronfenbrenner's unpublished lectures, colloquium presentations, and contributions to symposia. Not until 1986, did reference to an emergent new model first appear in print (Bronfenbrenner, 1986b). The following extended excerpt conveys both its spirit and intended substance. Because both of these attributes are relevant to the gradual evolution of the model to its present form, we quote from the 1986 statement at some length:

> It is now more than a decade ago that, being somewhat younger, I presumed to challenge the then-prevailing conventions of our field by describing the developmental research of the day as "the study of the strange behavior of children in strange situations for the briefest possible period of time" (Bronfenbrenner, 1974). Instead, I argued (as if it were simply a matter of choice), we should be studying development in its ecological context; that is, in the actual environments in which human beings lived their lives. I then proceeded to outline, in a series of publications, a conceptual framework for analyzing development in context, and to offer concrete examples of how various elements of the schema might be applied both to past studies and to studies yet-to-come. I also emphasized the scientific and practical benefits of a closer linkage, in both directions, between developmental research and public policy (Bronfenbrenner, 1974, 1975, 1977a, 1977b, 1979a, 1979b, 1981). Now, a dozen years later, one might think that I have good reason to rest content. Studies of children and adults in real-life settings, with real-life implications, are now commonplace in the research literature on human development, both in the United States and, as this volume testifies, in Europe as well. This scientific development is taking place, I believe, not so much because of my writings, but rather because the notions I have been promulgating are ideas whose time has come. . . .
>
> Clearly, if one regards such scientific developments as desirable, there are grounds for satisfaction. Yet, along with feelings of gratification, I must confess to some discontent. My disquiet derives from two complementary concerns. The first pertains to one of the main roads that contemporary research has taken; the second, to some more promising pathways that are being neglected.

> Alas, I may have to accept some responsibility for what I regard as the wayward course. It is an instance of what might be called "the failure of success." For some years, I harangued my colleagues for avoiding the study of development in real-life settings. No longer able to complain on that score, I have found a new *bête noir.* In place of too much research on development "out of context," we now have a surfeit of studies on "context without development."
>
> One cannot presume to make so brass an allegation without being prepared to document one's case. I am prepared. (Bronfenbrenner 1986a, pp. 286–288)

What followed was an early version of the newly evolving theoretical framework, but the purpose of the present chapter is better served by presenting the model in its current, albeit still-evolving, form now called the *bioecological model.* The term *evolving* highlights that the model, along with its corresponding research designs, has undergone a process of development during its life course (Bronfenbrenner, 2005). The bioecological model addresses two closely related but fundamentally different developmental processes, each taking place over time. The first process defines the phenomenon under investigation—continuity and change in the biopsychological characteristics of human beings. The second focuses on the development of the scientific tools—theoretical models and corresponding research designs required for assessing continuity and change.

These two tasks cannot be carried out independently, for they are the joint product of emerging and converging ideas, based on both theoretical and empirical grounds—a process called *developmental science* in the discovery mode (Bronfenbrenner & Evans 2000, pp. 999–1000). In the more familiar verification mode, the aim is to replicate previous findings in other settings to make sure that the findings still apply. By contrast, in the discovery mode, the aim is to fulfill two broader but interrelated objectives:

1. Devising new alternative hypotheses and corresponding research designs that not only question existing results but also yield new, more differentiated, more precise, replicable research findings and, thereby, produce more valid scientific knowledge.
2. Providing scientific bases for the design of effective social policies and programs that counteract newly emerging developmentally disruptive influences. This has been an explicit objective of the bioecological model from its earliest beginnings. To orient the reader to the present formulation of the biological model, a preview follows.

OVERVIEW

We begin with an exposition of the defining properties of the model, which involves four principal components and the dynamic, interactive relationships among them. The first of these, which constitutes the core of the model, is *Process.* More specifically, this construct encompasses particular forms of interaction between organism and environment, called *proximal processes,* that operate over time and are posited as the primary mechanisms producing human development. However, the power of such processes to influence development is presumed, and shown, to vary substantially as a function of the characteristics of the developing *Person,* of the immediate and more remote environmental *Contexts,* and the *Time* periods, in which the proximal processes take place.

The sections that follow examine in greater detail each of the three remaining defining properties of the model, beginning with the biopsychological characteristics of the Person. This domain was given sequential priority to fill a recognized gap in earlier prototypes of the ecological model. Thus, at midstage in the development of the present model, Bronfenbrenner criticized its theoretical predecessors and acknowledged his share of responsibility for failing to deliver on an empirical promise:

> Existing developmental studies subscribing to an ecological model have provided far more knowledge about the nature of developmentally relevant environments, near and far, than about the characteristics of developing individuals, then and now. . . . The criticism I just made also applies to my own writings. . . . Nowhere in the 1979 monograph, nor elsewhere until today, does one find a parallel set of structures for conceptualizing the characteristics of the developing person. (Bronfenbrenner, 1989a, p. 188)

Three types of Person characteristics are distinguished as most influential in shaping the course of future development through their capacity to affect the direction and power of proximal processes through the life course. First, *dispositions* can set proximal processes in motion in a particular developmental domain and continue to sustain their operation. Next,

bioecological *resources* of ability, experience, knowledge, and skill are required for the effective functioning of proximal processes at a given stage of development. Finally, *demand* characteristics invite or discourage reactions from the social environment that can foster or disrupt the operation of proximal processes. The differentiation of these three forms leads to their combination in patterns of Person structure that can further account for differences in the direction and power of resultant proximal processes and their developmental effects.

These new formulations of qualities of the person that shape his or her future development have had the unanticipated effect of further differentiating, expanding, and integrating the original 1979 conceptualization of the environment in terms of nested systems ranging from *micro* to *macro* (Bronfenbrenner, 1979b). For example, the three types of Person characteristics previously outlined are also incorporated into the definition of the *microsystem* as characteristics of parents, relatives, close friends, teachers, mentors, coworkers, spouses, or others who participate in the life of the developing person on a fairly regular basis over extended periods of time.

The bioecological model also introduces an even more consequential domain into the structure of the microsystem that emphasizes the distinctive contribution to development of proximal processes involving interaction not with people but with objects and symbols. Even more broadly, concepts and criteria are introduced that differentiate between those features of the environment that foster versus interfere with the development of proximal processes. Particularly significant in the latter sphere is the growing hecticness, instability, and chaos in the principal settings in which human competence and character are shaped—in the family, child-care arrangements, schools, peer groups, and neighborhoods.

The latter theme speaks to the fourth and final defining property of the bioecological model and the one that moves it farthest beyond its predecessor—the dimension of *Time*. The 1979 Volume scarcely mentions the term, whereas in the current formulation, it has a prominent place at three successive levels: (1) micro-, (2) meso-, and (3) macro-. *Microtime* refers to continuity versus discontinuity in ongoing episodes of proximal process. *Mesotime* is the periodicity of theses episodes across broader time intervals, such as days and weeks. Finally, *Macrotime* focuses on the changing expectations and events in the larger society, both within and across generations, as they affect and are affected by, processes and outcomes of human development over the life course. The treatment of this last topic draws on Elder and Shanahan, Chapter 12, this *Handbook,* this volume. Our primary emphasis, however, is on the role of developmental processes and outcomes in producing large-scale changes over time in the state and structure of the broader society over time, and the implications of those changes for the society's future.

Before turning to the task at hand, it is important to make explicit three overarching orientations that define the content and the structure of the chapter as a whole. First, we use the term *development* to refer to *stability and change in the biopsychological characteristics of human beings over the life course and across generations.* There are no restrictive assumptions of change for the better or of continuity in the characteristics of the same person over time. Rather, these are issues to be investigated.

Second, from the perspective of the bioecological model, the forces producing stability and change in the characteristics of human beings *across* successive generations are no less important than stability and change *in* the characteristics of the same person over his or her lifetime.

The third orientation is perhaps the most essential, and the most difficult to achieve. It was Kurt Lewin (cited in Marrow, 1977) who said that there is nothing so practical as a good theory. But to be "good," a theory must also be "practical." In science, a good theory is one that can be translated into corresponding research designs that match the defining properties of the theory. In the absence of such research designs—or worse yet, in the application of research designs that fail to match or even violate the defining properties of the theory—science cannot move forward. Hence, we have sought, as we proceed through successive stages of theoretical formulation, to specify, and, wherever possible, to illustrate the properties of a research design that corresponds with, or at least approximates, the proposed theoretical structure.

DEFINING PROPERTIES OF THE BIOECOLOGICAL MODEL

An early critical element in the definition of the bioecological model is *experience,* which indicates that the scientifically relevant features of an environment for human development not only include its objective prop-

erties but also the way in which the properties are subjectively experienced by the person living in that environment. This equal emphasis on an *experiential* as well as an *objective* view springs neither from an antipathy to behaviorist concept nor from a predilection for existential philosophic foundations but is dictated simply by the fact that very few of the external influences significantly affecting human behavior and development can be described solely in objective physical conditions and events (Bronfenbrenner & Evans 2000; Bronfenbrenner & Morris 1998).

Critical to the foregoing formulation is the word *solely.* In the bioecological model, both objective and subjective elements are posited as driving the course of human development; neither alone is presumed sufficient. Moreover, these elements do not always operate in the same direction. It is therefore important to understand the nature of each of these two dynamic forces, beginning on the phenomenological or experiential side. Both of the terms are relevant because, while related to each other, they are typically applied to somewhat different spheres. Experiential is more often used in relation to cognitive development and pertains mainly to changes in how the environment is perceived at successive stages of the life course, beginning in early infancy and proceeding through childhood, adolescence, adulthood, and, ultimately, old age.

By contrast, *experience* pertains more to the realm of feelings—anticipations, forebodings, hopes, doubts, or personal beliefs. Feelings, emerging in early childhood and continuing through life, are characterized by both stability and change: They can relate to self or to others, especially to family, friends, and other close associates. They can also apply to the activities in which we engage; for example, those that we most or least like to do. But the most distinctive feature of such experiential equalities is that they are emotionally and motivationally loaded, encompassing both love and hate, joy and sorrow, curiosity and boredom, desire and revulsion, often with both polarities existing at the same time but usually in differing degrees. A significant body of research evidence indicates that such positive and negative subjective forces, evolving in the past, can also contribute in powerful ways to shaping the course of development in the future (Bronfenbrenner & Evans 2000; Bronfenbrenner & Morris 1998).

But these forces are not the only powerful ones at work, other forces are more objective in nature. This presence does not mean, however, that the forces are necessarily either more or less influential, mainly because the two sets of forces are interdependent and affect each other. Like their subjective counterparts, these more objective factors also rely on their assessment of corresponding theoretical models and associated research designs, which evolved over time. These more objective relationships are documented propositions presented later (see too Bronfenbrenner & Evans 2000; Bronfenbrenner & Morris 1998). The first proposition specifies the theoretical model, and provides concrete examples; the second foreshadows a corresponding research design for their assessment.

However, before proceeding with formal definitions, it may be useful to point out that traditionally such phenomena as parent-child interaction—or, more generally, the behavior of others toward the developing person—have been treated under the more inclusive category of the environment. In the *bioecological model,* a critical distinction is made between the concepts of *environment* and *process,* with the latter not only occupying a central position, but also having a meaning that is quite specific. The construct appears in Proposition I stipulating the defining properties of the model. To place its meaning in context, we cite Proposition II as well.

Proposition I

> Especially in its early phases, but also throughout the life course, human development takes place through processes of progressively more complex reciprocal interaction between an active, evolving biopsychological human organism and the persons, objects, and symbols in its immediate external environment. To be effective, the interaction must occur on a fairly regular basis over extended periods of time. Such enduring forms of interaction in the immediate environment are referred to as proximal processes. Examples of enduring patterns of proximal process are found in feeding or comforting a baby, playing with a young child, child-child activities, group or solitary play, reading, learning new skills, athletic activities, problem solving, caring for others in distress, making plans, performing complex tasks, and acquiring new knowledge and know-how.

For the younger generation, participation in such interactive processes over time generates the ability, motivation, knowledge, and skill to engage in such activities both with others and on your own. For example, through progressively more complex interaction with their parents, children increasingly become agents of their own development, to be sure only in part.

Proximal processes are posited as the primary engines of development (see Gottlieb, Wahlsten, & Lickliter, Chapter 5, this *Handbook,* this volume; Tobach, 1981; Tobach & Schneirla, 1968). A second defining property, the fourfold source of these dynamic forces is identified in Proposition II.

Proposition II

> The form, power, content, and direction of the proximal processes effecting development vary systematically as a joint function of the characteristics of the developing person, the environment—both immediate and more remote—in which the processes are taking place, the nature of the developmental outcomes under consideration, and the social continuities and changes occurring over time through the life course and the historical period during which the person has lived.

Propositions I and II are theoretically interdependent and subject to empirical test. An operational research design that permits their simultaneous investigation is referred to as the *Process-Person-Context-Time (PPCT) model.*

Characteristics of the person actually appear twice in the bioecological model—first as one of the four elements influencing the *form, power, content, and direction of the proximal process,* and then again as *developmental outcomes*—qualities of the developing person that emerge at a later point in time as the result of the joint, interactive, mutually reinforcing effects of the four principal antecedent components of the model. In sum, in the bioecological model, the characteristics of the person function both as an indirect producer and as a product of development (see Lerner, 1982, 2002; Lerner & Busch-Rossnagel, 1981).

Finally, because in the bioecological model the concept of proximal process has a specific meaning, it is important that its distinctive properties be made explicit. For present purposes, the following features of the construct are especially noteworthy:

1. For development to occur, the person must engage in an activity.
2. To be effective, the activity must take place "on a fairly regular basis, over an extended period of time." For example, this means that with young children, a weekend of doing things with Mom or Dad does not do the job, nor do activities that are often interrupted.
3. Why not? One reason is that, to be developmentally effective, activities must continue long enough to become "increasingly more complex." Mere repetition does not work.
4. Developmentally effective proximal processes are not unidirectional; there must be influence in both directions. For interpersonal interaction, this means that initiatives do not come from one side only; there must be some degree of reciprocity in the exchange.
5. Proximal processes are not limited to interactions with people; they also can involve interaction with objects and symbols. In the latter circumstance, for reciprocal interaction to occur, the objects and symbols in the immediate environment must be of a kind that invites attention, exploration, manipulation, elaboration, and imagination.
6. The powerful moderating factors specified in Proposition II produce substantial changes in the content, timing, and effectiveness of proximal processes. In particular:
   a. As children grow older, their developmental capacities increase both in level and range; therefore, to continue to be effective, the corresponding proximal processes must also become more extensive and complex to provide for the future realization of evolving potentials. At the same time, in view of the ongoing developmental advance, the intervals between periods of "progressively more complex" activity can be increasingly longer, although they must still occur on a "fairly regular basis." Otherwise, the pace of development slows, or its course may even reverse direction.
   b. The principal persons with whom young children interact "on a fairly regular basis over extended periods of time" are parents, but especially as children get older, other persons—such as caregivers, relatives, siblings, and peers—also function in this role. These are soon followed by teachers or mentors in other activities, and then by close friends of the same or opposite sex, spouses or their equivalents, and coworkers, superiors and subordinates at work. As the examples indicate, the involvement of persons functioning

in this role is not limited to the formative years. Borrowing a term from G. H. Mead (1934), we refer to such persons as *significant others.*

The foregoing constitute the principal elements of the emergent theoretical model. If so, the question arises in what sense is the model *bio*ecological? Where and how does biology come into the picture? We present three answers to that question in an order of decreasing certainty about their validity. The first is an unqualified disclaimer. Little in the pages that follow speaks to the operation of biological systems *within* the organism. By contrast, considerable scientific attention is accorded to characteristics of the person generally regarded as *biologically based* that influence proximal processes and their developmental outcomes. Finally, the present model rests on the assumption that biological factors and evolutionary processes not only set limits on human development but also impose imperatives regarding the environmental conditions and experiences required for the realization of human potentials. The position is taken that, to the extent that the necessary conditions and experiences are not provided, such potentials will remain unactualized (Bronfenbrenner & Ceci, 1993, 1994a, 1994b).

It is our belief that, when applied, the bioecological paradigm is scientifically productive. At the present time, however, its most distinguishing characteristic is not its proven scientific power, but its rarity. To be sure, the rarity is hardly surprising, given the fact that successive revisions of the emerging model began to be published only in the past several years (Bronfenbrenner, 1989a, 1990, 1993, 1994, 1995; Bronfenbrenner & Morris, 1998; Bronfenbrenner & Ceci, 1994a). Paradoxically, some concrete examples nevertheless existed much earlier. They were the product of what Bronfenbrenner and Crouter referred to in the 1983 edition of this *Handbook* as "latent paradigms"; that is, theoretical models that were not explicitly stated, but were implicit in the research designs used in analyzing the data (Bronfenbrenner & Crouter, 1983, pp. 373–376). Indeed, a partial precursor of the bioecological model appeared in the 1983 *Handbook* chapter under the rubric of a "person-process-context model." In that chapter, however, what is meant by process is never specified, and the overwhelming majority of the examples cited do not include a proximal process component as defined in Proposition I. The same holds true for developmentally relevant characteristics of the Person. The 1983 chapter also made no reference to Time as a defining property of the theoretical model. In these and other respects to follow, today's bioecological model goes far beyond its predecessors both with respect to basic constructs and their bidirectional, synergistic interrelationships.

FROM THEORY TO RESEARCH DESIGN: OPERATIONALIZING THE BIOECOLOGICAL MODEL

We have come to the point where it is both possible and necessary to examine the requirements imposed by the bioecological model for corresponding research designs. We begin with a concrete example of the latter.

In the 1950s and 1960s, Cecil Mary Drillien (1957, 1964), a physician and professor of child life and health at the University of Edinburgh, carried out a 7-year longitudinal investigation of psychological development in two groups: 360 children of low birthweight and a control group selected "by taking the next mature birth from the hospital admission list" (1957, p. 29). In her follow-up assessments, the investigator found that children of low birthweight were more likely to exhibit problems in physical growth, susceptibility to illness, impaired intellectual development, and poorer classroom performance, with all of these tendencies being more pronounced in boys (1964). In a comparison of children's school performance with what would have been expected on the basis of their scores on an intelligence test, Drillien found that those of low birthweight were especially likely to be working below their mental capacity. In relation to this finding, the author comments as follows: "In most cases, failure to attain a standard commensurate with ability was associated with problems of behavior, which were found to increase with decreasing birthweight [and] to be more common in males" (1964, p. 209).

Figure 14.1 depicts the results. The figure does not appear in Drillien's monograph, but was constructed from data presented in tables in that volume. It shows the impact of the quality of mother-infant interaction at age 2 on the number of observed problem behaviors at age 4 as a joint function of social class and three levels of low birthweight—those underweight by a pound or more, not more than one pound, and those of normal birthweight. Measures of maternal responsiveness were based on

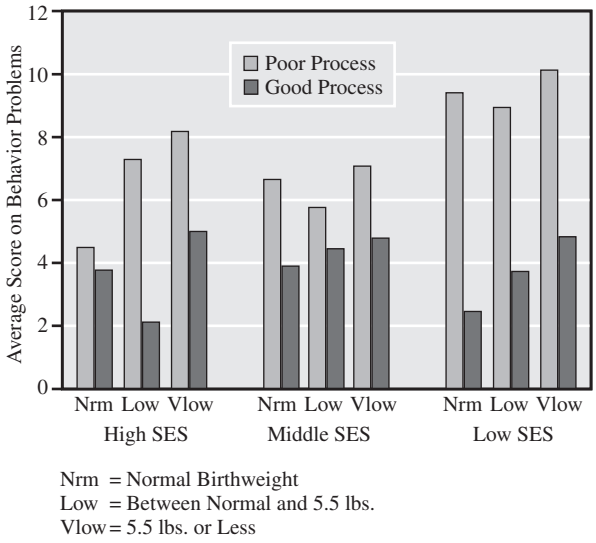

Figure 14.1 Effect of mother's responsiveness on problem behavior of child at age 4 by birthweight and social class.

observations in the home and interviews with the mother. The investigator's measure of social class was a composite index that took into account not only parental income and education but also the socioeconomic level of the neighborhood in which the family lived. The quality of interaction was assessed by extent to which the mother was responsive to changes in the state and behavior of the infant. The measure of the developmental outcome was the frequency of reported behavior disturbances such as hyperactivity, overdependence, timidity, and negativism.

Our primary interest is not in the research findings, but in the extent to which the structure of the research design corresponds with the defining properties of the bioecological theoretical model. The first point to be noted in this regard is that Proposition I defines Proximal Processes as bidirectional. Drillien's measure of process, however, was based only on the mother's responsiveness to changes in the state and behavior of the infant, and no data are reported that would permit calculating a complementary measure of the infant's responsiveness to changes in the state and behavior of the mother. This means that the operational measure available in Drillien's research taps only one side of the theoretical definition of proximal process. For that reason, it appears likely that, to the extent the infant's contribution to reciprocal interaction carries any weight, the obtained results may underestimate the true magnitude of the observed effects.

Nevertheless, as revealed in Figure 14.1, maternal responsiveness across time, a one-sided measure of proximal process, still emerges as the most powerful predictor of developmental outcome. In all instances, responsive maternal treatment reduces substantially the degree of behavioral disturbance exhibited by the child.

Herein lies the main justification for distinguishing between proximal process on the one hand, and, on the other, the environments in which the processes occur; namely, in accord with Proposition I, proximal processes turn out to be the most potent force influencing the developmental outcome (in this case, the frequency of problem behaviors at 4 years of age). Furthermore, as stipulated in Proposition II, the power of the Process varies systematically as a function of the environmental Context (i.e., social class) and of the characteristics of the Person (i.e., weight at birth). The process appears to have made its greatest impact on young children growing up in the most disadvantaged environment (i.e., the lowest socioeconomic level), but in that environment, it is those who at birth were of normal weight who benefited most. Moreover, it was in this same disadvantaged Context that, under high levels of maternal responsiveness, birthweight showed its most consistent effect, with the number of behavior problems steadily rising as birthweight fell. Finally, across the board, maternal responsiveness had the general result of decreasing or buffering against environmental differences in developmental outcome. Thus, at high levels of mother-child interaction, social class differences in problem behavior became much smaller.

From the perspective of developmental science, what is most noteworthy about these findings is not their specific content but that their simultaneous discovery was made possible by a research design based on a theoretical model that allowed for the emergence of patterns of this form. Not only are the four key components of Process, Person, Context, and Time all represented but the design also provides for the detection of the kinds of synergistic[1] interdependencies among these components that are posited in the bioecological model as a dynamic theoretical system. Two specific examples of such interdependencies are revealed in the analysis of Drillien's data:

1. Proposition II stipulates that the developmental effects of proximal processes vary as a joint function of

[1] *Synergism* refers to "cooperative action of discrete agencies such that the total effect is greater than the sum of the two or more effects—taken independently" (*Webster's Third New International Dictionary).*

Person and Context; that is, the indirect effects of Person and Context on the relation of Process to outcome are not to be conceived as simply additive. Consistent with this expectation is the finding that proximal processes had their greatest impact in the most disadvantaged environment but on the healthiest infant. The combination of Person and Context exhibit a mutually reinforcing, multiplicative, indirect effect on the power of proximal processes as the "engines of development."

2. In Drillien's research, the frequency of problem behaviors was assessed at two points in time—first when the infants were 2-years-old, and then again at 4-years-old. If one makes the not unreasonable assumption that mothers continued to interact with their children over the intervening period, then the results shown in Figure 14.2 provide evidence for the effect of proximal processes that have taken place over an extended period of time. Youngsters experiencing low levels of interaction with their mothers exhibited an accelerating increase in the number of problem behaviors from 2 to 4 years of age, whereas those exposed to substantially higher levels of this proximal process showed only a modest rise.

Developmental Science in the Discovery Mode

What about the possibility that the preceding results are chance findings? Some of them are statistically significant, yet others could not be tested because the variances needed for calculating error estimates were not reported. But that is not the principal issue at stake. With concrete examples of the relation between theoretical and operational models now before us, we can address what turns out to be a complex and consequential question: What is the function of research design in the bioecological model? The first point to be made in this regard is that the main function is not the usual one of testing for statistical significance. Rather, the research design must provide for carrying out an equally essential and necessarily prior stage of the scientific process: that of *developing hypotheses of sufficient explanatory power and precision to warrant being subjected to empirical test.* We are dealing with science in the *discovery mode* rather than in the *mode of verification.* In this earlier phase, theory plays an even more critical role. From its very beginnings, the bioecological model, through its successive reformulations, represents a sustained effort to meet this scientific need.

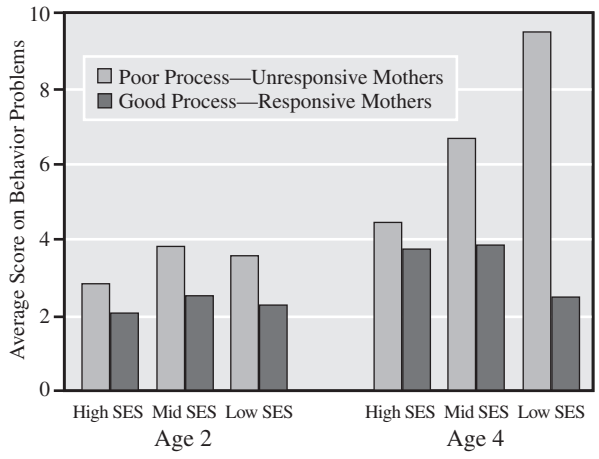

Figure 14.2 Effect of mother's responsiveness on problem behavior of child at ages 2 and 4 by social class.

What are the appropriate characteristics of research designs for developmental science in the discovery mode? Finding an answer to this question is complicated by the fact that, compared with the physical and natural sciences, developmental science is admittedly still in an earlier stage of development. Furthermore, because its scope falls between the natural and the social sciences, the discovery process must to some extent be adapted to the requirements of both. Perhaps in part for these reasons, we were unable to find any discussion of the issue in the developmental literature. Under these circumstances, we concluded that the best we could do was to try to make explicit the characteristics of the research designs that had been employed over the past several years to arrive at successively more differentiated formulations of the bioecological model.

These design characteristics depend on the constructs, and the possible relations between them, that are posited in the theoretical model at its present stage of development. Both the constructs, and the possible interrelationships, have been indicated in Propositions I and II, but as yet they appear in a relatively undifferentiated form. For example, the directions of the expected effects of Person and Context on proximal processes for different types of outcomes are not specified. The reason for such lack of specificity is that a more precise formulation could not be deduced either from the theory in its present, still evolving state, or induced from any already available data (at least, to our knowledge). Given these limitations, we concluded that an appropriate design strategy at this point in the discovery process could be one that involves a series of progressively more differentiated formulations and corresponding data

analyses, with the results at each successive step setting the stage for the next round. The research designs employed must be primarily generative rather than confirmatory versus disconfirming.

In this generative process, implications derived from the theoretical model play a more prominent role than those drawn from research findings, but the latter are also critical. Their importance is best conveyed by specifying a key feature of the corresponding research design: It must provide a structured framework for displaying the emergent research findings in a way that reveals more precisely the pattern of the interdependencies that are obtained in the data available. Of primary scientific interest are not those aspects of the observed pattern already anticipated in the existing theoretical model, but those features that point to more differentiated and precise theoretical formulations. These can then be evaluated in the light of new evidence, and, if deemed scientifically promising, can be incorporated in the research design for a next step. The proposed strategy for developmental investigations in the discovery mode involves an iterative process of successive confrontations between theory and data leading toward the ultimate goal of being able to formulate hypotheses that both merit and are susceptible to scientific assessment in the verification mode.

In presenting this definition of the discovery mode, we acknowledge that, in actual scientific practice, it is hardly likely to be a discovery. The process we have described, or something like it, is what scientists have always done. Our primary reason for seeking to make that process explicit was the belief that doing so could further the discovery process. But we also hope that the explication and examples of the discovery mode presented in this chapter will have broader utility in developmental research.

To return to the task at hand, the proposed criteria have more specific implications for the critical role in research design played by statistical analysis. First, in the discovery phase, Type I errors can entail an even greater risk than errors of Type II. To state the issue more broadly, dismissing as invalid a finding that points the way to a fuller and more precise explanation for the phenomenon under investigation may result in a greater loss than that produced by accepting a finding that is highly significant because of as yet undifferentiated and thereby confounded factors producing the phenomenon in question (e.g., the failure to distinguish Process from Context). The greater risk in the discovery process of dismissing findings as Type I errors is further compounded by the phenomenon of magnification of early environmental differences over time. Thus, as illustrated by the escalating effects of proximal processes shown in Figure 14.2, changes in outcome associated with a proximal process at Time 1 can be quite small and nonsignificant statistically. Yet, as shown, they can be powerful predictors of a marked increase in developmental outcome several years later (in the likely event that the process continued to be maintained over the intervening period).

At this point, a methodological note is in order. Statistical models widely used for the purpose of hypothesis testing are often ill-suited as operational models for developmental investigations in the discovery mode. This is particularly true for models that control statistically solely for *linear* relationships among the factors in the research design to obtain an estimate of the independent contribution of each factor in the statistical model to the outcome under investigation. The validity of such analyses rests on what in mathematical statistics is referred to as "the assumption of homogeneity of regression." To illustrate the assumption in its simplest general case: given a dependent variable y and two independent variables x_1 and x_2, then the relation between x_1 and y must be the same at all levels of x_2. This assumption is often not met in developmental data. For example, when applied to the analysis shown in Figure 14.2, it would require that the relation between proximal process and frequency of problem behaviors be the same at every social class level, which is not the case. Nor is this requirement likely to hold with respect to any combination of the four defining properties of the bioecological model. As Bronfenbrenner stated in his 1979 monograph, *"In ecological research, the principal main effects are likely to be interactions"* (p. 38, italics in original).

Any research design based on a bioecological model must allow for the possibility of such interactions. However, it is also essential, especially in the discovery phase, that the particular interactions to be examined be theoretically based, and that—if possible—their anticipated direction and form be specified in advance so that discrepancies between theoretical expectation and observed reality can be readily recognized and thus provide the basis for a next step in the typically slow, iterative process of seeking more differentiated formulations that merit further exploration both on theoretical and empirical grounds. In each case, the new formula-

tion should be consistent with the existing theoretical specifications of the bioecological model, but it also must take into account any old or new research findings bearing on the issue.

The foregoing criteria for research in the discovery mode do not imply neglect of the traditional issues of reliability and validity. These are honored in a somewhat different, theoretically guided way. Essentially, the process is one of cross-validation at two levels. First, in a given study, the results at each successive stage of analysis are validated in the next, more differentiated formulation. Second, the generalizations emerging from a given investigation are cross-validated against findings from other studies of theoretically related phenomena but with a specific focus on the defining components of the bioecological model.

Before we proceed with concrete examples, it is important to emphasize that the criteria we have proposed and applied for conducting developmental science in the discovery mode represent a first attempt to construct a working model. Moreover, the working model is subject to the curious qualification that it is itself the product of the same sequential design that it proposes. The criteria were developed by examining the changes introduced at each successive stage in the evolution of the bioecological model to identify the theoretical and operational properties leading to improvement in the model's predictive power. The example that follows illustrates these concurrent processes.

Different Paths to Different Outcomes: Dysfunction versus Competence

In this instance, our exploratory effort took as its point of departure the stipulation in Proposition II that the effects of proximal processes vary systematically depending on the developmental outcome. Once again, rather than taking time to retrace our steps, we begin with where we ended up; namely, with the following initial formulation:

> The greater developmental impact of proximal processes on children growing up in disadvantaged or disorganized environments is to be expected to occur mainly for outcomes reflecting developmental *dysfunction.* By contrast, for outcomes indicating developmental *competence,* proximal processes are posited as likely to have greater impact in more advantaged and stable environments.

The term *dysfunction* refers to the recurrent manifestation of difficulties on the part of the developing person in maintaining control and integration of behavior across situations, whereas *competence* is defined as the demonstrated acquisition and further development of knowledge and skills—whether intellectual, physical, socioemotional, or a combination of them (e.g., learning how to care for a young infant involves all three).

The preceding emergent formulation is based on the following considerations. Most parents have the capacity and the motivation to respond to manifestations of physical or psychological distress on the part of their children. In deprived or disorganized environments, such manifestations of dysfunction have been shown to be both more frequent and more severe (e.g., in Drillien's research), thus drawing on more of parents' available time and energy. Accordingly, to the extent that, in disadvantaged settings, parents are able to engage in proximal processes, these are likely to have greater impact in reducing dysfunction rather than in enhancing their children's knowledge about and skill in dealing with the external environment. With respect to problems of dysfunction, in deprived environments there is usually a match between young children's needs and their parents' capacity to meet those needs. This does not mean, however, that children in such environments will end up functioning as well as their age-mates growing up in more favorable circumstance, but rather that, over similar periods of time, they will show greater improvement in control over their own problem behaviors as a function of parental responsiveness.

The situation in advantaged and stable environments is rather different. Manifestations of dysfunction are likely to occur less often and to be less intense. Under these circumstances, parents are more apt to be attracted by and respond to the more frequent and more gratifying signs of their children's growing competence, with the result that proximal processes may to be focused mainly in this latter sphere. In addition, parents living in a middle-class world are themselves more apt to possess and exhibit the knowledge and skills they wish their children to acquire. They also have greater access to resources and opportunities outside the family that can provide needed experiences for their children. Taken together, the foregoing considerations led to the formulation of the previously stated "proto-hypothesis."

Because Drillien's study of the influence of mother-infant interaction dealt with only one developmental outcome, one has to look elsewhere for evidence that effects of such processes vary depending on the nature of the outcome under consideration. A rich data archive generously

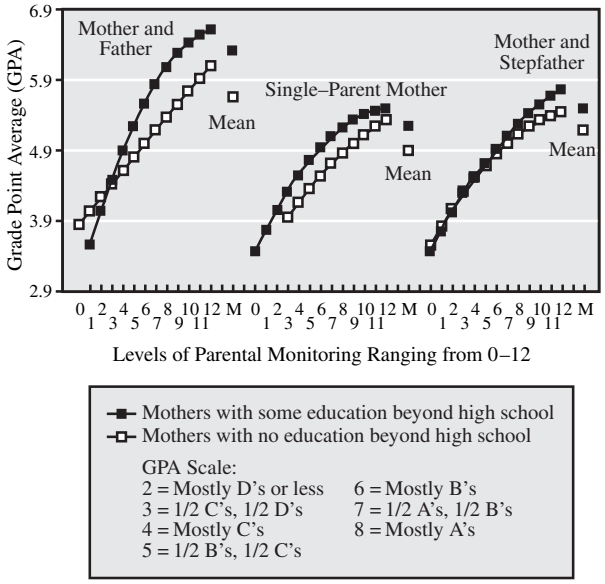

Figure 14.3 Effect of parental monitoring on grades in high school by family structure and mother's level of education. Analyses and graph based on data archives generously provided by Professors Stephen A. Small (University of Wisconsin) and Tom Luster (Michigan State University).

made available by Small and Luster (1990) from their statewide studies of youth at risk in Wisconsin met this need.[2] Figure 14.3 depicts the results from an analysis of the differential effects of parental monitoring on the academic achievement of high school students living in one of the three most common family structures found in the total sample of over 2,500 cases.[3] The students were between 14 and 16 years of age. It was also possible to stratify the sample by two levels of mother's education, with completion of high school as the dividing line. Parental monitoring refers to the effort by parents to keep informed about and set limits on their children's activities outside the home. In the present study, it was assessed by a series of items in a questionnaire administered to adolescents in their school classes. All items referred to parents in the plural, with no distinction as to whether the mother or the father was doing the monitoring. Levels of parental monitoring, ranging from 0 to 12, are shown on the horizontal axis, and grade point average (GPA) is shown on the vertical. The markers to the right of each curve record the mean GPA for each of the six groups.

Once again, the results reveal that the effects of proximal processes are more powerful than those of the environmental Contexts in which they occur. In this instance, however, the impact of the Process was greatest in what emerges as the most advantaged ecological niche—families with two biological parents in which the mother had some education beyond high school. Moreover, the developmental effect of the proximal process on school grades—a measure of *competence*—was stronger for families living in more advantaged socioeconomic circumstances. This finding is directly opposite to that revealed by the analysis of Drillien's data, where the outcome was one of psychological dysfunction (i.e., the frequency of problem behaviors). At the same time, the principal finding from both studies documents the powerful effect of proximal processes on human development, a result consistent with the first defining property of the bioecological model stipulated in Proposition I.

The reader may well ask why the data in each scattergram were fitted to a curve with a declining slope rather than simply with a straight line. In accord with the criteria for research in the discovery mode, the introduction of the quadratic term was based on theoretical considerations. Higher levels of academic performance require mastery of more complex tasks, and hence are more difficult to achieve. As a result, at each successive step, the same degree of active effort would be expected to yield a somewhat smaller result. More specifically, for pupils who are not doing so well in school, parental monitoring

[2] The analyses of data from the Wisconsin archive reported in this chapter were carried out in collaboration with Stephen A. Small (University of Wisconsin) and Tom Luster (Michigan State University) who designed and conducted the survey from which the data are drawn. We are deeply indebted to them for the theoretical thinking that underlies the construction of the survey. It is an excellent example of developmental science in the discovery mode. We are also grateful to Regina Cannon (then a graduate student at Cornell University) who carried out the statistical analyses with care and dispatch.

[3] The large number of cases in this study should not be taken to imply that the bioecological model can be applied only in samples with a large *N*. As illustrated here, precision in the formulation of the theoretical model and in its translation into a closely corresponding research design can produce reliable findings even when there are relatively few cases in some, or even all, the cells of the model. This comes about because, in effect, the bioecological model requires, in its discovery phase, advance specification primarily not only of main effects but also in the form and direction of their most plausible interactions in the light of both the evolving theoretical model and the then available research evidence. This is especially true for well-designed experiments. For examples, see pp. 808–809.

can have a substantial effect by ensuring more stability of Time and place so that *some* learning can occur. But for superior school achievement, students would require in addition high levels of motivation, focused attention, prior knowledge, and—especially—actually working with the material to be learned. These are all qualities that stability of Time and place by itself cannot provide.

As can be seen in Figure 14.3, the relation between parental monitoring and school grades shows a curvilinear trend. Moreover, in accord with criteria for research in the discovery mode (see pp. 801–803), both in its direction and form the trend corresponds with theoretical expectations in being more pronounced when the mother has some education beyond high school, especially in a two-parent family structure. A test for heterogeneity of regression confirms visual inspection. The differences in slopes between the two educational levels are highly significant ($p \leq .01$), with the quadratic component emerging as reliable only in the higher educational group.[4] Also statistically significant are differences in school achievement by family structure in each level of mother's education, with students growing up in two-parent families getting the highest grades, and those from single-parent families the lowest, a rank order corresponding to the power of the proximal process in each group as measured by the slopes of the associated regression coefficients.

Finally, a result not shown on the graph provides additional evidence pointing to another tentative generalization. The first indication appeared in the analysis of Drillien's data, which, among other findings, revealed that maternal responsiveness had the general effect of decreasing or buffering against environmental differences in developmental outcome. Thus, at high levels of mother-child interaction, social class differences in problem behavior became smaller. A similar pattern emerges for the effects of parental monitoring on school grades. Across the six groups shown in Figure 14.3, stronger parental monitoring was associated not only with a higher mean on school performance but also with a lower standard deviation. These differences, too, were statistically reliable. Hence the following working hypothesis:

> For outcomes of *competence,* proximal processes not only lead to higher levels of developmental functioning but also serve to reduce and act as a buffer against effects of disadvantaged and disruptive environments.

To turn from substance to method, the foregoing findings also demonstrate that tests of significance have a place in research in the discovery mode, but, as with hypothesis verification, only *after* a specific theoretical expectation has been formulated in advance.

In a discovery context, however, the aim is not to claim empirical validity for a particular theoretical formulation but to indicate its plausibility for inclusion in the research design at subsequent stages of exploratory work. To be sure, doing so may result in a failure of replication. But *not* doing so risks missing potentially important, theoretically guided research opportunities not yet recognized. Garmezy and Rutter (1983), in their landmark studies of stress and coping in children's development, did not differentiate between those protective or disruptive forces emanating from the environment, and those inherent in the biopsychological characteristics of the person. As evidenced from the analysis of Drillien's data shown in Figure 14.1, these vectors do not always operate in the same direction. Nevertheless, Garmezy and Rutter's formulations and findings played a significant role in the early stages of the process through which the bioecological model reached its present, still-evolving form.

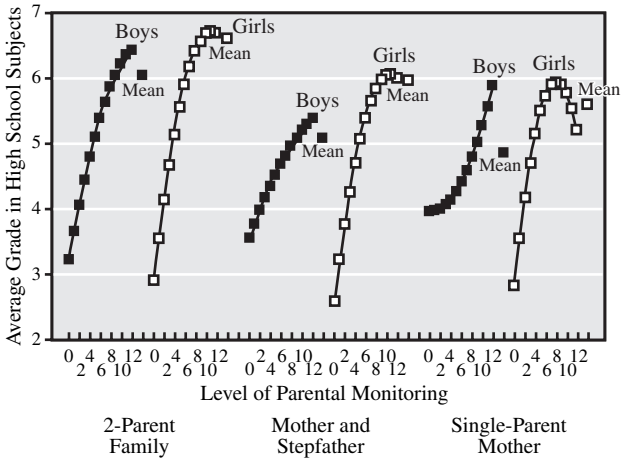
The still-evolving form imposes the obligation to take advantage of existing opportunities for continued exploration. With respect to the present inquiry, the next step in that process was once again to pose the question about the extent to which the research design meets the defining properties of the bioecological model. At first glance, we appear to be confronted with the same problem that we encountered with Drillien's study. Proposition I defines proximal processes as bidirectional. As previously noted, Small and Luster (1990) defined parental monitoring as the effort by parents to keep informed about and set limits on their children's activities outside the home. As stated, such behavior implies influence from one side only—that of the parents. An examination of the actual items used in their questionnaire, however, revealed that they were of two kinds. Some were cast in the language of parental expectation and prescription (e.g., "If I am going to be home late, I am expected to call my parent(s) to let them know"; "When I go out, my parent(s) ask me where I'm going"). By contrast, other items implied that the desired expectations or prescriptions were being met (e.g., "My parent(s) know where I am after school"; "I tell my parent(s) who

[4] The degree of curvilinearity is measured by the corresponding regression coefficients and not by difference in the length of each curve from top to bottom. The latter is determined by empty cells in the scatter plot below or above which entries for *both* monitoring level and GPA were available.

I'm going to be with before I go out"). Although the first type of item is unidirectional, the second entails some degree of reciprocity to the extent that the adolescent is providing the information desired by the parents. Accordingly, we hypothesized that items of the second type would show stronger relationships to developmental outcomes than those that described only the parents' expectations of how they wished their children to behave.

Separate analyses of scales based on each type of item provided substantial support for our working hypothesis. Although responses to both types of questions showed reliable effects on school performance, the relationships for the reciprocity scale were significantly stronger and were much more likely to show curvilinear effects. Accordingly, the latter was the scale used in analyzing the results presented in Figure 14.3.

From the perspective of the biological model, the research design producing the results shown in that figure is missing an important Person component. It is a general finding in educational research that at the high school level female students score higher on measures of academic performance than do males. The question therefore arises: To what extent is this gender difference attributable to variations in proximal process? Figure 14.4 provides a tentative answer to this question for students whose mothers had more than a high school education. In each family structure, parental monitoring exerted a more powerful effect on the school achievement of girls than of boys, a result that is paralleled by corresponding differences in average GPA for the two sexes.[5] In each of the three family structures, girls received higher grades than boys, with the difference being most pronounced in two-parent households and lowest in single-mother families.



High school students are between 14 and 16 years old.

Figure 14.4 Parental monitoring and high school grades by gender: mothers with more than a high school education. Analyses and graph based on data archives generously provided by Professors Stephen A. Small (University of Wisconsin) and Tom Luster (Michigan State University).

As seen in Figure 14.4, however, a distinctive feature of the pattern for girls is a marked flattening of the curve, especially for daughters of single-parent mothers. This result suggests that, in each of the three family structures, mothers may be pushing their already successful daughters to the point where conformity to maternal control no longer brings educational returns, particularly when the mother is the only parent.

An analysis of data on students whose mothers had no more than a high school education showed a similar general pattern, but the effects were less pronounced. The influence of monitoring was appreciably weaker, and its greater benefit to girls was also reduced. Nevertheless, girls with less-educated mothers both in single-parent and in stepfamilies still had higher GPA scores than boys. This means that some other factor not yet identified must account for this difference.

Although a number of possibilities come to mind regarding this unknown, regrettably the Wisconsin archive does not contain any data on the principal suspects. What is available is information about another trail of discovery that we have already begun to explore. Our successively more differentiated working models, both conceptual and operational, for assessing the effects of parental monitoring on school achievement have provided increasing support for the tentative hypothesis that, for outcomes reflecting developmental *competence,* proximal processes are likely to have greatest impact in the most advantaged environments. But what about the other half of the original formulation: the complementary postulate that the greater developmental impact of proximal processes growing up in poor environments is to be expected to occur mainly for outcomes reflecting developmental *dysfunction?*

Data from Small and Luster's archive also provide the opportunity for cross-validating this provisional claim. In addition to measures of academic achievement, the Wisconsin study also included information on teenagers' sexual activity. The decision to analyze this outcome in the context of a bioecological model was prompted by Small and Luster's (1990) finding that such

[5] Within each pair, both means and regression coefficients were statistically significant, the latter confirming reliable differences in slope.

behavior varied systematically by family structure. Sexual activity was measured by a single question: "Have you ever had sexual relations with another person?"

This documentation of variations in sexual activity by family structure takes on special significance in the light of broader social changes taking place in the lives of children, youth, and families in contemporary U.S. society. Today, the United States has the highest rate of teenage pregnancy of any developed nation, almost twice as high as that of its nearest competitors (Bronfenbrenner, McClelland, Wethington, Moen, & Ceci, 1996, p. 117). Adolescent sexual activity is also one of the prominent elements in the so-called teenage syndrome, an escalating pattern of co-occurring behaviors including smoking, drinking, early and frequent sexual experience, adolescent pregnancy, a cynical attitude toward education and work, and, in the more extreme cases, drugs, suicide, vandalism, violence, and criminal acts (for references and successive summaries of the evidence, see Bronfenbrenner, 1970, 1975, 1986a, 1989c, 1990, 1992; Bronfenbrenner et al., 1996; Bronfenbrenner & Neville, 1994).

In anticipating the effects of parental monitoring on teenagers' sexual activity, we were again confronted with the issue of the possible direction of influence. In relation to sexual activity as an outcome, however, some leverage for the resolution of the issue was provided because each direction could be expected to produce opposite effects. On the one hand, if parental monitoring functions to defer sexual activity, then the more monitoring the less sexual activity. On the other hand, if the parents begin to monitor only after the fact, the association would be reversed, with monitoring occurring in reaction to the adolescent's behavior; hence, sexually active adolescents would be monitored more.

The results of the analysis are shown in Figures 14.5 and 14.6.[6] The most salient finding for both sexes is that parental monitoring does substantially reduce adolescents' sexual activity. In many other respects, however, the patterns for female and male adolescents are quite different. The results for girls in Figure 14.5 show that the effect of parental monitoring is stronger for daughters of mothers with no education beyond high school—a finding consistent with the working hypothesis

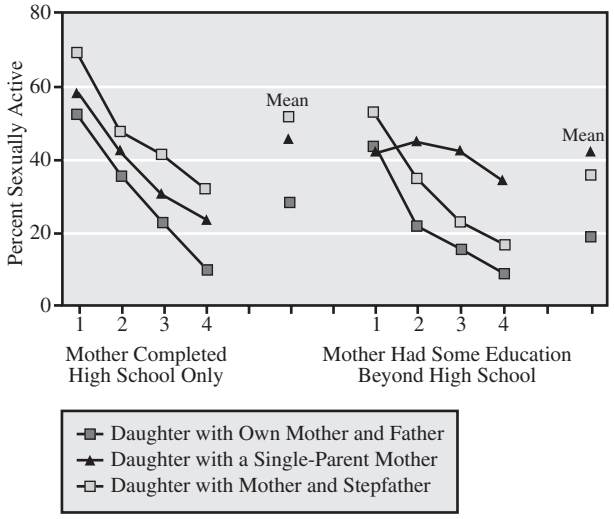


Figure 14.5 Effect of monitoring on girls' sexual activity (high school students between 14 and 16 years of age).

that, for outcomes reflecting lack of control, proximal processes have greater impact in poorer environments. Tests for heterogeneity of regression confirm that this finding holds for each of the three family forms.

Yet, as shown in Figure 14.6, the corresponding analysis of the data for boys reveals the very opposite result. Parental monitoring has a more powerful effect on boys whose mothers have had *more* education rather than less. Once again, the finding holds in each family structure and is confirmed by tests for heterogeneity of regression.

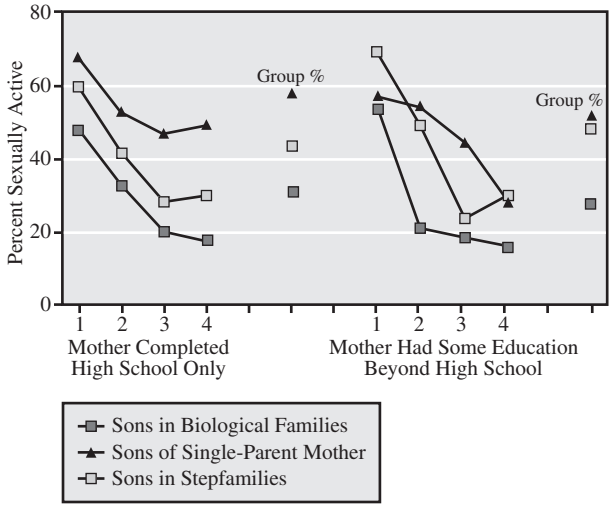

Figure 14.6 Effect of parental monitoring on boys' sexual activity (high school students between 14 and 16 years of age).

[6] We are also indebted to Kristen Jacobson, now a doctoral student at Pennsylvania State University, for her ingenuity and accuracy in translating into a common format data archives recorded on different computing systems.

This is not the only departure from the expectations generated by the most recent working model. For example, there was not always correspondence between the developmental power of proximal processes in a given family structure and the percentage of sexually active adolescents in that structure: In stepfamilies in which the mother has only a high school education, maternal monitoring of daughters is as high as it is in two-parent families, but the percentage of sexually active girls is even greater than that for single-parent mothers at the same educational level. The finding is consistent with research indicating that living in a family with a stepfather entails a special developmental risk for girls (Hetherington & Clingempeel, 1992).

And so, we find ourselves engaged in a next stage of the discovery process in which we are seeking to develop a more differentiated formulation that, through a corresponding research design, will be most effective in reducing the observed empirical departures from expectations based on the existing working model. The first step is to ask an obvious question: What is most likely to account for such discrepancies? Restating the question from the perspective of the bioecological model, which of the four components is a likely suspect? It has to be somebody who is already on the scene. Parents are already there. Who else is around who could exert some influence on the sexual activity of high school students? The question answers itself—the peer group. And if it is indeed true that proximal processes are at least as powerful determinants of development as either the characteristics of the person or of the environment, what might that process be?

A tentative first nomination is *progressively more intense interaction with peers who are already sexually active*. Among other considerations, this suggestion is guided by the possibility that peer pressure to engage in sexual activity and the prestige that such activity brings are likely to be higher for boys from less educated families with the result that parental monitoring is not as effective. With respect to the other components in the model, given the findings just reported, gender would still be a Person characteristic of major importance. The choice of an appropriate environmental Context depends on the precise research question being asked. Family structure would also still be appropriate. But from the perspective of the bioecological model, an option to consider would be the parents' beliefs about the activities they wanted their adolescent son or daughter to engage in or refrain from, as well as the closeness of the parent-child relationship.

We offer these suggestions not for their relevance to this particular issue but to illustrate two additional emergent corollaries of the bioecological model:

1. The specific components of Process, Person, Context, and Time to be included in a given investigation should be those that, from a theoretical perspective, are maximally relevant to the research question under investigation and complementary to each other in relation to the given developmental outcome.
2. From a theoretical perspective, the power of a PPCT design is most effectively enhanced by including more than one proximal process in the model.

The next section leads to yet another corollary.

The Role of Experiments in the Bioecological Model

The examples considered thus far are essentially experiments of nature: They show how development is influenced by variations in the components of the bioecological model occurring in already existing societies. They tell us nothing about whether, to what extent, or how these elements and their combinations can be changed. This limitation applies particularly to the most consequential component of the bioecological model—proximal processes. We know of no research bearing specifically on this question, but some indirect evidence does exist. In research findings already presented, improving the quality of the environment has been shown to increase the developmental power of proximal processes. The indirect evidence comes from experiments in which researchers have systematically introduced conditions into the environment in which people lived that were hypothesized to enhance their psychological functioning beyond existing levels.

Here are two examples at contrasting ages.

Environmental Dynamics in Old Age

The first example is Langer and Rodin's oft-cited experimental intervention conducted with residents of a New Haven nursing home for the aged (Langer & Rodin, 1976; Rodin & Langer, 1977). The contextual manipulation employed in this study is well summarized in the authors' words:

> The hospital administrator gave a talk to residents in the experimental group emphasizing their responsibility for themselves, whereas the communication to a second, comparison group stressed the staff's responsibility for them as patients. To bolster the communication, residents in the experimental group were offered plants to care for, whereas residents in the comparison group were given plants that were watered by the staff. (Rodin & Langer, 1977, p. 897)

Residents were assigned at random to either the experimental or the control group. Data on psychological and health characteristics were collected at three time points: (1) just prior to the introduction of the experiment; (2) 3 weeks later, when the experiment was formally ended; and (3) in a follow-up study conducted 18 months later.

The substantial effects of intervention found at the end of the experiment (Langer & Rodin, 1976) were still in evidence in the follow-up assessment. To be sure, because the residents were almost a year-and-a-half older, the added age had taken some toll, but, nevertheless, those in the "induced responsibility" group not only significantly surpassed their controls, but were appreciably better off, both psychologically and physically, than they had been months earlier before the intervention had begun. In ratings by observers blind to the experimental conditions, they were judged to be more alert, sociable, and vigorous. The most striking results were seen in the comparison of death rates between the two treatment groups. Taking the 18 months prior to the original intervention as an arbitrary comparison period, in the subsequent 18 months following the intervention, 15% in the "responsibility-induced" group died, compared with 30% in the control group.

Environmental Dynamics in Infancy

A remarkable, independent cross-validation of Langer and Rodin's principal hypothesis appears in the findings of another intervention experiment—this one almost unknown—that was carried out at about the same time with a sample of 100 9-month-old infants and their mothers in the Dutch city of Nijmegen (Riksen-Walraven, 1978). Although this author, Marianne Riksen-Walraven, appears not to have been aware of Langer and Rodin's work conducted during the same period, one of the two intervention strategies she employed with her sample of infants was similar to that used in the New Haven study of elderly patients. Mothers, randomly assigned to what Riksen-Walraven called the "responsiveness" group, were given a "workbook for parents" stressing the idea that "the infant learns most from the effects of its own behavior" (p. 113):

> Caregivers were advised not to direct the child's activities too much, but to give the child opportunity to find out things for himself, to praise him for his efforts, and to respond to his initiations of interaction. (p. 113)

By contrast, mothers of infants in the "stimulation" group received a workbook that emphasized the importance of providing the infant with a great variety of perceptual experiences of all kinds, "to point to and name objects and persons," and "to speak a lot to their infants" (p. 112).

In the follow-up assessment conducted 3 months later, infants of mothers who had been encouraged to be responsive to their babies' initiatives exhibited higher levels of exploratory behavior and were more likely to prefer a novel object to one that was already familiar. The babies also learned more quickly in a learning contingency task.

Neither of the preceding investigations included any systematic assessment of the activities in which the participants in the experiment subsequently engaged, of the balance between unidirectional and bidirectional behavior in the two groups, or of any other specific feature that could provide a measure of the extent to which proximal processes were operating in each of the two contrasting experimental conditions.

In both of the preceding experimental studies, elegant as they are, the keystone of the bioecological model—a measure of proximal process—was not included in the research design. In addition, the demonstration (in Figure 14.3) of the joint, indirect effects of family structure and parents' education on the relation of proximal processes to school grades does only half the job, for it provides no information on whether differences in students' personal characteristics (such as gender) exert a similar indirect effect. Nevertheless, viewed from the theoretical perspective of a bioecological model, all these findings are impressively consistent with expectations derived from the model; the findings illustrate the model's practicability, and—perhaps most promising for the future of developmental science—generate questions that, when answered, provide ways for enhancing the model's scientific power. It is these questions and answers that are addressed in the following sections.

Up to this point, our exposition has given primary attention to the core concept of proximal process and its

key position in the bioecological model as a whole. We now proceed to a more detailed examination of each of the other three defining properties of the model—Person, Context, and Time.

HOW DO PERSON CHARACTERISTICS INFLUENCE LATER DEVELOPMENT?

As already indicated, at midstage in the development of the bioecological model, an effort was begun to arrive at some answers to this question, and it has continued up to the present day. As before, rather than describe the successive stages in this emergent reconception, we present it in its most recent, still-evolving form.

Most developmental research treats the cognitive and socioemotional characteristics of the person as dependent variables; that is, as measures of developmental outcomes. Far less often are such characteristics examined as precursors and producers of later development From the perspective of the bioecological model, their effectiveness in the latter role derives from their capacity to influence the emergence and operation of proximal processes.

Accordingly, in an effort to identify such process-relevant Person characteristics, we applied the sequential design strategy described in the preceding section. Beginning with implications derived from the theoretical model, which are then related to existing research findings, successive applications of this strategy have resulted in the conceptualization of three kinds of process-relevant Person characteristics, which, for convenience of brevity, we have labeled as Person *forces, resources,* and *demands.*[7]

Force Characteristics as Shapers of Development

In the bioecological model, the characteristics of the Person most likely to influence future development would be active behavioral dispositions that can set proximal processes in motion and sustain their operation, or—conversely—actively interfere with, retard, or even prevent their occurrence. It is therefore useful to distinguish between these two propensities. We refer to the former as *developmentally generative* characteristics; to the latter as *developmentally disruptive.*

Examples of developmentally disruptive dispositions come more readily to mind. At one pole, they include such characteristics as impulsiveness, explosiveness, distractibility, inability to defer gratification, or, in a more extreme form, ready resort to aggression and violence; in short, difficulties in maintaining control over emotions and behavior. At the opposite pole are such Person attributes as apathy, inattentiveness, unresponsiveness, lack of interest in the surroundings, feelings of insecurity, shyness, or a general tendency to avoid or withdraw from activity.[8] Persons exhibiting either of the preceding propensities would find it difficult to engage in proximal processes requiring progressively more complex patterns of reciprocal interaction over extended periods of time.

By contrast, developmentally generative characteristics involve such active orientations as curiosity, tendency to initiate and engage in activity alone or with others, responsiveness to initiatives by others, and readiness to defer immediate gratification to pursue long-term goals.

We have found few investigations that shed light on the developmental effects of either type of dynamic characteristics on proximal processes and their outcomes. A major reason for this shortcoming is the absence of theoretical constructs for conceptualizing their changing nature over the course of development from early infancy, through adolescence, into and beyond early adulthood. The following framework is offered as an initial basis for meeting this requirement beginning in the Person domain in greater need of conceptual definition—that of developmentally generative characteristics. The corresponding structure for developmentally disruptive Person qualities can then be derived as an inverted mirror image of the former.[9]

Developmentally Generative Dispositions in Life-Course Perspective

The first and earliest manifestation of generative dispositions takes the form of what we call *selective responsiveness.* It involves differentiated response to, attraction by, and exploration of aspects of the physical and social environment.

[7] As is documented later in this chapter (p. 819), the recently renewed, and far stronger, claims by behavior geneticists for the predominant role of genetic factors in determining both individual and group differences in all forms of human characteristics are directly challenged by alternative explanations and research findings derived from the bioecological model.

[8] Depending on the available alternatives, withdrawal may be the only course left for dealing with an unbearable situation.

[9] The material that follows represents a further development by the present authors of ideas first introduced in Bronfenbrenner (1989).

The next generative characteristic to evolve goes beyond selective responsiveness to include the tendency to engage and persist in progressively more complex activities; for example, to elaborate, restructure, and even to create new features in our environment—not only physical and social but also symbolic. We refer to propensities of this kind as *structuring proclivities.*

The transition from one to the other of these dynamic forms of orientation during early childhood is illustrated in successive publications from a longitudinal study of infants being carried out by Leila Beckwith, Sarale Cohen, Claire Kopp, and Arthur Parmelee at UCLA (Beckwith & Cohen, 1984; Beckwith, Rodning, & Cohen, 1992; Cohen & Beckwith, 1979; Cohen, Beckwith, & Parmelee, 1978; Cohen & Parmelee, 1983; Cohen, Parmelee, Beckwith, & Sigman, 1986). Their imaginative and careful work reveals a progressive sequence of such environmentally oriented dispositions from birth through 7 years of age. Thus, immediately after birth, infants are especially responsive to vestibular stimulation (being picked up and held in a vertical position close to the body), which has the effect of soothing babies so that they begin to engage in mutual gazing; by 3 months, visual exploration extends beyond proximal objects, and the mother's voice is most likely to elicit responses especially in the form of reciprocal vocalizations.

From about 6 months on, the infant begins actively to manipulate objects spontaneously in a purposeful way and to rearrange the physical environment. By now, both vocalization and gesture are being used to attract the parents' attention and to influence their behavior. In addition, there is a growing readiness, across modalities, to initiate and sustain reciprocal interaction with a widening circle of persons in the child's immediate environment. This is the emergence of what we call structuring proclivities.

A number of other investigations have yielded comparable findings, and have extended them to still other activity domains; for example: individual differences in children's creativity in play and fantasy behavior (Connolly & Doyle, 1984; MacDonald & Parke, 1984) or Jean and Jack Block's longitudinal studies of "ego resiliency" and "ego control" (J. H. Block & Block, 1980; J. Block, Block, & Keyes, 1988).

The nature of the third and final class of developmentally generative Person characteristics reflects the increasing capacity and active propensity of children as they grow older to conceptualize their experience. It deals with what we call *directive belief systems* about oneself as an active agent both in relation to the self and environment, or, for short, *directive beliefs.* The oldest concept of this kind is Rotter's construct and measure of "locus of control" (Rotter, 1966). Subsequently, a more sophisticated formulation of the concept was introduced by Bandura (1977, 1982) under the rubric of self-efficacy. The principal distinction between these earlier constructs and their counterparts in the bioecological model is that the latter are conceptualized primarily not as characteristics of the person sufficient unto themselves but as directional dispositions interacting synergistically with particular features of the environment to generate successive levels of developmental advance.

The closest approximation to an operationalized bioecological model in which directive beliefs function as Person characteristics appears in a series of findings arising from a doctoral dissertation by Tulkin (1973, 1977; Tulkin & Cohler, 1973; Tulkin & Kagan, 1972). The investigator studied social class differences both in the behaviors and the beliefs of mothers of 10-month-old girls. The research was conducted in the home, employing both interviews and observations. Middle-class mothers were distinguished from their working-class counterparts not only by higher levels of reciprocal interaction with their infants, but also in their views about what a 10-month-old could do, and about their own abilities to influence their baby's development; the more advantaged mothers attributed greater potentials both to their infants and themselves. In addition, the correlations between maternal behavior and attitudes were substantially greater in middle-class than in lower-class families. Several years later, Tulkin and a colleague (Tulkin & Covitz, 1975) reassessed the same youngsters after they had entered school. The children's performance on tests of mental ability and language skill showed significant relationships to the prior measures of reciprocal mother-infant interaction.

Perceptive readers may have detected a sleight of hand in our analysis of Tulkin's research when examined from the perspective of the bioecological model. In that framework, we have been discussing characteristics of the developing Person that influence proximal processes and their outcomes. In Tulkin's work, the developing Person is the infant. But the directive beliefs we have been discussing are those of the mother. The reason for the substitution is the following. Although, in the line of work stimulated by Rotter and Bandura there are many investigations of the relation between personal

beliefs and development, to our knowledge there have been no studies of the effect of personal beliefs on the proximal processes in which the developing person herself or himself becomes engaged. To provide an example, we resorted to a substitution of roles.

The substitution also provides an opportunity to introduce a corollary formulation, the evidence for which appears later in this and subsequent sections of this chapter:

> In proximal processes involving interpersonal interaction, the personal characteristics that influence the power of the process and its effects are the same for all parties involved.

To return to the task at hand, we present a second form of Person characteristic posited as affecting future psychological growth—what we have called developmental resources.

Resource Characteristics of the Person as Shapers of Development

These are Person characteristics that in themselves involve no selective disposition to action, but constitute biopsychological liabilities and assets that influence the capacity of the organism to engage effectively in proximal processes. In the first category are conditions that limit or disrupt the functional integrity of the organism. Some obvious examples include genetic defects, low birthweight, physical handicaps, severe and persistent illness, or damage to brain function through accident or degenerative processes. By contrast, developmental assets take the form of ability, knowledge, skill, and experience that, as they evolve over most of the life course, extend the domains in which proximal processes can do their constructive work—thereby becoming another source of the progressively more complex patterns of interaction constituting a defining property of proximal processes.

The similarity between the definitions for the two types of developmental resources, and for the earlier distinction between developmental outcomes reflecting dysfunction versus competence, derives from the fact already noted that characteristics of the Person appear on both sides of the bioecological equation. Developmental outcomes at Time 1 indirectly influence developmental outcomes at Time 2 through their effect on proximal processes during the intervening period. The difference, therefore, lies not in the concepts themselves but in their place in the bioecological model.

A concrete example of a deficiency in developmental resources has already been documented in the analysis of Drillien's results depicted in Figure 14.1. Proximal processes exerted their most powerful effect on children growing up in the most disadvantaged environment, but in that environment youngsters who at birth were of normal weight benefited most. Weight at birth does not imply a directed propensity to engage in or refrain from a particular kind of behavior. What it does represent is variation in the biological resources available to engage in any activity requiring directed activity or response over extended periods of time. Thus, in the present instance, one plausible explanation for the observed asymmetric pattern is that, among families living in stressful environments, infants who are physically healthy from birth are more able to engage in reciprocal interaction than those who are biologically impaired.

This interpretation is called into question, however, by the corresponding results, shown in the same graph, for infants raised under the most favorable socioeconomic circumstances. Infants of normal birthweight profited least from interaction with their mothers. How might this paradox be resolved?

Even though the corresponding interaction term is statistically significant, under normal circumstances the preceding result would—and properly should—be called into question as a post hoc finding. But, in the present instance, that is not quite the case. To be sure, there was no a priori hypothesis predicting the precise pattern of the obtained results. The pattern is consistent, however, with several possibilities envisioned for a third Person attribute posited as influencing proximal processes and their developmental effects. And for science in the discovery mode, post hoc findings that are theoretically relevant are not to be lightly dismissed.

Demand Characteristics of the Person as Developmental Influences

The distinguishing feature of this last set of Person characteristics affecting development is their capacity to invite or discourage reactions from the social environment that can disrupt or foster processes of psychological growth: for example, a fussy versus a happy baby, attractive versus unattractive physical appearance, or hyperactivity versus passivity. Half a century ago, Gordon Allport (1937), borrowing a term originally introduced by Mark A. May (1932), spoke of such characteristics as

constituting "personality" defined in terms of its "social stimulus value." Rephrasing this concept in terms of its analog in contemporary theories of perception, we refer to such Person qualities as *demand characteristics.*

A striking example of the developmental effect of such a feature emerges as a major finding in one of the follow-up studies of children of the Great Depression carried out by Elder and his colleagues (Elder, Van Nguyen, & Caspi, 1985). The investigators found that economic hardship adversely influenced the psychosocial well-being of girls (but not boys) through its tendency to increase the rejecting behavior of fathers. The effects of rejection, however, varied inversely as a function of the daughter's physical attractiveness. In the authors' words, "Attractive daughters were not likely to be maltreated by their fathers, no matter how severe the economic pressure. [The results] underscore the importance of viewing economic decline in relation to both the child's characteristics and parenting behavior" (p. 361). Here is a classic instance of the power of a PPCT model in revealing the complex interactions between organism and environment that drive the process of development.

The concept of demand characteristics also introduces a new perspective for interpreting the contrasting developmental effects of birthweight by social class shown in Figure 14.1. As noted earlier, at the lowest socioeconomic level it was the children of normal birthweight who benefited most from maternal responsiveness. But does that mean they were also the ones who got the most attention from their mothers? Paradoxically, the picture turns out to be just the reverse. Only 14% of these lower-class mothers were judged to be responsive to changes in their infants' state or behavior, whereas the percentage for mothers of low-birthweight babies was more than twice as high (averaging 37%). In short, lower-class mothers were responding mainly to those infants who most needed their attention, albeit with a lower return on their investment.

But what characteristics of these babies were capturing the mothers' attention? It appears likely that in this instance, the mothers were responding mainly to their infants' expressions of distress—behavior less apt to occur among those of normal birthweight. If we look at the corresponding data for families at the highest socioeconomic level, we discover a rather different picture. Mothers are more responsive to the healthiest infants than to those of lowest birthweight, but as shown in Figure 14.1, they get the least return for their pains. Once again a key question becomes "What is capturing the mother's attention?" A plausible answer for children of normal birthweight living in the most favored circumstances is that their mothers would be responding primarily not to manifestations of problem behavior, but of growing competence.

THE ROLE OF FOCUS OF ATTENTION IN PROXIMAL PROCESSES

The preceding considerations, generated by a confrontation of data with theory, call for more differentiated formulations in the existing bioecological model. Here is the first of two tentative responses to the call:

> When a proximal process involves interaction with another person, the power of the bioecological model is substantially enhanced by including in the research design a measure of the other person's *focus of attention on the particular aspects of the behavior of the subject that are presumed, on theoretical and empirical grounds, to be most closely related to the developmental outcome.*

For Drillien's study, the measure of proximal process is the mother's responsiveness, but we do not know to what particular behaviors of her baby she was responding. As already suggested, the aspect most relevant for reducing future problem behaviors might be expressions of distress. If so, a more precise conceptual and operational definition of the proximal process in this study would be the proportion of manifestations of distress that were responded to by successful efforts to reduce that distress.

However, even though in the Drillien study the mothers' focus of attention was not known, the extent of her responsiveness was still a strong predictor of the outcome. Even when the theoretical and operational requirements of the bioecological model are not met in full, the results can still contribute to understanding the forces that shape human development.

A second, complementary tentative formulation derives from the definition of proximal processes as bidirectional. Stated succinctly, it posits that the preceding formulation also holds in reverse:

> When a proximal process involves interaction with another person, the power of the bioecological model is substantially enhanced by including in the research design a measure of the developing person's *focus of attention on the particular aspects of the behavior of the other person that*

are presumed, on theoretical and empirical grounds, to be most closely related to the developmental outcome.[10]

PROXIMAL PROCESSES IN SOLO ACTIVITIES WITH OBJECTS AND SYMBOLS

The foregoing considerations and complexities give added importance to those proximal processes that do not involve interpersonal interaction but instead focus on progressively more complex reciprocal interaction with objects and symbols. These are activities that can be carried on in the absence of other persons, and therefore the magnitude and effectiveness of the proximal process are not influenced by another participant's behaviors. One would therefore expect that the person's own disposition and resources would play a far stronger role in affecting the direction and power of the proximal process than in the case of interpersonal interaction. Furthermore, such solo activities significantly change the processes involved, their outcomes, and the features of the environment that become most relevant. The contrast in all three domains involves a focus on *human relationships,* on the one hand, and *tasks,* on the other. To understand the developmental importance of this contrast requires a fuller exposition of the features of the environment that influence proximal processes and their effects.

But before turning to this topic, we must give due recognition to three other Person characteristics that push us in the same direction. They are so pervasive in affecting future development that their possible influence routinely needs to be considered in relation to the particular phenomenon under investigation. These are the familiar demographic factors of *age, gender,* and *ethnicity.* Another reason for this recommendation is that all three of these factors, although based on differing physical characteristics of the Person, also place that person in a particular environmental niche that defines his or her position and role in society. Recognition of that ambiguity moves us to a change in focus from the developmentally relevant characteristics of the Person to their counterparts in the structure and substance of environmental Contexts as they affect developmental processes and outcomes.

[10] In terms of research design, both of the stated formulations are best assessed through direct observation, but, given the clarity and contrasting nature of the predicted relationship, valid measures can be obtained for older children and adults through well-designed interviews, and even for young children from information provided by parents and other family members.

THE MICROSYSTEM MAGNIFIED: ACTIVITIES, RELATIONSHIPS, AND ROLES

In addressing this topic, we return to the earliest formulation of the ecological model. Today, as then, "the ecological environment is conceived as a set of nested structures, each inside the other like a set of Russian dolls" (Bronfenbrenner, 1979b, p. 3). The contemporary definition of the innermost of these structures is similar, but contains additional elements that link it to the "center of gravity" of the bioecological paradigm:

> A microsystem is a pattern of activities, social roles, and interpersonal relations experienced by the developing person in a given face-to-face setting with particular physical, social, and symbolic features that invite, permit, or inhibit, engagement in sustained, progressively more complex interaction with, and activity in, the immediate environment. (Bronfenbrenner, 1994, p. 1645)[11]

We begin with consideration of the first feature of the environment introduced in the foregoing definition.

Effects of the Physical Environment on Psychological Development

The pioneering work in this sphere has been done by Theodore Wachs. In 1979, he published a seminal paper in which he showed a consistent pattern of relationships between certain features in the physical environment of infants during the first 2 years of life and their cognitive development over this same period. To permit examining effects over time, data were grouped into successive 3-month blocks. The results are reported in the form of correlations between characteristics of the environment at an earlier time and the developmental status of the infants at a later time.

From the complex results of the study, we focus on those physical features in the environment that were most frequently and strongly associated with cognitive functioning. These included a physically responsive en-

[11] The 1979 definition reads as follows: "A microsystem is a pattern of activities, roles, and interpersonal relationships experienced by the developing person in a given setting with particular physical and material characteristics."

vironment, presence of sheltered areas, "The degree to which the physical set-up of the home permits exploration," low level of noise and confusion, and "the degree of temporal regularity" (Wachs, 1979, p. 30).

Regrettably, few researchers have followed the exciting scientific path that Wachs has been the first to chart. Taken as a whole, his original and subsequent work (Wachs, 1987a, 1987b, 1989, 1990, 1991; Wachs & Chan, 1986) suggests two areas especially worthy of further systematic investigation, in both conceptualization and measurement. The first remains strictly in the realm of the physical environment. The second raises the issue of proximal processes as they relate to that environment.

In the first domain, Wachs's findings point to two general aspects of the physical environment that can affect the course of cognitive development—one for better, the other for worse. On the constructive side are objects and areas that invite manipulation and exploration, whereas instability, lack of clear structure, and unpredictability of events undermine the developmental process. From an ecological perspective, the existence of these countervailing forces in the physical environment leads to a new working hypothesis:

> Not only do developmentally generative features of the surroundings have greater impact in more stable settings, but they also function as a buffer against the disruptive influences of disorganizing environments.

The second issue introduces an additional component into the research design. As stipulated in Proposition I, proximal processes involve progressively more complex interactions not only with persons but also with objects and symbols. The question therefore again arises as to what extent solitary activities involving objects and symbols—such as playing with toys, working at hobbies, reading, or fantasy play—can also foster psychological development? And to what degree does involvement in both objects and symbols produce synergistic developmental effects in each domain? The answers to these questions are as yet unknown but are readily discoverable through the use of appropriate designs that differentiate between measures of process and of environmental structure.

However, the most promising terra incognita for research on the role of the physical environment in human development may well lie beyond the realm of childhood in the world of adults. A preview of this promise appears in the successive publications of the sociologist Melvin Kohn and his colleagues (for an integrative summary, see Kohn & Slomczynski, 1990) demonstrating the powerful effect of work environments on intellectual development in adulthood. Of particular importance in this regard turns out to be the complexity of the task that a given job entails.

At the conclusion of the preceding section, we called attention to a contrast that cuts across all four domains of Process, Person, Context, and Developmental Outcome. The contrast in all four domains involves a primary focus on *relationships* versus *tasks.* The findings of both Wachs and Kohn fall mainly in the latter category, but Drillien's data on mother-infant interaction and infants' problem behavior in lower-class families fall mainly in the former (i.e., an increase in maternal responsiveness functions as a buffer against problems in this sphere of emotional and behavioral control).

But that is not the only effect of rising levels of proximal process.

The Mother-Infant Dyad as a Context of Development

A substantial body of research indicates that such processes also foster the development of a strong emotional attachment between mother and child, which increases the quality of future interaction between the two parties (Ainsworth, Blehar, Waters, & Wall, 1978; Bowlby, 1969, 1973). In addition, the more recent work in this sphere strongly suggests that, as a result of continuing reciprocity in the context of a close relationship, the infant begins to develop a definition of self that mirrors the form and content conveyed through the evolving patterns of interchange between mother and child (Sroufe, 1990). Thus, proximal processes become the measurable mechanisms for bringing about what in an earlier era of developmental theory and research was called *internalization.*[12] Moreover, this sequential process does double duty. Though operating primarily on the relationship side, it also furthers task performance.

According to attachment theory, the emotionally loaded patterns of interchange processes between the infant and the primary caregiver become internalized in the form of "internal working models" (Bowlby,

[12] A resurgence of theoretical and research interest in this sphere has been stimulated by the elegant studies of Kochanska and her colleagues.

1969, 1973). Such working models are representations of the infant in relation to others and become the basis for the development of the self (Sroufe, 1990). Through interactions between the infant and the primary caregiver, the infant develops expectations of the caregiver's behavior and complementary beliefs about him- or herself. For example, an infant who has experienced a history of contingent responsiveness from a primary caregiver will develop a model of that caregiver as available, and expect such behavior. That child will also develop a complementary sense of self that he or she is worthy of responsive care. On the other hand, an infant who has experienced unresponsive care will develop a very different model of the relationship, expecting the caregiver to be unavailable. Such an infant is expected to develop a sense of self as unworthy of responsive care.

More generally, these internalized working models are seen as providing a framework for future interactions, resulting in a repetition of the early attachment relationship (Bowlby, 1973; Sroufe, 1990). The child seeks, responds, and interprets events based on the model that he or she has developed during infancy, and that model is adapted based on new experiences with the environment. A child who has developed a secure attachment relationship is likely to expect positive interactions with teachers, and thus elicit responsive care reminiscent of his or her caregiver's behavior. An insecure child, expecting rejection, will approach relationships with increased hostility, ultimately resulting in further experiences with rejection.

Support for these theoretical expectations comes from a number of studies. For example, the quality of the child's early attachment relationship with the mother has been found to affect the child's later functioning in social interactions with teachers and peers. Thus, early proximal processes produce proximal processes throughout development. Children judged as securely attached in infancy have been shown to approach unfamiliar peers and adults more positively and with greater acceptance (Booth, Rose-Krasnor, McKinnon, & Rubin, 1994; Main & Weston, 1981; Pastor, 1981). Furthermore, they have more positive relationships with peers and teachers in preschool (Sroufe, Fox, & Pancake, 1983; Turner, 1991). Because secure children have developed a positive internal working model in the context of a secure attachment relationship with a primary caregiver, these children expect and elicit positive interactions with other social partners.

This body of attachment theory and research has important implications for the bioecological model. Its relevance is most succinctly conveyed in operational terms, by assessing quality of attachment in different positions in the research design; for example, as an outcome at Time 2 of proximal processes at Time 1, or, alternatively, in the form of strong versus weak contextual dyads at Time 1 moderating the power of a proximal process to influence developmental outcomes at Time 2. The latter design fits a long-standing proposition derived from the bioecological model, which reads as follows:

> In order to develop—intellectually, emotionally, socially, and morally—a child requires, for all of them, the same thing: participation in progressively more complex reciprocal activity, on a regular basis over extended periods of time with one or more other persons with whom the child develops a strong, mutual, irrational attachment,[13] and who are committed to that child's development, preferably for life. (Bronfenbrenner, 1989c, p. 5)

A second proposition goes a step further:

> The establishment and maintenance of patterns of progressively more complex interaction and emotional attachment between caregiver and child depend in substantial degree on the availability and active involvement of another adult who assists, encourages, spells off, gives status to, and expresses admiration and affection for the person caring for and engaging in joint activity with the child. (Bronfenbrenner, 1989c, p. 11)

Taken together, the foregoing propositions present an important qualifier to the general finding that children growing up in single-parent families are at greater developmental risk than those in two-parent structures. What counts most is the quality of the relationships and activities that take place in the family, and situations can occur in which, from this perspective, quality overrides quantity (Hetherington & Clingempeel, 1992).

Both propositions take on added importance because their relevance may extend beyond parental ties to close relationships with other caregivers, relatives, peers, teachers, mentors, coworkers, and supervisors. The propositions may also apply beyond childhood and ado-

[13] What is meant by the term "irrational attachment"? One answer: This is the first child you try to save in a fire.

lescence to relationships in adulthood and old age. So far as we have been able to discover, these possibilities still await systematic investigation in correspondingly appropriate research designs.

BEYOND THE MICROSYSTEM

It is a basic premise of ecological systems theory that development is a function of forces emanating from multiple settings and from the relations among these settings. How can such multiple forces and their interrelations be conceptualized, and what kinds of research designs can be employed to measure their combined effects? The first stage in such an expanded model of the environment involves what in ecological systems theory is called a *mesosystem,* defined as comprising the relationships existing between two or more settings; in short, it is a system of two or more microsystems. Mesosystems and their operationalization in a research design are best conveyed through a concrete example.

Steinberg, Darling, and Fletcher (1995) reported on what they described as "an ecological journey," which was the consequence of a deliberate decision made at the outset of their research. The initial focus of investigation was on the impact of authoritative parenting on adolescents' academic achievement. They had at their disposal a range of data collected from a large multiethnic, multiclass sample encompassing several family structures. Under these circumstances, they concluded:

> [I]t made no sense at all to control for ethnicity, social class, or household composition in an attempt to isolate "pure" process. No process occurs outside of a context. And if we want to understand context, we need to take it into account, not pretend to control it away. (Steinberg et al., 1995, p. 424)

No sooner had the investigators embarked on this unconventional course than they encountered some unexpected findings. The first of these occurred not in the realm of environmental context but of developmental outcome. When they analyzed adolescents' school performance, they found that, in contrast to youth from European family backgrounds, Hispanic, African, or Asian American youth did not benefit from authoritative parenting. A first clue to this puzzle emerged when the investigators identified the values held by the different "peer crowds" (e.g., "jocks, brains, nerds, preppies, or druggies") in the nine high schools included in their sample. Their subsequent analysis revealed that "European-American youngsters from authoritative homes are more likely to belong to peer crowds that encourage academic achievement" (Steinberg et al., 1995, p. 445).

On the basis of these and related findings, Steinberg et al. (1995) formulated the following, new working hypothesis:

> There is a strong but indirect path between parenting practices and adolescent peer group affiliations . . . by fostering certain traits in their children, parents direct a child toward a particular peer group. Thus to the extent that parents can influence characteristics by which adolescents are associated by peers with a crowd, parents can "control" the type of peer group influences to which their child is exposed. . . . In essence, parents have a direct and primary impact on adolescent behavior patterns—prosocial as well as antisocial. Peer groups serve primarily to reinforce established behavior patterns or dispositions. (pp. 446–447)

But when the investigators put their new hypothesis to the test, they were confronted by yet another unexpected result:

> When we attempted to apply this model to youngsters from minority backgrounds, we were in for a shock. We found that among Black and Asian students, there was *no relation* between parenting practices and peer crowd membership. (p 447)

Once again, the researchers' "multiple context model" paved the way to solving the puzzle:

> Why was there not significant relation between parenting and peer group selection among minority youth? The answer, we discovered, is that models of peer group selection that assume an open system, in which adolescents can select into any number of groups as easily as ordering food off a restaurant menu, fail to take into account the tremendous level of ethnic segregation that characterizes the social structure of most ethnically mixed high schools in the United States. (pp. 447–448)

The authors' findings with respect to specific minority groups are of considerable interest:

> Although [African American] parents score highest on our measure of parental involvement in schooling, [Black adolescents] find it much more difficult to join a peer group that encourages the same goal. (p. 449)

By contrast:

> More often then not, Asian American students have no choice but to belong to a peer group that encourages and rewards academic excellence. . . . Asian Americans report the highest level of peer support for academic achievement. Interestingly, and in contrast to popular belief, [their] parents are the *least* involved in their youngsters' schooling. (p. 448)

The Expanding Ecological Universe

As if disappointed at not being confronted with yet another unexpected finding, Steinberg and his colleagues moved on to extend the ecological model to its next higher systems level—that of the *exosystem.* The formal definition of this environmental structure reads as follows:

> The exosystem comprises the linkages and processes taking place between two or more settings, at least one of which does not contain the developing person, but in which events occur that indirectly influence processes within the immediate setting in which the developing person lives. (Bronfenbrenner, 1993, p. 24)

The particular exosystem that Steinberg et al. (1995) undertook to investigate was "the network of families that develops through the child's peer relationships," more specifically, "the parenting practices of their peers' parents" (p. 450). The investigators' analyses led to a series of interrelated findings as shown in these two examples:

> Adolescents whose friends' parents are authoritative earn higher grades in school, spend more time on homework . . . have more positive perceptions of their academic competence, and report lower levels of delinquency and substance use.
>
> Adolescents whose parents are already more authoritative appear to benefit more from membership in a peer network with other authoritatively reared youngsters than do adolescents in similar networks, but from less authoritative homes. It appears that adolescents need certain "home advantages" in order to be able to take advantage of the social capital in their social networks. (Steinberg et al., 1995, pp. 452–453)

Presumably, even an ecological model can only be taken so far, but Steinberg and his colleagues appear to be trying to push it to its limits—their next analysis moves from the parental network of the adolescent's peers to the neighborhood's level of *social integration.* The measure of integration was based on a series of questions about parents' contact with their children's friends, participation in community and social activities, and ties to other families in the neighborhood. An analysis of the data revealed a modest effect of neighborhood integration on ado-lescent development. However, this finding was qualified in an important way that refocused attention on the key role played by family processes. In the author's words:

> When we reran these analyses separately in neighborhoods characterized by a high proportion of effective versus noneffective parents, we find that . . . social integration only benefits adolescents whose families live in neighborhoods characterized by good parenting. Social integration into a neighborhood characterized by a high proportion of bad parents has a harmful effect on adolescents' school performance and behavior. (Steinberg et al., 1995, p. 457)

A subsequent analysis revealed a second, equally critical but not surprising qualifier: "Living in a neighborhood characterized by a high degree of social integration is only beneficial to an individual adolescent if the child's family is also socially integrated" (p. 457).

Steinberg et al.'s final analysis adds psychological substance to social structure. By aggregating information on parenting practices and attitudes in a neighborhood, he and his associates were able to calculate a measure of the degree of consensus among parents in a given neighborhood. Once again, the principal finding emerging from the analysis was conditioned by a psychological reality:

> High neighborhood consensus augments the association between parenting and adolescent outcomes only when the consensus is around good parenting. . . . In other words, it is what parents agree about, not merely whether they agree, that makes the difference. (Steinberg et al., 1995, p. 458)

In this particular study, the investigators did not examine the extent to which the biopsychological characteristics of adolescents, or of their parents, influenced

developmental processes and outcomes. Today, a growing body of researchers (e.g., Plomin, Reiss, Hetherington, & Howe, 1994) claims strong evidence for the view that individual and group differences in a wide range of developmental outcomes are mainly driven by differences in genetic endowment ("Ability Testing," 1992; Plomin, 1993; Plomin & Bergeman, 1991; Plomin & McClearn, 1993; Scarr, 1992). This claim is called into question, however, by alternative explanations and evidence based on the bioecological model (see also Lerner, 1995, 2002, 2004a).

Nature-Nurture Reconceptualized: A Bioecological Interpretation

The theoretical argument is set forth in a series of hypotheses, each accompanied by a corresponding research design (Bronfenbrenner & Ceci, 1994b).

> *Hypothesis 1:* Proximal processes raise levels of effective developmental functioning, and thereby increase the proportion of individual differences attributable to actualized genetic potential for such outcomes. This means that heritability (h^2) will be higher when proximal processes are strong and lower when such processes are weak.
>
> *Hypothesis 2:* Proximal processes actualize genetic potentials both for enhancing functional competence and for reducing degrees of dysfunction. Operationally, this means that as the level of proximal process is increased, indexes of competence will rise, those of dysfunction will fall, and the value of h^2 will become greater in both instances.
>
> **1.** The power of proximal processes to actualize genetic potentials for developmental competence (as assessed by an increase in h^2) will be greater in advantaged and stable environments than in those that are disadvantaged and disorganized.
>
> **2.** The power of proximal processes to buffer genetic potentials for developmental dysfunction will be greater in disadvantaged and disorganized environments than in those that are advantaged and stable.
>
> *Hypothesis 3.* If persons are exposed over extended periods of time to settings that provide developmental resources and encourage engagement in proximal processes to a degree not experienced in the other settings in their lives, then the power of proximal processes to actualize genetic potentials for developmental competence will be greater for those living in more disadvantaged and disorganized environments.

To test the preceding hypotheses, Bronfenbrenner and Ceci (1994b) reviewed literature on genetic inheritance:

> We have been able to find no studies of genetic inheritance in contrasting environments that also contained data on proximal processes and hence would permit a direct test of the previous hypotheses. Hence, most of the available evidence is indirect.
>
> An indirect test can be carried out only when estimates of heritability are reported for the same developmental outcome in different environments. It is fortunate that there are several studies that meet this criterion. To begin with, both Scarr-Salapatek (1971) and Fischbein (1980) found support for the prediction that values of h^2 for IQ would be greater in higher than in lower social class groups. Subsequently, a group of Norwegian investigators (Sundet, Tambs, Magnus, & Berg, 1988) undertook to clarify a series of earlier findings regarding secular trends over recent decades in heritability for measures of cognitive functioning. Using IQ scores as outcome data, the investigators found some support for results of a previous study of educational attainment (Heath et al., 1985) that had shown an increase in h^2 for twins born after 1940. The trend for their mental test data, however, was considerably weaker. The authors offered the following interpretation of the observed similarity and contrast:
>
> > This is probably due at least partly to the fact that the Norwegian government in the postwar period has offered loans to young people seeking education, thus enabling youngsters with poor parents to attend higher education. Such factors, together with a more positive attitude toward education among poor people, would tend to decrease the effect of familial environments and maximize genetic potential. (Sundet et al., 1988, p. 58)[14]

[14] Sundet (personal communication, March 17, 1993) reported that, in response to a preliminary version of the article by Bronfenbrenner and Ceci (1994), he and his colleagues undertook a preliminary analysis that yielded the following results: "For twins with mothers having the least education, the correlation between identical twins is .80, whereas the correlation for fraternal twins is .47. For the twins having mothers with more education, these correlations are .82 and .39, respectively. As you will see, this yields a heritability estimate of .66 for the first group, whereas it is .86 for the second group. If I understand your [Hypothesis 2] correctly, this is in accordance with your predictions. However, the difference between the two DZ [dizygotic] correlations does not seem to reach statistical significance, although it is quite near."

> There are also a number of investigations that permit an indirect test of the hypothesized reverse pattern when the outcome is one of developmental dysfunction. For example, Jenkins and Smith (1990) found that the positive effect of a good mother-child relationship on children's problem behavior was stronger in a troubled marriage than in a harmonious one. More generally, in a recent review, Rutter and Rutter (1992) concluded that the impact of protective factors in buffering developmental disorders is greater in "circumstances of risk." (p. 56)

This concludes Process, Person, and Context as shapers of development, it is time to turn to *Time*.

TIME IN THE BIOECOLOGICAL MODEL: MICRO-, MESO-, AND MACROCHRONOLOGICAL SYSTEMS

Time, a defining property of the bioecological paradigm, appears more than once in the model's multidimensional structure. Indeed, its first appearance, in the second sentence of Proposition I, may have well gone unnoticed. Following the definition of proximal processes as involving progressively more complex reciprocal interaction, the Proposition stipulates that to be effective, the interaction must occur on a fairly regular basis.

Why this proviso? A first indication appears in the findings from Wachs's research (1979) on the features of the environment most frequently and strongly associated with individual differences in cognitive competence. Prominent among them were a physically responsive environment, presence of sheltered areas, instability and unpredictability of events, the "degree to which the physical set-up of the home permits exploration," low level of noise and confusion, and "the degree of temporal regularity" (p. 30). As noted earlier, it follows from such findings that proximal processes cannot function effectively in environments that are unstable and unpredictable across space and time.

It also follows that the cumulative effects at this *mesosystem* level are likely to jeopardize the course of human development. One reason for expecting such an escalating effect is that, at this next higher level of environmental structure, similarly disruptive characteristics of interconnected microsystems tend to reinforce each other.

The most informative research evidence bearing on this issue comes from a longitudinal study conducted by the Finnish psychologist, Lea Pulkkinen (1983). Beginning when participating children were 8 years of age, she investigated the effect of environmental stability and change on the development of children through adolescence and young adulthood, The "steadiness" versus "unsteadiness" of family living conditions was measured by the frequency of such events as the following: the number of family moves, changes in day care or school arrangements, extent of family absence, incidence of divorce and remarriage, and altered conditions of maternal employment. Greater instability in the family environment was associated with greater submissiveness, aggressiveness, anxiety, and social problems among children in later childhood and adolescence, leading to higher risks of violence and criminal behavior in early adulthood (Pulkkinen, 1983; Pulkkinen & Saastamoinen, 1986). Moreover, the factor of stability of family living conditions appeared to be a stronger determinant of subsequent development than was the family's socioeconomic status.

Analogous findings for the contemporary U.S. scene were obtained by Moorehouse (1986) in a study of how stability versus change over time in the mother's work status during the child's preschool years affected patterns of mother-child communication, and how these patterns in turn influenced the child's achievement and social behavior in the 1st year of school. A key analysis involved a comparison between mothers who had maintained the same employment status over the period of the study, and those who had changed in either direction: that is, to working more hours, fewer hours, or none at all. The results revealed that significant effects of work status were pronounced only in the group that had changed their working status. Although the disruptive impact was greatest among those mothers who had moved into full-time employment, it was still present even for those who had reduced their working hours or had left the labor force. Moorehouse concluded that "instability, on the whole, is associated with less favorable school outcomes than stability" (p. 103).

In the framework of the discovery mode, we are once again at a point where a series of findings from different studies suggests yet another tentative formulation. The corollary follows:

> The degree of stability, consistency, and predictability over time in any element of the systems constituting the ecology of human development is critical for the effective operation of the system in question. Extremes either of disorganization or rigidity in structure or function represent danger signs for potential psychological growth, with some intermediate degree of system flexibility constituting the optimal condition for human development. In re-

search design, this proposition points to the importance of assessing the degree of stability versus instability, with respect to characteristics of Process, Person, and Context, at each level of the ecological system.

This formulation also applies at the macrolevel to the dimension of Time, both during the individual's life course, and through the historical period in which the person has lived (see Proposition II). It was this observation that gave rise to the first systematic formulation of what was to become the ecological model of human development. The formulation appeared almost 4 decades ago in an article entitled "Socialization and Social Class through Time and Space" (Bronfenbrenner, 1958). In that article, Bronfenbrenner reanalyzed what appeared to be contradictory findings on social class differences in patterns and outcomes of child rearing. The analysis reveals that when the obtained results were reorganized by the years in which the data were collected, the contradictory findings disappeared. Instead, there was a systematic gradual change over the period just after World War II until the late 1950s, with middle-class parents moving away from originally more authoritarian patterns toward greater permissiveness and lower-class families going in the opposite direction. Changes in patterns of child rearing over historical time and their effects on development have been recurring themes in Bronfenbrenner's work beginning in the late 1950s (1958) and continuing up to the present (Bronfenbrenner, 1970, 1975, 1990, 1994; Bronfenbrenner & Crouter 1982; Bronfenbrenner et al., 1996); but in terms of theoretical and empirical contributions this work pales in comparison with that of Elder, beginning with his classic study, *Children of the Great Depression* (Elder, 1974; see also Elder & Shanahan, Chapter 12, this *Handbook,* this volume).

As Bronfenbrenner has noted, Elder's work on life-course development played a significant role in the formulation of the original ecological model (Bronfenbrenner, 1979a, see especially pp. 266–285 and 273–285), and has exerted even greater influence on the model's subsequent evolution in this same domain (Bronfenbrenner, 1986a, 1986b, 1989, 1993, 1995).

Because Elder's contributions deservedly receive extended coverage in Chapter 12, this *Handbook,* this volume, we confine ourselves to the four defining principles of life-course theory as presented in a recent formulation (Elder, 1998),[15] along with implications for corresponding research designs, and examples of relevant research findings.

The first principle is that of *historical time and place,* defined by Elder as follows: *The life course of individuals is embedded in and shaped by the historical times and events they experience over their life time.*

History is exploited as an experiment of nature. The corresponding research design compares groups similar in other respects who have been exposed, versus not exposed, to a particular historical event; for example, Elder's studies of the Great Depression (Elder, 1974; also see Elder, 1998; Elder & Shanahan, Chapter 12, this *Handbook,* this volume); military service and actual combat in World War II and Korea (Elder, 1986; Elder, Shanahan, & Clipp, 1994); the Iowa farm crisis (Conger & Elder, 1994; Elder, King, & Conger, 1996); urban inequality (Elder, Eccles, Ardelt, & Lord, 1995); and, Elder's most recent work, research on youth sent to the countryside during China's cultural revolution (Elder, Wu, & Jihui, 1993).

The second principle, called *timing in lives,* states that *the developmental impact of a succession of life transitions or events is contingent on when they occur in a person's life.*

Here an appropriate research design is one that compares early versus late arrivals at a particular transition with respect to their subsequent life course. For example, Elder et al. (1994) reanalyzed follow-up data on subjects from Terman's 1925 classic *Genetic Studies of Genius* (all subjects with very high IQs) and were able to show marked differences in subsequent adult development depending on early versus late entrance into military service during wartime. Some of the costs of late entry include:

- A higher risk of divorce and separation
- A work life of disappointment and loss of lifetime income
- An accelerated decline of physical health, most notably after the age of 50

On the opposite side:

- For many men, and especially those who entered at an early age, military service was a recasting experience. It provided a bridge to greater opportunity and an impetus for developmental growth up to the middle years.

[15] For an earlier, but more comprehensive account, see Elder's Chapter 16, this *Handbook,* this volume.

One is reminded of Brutus's fateful choice in response to Cassius's urgings:

> There is a tide in the affairs of men
> Which, taken at the flood, leads on to fortune;
> Omitted, all the voyage of their life
> Is bound in shallows and in miseries.
>
> —Shakespeare, *Julius Caesar* (IV. iii. 218–221)

The third principle, *linked lives,* asserts that *lives are lived interdependently and social and historical influences are expressed through this network of shared relationships.*

The basic research design corresponding to this principle involves examining the differential impact of historical events and role transitions on different members of the same family experiencing these same events and transitions. In a study of mother-daughter dyads in the broader historical context of the societal changes in gender roles that have taken place since World War II, Moen and Erickson (1995) offered the following concluding comment, on the basis of their statistical analysis of data across two generations:

> Conventional mothers embracing traditional gender roles may find themselves with daughters who are in the vanguard of the women's movement. Some mothers may even push their daughters to achieve what was impossible for themselves. The fact that mothers and daughters experience historical events and social changes from different vantage points means that their lives are differentially touched by them and that their perspectives may well diverge. (p. 180)

Environmental changes across historical time can produce significant developmental changes in either direction. On the one hand, they can disrupt the timing and duration of normative transitions during the life course, thus interrupting the sequence of learning experiences that are essential for meeting societal expectations as one gets older. On the other hand, they can offer to the person new, at once more stable and more challenging opportunities that enhance psychological growth or even reverse a previously downward course (e.g., Elder's 1974 studies of effects of military enlistment on young men from poverty backgrounds).

FROM RESEARCH TO REALITY

The fourth and last of Elder's principles of life course development he calls *human agency.* It states that *"individuals construct their own life course through choices and actions they take within the opportunities and constraints of history and social circumstances."* A striking example is his finding that the young men most likely to volunteer early for service in World War II were often those who came from the most deprived circumstances, but then benefited the most from the opportunities of training and experience that the military provided. Nevertheless, he cautions that "Not even great talent and industry can ensure life success over adversity without opportunities" (Elder, 1997).

Finally, to Elder's four principles, we add a fifth, which in effect reverses the direction of his very first principle regarding the importance of historical changes in shaping the course of human development. Simply stated, the fifth principle asserts that changes over time in the four defining properties of the bioecological model are not only products but also *producers* of historical change. To spell out the argument and evidence on which the principle is based: Periodically, since the late 1950s, Bronfenbrenner, together with colleagues, has been publishing articles documenting changes over time in three domains: child-rearing practices, the relation of these practices to child outcomes, and in family demographics reported annually in the U.S. Census and other government publications.

One report of these analyses appears in a volume entitled: *The State of Americans: This Generation and the Next* (Bronfenbrenner et al., 1996). The book consists of almost 300 pages and 150 graphs, but, for present purposes, the principal findings can be summarized in 10 points shown in Table 14.1. Considered as a whole, the findings constitute the basis for our proposed addition to Elder's four principles.

To illustrate, although proximal processes function as the engines of development, the energy that drives them comes from deeper sources that take us back to the experiential world of Proposition I (Bronfenbrenner et al., 1996; Bronfenbrenner & Evans, 2000; Bronfenbrenner & Morris, 1998). Both subjective and objective forces exert an especially strong influence on development during the formative years (from early infancy to young adulthood). A substantial body of research over the past century indicates that, 2 or 3 decades ago,

TABLE 14.1 Summary of Selected Findings

1. Annual surveys over the past two decades reveal growing cynicism and disillusionment among American youth, reflected in a loss of faith in others, in their government, in the basic institutions of their society, and in themselves.
2. In the United States far greater percentages of youth and women are victims of homicide, with rates more than 10 times as high as those for any other developed country.
3. The young are not only likely to be the victims of murder, they are also more likely to commit it. Youth and young adults (ages 18–25) now account for the majority of those arrested for homicide.
4. The percentage of Americans in prison is four times higher than in other developed countries, and the number is rising rapidly.
5. Despite recent gains made by youth from Black families. American high school students are still far behind those from other developed countries in academic achievement. This includes the top 10% of students in each nation. The trend already threatens our productivity and capacity to compete economically in the future.
6. The United States stands in first place in the percentage of children growing up in single-parent families, which now includes over a quarter of all America's children under 6 years of age.
7. Families with children under 6, particularly single-parent mothers, are those who most seek—and desperately need—a job. But they also have the highest unemployment rates. The proportion of Black mothers working full time is much higher than for white mothers (in 1994, 76% vs. 29%).
8. The percentage of U.S. children living in poverty today is twice as high as that for any other developed nation.
9. Among developed nations, the incomes of rich versus poor families are farthest apart in the United States. We are rapidly becoming a two-class society.
10. Two-thirds of children in poverty live in families with working adult. Less than one-third of poor families with a young child rely solely on welfare.

We are indebted to our colleagues who, as coauthors of chapters of the volume *The State of Americans: This Generation and the Next,* provided the findings summarized in Table 14.1. Besides ourselves, they include the following: Steven J. Ceci, Helen Hembrooke, Peter McClelland, Phyllis Moen, Elaine Wethington, and Tara L. White. *Source:* From *The State of Americans: This Generation and the Next,* by U. Bronfenbrenner, P. McClelland, E. Wethington, P. Moen, and S. J. Ceci, 1996, New York: Free Press.

these forces lay mainly in the family, with parents acting as the principal caregivers and sources of emotional support for their children, and with other adult family members living in the home being next in line. To a lesser extent, other relatives, family friends, and neighbors also functioned in this role.

However, there has been a marked change in this pattern over the past 4 decades. Parents, and other adult family members as well, have been spending increasing amounts of time commuting to and working at full-time jobs (in which overtime is increasingly required or expected). The nature of this trend and its relevance for human development are conveyed in the idea that to develop—intellectually, emotionally, socially, and morally—a child requires, for all of these, the same thing: participation in progressively more complex activities, on a regular basis over an extended period of time in the child's life, with one or more persons with whom the child develops a strong, mutual emotional attachment, and who are committed to the child's well-being and development, preferably for life (Bronfenbrenner & Evans, 2000; Bronfenbrenner & Morris, 1998; also see Lerner, 2004b). The establishment of a strong mutual emotional attachment leads to internalization of the parent's activities and expressed feelings of affection. Such mutual ties motivate the child's interest and engagement in related activities in the immediate physical, social, and—in due course—symbolic environment that invite exploration, manipulation, elaboration, and imagination.

The establishment and maintenance of patterns of progressively more complex interaction and emotional attachment between parent and child depend, to a substantial degree, on the availability and involvement of another adult, a third party, who assists, encourages, spells off, gives status to, and expresses admiration and affection for the person caring for and engaging in joint activity with the child. It also helps, but is not absolutely essential, that the third party be of the opposite sex from that of the other person caring for the child, because this is likely to expose and involve the child in a greater variety of developmentally instigative activities and experiences (Bronfenbrenner et al., 1996). Where this is an attachment to two or more parent figures, each can serve as a third party to the other.

The research evidence for this idea comes mainly by default. It was produced by demographic data documenting a rapid rise in the proportion of single-parent households. The trend began in the 1980s, and then continued at an even faster rate through most of the 1990s. The overwhelming majority of such homes were those in which the father was absent and the mother bore primary responsibility for the upbringing of the children.

A large number of investigations of developmental processes and outcomes in families of this kind have since been conducted across a range of cultural and social class groups. The findings lead to two complementary conclusions:

1. Even in families living in favorable socioeconomic circumstances, children of single-parent mothers, or of fathers, for whom no other person is acting reliably in a third party role are at greater risk for experiencing one or more of the following developmental problems: hyperactivity or withdrawal, lack of attentiveness, difficulty in deferring gratification, poor academic achievement, school misbehavior, and frequent absenteeism.
2. At a more serious level, there is the so-called teenage syndrome of behaviors that tend to be associated together: dropping out of school; involvement in socially alienated or destructive peer groups; smoking, drinking, frequent sexual experience: adolescent pregnancy; a cynical attitude toward work; and in the more extreme cases—drugs, suicide, vandalism, violence, and criminal acts. Most of these effects are more pronounced for boys than for girls (Bronfenbrenner et al., 1996).

Not all single-parent families, however, exhibited these disturbed relationships and their disruptive effects on children's development. Systematic studies of the exceptions have identified what may be described as a general immunizing factor. For example, children of single parents were less likely to experience developmental problems especially in families in which the mother (or father) received strong support from other adults living in the home. Also helpful were nearby relatives, friends, neighbors, members of religious groups, and, when available, staff members of family support and child care programs. What mattered most was not only the attention given to the child—important as this was—but also the assistance provided to the single parent or by others serving in the supportive roles previously noted. It would seem that, in the family dance, it takes three to tango.

But dancing is not the whole story. By the 1980s, theory and research in the ecology of human development had documented an accelerating trend toward greater permissiveness in styles of child rearing in U.S. families. At the same time, successive scientific investigations had revealed progressively greater developmental advantage for strategies that placed increased emphasis on parental discipline and demand. The interpretation that emerged from analyses of the available data suggested that widespread application of these research findings would serve as an effective response to the developmentally disruptive changes taking place in contemporary society.

At a more general level, the research findings reveal growing chaos in the lives of families, in child care settings, schools, peer groups, youth programs, neighborhoods, workplaces, and other everyday environments in which human beings live their lives. Such chaos interrupts and undermines the formation and stability of relationships and activities that are essential for psychological growth. Moreover, many of the conditions leading to that chaos are the often unforeseen products of policy decisions made both in the private and in the public sector. Today, in both of these arenas, we are considering profound economic and social changes, some of which threaten to raise the degree of chaos to even higher and less psychologically (and biologically) tolerable levels. The most likely and earliest observed consequences of such a rise are still higher levels of youth crime and violence, teenage pregnancy and single parenthood,[16] as well as reduced school achievement, and, ultimately, a decline in the quality of our nation's human capital (Bronfenbrenner et al., 1996).

Thus, we have arrived at a point where the concerns of basic developmental science are converging with the most critical problems we face as a nation. That convergence confronts us, both as scientists and as citizens, with new challenges and opportunities.

THE BIOECOLOGICAL MODEL: A DEVELOPMENTAL ASSESSMENT

In this chapter, we have undertaken two challenging tasks, each an example of science in the discovery mode with developmental science as its subject matter. The first was to describe a next stage in the evolution of an ecological theory of human development, first introduced more than 20 years ago. The second task was unintended, but nevertheless begun, for this chapter also documents early steps in the design of a third-generation model.

As one of those early steps, we found it necessary to spell out the requirements for conducting developmental research in the discovery mode. To our knowledge, this is a first effort to do so systematically, and may there-

[16] Once again we emphasize that the relationships and activities in which parent and child are involved can override the influence of purely demographic factors such as mother's age and family structure (p. 1015).

fore receive—and deserve—more criticism than any other section in the chapter. But at least readers will know what criteria we were trying to meet and will have a basis for assessing the validity of the proposed strategy as reflected in the more differentiated theoretical and operational models emerging from the successive confrontations between theory and data.

Among the more promising products of this effort is the demonstration of the power of *proximal processes* as the engines of development, and their systematic variation as a function of the characteristics of both *Person* and *Context*. We have also presented evidence that, in accord with specifications of the bioecological model, different pathways through space and time lead to different outcomes. In this regard, distinctions between two types of outcome appear especially relevant: (1) between outcomes of competence versus dysfunction and (2) between activities focusing primarily on interpersonal relationships versus objects and symbols. A third potentially productive contrast speaks to the question of who develops and who doesn't by identifying dispositional characteristics of the Person that are *developmentally generative* versus *developmentally disruptive*. Two additional Person characteristics deemed consequential for development are also distinguished and illustrated. The first are *resources* in terms of ability and acquired knowledge and skill. The second are *demand* characteristics that attract or encourage progressively more complex interaction. An analogous taxonomy is proposed for the quality of environments, accompanied by illustrations of their corresponding differential effects on proximal processes and outcomes. In each instance, the evolving tentative hypotheses derived from successively more differentiated formulations based on the bioecological model are accompanied by their operational analogs in terms of corresponding research designs and the findings generated by them.

The discovery process points also to the scientific need and benefit of including, in research designs for the same subjects, two different developmental outcomes that complement each other. For theoretical reasons deriving from the bioecological model, likely to be even more productive would be the inclusion in the same research design of two different, but theoretically complementary proximal processes.

Finally, in our view, the most scientifically promising formulation emerging from the discovery process documented in this chapter is easily stated, but it is also one that presents the greatest theoretical challenge:

> The four defining components of the bioecological model should be theoretically related to each other and to the developmental outcomes under investigation. This means that the choice of variables to represent each of the defining properties should be based on explicit assumptions about their presumed interrelations.

This may seem a disappointing conclusion for so long an exposition. Perhaps, even more in developmental science than in other fields, the pathways to discovery are not easy to find. The trails are not marked, there are many dead ends, the journey is far longer than expected, and at the end, little may be there. What counts is what one learns along the way and passes on to future explorers of the uncharted terrain. Here are some final ideas for those of you whose work will fill the future landscape of developmental science. At this still early moment in the twenty-first century, we are left with a troubling question: From the perspective of the bioecological model, what is the prospect for the future development of our species? The answer to that question lies with the willingness of the United States and other economically developed countries to heed the emerging lessons of developmental science. At the moment, it is difficult to know what the answer will be. The future could go either way. Given this alternative, it becomes the responsibility of developmental science to communicate such knowledge as we possess, and to do so in words that can still find an echo. Here is a first draft:

> In the United States it is now possible for a youth, female as well as male, to graduate from high school, or university, without ever caring for a baby; without ever looking after someone who was ill, old, or lonely; or without comforting or assisting another human being who really needed help. The developmental consequences of such a deprivation of human experience have not as yet been scientifically researched. But the possible social implications are obvious, for—sooner or later, and usually sooner—all of us suffer illness, loneliness, and the need for help, comfort, and companionship. No society can long sustain itself unless its members have learned the sensitivities, motivations, and skills involved in assisting and caring for other human beings.

CHAPTER 15

Phenomenology and Ecological Systems Theory: Development of Diverse Groups

MARGARET BEALE SPENCER

This chapter's organization serves to capture the *distinctive contributions of phenomenological variant of ecological systems theory (PVEST) to available human development theorizing*. Thus, following a brief introductory section, we provide a full presentation of the PVEST framework, and, although applying it to the preschool through adolescence period, introduce PVEST as a life-span model of human development. The next section demonstrates why the theory promotes an identity-focused cultural ecological (ICE) perspective. It reviews (a) the fact of human vulnerability (i.e., the presence of both risks and protective factors), (b) the

normative experience of stress, (c) the need for reactive coping responses, (d) the role of emergent (stable) identities, and (e) the links with the unavoidability of stage-specific and patterned coping outcomes. As lives unfold over time, stage-specific coping outcomes contribute to the next period's level of vulnerability. Thus, we also illustrate the dynamic character of PVEST. As a system of experiences, the interpretation of patterned outcomes (i.e., referred to as culture) are described as having important implications for group experiences (e.g., as stigma, bias, or privilege) or individual supportive models for emulation (e.g., character development).

To illustrate the themes noted and as a strategy for comparing and contrasting the experiences of diverse groups of youths, the third section affords an examination of several cross-cutting themes of human development established by the recursive character of PVEST, which exemplifies the connectedness between individual characteristics and context interactions.

We point out that *by diverse youth, we refer to all ethnicities and races (i.e., unless we specify—diverse youth of color).* This clarification is critically important because Whites are often not considered under diversity labels, given a frequent assumption that they represent the norm rather than one ethnic experience among many. The primary point is that, all groups have distinctive histories and responsive traditions that evolve into both unique yet similar cultural patterns. Accordingly, a major influence described throughout the chapter for diverse youth is the impact of distinctive conditions for each and the role of history.

The fourth section utilizes the 1954 Supreme Court decision in *Brown v. Board of Education* for highlighting and indicating the impact of policy change and its role in determining long-term youth experiences generally and schooling specifically. Additionally, the interactions between context and culture are presented and the contributions of critical race theory (CRT) explored for describing the individual-context-process links for White youth. In parallel fashion, the implications of White privilege for some and the implications of its absence for others is analyzed.

The fifth section provides an illustration of the recursive processes for African American male adolescents as an example for understanding their stage-specific coping outcomes as a function of vulnerability (i.e., balance between risks and protective factors) as demonstrated from a PVEST perspective. Finally, the sixth section of the chapter describes the distinct interpretational advantages of the PVEST framework and highlights competing traditional frameworks while also explaining their limitations.

INTRODUCTION AND RATIONALE: A NEED FOR NEW THEORY

An *inclusive framework* for understanding life-course development is long overdue. The narrowness of views concerning inclusiveness have made such a framework, at best, an illusive goal for child development. As used here, the term *inclusive* refers to a perspective relevant to the contextual and cultural experiences of diverse groups. Thus, an inclusive framework suggests an authentic rendering of developmental processes for humans considered diverse as a function of characteristics such as race, gender, ethnicity, socioeconomic status, immigration status, faith community, skin color, and nativity.

PVEST (Spencer, 1995) provides a *developmental, process-oriented, and context-sensitive* focus. Thus, it affords unique conceptual contributions to developmental psychology, specifically, and to the field of human development, more broadly. As a systems theory, PVEST considers and includes the prior emphases noted along with a combined concern with *culture,* as lived and experienced at multiple levels of the environment, and individuals' own *perceptions.* Similar to Glen Elder's (1974) sociohistorical analysis of the impact of the Great Depression on human development, the PVEST framework acknowledges as a central tenet the historical and contemporary impact of social policy (e.g., the *Brown v. Board of Education* decision or the significant immigration policy shifts) on the social, cultural, and political context for the nation's diverse youth and their families. Considered together, the theory's value emanates from simultaneous attentiveness to (a) multiple layers of the environment, (b) normal human processes that unfold in varied settings with multiple others, (c) historical factors and social policy that are associated with long-standing and contemporary structural conditions and social relations, and (d) cultural sensitivity to the traditional ways the authentic everyday experience of human development in context is interpreted.

The specific combination and integration of factors indicated improves our understanding about the *how* of life-course human development while it acknowledges both behavioral and genetic perspectives (e.g., Spencer & Harpalani, 2004). Accordingly, as a *systems frame-*

work that takes into account the individual's perspective, or phenomenology (see Rogers' perspective as reviewed in Schultz, 1976), PVEST affords specificity about the individual-context-process nexus as suggested by Bronfenbrenner's (1977, 1989, 1992, 1993) ecological systems theory. The integration imparts significant benefits. Foremost, given its linkages to both observed and perceived context features, the framework provides enhanced understanding of foundational processes and stage-specific outcomes of *diverse groups and individuals* (see Spencer & Harpalani, 2004). Specifically, as indicated, it enhances the interpretation of disparate appearing developmental patterns and outcomes by explicating the *how* of development for diverse groups (a) sharing what appears to be the same space and opportunities, (b) attempting behavioral responses to seemingly parallel human development tasks and stage-specific expectations for competence, but frequently (c) demonstrating disparate behavioral outcomes in response to myriad challenges.

This chapter is intended to provide an updated description and explanation of PVEST, first published a decade ago (Spencer, 1995). Given the 10-year interim, this update is informed by dozens of *empirical* publications that describe analyses designed to demonstrate components of the systems theory (e.g., Fegley, Spencer, Goss, Harpalani, & Charles, in press; Spencer, Dupree, Cunningham, Harpalani, Munoz-Miller, 2003; Spencer, Dupree, Swanson, & Cunningham, 1996, 1998; Spencer, Fegley, & Harpalani, 2003; Swanson, Spencer, Dell'Angelo, Harpalani, & Spencer, 2002). Additional published work utilizes the theory for *clarifying conceptual themes and relationships* (e.g., Lee, Spencer, & Harpalani, 2003; Spencer, Dupree, & Hartmann, 1997; Spencer & Harpalani, 2004; Spencer & Jones-Walker, 2004). Finally, *qualitative analyses* derived from PVEST (i.e., either single-method studies or multimethod publications that include empirical demonstrations) provide helpful illustrations. Multimethod publications augment and make obvious speculative theoretical linkages by providing the voices or expressed meaning-making of young people themselves (e.g., Spencer, Silver, Seaton, Tucker, Cunningham, & Harpalani, 2001; Youngblood & Spencer, 2002).

This current and updated version of PVEST is consistent with established associations demonstrated between young children's normal cognitive, affectual, and social-developmental processes (e.g., Spencer, 1982, 1983, 1985, 1990). It reasserts the important foundational role of perceptual processes in development (e.g., social cognition; children's theory of mind) and reinforces the need to integrate a phenomenological perspective (see Rogers & Kelly as reviewed in Schultz, 1976) to (a) explain life-course developmental processes and thematic outcomes, (b) explicate the role of cultural traditions, (c) specify the contribution of history (both for immigrants and more long-term and indigenous groups; [see Johnson-Powell & Yamamoto, 1997]), and (d) indicate the critical contributions of context quality for individual-context interactions. The expanded description of *context* this model allows specifies how the role of historical factors is important at several levels, and it acknowledges individual differences in levels of vulnerability (i.e., the presence of risk and protective factors). The framework also enhances the interpretation of varied outcomes (i.e., productive and unproductive) experienced by diverse group members as each transitions across contexts (see Figure 15.1). Additionally, the framework focuses on the roles mediating processes play between vulnerability levels and the coping outcomes individuals experience as they transition across the life course. The processes provide illumination as individuals confront both unique challenges and contextual provocation (see Lee et al., 2003) while attending to the sets of normative life-course developmental tasks initially described by Havighurst (1953).

Frequently, when attempting to disentangle and interpret the complexities of the multiple coping trajectories possible, given the normative character of the developmental tasks noted, several important contributing factors are usually overlooked. For example, vulnerability is often assumed to be the presence of risks only *without* an acknowledgment of protective factors. Worse yet, particular outcomes are assumed for specific groups. For example, unproductive outcomes are tacit expectations for marginalized groups (see Figure 15.2).

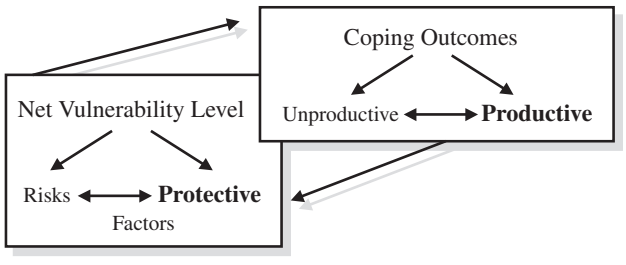

Figure 15.1 Deterministic thinking: Traditionally linear hypothesized relationship between youth characteristics and outcomes.

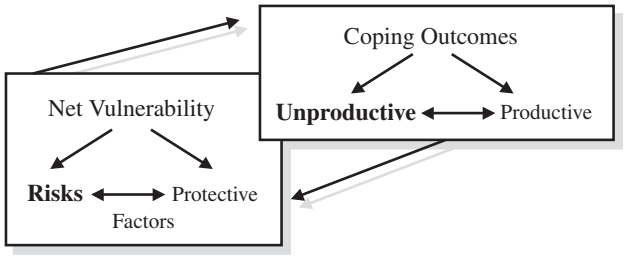

Figure 15.2 Deficit emphasizing: Perspective generally assumed a priori for minorities.

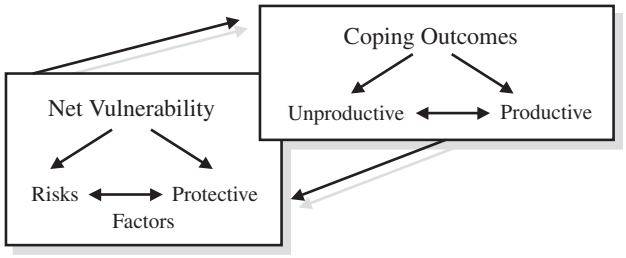

Figure 15.3 Creating new inclusive theorizing requires analyzing both protective factor presence as well as the nuanced character of risks (e.g., unacknowledged privilege).

In the first published rendering of the theory, only risks were explicitly indicated, although the buffering power of protective factors was inferred. However, given ongoing readings of the literature, a pattern has emerged. Assumptions of productive outcomes and successes (i.e., as the standard applied to all) have often been implied for those considered to be empowered (i.e., males, middle-income people, and generally Caucasians). Even if vulnerability is acknowledged and coping products are specified for privileged youth, there is often a narrow focusing on only productive outcomes and success. This results in a degree of conceptual shortsightedness, which produces very deterministic analyses, as suggested by Figure 15.1. Another pattern, however, is also evident. For those youth perceived as marginal individuals (i.e., African Americans, low-resource persons, Hispanics or subgroups of Asian Americans—e.g., Hmong), too much emphasis is often placed on unproductive coping products. Given the lack of economic viability that often exists in communities where marginalized individuals live, countless protective factors matter but are often overlooked. Protective factors as buffers have important implications for overall level of vulnerability. Unfortunately, as suggested, protective factors are neither assumed nor frequently explored for those perceived as marginal.

Identity processes, as either the product of basic temperament and/or particular socialization experiences, have been shown to serve specific protective functions (e.g., Spencer, 1983, 1988). Unfortunately, except for the copious self-esteem studies, they are *infrequently inferred* and considered in research and theorizing about individual vulnerability level. Thus, as suggested in Figure 15.3, this chapter and suggested framework also consider the numerous unique and shared protective factors available to and accessed by diverse youth.

Accordingly, several essential factors are emphasized that allude to both risks *and* protective factors that are generally ignored even though they certainly contribute to a priori assumptions and inferences made about the vulnerability of individuals and groups. Moreover, they are often overlooked in the conduct of basic developmental science. They are not only included here but also especially highlighted because they represent core perspectives and contribute to specific social dynamics, which include: (a) *social stigma*—the disparagement of groups and individuals based solely on particular person characteristics (e.g., color, race/ethnicity, immigration status, religion, and social class; see Jaret, 1995); (b) *privilege*—the unacknowledged advantaging of some that places others at a distinct disadvantage (see Ignatiev, 1995; McIntosh, 1989); and (c) *persistent economic and social inequities*—the unfair burden and challenge to specific individuals, families or groups (see Darity & Myers, 1998; Jarrett, 1994, 1995).

When all three are considered together, the combination suggests the salient contributions of CRT for the explicitly broadened framework. Although these themes have always been implicit in our view of the theory's many strengths, the specific integration and inclusion of CRT allows for a more productive consideration of race. Originating in legal scholarship, CRT explicates how the use of policies upheld by laws but shaped by biases and perspectives concerning race are not unimportant to the unfolding life course (e.g., Bonilla-Silva, 2001). CRT—the perspective acknowledging the historical centrality and involvement of law in upholding White supremacy and associated hierarchies of gender, sexual orientation, immigration, faith community, and social class (see Crenshaw, Gotanda, Peller, & Thomas, 1995)—illustrates how law and policy are frequently shaped by race. All have important implications for the flaws that continue to hamper our research efforts to understand both the processes and outcomes, which promote and protect the well-being and development of diverse youth.

CONCEPTUAL SHORTSIGHTEDNESS IN THE STUDY OF DIVERSE YOUTH: CHILDREN OF COLOR AND PRIVILEGE

Shortsighted and erroneous perspectives about diverse youth fall into two major categories. The *first major categorical error* suggests that Caucasian children (i.e., or assumptions about their development) represent the standard of normalcy for all others. This group is most often the subject of *normative* studies conducted in developmental and social sciences. The *second category of conceptual errors* represents the perceptions about minority status youth or youth of color and their assumed atypicality. This shortsightedness also includes references used to describe the group itself: Given the changes in American population statistics, the grouping previously referred to as *minorities* is moving toward *majority status* and—although not widely—has more recently been referred to as AHAANA (Asian, Hispanic, African American, and Native American). An aspect of the privileged status associated with Caucasians is that even the term *diversity* or *diverse youth,* unfortunately, *in*consistently elicits images of Whites. Frequently, referencing diversity suggests a concern with adding minorities to a particular issue or task. For example, the role of diversity task forces is often to highlight issues that are inclusive of non-Whites. Implicit in the designation is that, without a gentle reminder, the tradition is to ignore non-Whites: Whites are assumed to represent normative development themes, and minorities (or the poor) are highlighted when adversity, pathology, deviance, or problems are of topical interest.

In this chapter, we evoke a different approach. We use the term *diverse youth* in this chapter *to include both European American (Caucasian) and AHAANA (frequently marginalized) youth*. Unlike the narrow and exclusively positive connotations associated solely with European Americans (Caucasians) and the more limited (and generally negative) imagery linked with diverse youths' of color representation in the social sciences generally and developmental science specifically, we posit a strategy that acknowledges several major conceptual defects that our proposed framework seeks to remedy.

Flaw One: Context Ignored

First, as consistently shared (e.g., Spencer 1985, 1995; Spencer et al., 2006), ecology has been frequently *viewed as* a nonissue in the consideration of human development. Context has also been ignored. This appears particularly relevant, when context creates a source of consonance (i.e., inferences of mainly support), or, in contrast, dissonance (i.e., a lack of individual-environment fit). Thus, when behavioral outcomes are viewed as problematic, the pattern has been to *not* consider the context, but to infer a relational pattern that localizes the problem in the individual. As suggested, negative inferences have more often than not been localized around human development experiences assumed for youth of color (see Kardiner & Ovesey's, 1951, *Mark of Oppression;* Pettigrew's, 1964, *Profile of the Negro American*). The position of these treatises has been consistent in either pathologizing individuals or positing a style of analysis that associates particular behavioral patterns with specific characteristics of settings (see Elliott Liebow's 1968 classic sociological statement *Tally's Corner*). An acknowledgment that these early and significant social science contributions never placed the burden on a socially constructed context is important. Rather, more often than not, problematic behavioral correlates reported or inferred were linked with or credited to individuals who happened to live in those contexts. The consistent assumption communicated was that the pathology of the individuals themselves created the untoward character of the settings, however, at the same time, enlightened and more sophisticated analyses were available.

The critical and long-term insights provided by early ecological psychologists such as Roger Barker, Herbert Wright, and Paul Gump (see Barker & Wright, 1949, 1954; Gump & Sutton-Smith, 1955; Wright, 1967), and later broadened and refined by Urie Bronfenbrenner (see Bronfenbrenner, 1985, 1992, 1993; Bronfenbrenner & Crouter, 1983), existed and continue to provide critical insights. Fieldwork by ecological psychologists in the United States and England obtained definitive findings concerning the reciprocal links between the individual and context: Conceptual contributions by Bronfenbrenner illustrated the indisputable interactions, and space psychologists such as Joachim Wohlwill (Wohlwill, 1985; Wohlwill & Heft, 1987) clearly explicated the reciprocal links further. Considered together, given the different though parallel methodological and conceptual strategies, they quite persuasively linked individual experiences with context character.

Relatedly, if the character of context is socially constructed (i.e., given provisions and omissions of support as policy decisions and social traditions), then, from a CRT perspective, policies concerning (a) the owning of

slaves, (b) the separations imposed on slave families (i.e., separating fathers from mothers and children), (c) the use of immigrants and slaves for free labor (see Baron, 1971), and (d) the framed policies and enacted traditions to limit the education of slave children (see Spencer, Cross, et al., 2003) or import immigrant men only as free laborers had long-term consequences: The attendant decisions virtually guaranteed contextual conditions as stigma-producing and peculiar situations that would foster problems for subsequent generations (both for those deemed marginal and those—although unacknowledged—deemed privileged). Accordingly, and as suggested by the examples provided, the observations noted have special import to diverse youth of color and their families.

Frequently, these youngsters' development is assumed to be and studied as if it emanates from a vacuum of experience. Inferences about diverse youths' of color development associated with broad structural, physical, historical, and social contexts as well as inherited conditions are overlooked. CRT's emphasis on the methods by which attitudes about race influence decisions in the U.S. court system aids in excoriating the shortsightedness concerning guarantees of equity and equality of experience. However, in the social sciences and child development literatures, the unequal conditions and historical circumstances that diverse youth have inherited, grown up with, and psychologically developed in response to are, for the most part, inadequately considered or totally ignored. For example, considered as oversights are the numerous manifestations of symbolic and structural racism, economic hardships, social inequities, and related barriers that appear to characterize the environments encountered by children and youth of color. Moreover, their stage of development (i.e., cognition-based meaning-making processes) determines the level of sophistication concerning their own inferences about their situation. Further, given vulnerability level as a function of cultural socialization, parental monitoring, and other available protective factors, diverse youth reactively cope in ways that may be either facilitating or exacerbating.

Protective factors often remain unnoticed in the design and conduct of developmental science, even though an anthropologist would never purport to engage in field-based research without knowing something about the group of interest. This knowledge is assumed to go significantly beyond self-esteem knowledge (i.e., the construct of choice by many social scientists). Unfortunately, the implicit, conceptually intrusive, although unappreciated, prevalent mind-set by scholars in developmental psychology is that *macrolevel conditions* experienced at the micro-, meso-, and exolevels of social ecologies (i.e., generally reported as sample demographics) do not deserve serious attention. However, enough research, conceptual frameworks, and new theories demonstrate not if but *how much* these factors *matter* in the lives of children.

Further, the resistant and limiting shortsightedness described suggests that when these factors are brought to conscious awareness through journal policies and federal funding initiatives, the impact of the many levels of ecologies described by Bronfenbrenner (1979) and others persist as merely *acknowledged* (i.e., as statistically manipulated control variables), but not as factors that impact the questions posed, balanced character of the samples (or not), and constructs identified and measured. Moreover, there has been a general disregard for individuals' own perceptions and meanings made from the multiple ecologies traversed, contexts psychologically experienced (see Steele, 1997; Steele & Aronson, 1995), and limitations explicitly and subtly imposed (see Chestang, 1972). Perceptions have important implications for emotional reactions and subsequent analyses inferred as human processes that fuel reactive (see Stevenson, 1997) and stable repetitive coping responses. Patterns of shortsightedness remain for those producers of science following 3 decades of cogent critiques, which highlighted major methodological and conceptual shortcomings of the research enterprise (e.g., Banks, 1976; Guthrie, 1976). For example, the continuing use of uneven comparison groups (e.g., low-income diverse youth compared to middle-income European American samples) has implications for the interpretation of findings and perpetuation of social stigma (see Steele, 1997; Steele & Aronson, 1995).

Frequently, the conceptual problems described appear to be resistant to change. Even when the problem of unequal samples is not an issue, the measurement of identified variables is frequently insufficient. Identified variables and measures lack psychometric integrity across diverse groups, and inferred meanings represent an unaddressed conundrum: Constructs may lack conceptual validity (i.e., meanings may not be shared). Often, particular group members' experiences at the microsystem level may vary, given individual-context linked challenges, coping requirements (i.e., the degree to which social dissonance or consonance is experienced), and reactive coping strategy availability (see Stevenson, 1997). Further, because many research ini-

tiatives are well-funded as large multisite, longitudinal data-gathering enterprises, particularly for young investigators and dissertating students, *strong encouragement is provided or incentives are made available for secondary data analytic options—no matter how ill-conceived the study.* Consequently, the predominance of inadequate conceptualizations and data interpretations remains in the literature for significant periods.

Deficit Perspectives and Stigma about Diverse Youth of Color

As suggested in Figure 15.2, research that depicts diverse youth of color's development in the context of family, school, community, and broader macrostructural determined conditions continues to be highly deficit-oriented. For over a 50-year period, presented through a deficit-oriented, linear, and deterministic conceptual lens, diverse youth of color were shortsightedly viewed as pathological products of oppression (e.g., Kardiner & Ovesey, 1951), where only the negative outcomes associated with some of these youth were studied. Such myopic tendencies continue to this day. The resiliency—health and mastery demonstrated in high-risk environments—associated with many youths' coping efforts remains generally ignored. As noted in Figure 15.2, the monolithic perspective about youths' experiences is not only deterministic in nature but also ignores the resilience of those who do succeed in spite of tremendous barriers. Given recent discourse on the topic of resiliency, the penchant to ignore resiliency may be an effort to underemphasize the contributions of socially constructed conditions that privilege some and undermine others (see Luthar & Cicchetti, 2000), thus, making particular diverse youths' developmental tasks difficult, at best, or a double quandary, at worst (see Boykin & Ellison, 1995).

For some, perhaps a triple quandary is more accurate when the special burden of gender is added and considered for African American male youths' experiences (Boykin, 1986). In addition to the chronic struggles that are linked to race, ethnicity (see Allen, Spencer, & Brookins, 1985; LaFromboise, 1988; Spencer, 1990; Spencer & Markstrom-Adams, 1990; Spencer & Dornbusch, 1990), and immigration status (Huang, 1989; Liu, Yu, Chang, & Fernandez, 1990), socioeconomic challenges frequently remain. Importantly, these challenges appear endemic, persistent, and are associated with parenting conditions (i.e., work, housing and neighborhood adequacy, stable relationships, and parenting time availability); they also present unique difficulties for adults caring for the very young (Jarrett, 1994, 1995) through to the middle childhood period (McLoyd, 1990). They may be further imperiled by biculturalism efforts (LaFromboise, Coleman, & Gerton, 1993). Struggles experienced include those that are encountered not only at home (Boyd-Franklin, 1989; Boykin & Toms, 1985) but also at school (Ladson-Billings, 1994; Lee et al., 2003). Their impact may be exacerbated by gender when experienced by girls under dense and unsafe conditions (e.g., Ladner, 1972). Although such struggles are particularly difficult for males given the more valued status enjoyed by most males in the majority of the globe, thus providing high expectations for *all males* without necessarily conditions of attendant supports (Nanda, 1974). Problematic structural conditions persist, yet the majority of young diverse youth of color manage to cope adaptively, although their efforts are infrequently recognized and factored into the design of research, selection of constructs, specific questions posed, or the interpretation of findings.

Accordingly, a priori assumptions about diverse youth of color infer risks alone without *also emphasizing and exploring the presence of protective factors.* Moreover, the frequent focus on risks and their linkages to problems leads social scientists to assume only unproductive and homogeneous outcomes and labels such as castelike minorities (see Fordham & Ogbu, 1986; Ogbu, 1985; and critiques by Spencer, 2001; Spencer, Cross, et al., 2003; Spencer & Harpalani, under review). The shortsighted perspective and concomitant assumptions fuel deterministic assumptions, which may reinforce stereotypes (see Figure 15.2). Although infrequently acknowledged for privileged youngsters (i.e., middle-income Caucasians), all humans are vulnerable at some level (i.e., burdened with risks and buoyed by protective factors). However, as suggested previously in Figure 15.1, the degree of vulnerability can be determined only from an appreciation of *both* risks *and* protective factors. A narrow assessment of high vulnerability that is associated with socially constructed risk conditions but which frequently ignores protective factors epitomize poor science. There is a specific need to also understand available protective factors to achieve an accurate understanding and assessment of vulnerability (Luther & Becker, 2002; Luther & Latendresse, 2002).

An analogy from the pharmaceutical sciences is easily understood because the public would not use, or the medical establishment designate, a drug regimen without also understanding the other "knowns" or protective

factors concerning its intended use. For example, information related to safety and protection might include (a) establishing the number of milligrams of the drug's active ingredient per kilogram of the user's body weight, (b) possessing no known allergies to the drug, (c) not taking other drugs known to cause untoward interactions with the drug intended for use, and (d) lacking the presence of concomitant medical conditions for which the drug would be counter-indicated (e.g., a pregnant woman drinking alcohol during the pregnancy). This illustration is helpful given scientific knowledge concerning the teratogenic influence of many over the counter, nonprescription drugs (e.g., aspirin and motion sickness remedies) on prenatal and neonatal development (Note: Teratogenic substances are those found to have an adverse impact on fetus and infant health, growth, and development). Thus, it is *not a new perspective* to undertake thorough understandings about individual and group vulnerability in some fields. This is done by contemplating both anticipated risks and protective factors. This procedure appears relevant irrespective of a specific issue (e.g., applying for a job, contemplating a vision screen for contact lenses or laser surgery, considering a medicinal regimen for health maintenance, or contemplating marriage). Curiously so, and as illustrated, a decision-making style that bears in mind both risks *and* protective factors appears less prevalent when inferences concerning race, ethnicity, and socioeconomic disparity themes are at issue.

Unfortunately, for diverse youth of color, simplistic analyses and dependence on risk characteristics are most often the norm rather than the analytic exception. As suggested, the approach is not only ultimately stereotype-dependent but also tends to produce or reinforce further stigma and stereotyping. In presenting alternative and inclusive theorizing, we propose an improved and nuanced analysis. The conceptual strategy described suggests improved interpretations of disparate findings frequently obtained for youth who *appear to share* family, school, and neighborhood contexts. Additionally, a more analytic approach that recognizes, incorporates for consideration, and specifically elucidates the role of protective factors in youths' lives might facilitate improved understandings about high-risk presence *along with* patterns of positive coping outcomes (i.e., resiliency). The suggested approach might aid the identification of culture-sensitive and context-linked supports and remedies. In sum, for youth of color, social scientists too frequently err on the side of negative, linear, and deterministic thinking (i.e., high risks are linked narrowly and often solely with untoward expectations). Figure 15.1 noted another deterministic pattern used in the consideration of European American youths' experiences.

As reported, the prevalent although simplistic perspective noted in Figure 15.2 leaves the analogous issues *ignored* among European American youth (e.g., teen pregnancy and abortion use, White male aggression, and high suicide rates). Further, when pursuing remedies for enhancing productive youthful outcomes, the situation described (i.e., overlooking protective factors) for diverse youth of color leaves practitioners with the narrow and erroneous assumption that untoward outcomes can be remedied from a one-size-fits-all perspective. As suggested by Figure 15.3, assumptions about inherent protective factor presence and a total absence of acknowledged risks (i.e., in the case of privileged youth) may exacerbate vulnerability level. Examples from Littleton, Colorado, manifested by the Columbine High School killings by upper middle-income European American youths, clearly demonstrate the downside of privilege and reaffirm the salience of adaptive coping skills for promoting healthy identity processes and stage-specific competence (refer to Figure 15.3). Undoubtedly, the appearance of resilience among low-income, immigrants, and minority youth is not well-studied and is often misunderstood or overlooked (e.g., Fordham & Ogbu, 1986) as illustrated by Ogbu's "acting White" assertions concerning patterns of *under*-achievement for some African American and Hispanic youth. Unfortunately, given its broad presence in the popular media, Ogbu's (1985) limited perspective frequently reinforces stigmatizing and stereotyping beliefs without affording an understanding of the outcomes and mediating processes. As suggested, this penchant is most evident when matters of race, ethnicity, and social class are at issue. CRT would suggest that *assumptions concerning each* are frequently made and impair the possibility of equitable treatment.

Flaw Two: Racism Ignored

Unaddressed contextual and psychological issues such as racism and class inequities may potentially impact child and adolescent perceptions of self, others, and decision making about the current coping responses expected and required given normative and unique challenges; also influenced are preparations for future life prospects. In parallel fashion, although there are a few recent exceptions (e.g., Luthar, 2003; McIntosh, 1989), beliefs about

privilege (or its absence) are seldom acknowledged and considered in the conceptualization and conduct of research on European American youth, while behaviors such as off-time sexual activity, behavior problems, underachievement, and aggressiveness are emphasized for youth of color.

As stated previously, endemic and long-term economic and social barriers are ignored frequently, leaving to be inferred that all problems are inherent in the individual. Further, and most important, the unacknowledged social consonance (i.e., optimal individual-context fit) frequently experienced by European Americans, given race-associated privileges, are imposed as the norm and expressed as the *outcomes expected for all.* Although for youth of color, supports afforded from protective factors (e.g., prior cultural socialization experiences including church engagement and very close parental monitoring) and manifested individual or family level resiliency factors evident are *infrequently assumed.* Critically important, the social construction of inequality through discounting the inequities noted within and between groups is infrequently recognized. They are not only *un*acknowledged but also often overlooked in the actual design of research and programming efforts. Worse, they are ignored in the evaluation of programs and attendant social policy development. Published review papers often list egregious scientific shortcomings (see Fisher et al. 2002); however, the challenges implied for their continuing presence and utilization in the making of public policy are *seldom actually acted on as sanctions*—when considering "what" gets funded, which research strategies are modeled, why there is a continuing general absence of research professors of color in academia, and how students are taught to understand the issues. Not only do programs of research and attendant publications continue to ignore the conceptual concerns identified thus far but also fail, as indicated, to consider the special relevance for White youths' developmental experience.

The issue of privilege is foundationally important particularly to the human development of Western youth. The *absence of dissonance* or appearance of maximal and patterned social consonance (i.e., maximized individual-context fit) may compromise the normal development of important *coping skills* (i.e., the handling of normative concerns and the responses to unique challenges) and *healthy identity processes* among these youths. Positive coping skills are important life-course acquisitions because they provide psychological protection and stability across time and place given the unavoidable, developmental, and countless challenges that accompany youths' pursuit of competence in response to stage-specific developmental tasks (see Havighurst, 1953). Moreover, the lack of an authentic identity that is linked to stable coping processes may have implications for the character of contexts enjoyed (or not) by others; this is particularly important given the universal life course need to cope effectively with stage-specific challenges and to maintain balance, even when not generally expected. Even after "objective needs" have been satisfied, Robert White eloquently describes the importance of "effectance" motivation in responding to the need to have an impact on the outside world (i.e., to demonstrate competence; R. White, 1959, 1960). Such a need has also been described as personal causation (see DeCharms, 1968). In sum, volitional history matters and a history of effective coping has implications for life-course demonstrated competence given numerous unique and normative challenges. An important challenge for many youngsters has been significant changes in family structure (e.g., increase in two-parent working families for European Americans and fewer three-generational family systems for youth of color).

Hetherington and Kelly (2003) and others have been prolific in describing the impact of divorce as a source of challenge for European American youth. Inferred is that a lack of experience with challenges and stress may have implications for the development of support-accessing abilities and the acquisition, honing, and exercise of adequate coping skills. Although generally not addressed in youth development studies, a consistently elevated pattern of completed suicide rates for European American males has not provoked the cause for alarm that the statistics and their stability over decades actually deserve. Given the economic, social, and developmental specific supports particularly available for European American males irrespective of social class versus youth of color (see Sullivan, 1989), broad research efforts focused on understanding this pattern's etiology failed to solve the conundrum. As tallied across 5 decades in half-decade analyses by Carroll and Tyler (2001) for the period 1940 to 1989, there are no differences for the 25- to 34-year age range between Black and White males. This period represents the highest peak for Black young adult males, however, suicide rates begin sooner and continue to increase through age 85 for European Americans. At that age, the average reported rate indicates three times the rate evidenced in the early adult years. When analyzing the data trends, Carroll and Tyler (under review) suggest a gender by race interaction in the maladaptive

response to stress. At the same time, even though European American males continue to enjoy the most lucrative life-course averages, when earnings and number of years of education completed are considered over the several decades of the life course, these males have a surprisingly high suicide rate. Although, attention has been paid to the change in peak level of completed suicides for Black young adult males (see Joe & Kaplan, 2002), the lack of anxiety or explanation for the *parallel lines of data* for European Americans when compared against average life income, cumulative education achieved, and *completed suicides* considered together and examined over several decades is cause for alarm.

Flaw Three: General Lack of a Developmental Perspective When Considering Youth of Color

As indicated, the developmental literature disproportionately focuses on the experiences of European Americans. Alternatively (as suggested by Figure 15.2), theorizing about youth of color frequently *underexamines* developmental processes and *overemphasizes* risk factors and unproductive stage-specific outcomes (e.g., early pregnancy, disproportionate incarceration rates, school failure, and aggression). The thematic patterns are both interesting and troublesome because the *normative* developmental thematic stressors experienced by youth of color, such as off-timed physical and social maturation and peer pressure issues, may be compounded by context character factors that are associated with racial stigma and color-linked traditions that assume equality of experience and exposures (see Spencer, 1985; Spencer & Dornbusch, 1990; Spencer & Markstom-Adams, 1990). Normative child and adolescent developmental processes, such as early maturation, when considered in conjunction with encounters of race and economic disparities (e.g., lack of job availability for parents, under-funded schools, unsafe neighborhoods, inadequate schooling opportunities, and unacknowledged racism) suggest inordinately stressful contexts for achieving healthy normative social experimentation opportunities necessary for development. Such conditions would be expected to have implications for phenomena such as off-timed pregnancies, juvenile justice contact, and underachievement in school. Yet, apart from a few exceptions (see Spencer et al., 2001), these perspectives are seldom acknowledged in publications on the topic. In short, developmental, process-oriented, and context-linked analyses are not emphasized for youth of color. Alternatively, for European American youth, the concomitant stress and challenges associated with unacknowledged privilege and its downside (e.g., inadequate coping opportunities that may be linked with high rates of male suicides), unfortunately, are seldom integrated into conceptual formulations of development. Certainly, as indicated, the implications of the latter for the development of coping skills remain an oversight in child psychology. The absence of publications on the downside of privilege is clearly demonstrated when considering the several examples of school-based killings. These occasions are made similar given the unexpected demographics of the perpetrators; one of the more recent examples, as noted, was the killings of fellow students at Columbine High School by three youth from economically well-endowed families and communities that were unaware of the threat within.

Domains of Human Development and Competence

Social science research with youth often lacks both cultural understandings (see Lee et al., 2003) and awareness of the *affective* component in cognitive functioning generally (e.g., see DeCharms, 1968) and social competence formation specifically (i.e., effectance motivation; R. White, 1959, 1960). The shortcomings are evident both in the design and the interpretation of scholarship on youth of color. Similarly, a general oversight of cultural inclusiveness, including *lived privilege as culture* as experienced by White youth, is lacking. Minority children and adolescents developing in contexts defined by a unique family structure and sets of cultural practices are (a) generally *not well* understood, (b) behaviorally misinterpreted, (c) burdened with demonizing assumptions, and (d) frequently absent from developmental science concerned with normative human processes. The oversights have implications for schooling experiences (i.e., both for the training of teaching and administrative professionals), and the general context-linked socialization experiences of relevance for competence formation and human development more broadly. To sum, conceptually inclusive approaches to developmental science have important societal implications regarding how policies are framed and implemented, how contexts are structured, and how socializing adults (e.g., teachers, administrators, and service providers) actually deliver the supports intended for youth of color. Good science representative of the breadth of human experiences facilitates the best practices and policies. Accordingly, needed are viable and

broadly inclusive approaches to child development for use in maximizing the best possible youth outcomes.

Need for Inclusive Approaches to Human Development

Particularly during childhood and adolescence, exposure to social factors experienced as challenges (e.g., social stigma)—particularly those creating *bias* (i.e., whether inferred collectively by the group or experienced individually)—are important. Further, they have explanatory relevance for interpreting individuals' stage-specific outcomes. For example, the function and experience of negative teacher perceptions experienced by youth help explain performance disparities documented both between and within diverse groups (see Spencer, 1999a; Spencer & Harpalani, under review; Steele, 1997). For a significant length of time, inferences about teachers have aided the interpretation of gender differences in achievement findings for European American students (see Dweck, 1978). Dweck's research findings suggest that in the primary grades, European American female students tend to internalize failure and externalize success. The opposite pattern has been observed for elementary school boys who learn early on to internalize success and externalize failure. The findings are in keeping with observations that boys and girls have very different school experiences (Irvine, 1988).

Because elementary teachers are often female, Dweck's (1978) findings suggest that female teachers may be more accurate when anticipating and evaluating the behaviors of girls. Alternatively, boys tend to learn that elementary school teachers are in error at least half of the time when providing evaluative feedback to them. Dweck (1978) suggests that boys compensate by "discounting" the feedback and "celebrating" their successes by crediting only themselves. However, although not included in her study, other conceptual analyses would suggest a quite different pattern if investigating the experiences of male youth of color (see Irvine, 1988). These youngsters have the *added task* of sorting out the contribution of teachers' racial attitudes and bias that become intertwined with academic evaluation and behavioral feedback. Minus a few exceptions (e.g., Dweck, 1978; Ladson-Billings, 1994), student characteristics as linked with feedback patterns, unfortunately, are infrequently and not seriously considered as part of the context for evaluating the competence and character of youths' social relations.

Inferred or intended bias may serve both conscious and unconscious roles in human relations. Bias represents frequently unacknowledged adverse beliefs about particular individuals and is often experienced as the invisible elephant in the room in that it potentially creates extreme *emotional discomfort.* The emotional response may be apparent and different for those either recognizing its presence or feigning its absence. Importantly, as described by Chestang (1972), in either case, the emotional reaction to the experience potentially compromises stage-specific character formation (i.e., as either specifically patterned behavioral responses or developmental processes more generally). In many ways, given gradually emerging cognitive schemas beginning at infancy, the emotional response may be not unlike the experience of marasmus (failure to thrive syndrome). For infants, this syndrome suggests an expressive response to inadequate emotional or physical care. Alternatively, when applied to the experience of adults with highly vulnerable infants, Kennell, Trause, and Klaus (1975) have described the difficulties encountered in emotionally bonding with infants deemed terminally ill and not expected to survive; in such cases, interventions are needed for maximizing infant-caregiver bonding. Accordingly, when considering social relations between and among adults and children, the presence of bias may not only serve as a source of negative stereotyping and shame for some but also, as described by McIntosh (1989), may afford disproportionate protective factors (i.e., conceptualized as privilege) for others. Thus, barring a few exceptions (e.g., Spencer, Brookins, & Allen, 1985), the dilemmas of *individual-context consonance* for some (e.g., the privileging experiences afforded some European American youth) and the psychological experience of *social dissonance* for others (i.e., more often than not, experiences of youths of color; see Chestang, 1972) are not equivalent. The conundrum remains inadequately integrated and considered in psychology's mainstream journals and for most theorizing about human development particularly for diverse youth, specifically those of color (see Spencer, 1999). This conceptual shortcoming (i.e., of interpretation and ultimate planned support as social policy and innovative program design) has implications for generalized human development enhancement, basic human rights infractions, and social justice. Specifically, when describing diverse populations, the oversight has salient implications for the design of precise policy, the

incentive structure in support of best practices, the interpretations made of evaluation study outcomes, the character and process of juvenile justice system-based experiences and consequences, and decision-making processes about basic programs of research to be supported (e.g., the actual types and sets of questions posed). The specific points of view espoused in this chapter support greater *conceptual inclusiveness* that goes beyond the mere inclusion of diverse samples in a study's design or program of research. As suggested, good human development theorizing representing real time and valid human development experiences of diverse groups and their members serves important interpretational and decision-making functions. As a strategy, it impacts the quality of child development and youth outcomes through implicit *social engineering as social policy.* Such a strategy provides ways of articulating challenges and specifying precise supports required for facilitating best practices (i.e., as policy and application) while at the same time altering deleterious contexts that interfere with the promotion of productive coping methods, which maximize the various expressions of positive youth outcomes as reactive coping practices and stable healthy identities.

Particularly for highly stigmatized groups, within-group variation is seldom acknowledged and, instead, homogeneity is often assumed. In contrast, between-group differences frequently serve to further marginalize or stigmatize outliers (i.e., those performing significantly outside the mean). The sources of variability observed both within and between groups are broad and may be due to multiple human characteristics or contextual experiences that operate as processes and mediate between an individual's vulnerability level and stage-specific coping outcome. For example, high performance associated with privilege may be a valid explanation for some; alternatively, high performance for youth of color may be due to significant levels of adaptive coping and resilience. The implications of each may be different when individuals of each type are confronted with similar challenges *and equivalent supports.* Resilient youth may get better scaffolding from extra supports, already have a history of dealing with challenges, and thus, possess well-developed coping skills. However, the same level of challenge for privileged youth may be more disconcerting than expected because a history of privileging experiences would not afford similar opportunities for the developing of multiple coping strategies. Similarly, responses to a standard level of support may be different as a function of privileged individuals' level of personal vulnerability, which, historically, may not have been an issue if maximized support had remained the standard. However, with the standard of support, perhaps, being lowered to a level different from individual history, individual vulnerability characteristics might provide ways of explaining expected differences. Discussion and exploration of such within-group variation is infrequently addressed for Caucasian youth. Variation of responses to challenge for youth of color is generally not sought and perhaps is undermined by the very design of research studies (e.g., given the frequent comparison of middle-income European American youth with low-income youth of color).

Accordingly, when considering either within- or between-group differences, an individual's accrued vulnerability represents the balance between risks and available protective factors. On the one hand, risk types have implications for the character of challenges that one experiences or anticipates. On the other hand, protective factors may vary, ranging from the intergenerational sharing of cultural traditions to unusually high levels of accumulated wealth. Obviously, both would demonstrate different manifestations as each serves as a source of support. Further, it is important to acknowledge that both types of protective factors (e.g., cultural socialization versus intergenerational transmitted accumulated wealth) have important implications for both the specific *nature* of anticipated supports available and their character (e.g., stability and persistency or internal versus external origin).

Risks and protective factors may take a variety of forms given variations in race/ethnicity, gender, faith community, body type, immigration status, skin color, privilege, health quality or disability status, cultural traditions, social class, and temperament. All are linked to the character of the context and the individual's history of experiences and even the group's history in the nation (e.g., generational experiences of immigrants as newcomers and long-term adaptations of indigeneous groups such as Native Americans, Hispanic, and African American youth and families). When experienced as challenges or supports, the sources of variation within or between groups may be biologically inherent (e.g., due to the heritability of temperament, skin color, or body type) or socially constructed (e.g., beliefs and biases concerning race/ethnicity, social class, and physical attractiveness). When considered together, as suggested, the noted basis of variation represents potential sources of *risk* or *protec-*

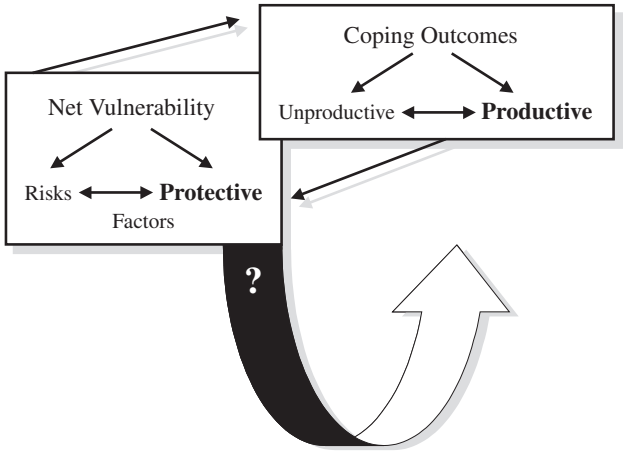

Figure 15.4 Non-deterministic theorizing: Acknowledges intervening mediating/moderating processes thus illustrating potentially diverse outcomes given unique individual-context-process interactions.

tion that are associated with some level of human vulnerability. The actual character of individual vulnerability is unavoidably associated with the nature of the context and its provision of either excessive challenges or supports. The level of vulnerability has implications for achieving stage-specific manifested competence (White, 1959, 1960), resiliency (Anthony, 1974, 1987; Luthar, 2003), or under-development. In addition, and as described in Figure 15.4 as an example of nondeterministic theorizing, generally ignored or inadequately recognized (i.e., particularly as it relates to child development and adolescent experiences) is an emphasis and acknowledgment of the individual's awareness of (cognition-dependent) perceptions and stage-specific meaning-making processes.

Mediating Processes between Vulnerability and Coping Outcomes

From our conceptual perspective (as illustrated in Figure 15.4), we hypothesize that intervening processes between vulnerability level and coping outcomes go beyond an understanding of the "what" of the individual-context relationship. A focus on the mediating processes aids in explaining the "how" of development (Spencer & Harpalani, 2004), not merely the "what," as eloquently illustrated by Bronfenbrenner's model (Bronfenbrenner, 1989). Individuals' awareness of (cognition-dependent) perceptions and stage-specific meaning-making processes afford the consideration of critical inferences salient for understanding youths' coping and identity-formation processes. Further, it is the socially linked and maturation-based variability of youths' cognition dependent perceptions that supports the acquisition of unavoidable awareness of their own (i.e., assumed internal states) and *social others'* perspectives. For example, research on children's awareness of race as a social category (i.e., understandings or knowledge about race) assessed frequently as racial attitudes and preference behavior demonstrate the complexity of youthful meaning-making when cognition-dependent awareness is also considered (e.g., see Spencer, 1982, 1983, 1985; Spencer & Markstrom-Adams, 1990). Specifically, the insight affords greater understanding about the *unfolding processes of child and adolescent* cognitive, social, and affective *capacities* when linked with context-linked challenges (e.g., race biased treatment), given varying degrees of human vulnerability (i.e., countless levels of race-associated contextual risks versus privilege-associated, Caucasian-linked protective factors). Characteristics of the context observed as numerous patterns of stable conditions and the inferred meanings made about them are not lost on youth. Accordingly, PVEST as a context-linked systems framework goes beyond merely linking human vulnerability (i.e., risk considered against protective factors) linearly and deterministically with stage-specific coping products. Moreover, when considering stage-specific developmental tasks that are experienced as challenges, the framework also acknowledges and specifies the breadth of available supports possible; at the same time, it recognizes the role of supports for productive stage-specific coping products (see Figure 15.5).

The framework also focuses on the mediating/moderating function of net-stress responses and

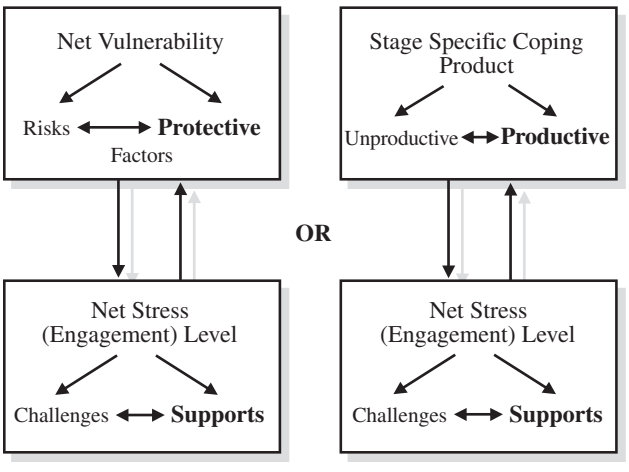

Figure 15.5 Stress-focusing research exemplars: Stress conditions may link with either individual vulnerability level or stage-specific coping outcomes.

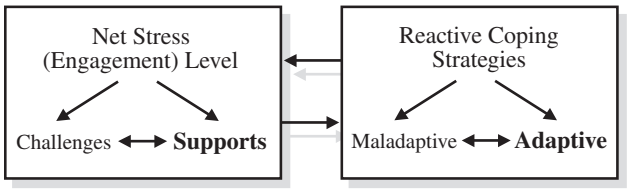

Figure 15.6 Stress and coping links: Emphasizes linkages between reactive coping methods and net level of stress experienced.

reactive coping styles available through a history of socialization (see Figure 15.6), and, consistent with ego psychology theorizing by Erikson (1959), it bears in mind the critical function of emergent, stable, identity-formation processes (see Figure 15.7).

The three mediating processes were illustrated previously and collectively (see Figure 15.4) and depicted as a large question mark and thick arrow between vulnerability and stage-specific coping outcome. The mediating processes assist with explanations about the diversity of individual-context-process mediated links. These associative relations provide the reason for a simultaneous consideration of structural factors, cultural influences, individuals' perceptual processes about the self, bidirectional interactions with others, and myriad daily life experiences that impact individual vulnerability, productive coping outcomes, and, for some, manifested resiliency. The perceptions and patterned responses occur as individuals confront normative developmental tasks while navigating countless contexts in pursuit of demonstrating competence given the unavoidable impact of effectance motivation (R. White, 1959, 1960). Accordingly, given both between- and within-group variations for diverse individuals and associated contextual heterogeneity, the resulting person-context-processes system of mediating/moderating effects may vary. As depicted in Figure 15.5, it is interesting that the literature often narrowly focuses stress questions (i.e., balances between challenges and supports) around vulnerability themes for some groups (e.g., European Americans) while it provides a stress focus as linked to outcomes of competence or failure for others (e.g., diverse youth of color). We suggest that the approach taken often varies by ethnicity. For example, being African American or poor is frequently linked with studies of stress for Blacks. Although divorce as a significant stressor is often linked with particular coping outcomes for European Americans (refer to Figure 15.5), the level of support provided by privilege as experienced by European American youth has just recently become the focus of rigorous developmental science efforts concerned with maladaptive coping (see Luthar, 2003; Figure 15.6).

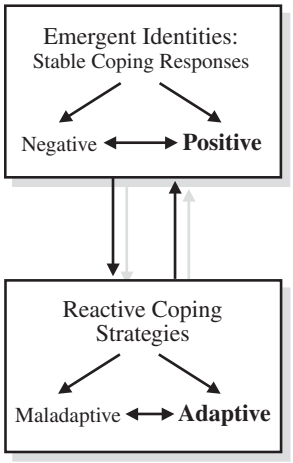

Figure 15.7 Identity-emphasizing research.

Consistent with the emphases described and theorized by Cross (1991) and Erikson (1959) about reference group orientation and broad ego processes, respectively, the multiple functions of *identity processes* are foundational to this framework. Specifically, the central placement of identity processes is evident through its mediating links between human coping (i.e., net reactive coping) with broad ego processes (i.e., stable emergent identities; see Spencer, 1985; Spencer & Dornbusch, 1990; Spencer & Markstrom-Adams, 1990; Swanson, Spencer, & Petersen, 1998).

The central role of identity and self processes affords the framework an ICE (identity-focused cultural ecological) perspective, given the important and implicit function of social cognition, perceptual processes, and context character (e.g., Spencer, 1984, 1985). As described in Figure 15.7, negative identity processes for youth of color have been assumed to be a reactive coping response to racial group membership; the relationship is frequently assumed particularly for African American youngsters. However, the assumptions have not been confirmed with empirical data (see Hare & Castenell, 1985; Spencer & Dornbusch, 1990; Spencer & Markstrom-Adams, 1990). Beginning with the work of theorists such as Kardiner and Ovesey (1951) and Pettigrew (1964) and as inferred from the *Brown v. Board of Education* decision (i.e., as in the citations of Kenneth and Mamie Clarks' research as cited in Cross, 1991), the

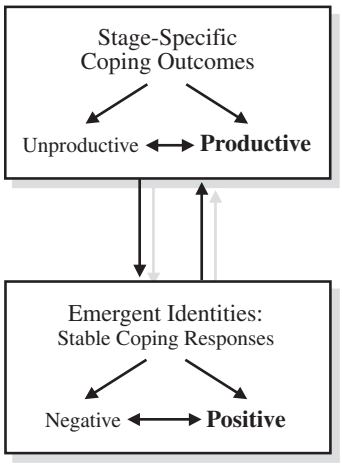

Figure 15.8 Outcome- and identity-emphasizing theorizing: Approach narrowly focuses on specific life stage coping outcomes and makes assumptions about identity character.

consistent assumption of psychopathology and negative identity processes continue to be associated with assumed internalized risk related to the stigma associated with skin color and identifiability (i.e., and implications for biased treatment; see Figures 15.8 and 15.9; Cross, 1991, for a review).

It is interesting that identity processes for African American youth are not more carefully analyzed and interpreted given their often co-occurrence with appearances of unproductive stage-specific coping outcomes (e.g., school failure). The *lack of anticipated (i.e., negative) linkage* between self concept and unproductive outcomes is due to the not unexpected and greater salience of *own-group significant others* for children's psychological functioning and well-being. In other words,

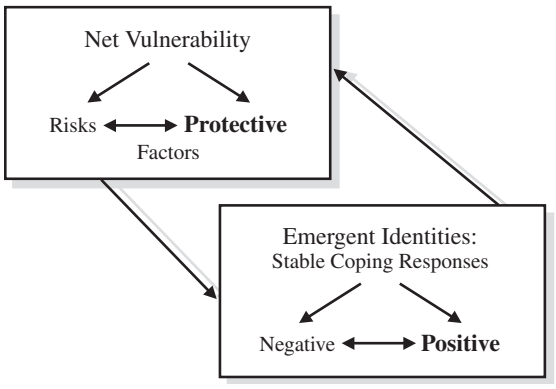

Figure 15.9 Identity- and vulnerability-focusing approaches: Perspective focuses mainly on individual vulnerability associated with speculated identity statuses.

youths' own families, friends, neighbors, and extended kin represent the *comparison others* of salience for social emotional functioning (i.e., inferred self valuing is reflected from *referent others*) rather than externally and negatively evaluated life-stage specific outcomes.

As particularly applied to youth of color, process-oriented theorizing is needed that acknowledges context and, at the same time, demonstrates mediating processes and avoids the conceptual assumptions and erroneous conclusions of the past. Finally, unlike many theories of human development that merely mention context and acknowledge processes, our conceptual approach more specifically and directly demonstrates the person-context-process view as espoused by Bronfenbrenner (1985, 1989). PVEST provides insights about the "how" of development (see Spencer & Harpalani, 2004), and, we believe, more directly links the daily experiences of diverse people given individual characteristics and protective factors (i.e., by ethnicity, race, social status, religious faith, and physical attributes—skin color or body type) with environmental quality (including the availability of supports and challenges) as individuals traverse multiple contexts. Specifically, successful transitions require good person-context fit for maximizing human processes and behavioral outcomes (see Matute-Bianchi, 1986; Spencer & Harpalani, 2004). An approach of this type aids in interpreting the "how" or "why not" of youth outcomes as promulgated by positive youth development theorists included in this set of volumes such as Benson (Benson, Scales, Hamilton, & Sesma, Chapter 16, this *Handbook,* this volume) and Lerner (Chapter 1, this *Handbook,* this volume). The broad, dynamic, developmental, identity-focused, and context-linked perspective suggested by PVEST and relevant to numerous groups, to date, has not characterized approaches to child and adolescent development nor life course theorizing (see Spencer, 1999; Swanson & Spencer, 1999; Swanson et al., 1998).

Summary

In summary, this chapter's organization was structured to delineate the advantages and contributions of PVEST for maximizing the applicability of human development theorizing for many ethnicities or diverse groups of humans (both youth of color and European Americans). The first section indicated the chapter's focus on the period of preschool through adolescence and explained why the theory affords human development a life-course

and identity-focused perspective that highlights cultural patterns as linked to context character. The next section afforded a detailed introduction to the PVEST framework, and was followed by a discussion of the framework's useful dynamic character. Several cross-cutting themes of human development were used for illustrating the connectedness between individual characteristics and context interactions, thus, providing a mechanisms for interpreting nuanced cultural patterns. *Brown v. Board of Education* was introduced as relevant for highlighting and demonstrating the impact of policy change and its role in determining long-term youth experiences and schooling. The next two text divisions introduce final sections that indicate the distinct interpretational advantages of the framework.

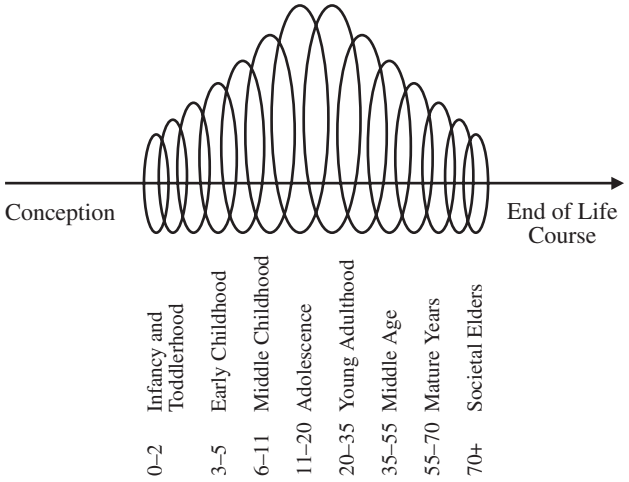

Figure 15.10 Spiraling and interactive systemic processes: An assumed "unfolding" of human processes occurs across the life course from conception to death.

PHENOMENOLOGICAL VARIANT OF ECOLOGICAL SYSTEMS THEORY: MULTIDISCIPLINARY, DYNAMIC, SYSTEMIC INFLUENCES, AND PROCESSES OF A SYNTHESIZED RECURSIVE FRAMEWORK

The meaning-making that individuals formulate about their lives evolves from basic social and cognitive development processes. These formulations become more sophisticated with broadened social experiences and increases in cognitive maturation (Flavell, 1968; Spencer, 1982, 1983, 1985; Spencer & Markstrom-Adams, 1990). These relationships are better understood both from a dynamic framework that crosses interdisciplinary boundaries (e.g., individual and group experience, biological foundations, and cultural traditions), one that is indelibly linked to contextual forces, and from a perspective that includes recognition of individuals' information processing efforts available and reflecting the opportunities and constraints of the various developmental periods.

The Foundational Role of Social Cognition and Linkages to Phenomenology: Inference-Making, Perceptions, and Youths' Everyday Experiences

More recent theorizing about children's theory of mind adds to our understanding about recursive and development-dependent processes (Frye, 1992; Frye & Moore, 1991; Nguyen & Frye, 1999). We've learned that the character of these recursive processes have implications for more general competence as lives unfold across the life course (see Figure 15.10), and, as sources of social feedback, the social environment represents an unavoidable and critical component of this process (see Figure 15.11).

From the earliest interactions between infants and parenting adults, feedback impacts children's behavior on the environment and a reverse interaction occurs as well (or consider the lack of feedback and the sequelae of minimally responsive babies as described by Kennell, Trause, & Klaus, 1975). Infants' cognitive awareness was described by Piaget (1926, 1967) as evolving schemata. At the same time, early ego functioning was the subject of theories by Erikson (1968) and others as

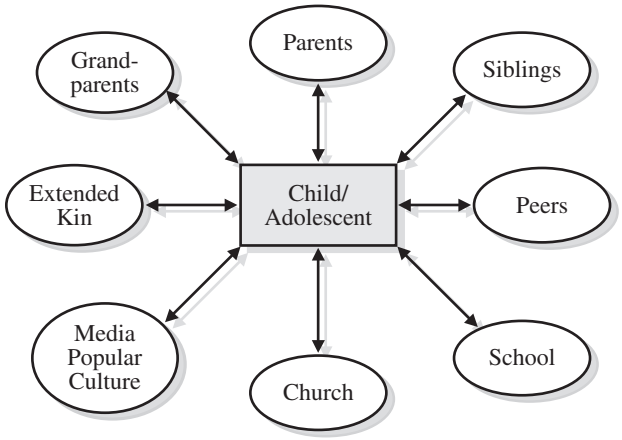

Figure 15.11 Bidirectional influences of significant others on youths' development.

not independent of cognitive development. Both domains are involved in critically important personifications or early self processes of human functioning. These linked processes occur simultaneously in social contexts and serve critical roles for life-course development. Independent of the domain stressed or the theoretical approach to which one subscribes, the salient implications of social feedback for the development of general competence as defined by R. White (1959, 1960) is apparent. Children's successful use of cognition-dependent social cues reinforce and support effective management of the environment and demonstration of stage-specific competence. Given this recursive process, the feedback concerning a successful impact on the environment has implications for subsequent efforts expended and is described by R. White as "effectance motivation." Thus, as suggested by Figures 15.10 and 15.11, socializing adults and others are critically important for these bidirectional processes.

Social Cognition and Development

Unavoidable inferences made from experiences may be linked to individuals' meaning-making processes. They include the (a) perception of challenges and available resources; (b) exposure to modeled strategies for reactive coping, and (c) character of self processes inferred and enacted, which then contribute to stable emergent identity processes. Following this line of thought, individuals' life-stage specific coping products (i.e., as a consequence of a stable identity providing consistency in coping responses over time and place) are linked to context character and which have societal implications as outcomes for what Damon (2002) refers to as either noble versus ignoble "deeds." We suggest that the processes frequently overlooked are imbedded in contexts that vary by risk level and the availability of protective factors that make accessible specific types of supports. To illustrate, a priori assumptions imposed from the outside *matter* and overlap with youths' unfolding sense of purpose (e.g., the media's characterization of particular youth as deviant or delinquent, while ignoring the wrong doing or immature behavior of others, reinforces assumptions of privilege for some and pathology for others). Risk level also matters as it is associated with our human and unavoidable inference-making processes (i.e., social perceptions). Both the unavoidable cognition-linked perceptual processes and a priori context-associated risk factors make a difference for self processes (e.g., Spencer, 1981a, 1981b). Experienced as stigma, underanalyzed, or unsubstantiated assumptions may contribute as core features to context character for some (e.g., underresourced housing and more general neighborhood conditions) and, as stereotypes, produce additional risk that compromise self processes.

Self Processes of Diverse Youth

The ecology of youth development may take on a particularly troubling hue when examined for culturally marginalized or diverse youth of color (e.g., Chestang, 1972). Youths' knowledge of or inferences about the world have important implications for psychosocial functioning. As applied to the experiences of youth of color, epistemology is seldom a concern in the literature. Epistemology is a branch of philosophy concerned with the nature of knowledge (see Piaget, as reviewed in Hergenhahn & Olsen, 1993, p. 275). Relative to patterns of achievement and minority status issues, the acting White inferences from particular ethnographic assumptions and analyses (e.g., Fordham & Ogbu, 1986) provide an example. Although theoretically critiqued (e.g., Spencer et al., 2001; Spencer & Harpalani, under review) and empirically demonstrated as incomplete (e.g., see Steele & Aronson, 1995), the negative impact of the achievement-linked stigma on the ecology of learning and development particularly for African American youth is both unfortunate and undeniable. Specifically, unwarranted stigma makes it difficult for adolescents to engage in positive character formation given that the process is attempted under what Chestang (1972) describes as "hostile conditions" (see also, e.g., Phelan, Davidson, & Cao, 1991). Further, when applied to the context-associated experiences of African American youth, correlates of stigma can contribute to youth feeling "missed, dissed, and pissed," as described by Stevenson (1997).

Social science has always benefited from analyses that provide perspectives of others outside the person. However, we restate that a systems-oriented analysis that acknowledges the critical and ever-present role of the person's own *phenomenology* or unique set of perceptions is also needed. This perspective affords an often-ignored or assumed analysis of the individual-context interface and, consequently, *context and culturally linked behavioral response.* As suggested, the latter is particularly salient because it is inherently ecological and represents the character of experiences associated with a particular context. Claude Steele and his

colleagues' excellent illustrations provide an effective vehicle for explaining achievement behavior and school orientation of a long-term stigmatized group who the media would infer lack a sense of purpose: African American students (e.g., Steele & Aronson, 1995).

Because youths' own perceptions of social contexts (both past and present) and unique level of individual vulnerability coexist, it is not unexpected that associated net-level experiences of stress vary *and matter*. The noted associations are seldom acknowledged, accounted for in the design of programs of research, or directly measured. Further, these themes are not considered in a culturally sensitive, contextually linked, or developmentally framed perspective. Considered together, the shortsightedness considerably narrows the view of sense of purpose and suggests a false dichotomy of noble versus ignoble purpose as expressed behavior (see Spencer, Fegley, & Harpalani, 2003). Efforts that represent noble efforts in the face of great adversity are generally unacknowledged, not recognized, or undervalued, given traditional assumptions concerning representations of sense of purpose. Erroneously inferring a lack of purpose is more probable than not for youth of color or those from low-resource communities. Their attempts at orientation toward right action (see Spencer, 1999a) is frequently hampered by very challenging contexts and circumstances (e.g., the multiple opportunities for adverse profiling by police officers, social experiences in peer groups are generally viewed as suggesting gang membership, driving or riding in motor vehicles are frequently assumed to be drug vans). Most important, European Americans of diverse groups do not generally encounter similar stigma; most youth enjoy the privileges associated with innocent forays and youthful experiences associated with suburban and affluent communities without attendant and persistent concerns about harassment based solely on race, ethnicity, class, faith community, national origin, or skin color. Contrary to European Americans' experiences and as encouraged by Erikson (1968), diverse youth of color are not provided opportunities for social experimentation without significant consequences and personal risks.

As indicated, we view an ICE perspective (Spencer, 1995; Spencer et al., 2006) as a theoretical framework of human development that is inclusive of culturally diverse youths' potential breadth of experiences and normative identity needs. Given the countless developmental trajectories possible, unavoidably youngsters infer supports, cope reactively with adversity in the moment (see Stevenson, 1997), and internalize emergent identities that have implications for stage-specific coping outcomes. Particularly for African American and Hispanic youths, their social experiences along with an evolving sense of purpose may be highly stigmatizing and compromising to the latter. For that reason, we view the theory-driven analysis proposed as a source of protection against the continuing penchant to misinterpret youthful efforts for demonstrating a sense of competence or achieving a sense of purpose albeit frequently under unacknowledged difficult circumstances traditionally ignored in developmental science specifically and the social science more generally.

Thus, PVEST utilizes an ICE perspective, integrating issues of culture, social and historical context, and normative developmental processes involved in identity formation and broad psychosocial processes (see Dupree, Spencer, & Bell, 1997; Spencer, 1995; Spencer & Harpalani, 2004; Spencer, Hartmann, & Dupree, 1997). While Scarr (1988) correctly argues that "the phenomenology of experiences is . . . correlated with the genotype of the individual perceiver and processor" (quoted on p. 241), we believe that this view is far too unsophisticated; in the mold of much of the behavioral genetics research we have reviewed, it is an accurate but oversimplified statement (see Spencer & Harpalani, 2004). We submit that *delineating the processes* involved, rather than a mere statement of obvious correlation, is necessary for an understanding of nature-nurture interaction in human development. A fuller understanding of process and context is necessary to understand how the genotype impacts development. We treat the genotype similarly to Bronfenbrenner's, as it is an important and influential aspect in human development, but the *expression of the genotype* in context is actually a component of the developmental system.

Phenomenology and Context Character

The PVEST framework combines a phenomenological perspective with Bronfenbrenner's ecological systems theory (1989), linking context and perception. The critical role of phenomenology, among others of the period, may be best represented by the personality theorizing of Carl Rogers who described the perspective during the first half of the twentieth century (e.g., see Schultz, 1976). In combining ecological perspectives with phe-

nomenology, the integration provides an analytical mechanism for understanding the individual's meaning-making processes that underlie identity development and coping outcomes (Spencer, 1995; Spencer, Dupree, et al., 1997). PVEST serves as a model to examine normative human development—framed through the interaction of identity, culture, and experience (given a particular psycho-historical moment)—in fact, the systems framework is *apropos to individuals of all ethnicities and operates as a set of recursive processes throughout the life course.* As suggested, PVEST utilizes an ICE perspective, integrating issues of cultural context with normative developmental processes. Each component represents part of a system that is nestled in the multiple levels of youths' contextual experiences.

Systems Framework in an Ecological System

As described, the framework acknowledges the critical role of *perceptions* (Spencer, 1995) and focuses on identity formation while considering macro-, exo- and mesolevel structural factors, cultural influences, individual perceptions of the self, significant others, life experiences, and the environments in which individuals live and function. Identity formation takes place across the life course and is especially relevant for adolescents given their heightened self-consciousness. PVEST combines this emphasis on individual perceptions with Bronfenbrenner's ecological systems theory (1979), thus linking context and perception. Consistent with classic ecological psychologists, Bronfenbrenner's model provides a means for describing how multiple levels of context can influence individual development; additionally, PVEST directly illustrates life-course human development *within* context. In doing so, it allows an analysis of the meaning-making processes that underlie *identity development* and behavioral outcomes (Spencer, 1995, 1999a; Spencer, Dupree, & Hartmann, 1997). This is important because, as reviewed earlier, most theories of development assume a priori deviance and psychopathology for highly vulnerable populations; yet they *cannot explain* diverse outcomes for individuals in shared *contexts* (e.g., siblings' development in the same family, neighborhood, and socioeconomic status often manifest different life-stage outcomes—one sibling graduated from secondary school versus the other incarcerated in a juvenile facility).

Illustrated as a recursive system in Figure 15.12, the PVEST framework consists of five basic components that form a dynamic theoretical arrangement.

The first component, *Net Vulnerability Level (1),* consists of individual, family, and community characteristics that may serve as risk versus protective factors (or both if considered at different developmental periods) during an individual's development. *Net* Vulnerability Level is so described because risks usually do not exist without some protective factors: Accordingly, the effects of apparent risks may be offset or balanced by the presence or availability of protective factors (e.g., privilege group membership, a particular cultural socialization history, skin color, facial features, body type, intellectual superiority, attractiveness, economic stability, well-educated parents and protective extended family networks, emotionally available and caring adults or nonrelated kin, and an individual's personal history of productive coping during a *prior period of stage-specific outcomes*). We suggest that a net balance between evident risk factors and accessible protective factors defines an individual's net vulnerability level for a particular period. The content and character of the protective characteristics available at one stage (e.g., middle childhood) may not remain adequate enough, without additions, when traversing another stage (e.g., adolescence). Particularly for marginalized youth (e.g., youth of color, immigrants, and low-resource youths), identified risk factors may include socioeconomic conditions, such as living in poverty, and imposed expectations based on race, immigration status, unstable family economic status, and gender stereotypes.

As illustrated in Figure 15.12, the bidirectional arrow of the Net Vulnerability Level indicates an unavoidable linkage between risks and protective factors and suggests a particular level of vulnerability. The transactional and dynamic relationship between risks and protective factors is apparent at different developmental stages as lives unfold with increasing complexity over time. The balance between risks and protective factors and consequent level of vulnerability evokes a particular psychosocial status that can produce either worse or improved conditions dependent on or due to prior or attendant experiences. Most important, as individuals transition across time and place, net vulnerability is itself recursively linked to its transformation as everyday stress processes for individuals as each interfaces with multiple environments of varying character.

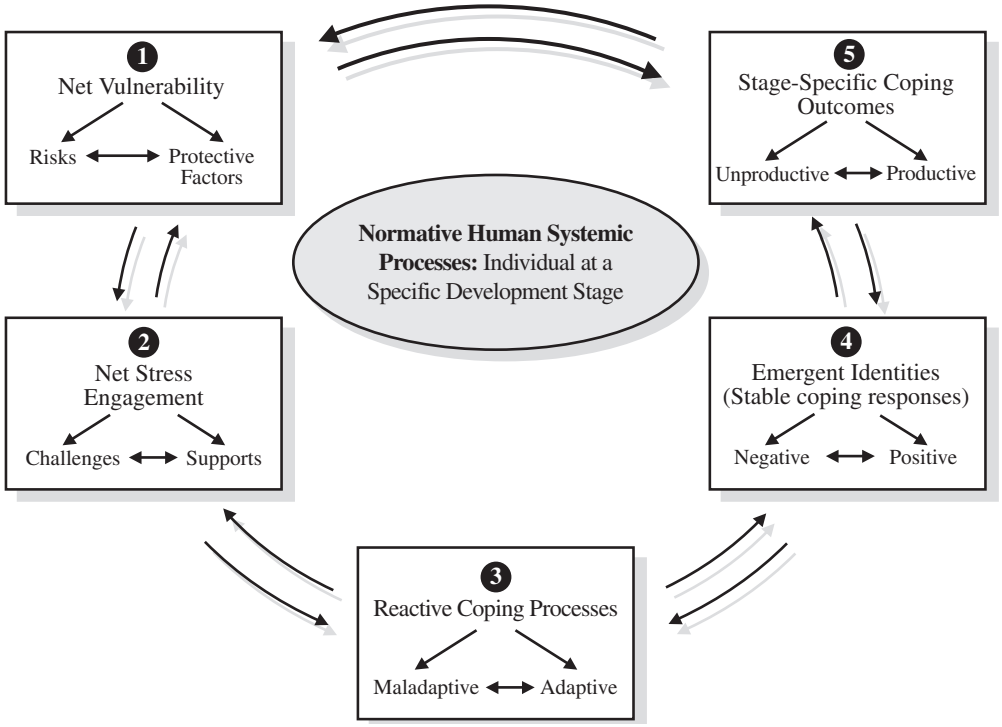

Figure 15.12 Phenomenological Variant of Ecological Systems Theory (PVEST): Revised (2004) Process Emphasizing Version.

The second component of PVEST, *Net Stress Engagement (2),* refers to the actual experiences of challenge and support that can impinge on an individual's well-being. In contrast to the risk factors referred to in the Net Vulnerability Level, stressors are *actualized risks encountered* that require some level of response because they are experienced as specific challenges. Net Stress Engagement is recursively linked with Net Vulnerability Level, and represents the balance between challenges actually encountered and available supports accessible or available. Challenges and supports may be physically experienced or symbolically assessed and their significance inferred (e.g., assumptions about privilege expected and supports available or perceptions about tests or confrontations to be weathered).

Again, Steele (2004) describes the impact of identity or social stigma on performance outcomes. He describes the inferred meaning of a stigma's content that an individual may make (i.e., experienced as some level of challenge) concerning the character of the performance "expected"; the social experiments by Steele and his colleagues suggest that the effect can be nullified or its impact diminished by specific supports provided or through the reframing of expectations. The nature of the "balance achieved" (net stress level experienced) has implications for an individual's state of psychological well-being. Thus, given the media-hyped stigma associated with the achievement gap for African American youth (e.g., high achievement's hypothesized association with acting White beliefs or expectations for low performance), the ways in which an achievement test situation or other evaluative setting (e.g., work site) is framed or inferences about personal performance are communicated may represent significant sources of psychological challenge or fuel assumptions about inherent support possible (see Spencer & Harpalani, under review). What is interesting about the character and use of stigma is that it represents a social construction experienced in particular and nonequivalent ways across groups. For example, Lesser and Stodolsky (1967, 1970) describe the superior performance of Jewish Americans over Caucasians and all other groups. However, the high achievement efforts of other groups have never been described as "acting Jewish." Similarly, when considering the high performance of Asian American students when compared with Caucasians, Hispanics, and African Americans, it remains curious that only African American youths' high achievement behavior is described as acting White. African American performance disparities are usually associated with deficit characteristics of

self or the group although the lower performance of Caucasians when compared with Jewish children is never adversely depicted in parallel ways. Considering the appearance of particularly structured, widely circulated, and socially constructed media images for subgroups of marginalized youth, it is not surprising that the cultural socialization literature (see Arrington, 2002; Slaughter & Johnson, 1988; Spencer, 1983, 1990) provides detailed illustrations of how culturally specific strategies serve as exact types of *support* for precise diverse group members. Jackson, Boostrom, and Hansen (1993) suggest a group of positive qualities or virtues that individuals occupying particular systems possess, or contexts themselves exhibit (e.g., teachers, students, or classrooms), which maximize the probability of finding positive virtues. They suggest that the best strategy for accomplishing this "is by adopting and maintaining a sympathetic outlook, by going about the task biased in the direction of making positive errors, of seeing virtues where they are not, rather than the other way around. . . . For many of the positive qualities of teachers, students, and classrooms are subtly expressed and are visible to those who look closely and who do so with a sympathetic eye" (Jackson, Boostrom, & Hansen, p. 258). The unfortunate dilemma for marginalized youngsters is that the process described for seeing positively about others is usually reserved for those who enjoy a privileged status. Thus, diverse students also receive *ranges of feedback* about their status and inferred social station, which is not independent of the protective factors available and contributes to youths' level of net vulnerability (i.e., first component of PVEST).

As suggested, accessible or available social supports are transformed protective factors described as the first component of PVEST. They aid youths' transitioning through challenging experiences thus serving to reduce or offset the net level of stress experienced. In many ways, supports are actualized protective factors. Whereas risks and protective factors denote demographics or descriptors relevant to individuals, family members, or community, *net stress* level is the balance between *challenges and support.* The character or quality of balance suggests the *actual phenomenological experiences of risk and protection in context.* For example, the addition of an adult male to a household may act as either a stress or a support depending on the context and, perhaps, the gender or parentage of the offspring in question. A single mother may marry the biological father of one of her children. The introduction of an adult male into the family may be perceived as a source of significant support by the mother and other family members, particularly if he adds significant economic resources to the household. However, the presence of this new adult male may be perceived differently by adolescent children in the household who are not biologically related to this new adult male and his intended role as a source of support. For example, an adolescent male may perceive this new presence as a loss of his own perceived role as the man of the house; the source of support may be actually inferred as a serious threat to the male youth's inferred status or his very identity.

The scenario may evolve differently for adolescent females who look to inferred safe adult males for feedback to reaffirm femininity and other aspects of gender identity. However, as a nonbiologically linked male, the mother's husband may or may not have the appropriate understandings about the daughter's intent or need for specific and safe feedback. The adult male may (mis)interpret the girl's efforts as a hyper-sexualized display. He may not understand the *teen's actual interest in obtaining affirmation for her femininity.* The transactional outcomes from interactions with her mother's spouse may serve to increase the girl's risk due to increase challenges encountered in interactions with her mother. The girl's mother may view her daughter's behavior as sexually alluring versus the girl's actual intent (i.e., to evoke feedback for the purpose of promoting psychosexual development).

Alternatively, as a second scenario, for youth developing in households burdened with economic insecurity, a mother's need to obtain work for maintaining the household economy might invite greater stress due to expectations for shared household responsibilities. Privileged youth unfamiliar with the strategies for successfully coping with schoolwork and, at the same time, contributing to household chores might find it difficult to adjust to a change in lifestyle when a family is confronted with sudden economic downturns and attendant stressors; a youth from a privileged family history may have less time to hone the necessary skills for accommodating the new family stresses and attendant required role expansions. Having to cope with the noted role challenges concomitantly with traditional peer expectations and new family constraints may potentially increase overall level of stress experienced in the moment when confronted by associated challenges (e.g., cooking, cleaning, or child care responsibilities for a younger sibling). It is not only the balance between the

current challenges, given accessible supports that impact overall stress, but also the recursive links with net vulnerability because the family situation is increasing its level of effective risks with potential changes in its ability to maintain the prior protective factors. In sum, given the recursive links between net vulnerability evolving and net-stress level currently experienced, youth may respond by adopting an in-the-moment reactive coping response.

In response to the challenges noted and in conjunction with available supports, the net level of stress experienced requires that the third component, *Reactive Coping Methods (3),* is deployed. Figure 15.12 illustrates that reactive coping responses include problem-solving strategies that can be either adaptive or maladaptive. For instance, given the prior illustration, in response to decreased time and attention from parents and the need for adolescents to take on more familial responsibilities, youth may engage in more risk taking behavior (a maladaptive response) or seek more support through greater interaction with extended kin (e.g., grandparents) and non-kin adults (e.g., school counselor, teacher, or religious leader). Accordingly, there will be options for positive or adaptive responses when particular issues surface in peer contexts, the family system, or with social institutions such as schools. Conversely, models of maladaptive problem solving would also be possible reactive coping responses (e.g., staying away from home or other sources of support, using drugs, dropping out of school, or becoming committed to negative peer models).

As youth employ various reactive coping strategies consistently over time and place, self-appraisal continues, and those strategies yielding desirable results (i.e., objectively viewed as either positive or negative) are repeated. For example, negative peer approval might still feel comfortable and psychologically safe than the work involved in creating more adaptive solutions, which might require a change in peer relationships. The consistency of the reactive coping pattern has important implications for psychosocial processes. As suggested in Figure 15.12, the reactive coping strategies become stable coping responses, and, over time, yield *Emergent Identities (4).* Thus, the fourth component of PVEST defines how individuals view themselves in and between their various contexts of development (e.g., family, school, peer group, and neighborhood). The combination of factors such as cultural/ethnic background, understandings about gender roles, and self and peer appraisal all define our identity. As new challenges are met, the stable method of responding has implications for decision-making processes, options elected, and, given individual-environment transactional influences and the role of stereotyping and stigma, objective optional choices available.

As reviewed in great detail elsewhere (e.g., Spencer & Markstrom-Adams, 1990; Swanson et al., 1998), identity processes provide behavioral stability over time and place and lay the foundation for future perceptions, self appraisals, and behavior such as decision-making processes. Given the sets of stage-specific developmental tasks outlined by Havighurst (1953), the resulting and ongoing problem-solving and decision-making behavior can yield adverse or productive *Life-stage Specific Coping Outcomes (5).* Figure 15.12 describes the fifth component and indicates that productive outcomes might include school engagement, positive family relationships, adequate employment preparation, staying out of jail, and low levels of high risk behavior. Alternatively, adverse outcomes can include school dropout, poor school performance, illegal means of earning income, poor health, incarceration, and teenage or out-of-wedlock child bearing.

The dynamic and ongoing recursive process of negotiating risks while identifying and garnering protective factors for decreasing vulnerability continues between, within, and throughout each life stage. More specifically, this recursive process occurs as individuals encounter new stressors (i.e., through balancing challenges with supports), establish more expansive repertoires for reacting to coping needs (i.e., given the availability of both maladaptive and adaptive coping "opportunities"), and redefine how individuals view themselves, which also *impacts how others view them.* As noted by Erikson (1968), unresolved issues in one life stage influence future coping and identity-formation processes. Accordingly, PVEST aims not only to capture this developmental process but also to place it in broader social contexts. As illustrated in Figure 15.13, one could use the framework for testing any set of orienting issues as an entire system or as easily pursue its use for examining variable relationships both within and between only two or three components (e.g., Net Vulnerability and Net Stress Experienced). As suggested by the illustration, one could explore parent- or policy-level variables for Components 1 through 4 with an examination of youth outcomes as Component 5. Indeed, Figure 15.13 illustrates several of the numerous constructs

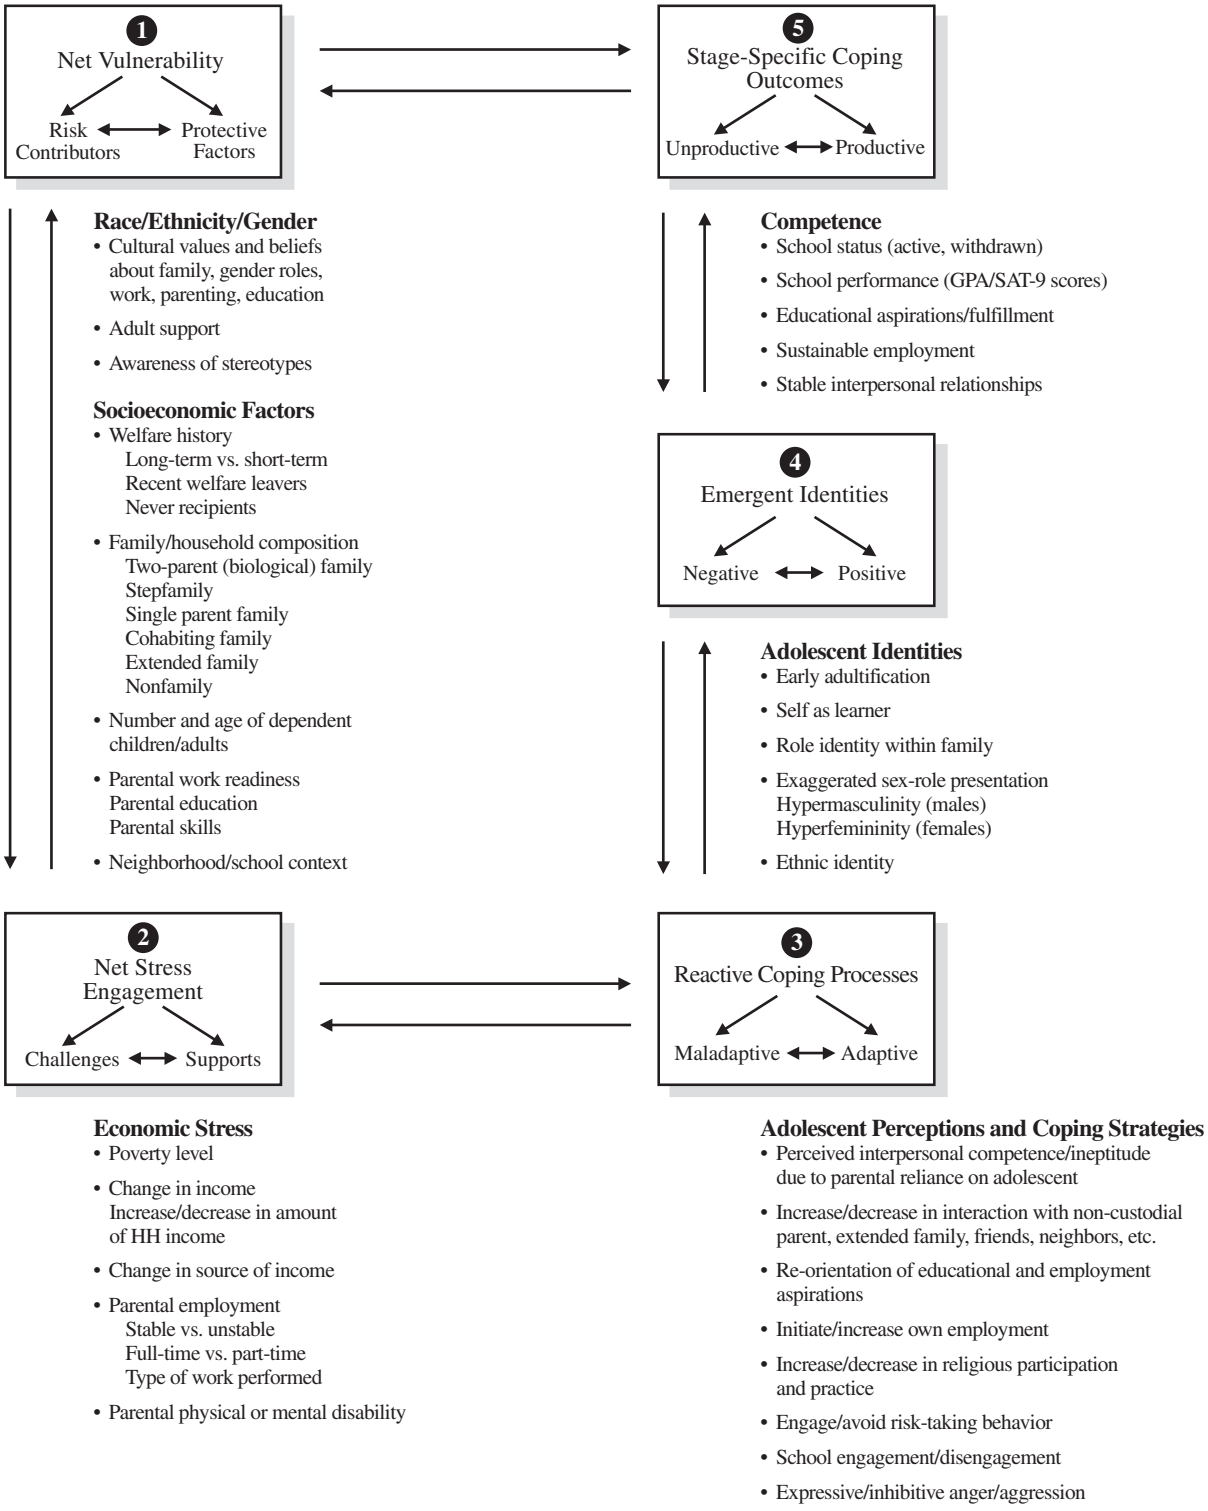

Figure 15.13 Demonstration of Phenomenological Variant of Ecological Systems Theory (PVEST) application: Using framework for analyzing the effects of specific economic policies and requirements for parents on adolescent academic and employment outcomes.

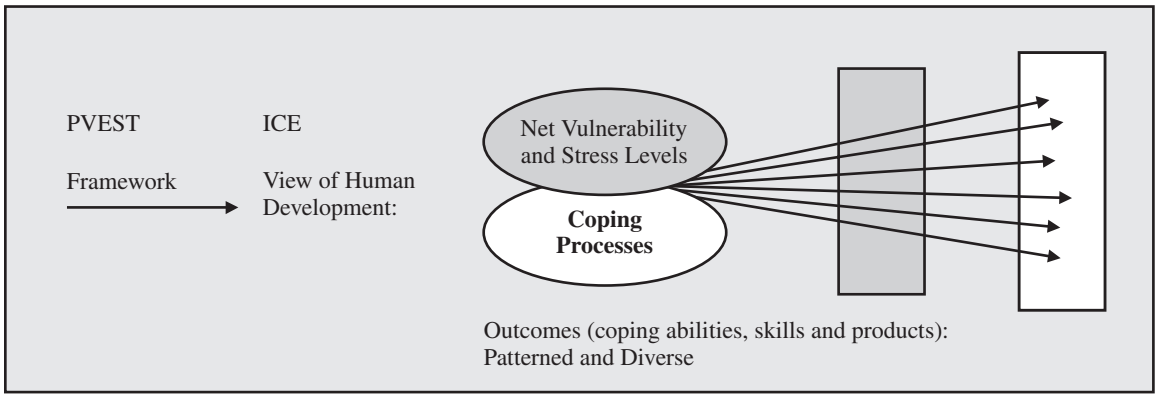
possible for examination in considering each of the five components of the framework.

The illustrative possibilities would vary as a function of the populations of concern and specific developmental period of interest. Further, it is necessary to appreciate the unique role gender plays because, for instance, when studying outcomes among boys, the illustrative constructs represent unique experiences that are distinctive to boys across the components. As suggested by the introduction to the framework and illustrated in Figure 15.14, PVEST is a synthesis of many contributing perspectives and provides an ICE perspective of human development.

In examining the relationship between net vulnerability and net stress, PVEST explores the combined impact on coping processes specific to particular developmental stages. Given the contributions from multiple theoretical perspectives, it aids our explanations and interpretive analyses of both similar and different outcomes. As illustrated in Figure 15.15, the outcomes of these interactions and processes occur in nested ecologies that vary significantly in character as a consequence of particular social constructions and individual characteristics, histories, and experiences.

Most important, as illustrated in Figure 15.16, coping outcomes may differ both between groups and within groups (e.g., including ethnicities, races, and families). There are numerous differences in meaning-making processes expected for youth sharing the same race, household, or classroom.

Our approach is quite different from those that anticipate homogenous group outcomes that are generally assumed to represent either deficits or inferred privilege. PVEST provides a systems framework for understanding all possible variability. More important, given the impact of the context on individual or group attitudes and beliefs, the pattern of coping outcomes has the potential of contributing to the level of vulnerability. Figure 15.17 on page 854 illustrates the feedback loop created as a function of societal stereotype dependence thus demonstrating the recursive relationship between the unique



Theoretical and Conceptual Formulations:

- Eriksonian theorizing about ego identity processes
- Du Bois' notion of double consciousness
- Symbolic interactionists theorizing about phenomenological processes (e.g., Sullivan & Mead)
- Competence and socialization perspectives (e.g., Robert White & Brewster Smith)
- Resiliency and vulnerability (e.g., J. Anthony)
- Cross' Reference Group Orientation (RGO) framework
- Chestang's views of character development and context quality
- Critical Race Theory (Crenshaw and others)
- Spencer's notions about the social cognition/culture cognition interface
- Ecological psychology and Bronfenbrenner's views about context
- Boykins' notions about a "triple quandary"
- Normal human development life-course theorizing (e.g. Brim's notions about continuity and change)
- Historical perspectives (e.g., V.P. Franklin, John Hope Franklin, & Glen Elder; Brown vs. Board of Educ.)
- White Privilege (McIntosh)

Figure 15.14 Acknowledging exemplar conceptual contributors to Phenomenological Variant of Ecological Systems Theory (PVEST) .

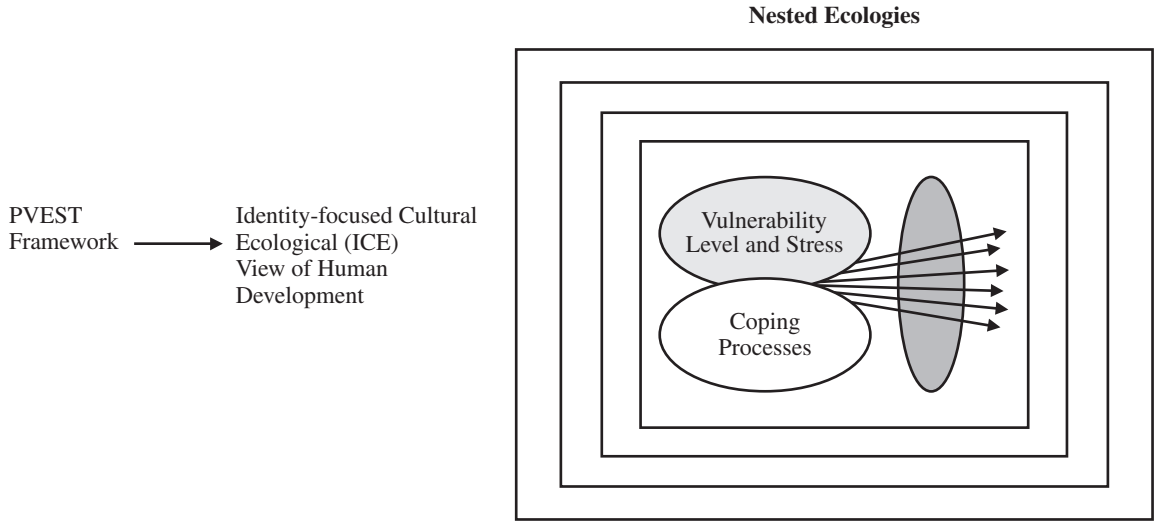


Figure 15.15 Advantages of framework: Phenomenological Variant of Ecological Systems Theory (PVEST) enhances interpretations of vulnerability with coping processes as linked with diverse sets of life course outcomes specified for particular developmental periods.

and patterned outcomes produced and their subsequent impact on net vulnerability, net stress experienced, mediating coping processes, and produced coping outcomes.

The modeled recursive feedback loop aids the explanation suggested by Claude Steele concerning achievement performance as linked to social stigma. Steele's perspective (2004) indicates that anyone is privy to *identity insecurity,* and social contingencies (i.e., the priming of social perceptions) have implications for performance. Parallel with our own interpretation, his views have important implications for the character of interventions needed to impact youths' academic performance. All of the bidirectional relationships between components of the framework suggest critical cross-cutting themes of importance in the design and support of prevention and intervention strategies.

CROSS-CUTTING HUMAN DEVELOPMENT THEMES OF PHENOMENOLOGICAL VARIANT OF ECOLOGICAL SYSTEMS THEORY: SALIENT FOR THE DESIGN OF INTERVENTIONS AND THE INTERPRETATION OF COPING OUTCOMES

It is not only symbolically important but also critical to conceptualize the unfolding of lives in cultural context. However, for groups such as urban youth of color, this is

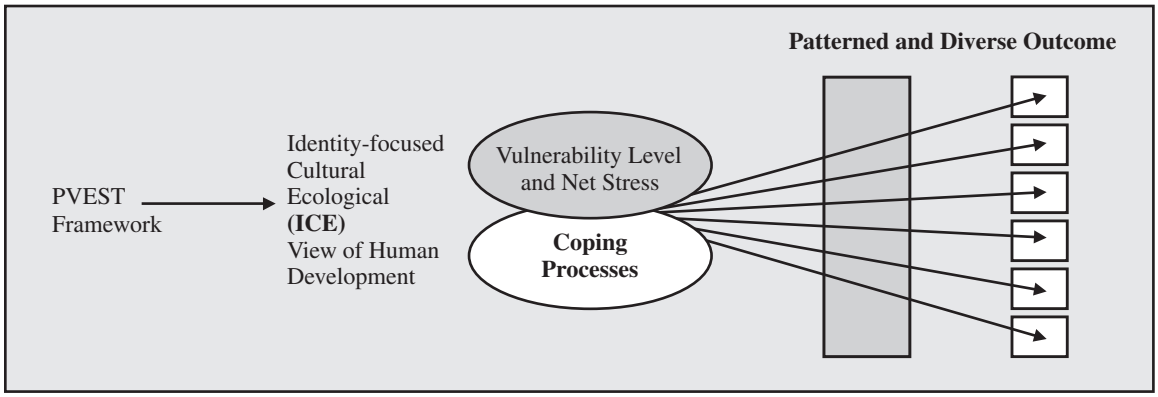

Figure 15.16 Predicting diversity: Phenomenological Variant of Ecological Systems Theory (PVEST) demonstrating the probability of both unique and patterned outcomes.

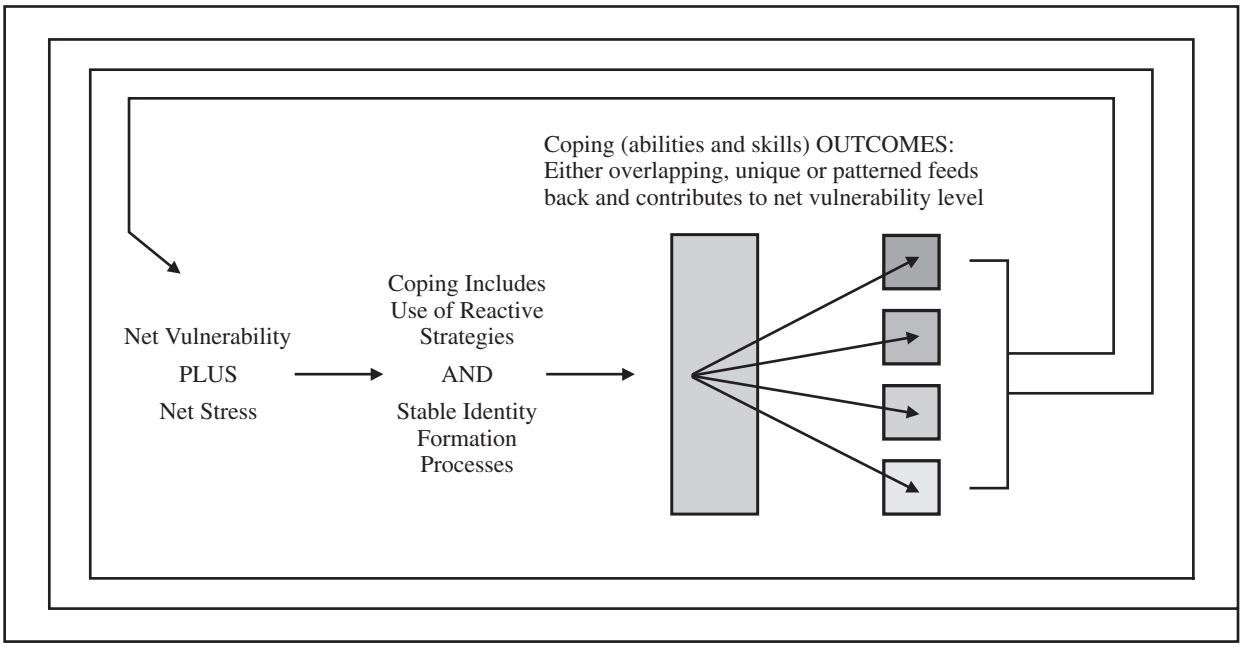

Figure 15.17 Phenomenological Variant of Ecological Systems Theory (PVEST) analyses afford an integration of individual coping with context character: As an ICE perspective the framework suggests exacerbating influences (through an acknowledgment of nested ecologies) that impact coping outcomes (i.e., either productive or adverse) given the experiences of net vulnerability and stress level associated with coping processes (i.e., manifested as coping strategies and identity formation efforts).

not frequently the conceptual strategy employed as illustrated by the ways in which we formulate questions, identify constructs, theorize about phenomena, interpret results, conceptualize, and implement social policy. There are few places in which this phenomenon—the study of lives in context—is less apparent than in the study of human development of marginalized youth in *urban contexts*. Further, when considered over time, there are few developmental periods for which this shortsightedness has had more dire consequences than in the formulation of research, theory, practice, and policy of relevance for middle childhood youth and adolescents.

Importance of Broad Cultural Inclusiveness and Context

A succinct tracing of the history of psychological science and the alternative advent of cultural-historical psychology helps in highlighting the importance of emphasizing and integrating the meaning and experience of culture in the consideration of human development. Although generally not acknowledged as a social construction, it is important to describe and explore the exacerbating influence of urban character on our thinking about culture, the conduct of psychological science, the character of educational praxis, and life-course human development experience. Considered from a PVEST perspective, all have implications for the unique challenges experienced by specific communities for some, and the occurrence of privilege and significant but unacknowledged support for others.

Meaning and Experience of Culture in the Consideration of Lives in Context

Developmental psychology came to life as a field of research virtually 100 years ago at the turn of the 20th century (S. H. White, 1996). Sheldon White notes that the field's birth followed an increase of nineteenth century writings about children. He reports that their lives and circumstances were examined philosophically, pedagogically, medically, politically, autobiographically, statistically, didactically, sentimentally, and apocalyptically: There was a commitment to the scientific study of child development. He goes on to report that, in the beginning, the approach stood insecurely on scattered facts strung together with much theorizing. Followers of Darwin put together observations of children, animals, cross-cultural beliefs and practices, psychopathology, and so on to sketch out an evolutionary picture of the human mind. It was risky, speculative science. Sheldon White reports

that Williams James, in the *Principles of Psychology,* called it "wild work" (S. H. White, 1996, p. x).

S. H. White describes the late nineteenth and early twentieth centuries as periods with organized cooperative research enterprises that were modeled on the natural sciences and describes the emulation as a fledgling discipline that yearned for status as a real science. S. H. White described it as "physics envy" because the physical sciences were well-formed and producing findings that were intellectually interesting and practically useful (S. H. White, p. xi). S. H. White's description allows the inference of a current and historically similar situation. There was a reasonable explanation for psychologists to imitate the particular pattern of cooperative activity; it provided the model for determining how far the approach would take it as a new science. By focusing on naturalistic questions and methods, psychologists sidestepped some tricky and risky concerns (S. H. White, 1996, p. xi).

S. H. White's analysis recognizes that the new psychology was also saddled with unique and awkward restrictions. The program of methods of the naturalistic scientific effort revealed particular patterns of organization of human perception, learning, and development, and the rhetoric of that research program asserted that such patterns must be true for everyone everywhere (S. H. White, 1996, p. xi). Most important, S. H. White (1996) champions Michael Cole's point of entry into the problems of twentieth-century psychological science as a reminder that aspects of the early assertion of universality were not true. He references Michael Cole's work with the Kpelle in Africa in the 1960s that led to a salient observation:

> Although tribal children classify, learn, remember, form concepts, and reason in everyday life, they do not perform in a sophisticated manner on experimental procedures designed for the study of age changes in those faculties. Western research procedures are grounded in a world in which children go to school at 6 years of age and are surrounded by the life, language, and thought of a modern society. Much of what we consider to be normal to child development is simply a recognition of what usually happens when children grow up in such a world. (S. H. White, 1996, p. xii)

S. H. White's point was that Cole's work along with other cultural psychologists suggested significant difficulties in the use of traditional natural-scientific inquiries to compare people across cultures. An analogous point may be made when considering the conjectures drawn from urban research contexts because a broadly made assumption is that proximity suggests similar experiences, which represents yet another fallacy. S.H. White also notes that:

> The fact that some twentieth-century psychology has produced findings that are only true within situational boundaries is not completely surprising. Before this century, a number of distinguished philosophers argued that in order to fully understand how the human mind works we will require two psychologies of different orders. We will need the kind of naturalistic psychology with which we are familiar, analyzing mental phenomena as constructions built out of sensations, ideas, associations, reflexes, or sensorimotor schemes. We will need also a less-familiar "second psychology" describing higher-level mental phenomena as entities given form by the language, myths, and social practices in which the individual lives. Such a second psychology would not be expected to yield universal findings. Since higher mental processes are formed by culture, they differ from society to another. (1996, p. xii)

In addition to Cole, S. H. White posits there has always been a lineage of *cultural psychologists* who have argued for:

> An emphasis on *mediated action in a context*; the use of the "genetic method" understood broadly to include historical, ontogenetic, and micro-genetic levels of analysis; the grounding of analysis in everyday life events; the assumption that mind emerges in the joint activity of people and is in an important sense, "co-constructed"; the assumption that individuals are active agents in their own development; rejection of cause-effect, stimulus-response, explanatory science in favor of a science that emphasizes the emergent nature of mind in activity and that acknowledges a central role for interpretation in its explanatory framework; methodologies that draw upon the humanities as well as the social and biological sciences. (1996, p. xii)

Sheldon White describes efforts expended for this second psychology that began in the 1920s with work by Vygotsky who suggested the need for a human science of psychology that could stand beside the existing natural science of the time. He argued that the need to "understand" human mental life was deeply connected to the manufactured objects in our world. Human beings live in a world of human artifacts—tools, words, routines, and rituals—changeling objects that are at once and the same time things the individual must deal with and repositories of prior human thought and judgment (1996, xiii). As reported by S. H. White, the integration and consideration of *culture,* for Michael Cole (as a cultural-historical psychology) means understanding

that psychology comes to life *only* when there are research procedures through which people can experience and know the world together. As noted by S. H. White, Vygotsky asserts a critical philosophical position of importance in this regard. "An artifact is an aspect of the material world that has been modified over by the history of its incorporation in goal-directed human action. By virtue of the changes wrought in the process of their creation and use, artifacts are simultaneously ideal (conceptual) and material" (p. xiv; emphases added). S. H. White is quite clear that "artifacts" are the fundamental constituents of culture. The growth of the human mind, in ontogeny and human history, must properly be understood as a co-evolution of human activities and artifacts. The words we speak, the social institutions in which we participate, the man-made physical objects we use, all serve as both tools and symbols. They exist in the world around us; they organize our attention and action in that world and, in the aggregate, they create "alternative worlds" (p. xiv). It would appear that including the individual's own reporting (i.e., as phenomenology) of the particulars of "alternative worlds" would be critical for arriving at an understanding of specific meaning-making processes by individuals as they mature over time, transition across multiple settings and physical spaces, and cope with the attendant contextual demands.

Accordingly, there are few places where this phenomenon is as evident as in the coping processes of youth growing up in *socially constructed urban contexts.* There are few examples more poignant than the unique and co-existing struggles of diverse urban youth and families in their efforts to demonstrate resiliency in socially constructed although infrequently acknowledged urban cultural contexts. S. H. White (1996) suggests that a "cultural-historical approach to the study of mind dictates that when we study human development we must make the study of surrounding social practices part and parcel of our inquiry." And relative to policy and programming issues, "Similarly, if we want to change the pattern of a human being's activities, we need to address the surrounding situations in which those activities live" (p. xiv).

As scholars and researchers interested in human development from a global perspective, there are few context-concerns of more importance than the need to examine the assumptions and questions that guide the conduct of the research industry and policy enterprise. A clear demonstration of this dilemma is the experience of immigrant youth (see Spencer, Harpalani, Cassidy, et al., 2006). As an illustrative case, the cultural context of African American *male youths* is described before moving to the unique experiences of immigrants.

The Cultural Context of African American Males

S. H. White's "alternative worlds" perspective is particularly evident in the coping processes of African American boys growing up in socially constructed urban contexts, particularly in public schools in low-resourced and unusually stigmatized social systems. Boykin (1986) suggests that the behaviors and practices evident in contemporary communities where African American boys develop have their genesis in African cultures. These behaviors and practices manifest themselves differently, depending on the social, physical, historical, and economic contexts in which the boys interact. Although this assertion has multiple political implications, it also offers insight into the dynamic nature of culture. Simply by their contrast to mainstream culture, the behaviors and practices that characterize African American communities are assumed not to be cultural but, instead, deviant (Jarrett, 1994; Oyemade, 1985). Kottak (1987) notes that culture is learned and cultural learning is dependent on "the uniquely human capacity to use symbols, signs that have no necessary or natural connection to what they stand for. . . . A person born anywhere begins immediately through a process of conscious and unconscious learning and interaction with others, to internalize, or incorporate, a cultural tradition through the process of enculturation" (p. 23). As Kottak implies, a great deal of culture is expressed in the human ability to give meaning and value to a thing, activity, or event. The next section places emphasis on understanding the meanings that is given to experiences that appear to be unique to African American children and families. Particularly illustrative to this point are the findings of race awareness and racial attitudes studies.

From a set of programmatic studies of race awareness, racial attitudes, and self-esteem findings from the early childhood years to adolescence, Spencer and colleagues have obtained quite interesting findings for Black boys. Beginning in the preschool stage (e.g., Spencer, 1970; Spencer & Horowitz, 1973), findings suggest that Black boys learn the cultural symbols for group membership at the same rate as girls. There are no gender differences in preschoolers' Eurocentric (i.e., White valuing and Black devaluing) evaluative judgments of things dark in hue and of pictures depicting African American people: Three-year-olds learn the symbols as effectively as 5-year-olds (see Spencer,

1970, 1999b; Spencer & Horowitz, 1973). As indicated by Spencer (2005), those cultural symbols and meanings for "self processes" become increasingly more complex for Black males by adolescence.

The Unique Experiences of African American Male Adolescents

As reviewed by Spencer (1999a), for African American boys who are generally viewed with some degree of dissonance and trepidation by the larger society (see Cunningham, 1993), the task of managing an ego-supporting identity while coping with generalized negative imagery is daunting. The dilemma may be parallel to male adolescents generally, however, African American males specifically are expected to shoulder the traditional negative stereotypes associated with male adolescence, along with the added burden of enhanced, often unacknowledged negative imagery linked with minority status. Often overlooked, negative stereotypes influence character and reactions to socialization efforts such as those extended both in and out of school. That these conditions and experiences are not formally recognized (although are part of youths' daily experiences) make the individual's management of normative developmental tasks more challenging. Specifically, those tasks associated with establishing a moral identity or academic (achievement-linked) identity are particularly salient when coupled with attendant outcomes potentially more diverse and open to *mis*interpretation. Accordingly, African American male adolescents, in their efforts to cope with normative developmental tasks with few resources and supports, may deploy coping methods that prove to be less than constructive. The responsive methods deployed by African American youths (i.e., what we generally term as *coping methods*) may be emotionally comfortable for a short period. These strategies are also used by privileged youth in their pursuits of autonomy; however, given stereotyping they frequently further exacerbate an already challenging situation in the end when deployed by African American male youth.

The struggles associated with autonomy linked developmental tasks are quite challenging. Theorists suggest that growth in value autonomy is linked to expected cognitive changes. We suggest that these changes, although infrequently considered for African American youths, particularly males, require a sensitive and simultaneous synthesis of context character. Necessary for consideration in this synthesis includes both the process and product of individuals' evolving understanding of the world as youth struggle with inequitable conditions, normative stage-specific processes, growth in value autonomy, and expectations for positive outcomes in response to normative developmental tasks. Irrespective of societal status, youthful performance expectations are generic across groups and an equivalent level of competence and resiliency is anticipated for all peers *independent of degree of special challenges experienced by specific groups.* For the most part, both entitlements and extra challenges are ignored, although similar stage-specific positive outcomes of competence, physical and psychological health status, and broad achievements are expected for all. Generally lacking in our thinking, however, as we consider achievement-linked outcomes such as the achievement gap between Black and White academic performance, is *an appreciation of youths' interpretive framework and perceptions concerning (a) context risk and presence of protective factors, (b) attendant stress and accessible supports, (c) available coping methods for reactive deployment (used for guaranteeing psychological health and physical survival), and (d) models of stable coping processes (identities) and patterned coping outcomes (e.g., including both achievement-relevant and moral identity-linked).* An awareness of youths meaning-making including assessments of resources and challenges have implications for *how they traverse* patterned and unique psychological and physical challenges. There are also intriguing interactions between factors.

The dilemma of competing allegiances (triple quandary; see Boykin, 1986) and competing socialization contexts (see Allen, 1985; Boykin & Ellison, 1995; Boykin & Toms, 1985; Brookins, 1985, 1988; Hare & Castenell, 1985; Johnson, 1988) is rarely perceived as being more evident than in the experiences of African American males. The growth of value autonomy may be dramatically illustrated by urban youths' pursuit and acquisition of respect. For many boys growing up in low-resource communities, the demand and demonstration of independence and responsibility occur early (see Holliday, 1985a, 1985b). The value and recognition of both of these character qualities are evident in microsystems such as family, community, and church. The recognition and the early assignment of characteristics of maleness to African American boys is interesting. Generally reported anecdotally, there is a penchant to refer to a male baby or toddler as "little man." The motivation for the term's frequent usage is linked to an expressed and global valuing of maleness and may not represent a conscious effort to "adultify" male children. Instead, the widespread use of the term, particularly by

African American men, suggests an effort to short-circuit the use of the slavery-associated penchant of Whites to refuse adulthood status to Black men by referring to them as boys. Thus, from an African American adult male's perspective, a father's use of "little man" to his son may be solely one of endearment. The particular language used connotes pride in his son and expectations for a future manly role.

The purpose of such language is its attempt to neutralize the prevalent use of Black male stereotyping and undervaluing of Black males by the broader society. Young children, however, are developmentally egocentric (appropriately self-centered) and remain so until about 6 or 7 years of age (see Spencer, 1976, 1982). Therefore, taking the perspective of another can depend on a combination of cognitive maturation and social experience. As a consequence, children hear, use, and understand language and interpret its content from their own (appropriately) limited cognitive perspective. Accordingly, in the case of African American men and boys, use of "little man" language may unavoidably result in children's inferring a set of expectations to behave and take on the responsibilities of manhood while still a youngster. From a PVEST perspective, specific socialization strategies, expressed as reactive coping methods, that are deployed by parents and intended to short circuit the internalization of prevalent stereotypes, may themselves introduce errant self perceptions. Cultural socialization is in addition to the other traditional socialization tasks for which all parents are responsible; thus, the additional need of contemporary Black adults to responsively cope with historical conditions (e.g., the verbal strategy used by slave owners to render adult African American men to child status) ultimately makes child-rearing responsibilities particularly onerous for African American parents (see Spencer, 1983, 1990).

African American male adolescents' pursuit of and sensitivity to obtaining respect from others (e.g., teachers, police officers, unknown citizens) can be problematic (see Spencer, 1999a). Teachers uniformly expect student-like behavior from children irrespective of the problematic and frequently unacknowledged affective school climate experienced by many African American and Hispanic children. Given particular cultural traditions, gender appears to be an exacerbating factor for *diverse* youth, particularly males. Without carefully internalized reactive coping strategies obtained from persistent cultural socialization efforts by parents, the dissonance created for African American males given social stigma is experienced as an early social challenge. As a basic ego need, youths' pursuit of respect may take on greater importance than the highly shared and valued acquisition of academic achievement (Spencer, 1999a). Irvine (1988) observes teacher-student tensions beginning in the early grades for boys. Accordingly, in the absence of close parental monitoring, if generalized respect from the broader society and the school are not forthcoming, adolescent males' reactive (or less constructive) coping response may be problematic; specifically, the taking on of "habitual right actions," which are polar opposite to those generally valued by society and expected by schools, may potentially have adverse academic performance implications (see Cunningham, Swanson, Spencer, & Dupree, 2003). The awareness of inequities and need for respect may complicate family dynamics particularly when accompanied by biological-based normative challenges such as off-timed maturational rate differences (Swanson, Cunningham, & Spencer, 2003).

Gender-intensified behavior, such as hypermasculinity, may be seen by youth as potentially more effective in generating respect than the instrumentality- and future-linked outcomes associated with academic achievement. Another exacerbating but normative factor is the relatively late acquisition of a time-perspective (a true sense of the future), which is linked to the present and past as a cognitive construction and acquisition, and is usually reserved until mid- or late-adolescence. Before then, young people require significant aid in understanding and implementing the links between current behavioral investments (e.g., studying and school engagement) and long-terms valued outcomes (e.g., secondary school graduation and successful career preparation). Given the normatively late acquisition of a time concept, it is not surprising that many male youth do not understand that the 12 years of primary and secondary school preparation and academic engagement provide a critically important opportunity; this is another reason why *parental monitoring* is closely linked to academic outcomes for youth generally, and, given the problem of stereotype threat described by Claude Steele and colleagues, this appears particularly salient for African American youth (see Spencer et al., 1996; Spencer & Swanson, 2000). As a long-standing value espoused by African Americans, documented both before and after slavery (Spencer, Cross, Harpalani, & Goss, 2003), and integrated as a cultural value shared through parental socialization efforts, education contin-

ues to be highly valued by the African American community (Spencer, 1983, 1990). Educational success increases (not guarantees) the probability of acquiring the long-term respect that hypermasculine reactive coping behavior connotes and that Black boys and adolescents desperately seek and need (Swanson, Cunningham, & Spencer, 2003). However, the variety of historical, structural, and contemporary barriers and challenges make the educational process inopportune for some youth. Similarly, the normative experiences of immigrants to the United States appear no less complex and, from a PVEST perspective, suggest different sources of risk that may contribute to youths' vulnerability level. An inclusive and broad understanding of risks for diverse groups promotes an improved articulation of basic supports required and culturally specific interventions necessitated for obtaining competence for youth generally. A PVEST approach provides a culturally sensitive mechanism for linking unique risks and protective factors with context features experienced by specific groups—the individual-context analysis, given evolving perceptual developments aids, determining the level of vulnerability anticipated and the kinds of supports required for obtaining the best possible outcomes.

Special Experiences of Immigrants

Given the cautions described by S. H. White (1996) concerning the need for a cultural-historical approach, this section explores various risk and protective factors that second-generation immigrants from collectivist societies may experience living in the United States. Focusing particularly on the experiences of Asian Americans, specifically South Asian Americans, we emphasize that the problems and concerns addressed here are certainly not indicative of all South Asian Americans. Consistent with Cole's (1996) cultural psychology perspective and S. H. White's (1996) critique, we believe that an individual constructs his or her own worldview in his or her own way. However, the construction is unavoidably linked to context character (Lee et al., 2003). As discussed elsewhere (Spencer, Harpalani, Cassidy, et al., 2006), using the phrase "South Asian Americans" or "second-generation South Asian children," we actually refer to individuals who are specifically born and raised in the United States and who have immigrant parents from the following countries in South Asia: India, Pakistan, Sri Lanka, and Bangladesh. As illustrated previously in Figure 15.12, PVEST provides a helpful framework for exploring the development of identity in South Asian Americans. Relative to the first component, Net Vulnerability (the balance between risks and protective factors), the particular risks to South Asian Americans become salient when discussing the differences between what constitutes individualistic societies, such as the United States, and collectivist cultures such as those of South Asian countries.

Individualistic societies follow an ideology that revolves around personal autonomy, independence, and self-reliance. These societies aim to create individuals who are able to separate themselves from others and from situational contexts. The independent self is constructed to be a fixed entity that does not change when social situations change. "The independent self-system thus seeks to display or assert attributes or features of the self. The others in a social situation are important, but they are important primarily as standards of social comparison or for feedback that can validate the inner attributes of the self" (Markus & Kitayama, 1991, p. 22).

Collectivist societies strive to emphasize obedience and conformity. Their primary goal is to shape individuals into interdependent beings who are defined by their relationships. The interdependent self is seen as being fluid (able to change when the social environment around them changes), dynamic, and defined by roles according to situation and context. "Such an interdependent self is not properly characterized as a bounded whole, because it changes structure with the nature of the particular social context" (Markus & Kitayama, 1991, p. 23).

Given the drastic differences inherent in these two types of societies, it is highly probable that immigrants from collectivist societies who move to the United States may experience many difficulties adjusting to their new surroundings. When individuals choose to immigrate, they may come with practical knowledge of the country to which they are moving. However many will not be adequately versed in the cultural and societal values, beliefs, attitudes, and so on of the foreign country they are adopting as their new home. This circumstance may produce significant problems for some immigrants, especially for those who may have difficulties in acculturation. Even though these immigrants may be aware that they are going through intense emotional and mental changes, they may be reluctant to seek help from outsiders, including mental health professionals. This reluctance may be attributable to suspicion, doubt, fear, uncertainty, confusion, shame, or ignorance of Western psychology and psychologists. This analysis and decision to refrain from accessing objective support may be acceptable for the immigrants themselves,

but what about their children? The acculturation process can be daunting for immigrants who may have already developed a strong sense of identity and self while living in their mother country. However, the processes of acculturation and identity development are heightened in intensity for second-generation immigrant children living in the United States (Spencer, Harpalani, Cassidy, et al., 2006).

Theorizing by Mehta (1998) addresses these processes in the South Asian Indian American population and suggests that "the second generation has been exposed to distinctly different language, goals, food, rituals, dress, music, landscapes, and values than their parents. There is a strong urge to retain ethnic identity while rapidly acquiring awareness of American values, partially due to financial gains" (p. 133). Because of this disparity between their ethnic identity and their national identity, South Asian American children are faced with what many have coined a clash of cultures: the collectivist ideologies from their families constantly coming into conflict with individualistic ideologies from the surrounding environment. Second-generation South Asian Americans must grapple with the exceedingly difficult task of juggling opposing philosophies successfully to survive. From a PVEST perspective, it is safe to say that protective factors in one cultural setting may not serve as an effective source of support when acculturating to a new cultural niche.

The tension from a clash of cultures that many South Asian Americans experience is a significant risk contributor that increases vulnerability and net stress and has implications for identity development (Spencer et al., 2006). Similar to identifiable diverse youth, South Asian youths' physical features serve as a risk contributor because being easily identified can lead others to perceive them as foreign, even though they have been born and raised in the United States and are U.S. citizens. This dichotomy between the physical and internal selves may have implications for disruptions in self-image and self-esteem, which may interfere with competence strivings and mental health. Interestingly, given available protective factors, social supports, and models of adaptive coping methods, many youth still maintain a healthy sense of self and demonstrate resiliency.

Similar to many families of color, a protective factor, which also functions as a potential source of support in the PVEST framework, is the South Asian immigrant family unit. To understand the relevance of the self in relation to the family, which may function as a risk contributor, it is important to discuss the concept of in-groups and out-groups in a collectivist cultural context. An *in-group* constitutes an individual's immediate social environment. In South Asian countries, this may include the family (both nuclear and extended), friends, coworkers, and peers (Markus & Kitayama, 1991). The individual is connected intimately with their particular in-group and therefore, according to Sethi, Lepper, and Ross (1999) "the self and relevant in-group members may become psychological entities prone to relatively similar inferential, judgmental, attributional, motivational, and perceptual biases" (p. 10). The collectivist self is thus defined according to his or her in-group. However, the process of immigration disrupts the concept of an in-group.

Especially relevant in the case of children, when individuals drastically change their social, societal, and cultural environments by moving to another country, extended family, friends, coworkers, and peers are left behind. These individuals must break the close bonds they shared with their established in-group in South Asia and leave the stability and security of their lives to seek fulfillment of their goals and aspirations in another country. For people who are interdependent, the experience of leaving their in-group can be very traumatic. The severing of ties may be exceedingly difficult, especially if a comparable kin network is not already established in the adopted country. From a PVEST perspective, to maximize supports for offsetting challenges, immigrants must learn to create their own kin networks with other immigrants in their new environment. Although the friendships formed may be comforting and provide emotional, psychological, and perhaps financial support they may not compare as favorably to those relationships between family members or lifelong friends that were established in their country of origin. Accordingly, the identification and acquisition of supports *may themselves introduce challenges* that interfere with the positive balance sought for overall net stress level.

The character and experience of an in-group may function differently in a foreign country. Triandis (1989) suggests that "collectivism is associated with child-rearing patterns that emphasize conformity, obedience, and reliability. Such patterns are usually associated with rewards for conformity to in-group goals, which leads to internalization of the in-group goals. Thus people do what is expected of them even if that is not enjoyable" (p. 513). However, characteristics that might suggest psychological protection in the country of origin might function differently in the adopted country. For example, the heavy emphasis on obedience and conformity, especially among individuals who are highly traditional and conser-

vative about upholding the customs of their culture may tend toward strict parenting. Accordingly, this poses a definite risk for South Asian American children living in an individualistic society that focuses on independence and autonomy (Spencer, Harpalani, Cassidy, et al., 2006).

The South Asian family's economic status also poses a risk and potential for experiencing a downside of privilege. Mehta suggests that "Given the fact that immigration from India has largely been restricted to the educated groups, this immigrant population in the United States, unlike other immigrant groups, has achieved remarkable economic prosperity" (Mehta, 1998, p. 132). Already, Asian Americans are viewed as the model minority in U.S. culture. The financial success of South Asian immigrants may invoke animosity in other racial and ethnic groups, which can lead to racial conflicts, leaving South Asian American children vulnerable to threats, harassment, and potential violence. Accordingly, from a PVEST perspective, protective factors generally available to offset more traditional risks may not necessarily serve that purpose if the context presents other risk factors associated with stigma, stereotypes, and associated stress.

Gender may be another important risk contributor that enhances vulnerability. Given the varying expectations and viewpoints in South Asian culture toward both sexes, we can expect that the processes underlying identity development have the potential to be drastically different for males and females. However, due to lack of extensive research available with regards to this racial group, it may be a better strategy to focus on South Asian Americans as a collective whole.

Spencer, Harpalani, Cassidy, et al. (2006) suggest that the theoretically close relationships assumed for collectivist cultures are expected to serve as protective factors that are transformed into sources of stress. However, two of the most problematic, controversial, and emotionally charged areas in a South Asian American's life are choice of career and romantic relationships because these are two of the most important decisions that directly affect youths' relationship with their parents. Mehta supports this assertion by including "sexual conflicts" and "career conflicts" in her five proposed areas of developmental conflicts (1998). However, more generally, the stressor can be any situation where immigrant parent expectations conflict with U.S. societal expectations.

Like other youth of color, South Asian American children must confront a complex social environment in the United States, including school, university, peer groups, and the media. The latter teaches them to be their own person, exert their autonomy and independence, and follow their own aspirations and desires. They see that there is more than one option available and are encouraged to choose what *they* feel is best for *themselves* (including what makes them happiest). However, South Asian American children are also expected to follow what their parents say and fulfill their obligations to their families. "The Anglo-American social and cultural values of self-sufficiency, autonomy, and personal responsibility are often misinterpreted by immigrant parents as selfish, and the parents place excessive restrictions on their children" (Mehta, 1998, p. 150).

Second-generation South Asian Americans therefore receive two completely different messages about construction of self. This dilemma poses a serious challenge for successful identity development. The South Asian family unit can serve as a significant and comforting source of support, especially given its probable closeness and intimate nature. Alternatively, given the diametrically opposed identity messages received by youth, families may also represent a significant source of stress. Family friends who are a part of the South Asian family's kin network and the South Asian American's peers from various social settings, including school and neighborhood, could also serve as potential supports. However, these supports can also become potential sources of pain and confusion, depending on how South Asian Americans choose to handle the decisions regarding choice of spouse and career.

In some South Asian families, it is possible for parents to accept and feel comfortable with their son's or daughter's choice to adapt and conform to their American surroundings. It is still highly unlikely that conflicts with these more open-minded immigrant parents will never occur because most South Asian American children describe being caught between the two cultures as living an "American life from 9 to 5 and an Indian life from 5 to 9. This duality represents a very important feeling of split identity in the second-generation immigrant from South Asia" (Mehta, 1998, p. 137). Ideally, these conflicts may be minor and not hinder the South Asian American's identity development, but it is not always the case.

In most instances, children will reach a crossroad at some point in their lives where they must choose one or the other. The question is which ideology do they follow, and how does this play out? Of importance is that PVEST elaborates the role of reactive coping strategies specifying salient implications for identity processes. It

may be this recursive stage between net reactive coping strategies and emergent identity processes that the South Asian American's self-perceptions prove to be most crucial. As described elsewhere, stable self-perceptions can determine whether one uses or downplays certain abilities, emphasizes or draws attention away from certain physical attributes, adopts or suppresses certain behaviors, and engages in or shies away from certain activities (Spencer, Hartmann, et al., 1997, p. 47).

If a South Asian American chooses to adapt to his or her environment by identifying fully as American and rebelling against their parents to participate in normal American cultural activities such as dating, going to the prom, or even choosing a career path that immigrant parents do not deem as acceptable, this action may be viewed as either adaptive or maladaptive and thus youths' weighing of consequences is critical. On the one hand, this coping strategy can definitely be seen as positive given the tremendous pressure from society to fit in with their peers. However, it can also be seen as negative, considering the tenacity of the bonds between family members, second-generation South Asian American children must face the severe trauma of shaming their family if they follow the motto of American culture: "Following one's own heart and pursuing one's own dreams." Additionally, depending on the amount of conservatism the family observes, South Asian American children run the risk of losing their families altogether because of exerting their independence. This sense of shame and loss of the family happens because, according to their South Asian parents' perspective, the action of South Asian American children making their own choices in life becomes translated into exhibiting complete disregard and disrespect for their elders and family as well as displaying outright disobedience.

However, if South Asian American children conform to what their families want for them in cases where they internally would like to choose another option, this may also have negative and positive adaptive implications. By obeying their parents, these children run the risk of facing a life of unhappiness because they did not follow their own dreams. South Asian Americans may immediately experience this as they begin to feel disconnected from their peers, particularly if they are not allowed to participate in activities and events that are paramount in American culture, such as going out with friends, dating, and so on. The relinquishment of personal desires is exceedingly problematic when considering major life-altering decisions, especially if subsequently South Asian American children regret having listened to their families and are trapped in jobs or marriages that they find unbearably dissatisfying and unpleasant. They may eventually feel that they wasted their lives on the dreams and expectations of their family and culture and come to resent both (Spencer, Harpalani, Cassidy, et al., 2006).

Phoebe Eng, in her book entitled *Warrior Lessons,* addresses this choice of many Asian American children: "When asked why we frequently forgo our own wants in order to fulfill our parents' expectations, many of us respond with reasons that incorporate notions of filial piety and reverence for our elders" (p. 25). With observations such as Eng's, we can see how collectivist thoughts learned from the family can influence South Asian American children. The power of "filial piety" can be overwhelming and perhaps even suffocating at times, especially considering these feelings can be complicated further with guilt. Eng comments, "'Filial piety' is often synonymous with payback—a [child's] guilt and obedience in exchange for a [parent's] undying but tacit support. Our guilt can come in many currencies" (p. 26). These currencies, Eng continues, include words from immigrant parents that point out the many sacrifices they may have made. The opportunity to grow up with privileges and luxuries that immigrant parents never had and worked hard to give becomes tainted with guilt, and this guilt can lead South Asian Americans to feel compelled or obligated to obey their parents.

It is important to note that immigrant parents should not be viewed as selfish or wrong. These views and attitudes toward children are embedded within South Asian culture and are normal for collectivist societies. However when South Asian immigrants are placed within an individualistic framework, they may not realize that the same rules and social norms that they held in their mother country cannot necessarily be applied to all situations. The amount of conservatism immigrant parents may observe can directly relate to whether or not they themselves have successfully acculturated and dealt with the immigration process.

South Asian Americans therefore choose to adapt in various ways, according to how they perceive they should. They could go through one extreme, rebelling against their parents and essentially their culture to identify completely as American, or through another by identifying completely with their ethnic culture and denying their national identity. A third possibility is for

South Asian Americans to choose neither. These three coping strategies can be maladaptive and lead to potential problems. A fourth possibility is that they may negotiate and balance both identities successfully, which is obviously the most positive and adaptive solution.

The next phase of the PVEST model involves emergent identities. If South Asian Americans choose to rebel, they may come to view themselves positively if they gain acceptance and support from their American peers or friends. Mehta (1998) coins this identity as the "Amerocentric identity" where they hold "strong American values and [have] little contact with their ethnic background" (p. 134). They are most likely to feel comfortable in U.S. society, but feel disconnected to their families. South Asian American children may also view themselves negatively, especially if they are labeled as bad by their parents, which translates to meaning that they are a failure or have brought shame to the family. In extremely strict South Asian households, South Asian Americans may eventually be disowned or cast away from their families. They essentially take on the identity of being the black sheep of their family.

If South Asian Americans conform to their family's expectations, they may develop a positive identity with relation to their parents. Their family and culture become primary sources of support, and they are viewed and come to view themselves as the good and obedient child. However, these children may confront isolation and possible humiliation or ridicule from their peers, especially if they focus entirely on studies and do not participate in social gatherings, activities, or events. Mehta (1998) refers to these individuals as having developed the "Ethnocentric identity" (p. 134).

When South Asian Americans choose neither, they develop the "Compromised identity" which Mehta claims is the most problematic. In this case, South Asian Americans cannot connect to either their surroundings or their family's culture and become lost or alienated. Interestingly, this identity may develop if the South Asian immigrant parents have not dealt with acculturation successfully and they feel confused or conflicted about their own identity development since they immigrated themselves (Mehta, 1998).

The "Bicultural identity," which results from successful negotiation of both national and ethnic identity, develops in those children whose parents are willing to be flexible and open-minded toward U.S. culture and have successfully adapted to the United States themselves. These children feel connected to both their South Asian heritage and to their national identity as American (Mehta, 1998).

This leads to the final component of the PVEST model, "life-stage specific outcomes or coping products" (Spencer, 1999a, p. 47). Depending on which emergent identity eventually develops, the South Asian American can experience positive outcomes such as healthy relationships with their family, friends, kin network, peers from school or the neighborhood, and so on. They may experience healthy identity formation. However they may also experience identity confusion, psychological problems, disownment, and development of psychological disorders, which can lead to depression, even suicide.

The plight of South Asian Americans is serious when considering possible maladaptive coping strategies that lead to negative emergent identities and unproductive outcomes. These problems must not be taken lightly or overlooked. More and more cases of psychological disturbance, psychopathology, and suicide in the South Asian immigrant community are surfacing. Although it is difficult to determine what the exact cause of these problems may be, it is safe to guess that conflicts with marriage, love relationships, academics, and career play pivotal roles in troubling and complicating the lives of South Asian Americans to a great extent.

Despite the negative stigma attached to mental health and psychological problems in the South Asian immigrant community, more research needs to be conducted to investigate these issues. Additionally, clinical psychologists must be cognizant of these problems when treating South Asian American clients. The issues brought up in this section underscore the fact that it is imperative for psychologists in the United States to be trained in ethnic minority concerns and to be sensitive to the needs of their clients. By understanding the cultural context in which immigrant children live, psychologists can help South Asian Americans develop healthy emergent identities that leave them with stable, positive coping products.

Consistent for marginalized youth generally, immigrants specifically, and for youth who enjoy the appearance of consonant individual-context experiences (i.e., although, as indicated, European Americans may be vulnerable to the downside of privilege), *context matters.* Integrated and implicated in multiple ways from a PVEST perspective and as applied uniquely to diverse youths' experiences, *positive outcomes more frequently occur when programming, socialization efforts, social*

practices, and broad policies are linked to context character. Multiple perspectives about ecological contexts are available, vary by emphasis, and provide unique contributions to understanding transactional individual-context interactions.

ECOLOGICAL PERSPECTIVES: EXPLORING THE BIOECOLOGICAL MODEL

As reviewed in several places (e.g., Spencer & Harpalani, 2004), Bronfenbrenner and Ceci (1994) present four distinguishing attributes of the bioecological model. First, they define measurable mechanisms, known as *proximal processes,* through which genetic influences are actualized into observable phenomena. Thus, the processes that mediate genetic and environmental influences on human development are a fundamental component of the model. Second, Bronfenbrenner and Ceci (1994) highlight the aforementioned variability of heritability, noting that the bioecological model stipulates system variation in heritability as a joint function of proximal processes and characteristics of the environment in which these processes take place (p. 570). With this second feature, the bioecological model provides heritability as a measure—which ironically is the same measure used in most behavioral genetic studies. In the model, heritability is interpreted as the proportion of variance attributable to actualized genetic potential (Bronfenbrenner & Ceci, 1993, 1994), as opposed simply to genetic influences. Bronfenbrenner and Ceci (1994) note that heritability matters; they view its most important contribution in social science as those instances when researchers focus on its variability. The variation in heritability allows a linkage between heritability and developmental functioning, with the proximal processes defined in the first feature serving as the conceptual bridge between the two. The third characteristic of the bioecological model is that it considers variation in heritability as it relates to particular developmental outcomes (see Figure 15.18).

The fourth feature is that the model simultaneously evaluates heritability and absolute level of developmental competence. Bronfenbrenner and Ceci (1994) postulate that improving the quality of proximal processes will lead both to higher levels of heritability and to elevated levels of developmental functioning. The reason for the latter is readily apparent: Heritability will increase because as proximal processes improve in quality for individuals in a given population, these individuals will maximize their genetic potentials, and observed differences in the population will be due to these differing genetic potentials.

Bronfenbrenner and Ceci (1994) derive three propositions from their bioecological model, which they use to formulate hypotheses. The first proposition delineates the person-environment interaction in human development, stating "human development takes place through processes of progressively more complex reciprocal interaction between an active, evolving biopsychological human organism and the persons, objects, and symbols in its immediate environment" (p. 572). Bronfenbrenner and Ceci (1994) note that this interaction must be consistent over time to effectively facilitate development. Consistent patterns of interaction are the proximal processes defined earlier. Examples of proximal processes include a child's interactions with parents and peers, development of competencies and problem-solving skills, and acquisition of knowledge.

The second proposition of the bioecological model states, "The form, power, content, and direction of the proximal processes effecting development vary systematically as a joint function of the characteristics of

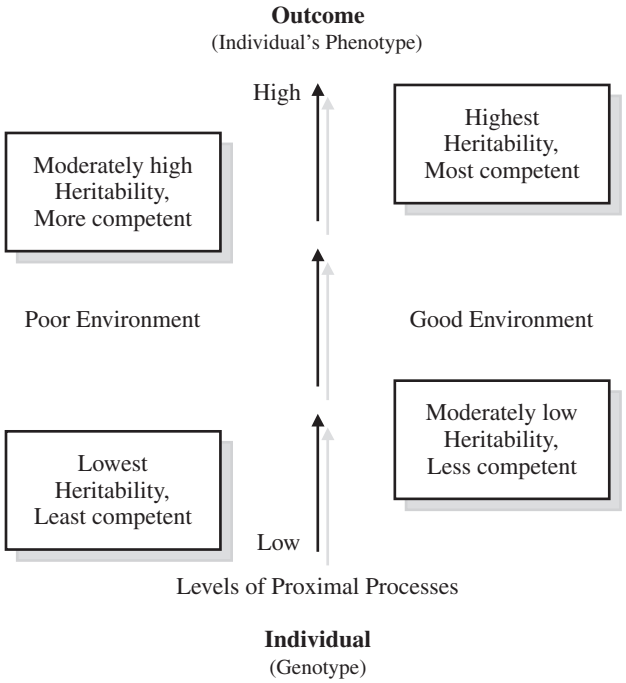

Figure 15.18 Bioecological model. Figure adapted from Bronfenbrenner and Ceci (1994). *Source:* From Spencer & Harpalani, 2004.

the developing person, of the environment—both immediate and more remote—in which the processes are taking place, and of the nature of the developmental outcomes under consideration" (Bronfenbrenner & Ceci, 1994, p. 572). With this precept, Bronfenbrenner and Ceci (1994) introduce the factors—attributes of the person and the environment, and the character of developmental outcomes being analyzed—that govern proximal processes and their impact.

With the third proposition, Bronfenbrenner and Ceci (1994) restate that proximal processes transform genetic potentials into actualized outcomes (phenotypes) and note that the factors that govern proximal processes dictate their power to actualize genetic potentials. From these three propositions, Bronfenbrenner and Ceci (1994) derive three hypotheses. First, they restate the view that effective proximal processes will increase heritability by increasing the proportion of variation attributable to actualized genetic potential. Second, they propose that in actualizing genetic potentials, proximal processes work to both enhance competence and reduce dysfunction, increasing heritability in both cases. The implications that follow from this hypothesis are:

1. Proximal processes have more power to actualize genetic potentials for positive developmental outcomes in organized, advantaged environments than in inconsistent, disadvantaged environments.
2. Proximal processes have more power to buffer genetic potentials for negative developmental outcomes in inconsistent, disadvantaged environments than in organized, advantaged environments.

These first two hypotheses essentially state that heritability, defined in terms of variance attributable to actualized genetic potential, varies as a direct function of the quality of both proximal processes and the environment. Bronfenbrenner and Ceci's (1994) third hypothesis is that proximal processes have a greater ability to actualize genetic potentials for positive developmental outcomes for individuals living in more inconsistent and disadvantaged environments. Bronfenbrenner and Ceci (1994) cite a few studies that they interpret as supporting their first two hypotheses (Fischbein, 1980; Riksen-Walraven, 1978; Scarr-Salapatek, 1971), and they note the obvious implications for intervention of the third hypothesis, which is derived from the first two. However, the authors also note that the model still needs to be tested extensively.

Ecological Systems Theory

While the bioecological model lays out the relationship between genetic influences, heritability, and proximal processes as they take place in particular environments, ecological systems theory (Bronfenbrenner, 1979, 1989, 1993) focuses on characterizing levels of environmental influence in terms of dynamic, interactive, systems of person-environment relationships (Figure 15.19).

As suggested by Figure 15.19 and carefully reviewed by Spencer and Harpalani (2004), ecological systems theory is organized hierarchically, involving interactive systems of increasing complexity embedded in the framework of human development. Bronfenbrenner (1979, 1993) begins by transforming Lewin's (1935) formulation that behavior is a coupled function of the person and the environment. He substitutes development for behavior, stating that development is also a function of the person and the environment over time. Also noted is the temporal contingence of developmental function. Each successive developmental period is dependent on all previous periods of development.

Bronfenbrenner (1993) notes that through most of developmental psychology, theoretical constructs devised to describe the characteristics of the person have not considered issues of context; developmental qualities of individuals are conceived without reference to the environments in which they are occurring (see Figure 15.19). Examples of such qualities include standardized psychological measures such as personality and IQ tests. This type of analysis reflects the *personal attributes model* (Bronfenbrenner, 1989) and has a narrow focus on the individual, assuming that findings from standardized measures can be generalized without attention to context. Bronfenbrenner (1993) questions the assumptions of environment generalizability that underlie the personal attributes model; he does recognize that these standardized measures are useful, but he argues that research designs must simultaneously consider issues of social, cultural, and historical context and incorporate context-oriented measures.

Conversely, the *social address model* (Bronfenbrenner, 1989), which is the most common approach, considers only environmental factors, such as social class, family size, and other demographic variables. The specific characteristics of the environment, activities that occur in particular environments, and the impact of these activities on individuals are all neglected in the social address model (Bronfenbrenner & Crouter, 1983). The *person-context model* examines both the individual and the context but

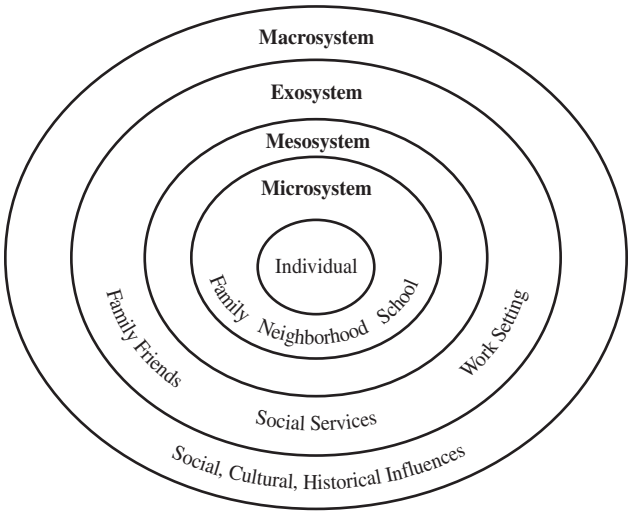

Figure 15.19 Bronfenbrenner's Ecological Systems Theory. *Source:* From "Ecological Systems Theory" (pp. 187–248), by U. Bronfenbrenner, in *Annals of Child Development.* R. Vasta (Ed.), 1989, Greenwich, CT: JAI; and "The Ecology of Cognitive Development" (pp. 3–44), by U. Bronfenbrenner, in *Development in Context: Acting and Thinking Is Specific Environments,* R. H. Wozniak & K. W. Fischer (Eds.), 1993, Hillsdale, NJ: Erlbaum.

does not analyze the processes involved in development. This model specifies ecological niches (Bronfenbrenner, 1989), but it does not delineate the processes by which developmental outcomes are attained.

Bronfenbrenner's (1979, 1989, 1993) ecological systems theory, in contrast, is a *process-person-context model* that, like the bioecological model, highlights variability in developmental processes as a function of the characteristics of the person and the environment. Ecological systems theory is organized in four levels of environment, which mediate person-environment interaction: *microsystem, mesosystem, exosystem,* and *macrosystem* (refer to Figure 15.19). The first level of Bronfenbrenner's model, the *microsystem,* involves the interaction of the person with the immediate social and physical environment: home, family, or school settings. All of the levels of environmental influence are filtered through microsystems, where actual experiences take place. *Proximal processes,* earlier defined in the bioecological model as the mechanisms through which genetic influences are actualized into observable phenomena (Bronfenbrenner & Ceci, 1994; refer to Figure 15.18), are essentially patterns of person-environment interactions in the *microsystem* and change during the development of the person (Bronfenbrenner, 1979, 1989, 1993). The *mesosystem* describes interactions between the various microsystems in a person's life, essentially constituting the network of interpersonal relationships that overlap across the various settings. The *exosystem* entails more distal influences, including the structure of the community where the person resides and settings where the person is not directly involved. Finally, the *macrosystem* is comprised of the larger societal institutions, such as government, economy, media, and so on, which lay the social and historical context for development (Bronfenbrenner, 1979, 1989, 1993).

Spencer and Harpalani's (2004) analysis suggests that ecological systems theory provides a dynamic, contextually sensitive framework from which to analyze environments and gene-environment interactions. It can be applied to shed light on the behavioral genetic theorizing noted earlier. For example, to the extent that they can occur, the active and passive effects of gene-environment correlation (Plomin, DeFries, & Loehlin, 1977; Scarr & McCartney, 1983) primarily involve the lower levels of the model. Individuals may have some ability to shape their own environments and those of their relatives (perhaps based on their genetic makeup) at the level of the microsystem, and perhaps even at the mesosystem. However, individuals are by definition not involved in their exosystems of development, and notwithstanding a few extraordinary examples (e.g., Dr. Martin Luther King and Mahatma Gandhi), few can influence the macrosystem. Broad, societal influences such as structural racism (Spencer, Cross, et al., 2003; Swanson, Cunningham, & Spencer, 2003) and racial stereotyping (Harpalani, 1999) are filtered through macrosystems to impact the development and experiences of minority youth. Regardless of their genetic makeup, individuals can do little to eliminate these factors. Even more mundane situations of stress—such as being ignored in commercial venues (e.g., not provided service) or followed and closely monitored in a place of business may be cumulatively experienced as "microoppression"; given their patterned and persistent impact, the cumulative exposure can have a significant impact on stigmatized groups such as African Americans (e.g., Carroll, 1998).

In addition to the uncontrollable effects of the macrosystem and their impact on everyday experiences, the ability to shape immediate environments is limited for many youth. For example, Stevenson (1997) de-

scribes how African American youth are "missed" and "dissed" by mainstream American society, and how this treatment in conjunction with neighborhood factors relates to African American youth becoming "pissed" while managing their anger. Black youth are missed as stereotypical media-based images distort the meanings of their social and affective displays—usually in negative terms. Hence, these unique cultural displays are devalued and viewed with insolence—dissed. These are effects of the macrosystem that cannot be regulated by individuals. In conjunction with these misrepresentations, many Black youth reside in high-risk contexts where anger display may be an appropriate coping mechanism. Anger may indeed become a form of competence for social and emotional viability in certain high-risk contexts, such as neighborhoods, which are microsystems. These displays may also be misconstrued or constitute inappropriate behavior in other microsystems such as school settings. Hence, misrepresentation, disrespect, and hazardous contextual factors at various ecological levels interact in creating the anger of Black youth (i.e., pissed). Phelan et al. (1991) describe how dissonance between various microsystems—hence, at the level of the mesosystem—can impinge on resiliency and health development.

It is useful to consider the role of the genotype in ecological systems theory. Ecological systems theory focuses on delineating environmental influences rather than genetic influences. The genotype (i.e., genetic makeup), is an implicit component that Bronfenbrenner obviously considers but does not identify explicitly in his model. This is probably because the genotype involves only the person and not person-environment interaction; it is not changed by environmental influences. Indeed, focus on the genotype in part leads behavioral geneticists to often take a rather static view of human development. However, as reviewed by Spencer and Harpalani (2004), the important component in development may not be the genotype itself, but rather its expression (i.e., phenotype). The expression of the genotype is dependent on environmental interaction, and this expression cannot be determined accurately without actually observing the particular genotype being expressed in a given environment (Gottlieb, 1995). While the genotype is an important and measurable component in developmental analysis, its expression (and thus its true impact) should be considered in conjunction with environmental influences and developmental processes. Specifically, cognition-linked perceptions matter.

For twentieth-century America, there have been few proximal processes left unaffected by the particular gene expressions manifested as *skin color* (see Franklin, 1968). Additionally, there have been sets of attendant historical conditions created (Du Bois, 1903), socially constructed meanings made of race (Pettigrew, 1964), associated professional practices and perspectives produced (e.g., Kardiner & Ovesey, 1951), and policy decisions determined (see Crenshaw et al., 1995). However, *few policy changes up through the last century have been more pregnant with meaning for youth of color than* Brown v. Board of Education. Consistent with the perspectives shared about immigrant youths' experiences, immigration policy has had parallel influences on the lives of American newcomers.

Unfortunately, there is inadequate space for a thorough and integrated coverage of the many salient immigration policies of relevance for contemporary child development outcomes of special relevance particularly for marginalized youth. However, excellent reviews are available. Prashad's (2000) analysis has particular salience for the contemporary experiences of South Asian Americans. Further, many of the early policy decisions remain especially significant for today's newcomers given the greater within-group diversity and relevance of the historical timing of arrival for particular waves of immigrants. The within-group diversity of values, beliefs, global economic factors, and perspectives along with inferences and stigma held by the broader society (e.g., model minority stereotypes) have particular relevance for the experiences of all youth of color and immigrants, particularly more recent arrivals (e.g., Hmong) and second-generation Asian Americans (e.g., see Koshy, 1998).

Yet, independent of their actual authenticity, *social constructions and inferences* made about the psychosocial functioning of diverse group members *matter.* They represent the Zeitgeist held about diverse group members' social standing and inferred psychological well-being. Most important, from a PVEST perspective that acknowledges the central role of ecological and phenomenological factors, *externally based assumptions and assessments* of salience to policy matters may actually *function in opposition to their intended role.* As significant influences on policy decisions, particularly in the case of undervalued (marginalized) youth and families, manifested policies may inadvertently serve as sources of risk as opposed to their desired and intended protective function (attenuating the significant social vulnerability of particular citizens).

TWENTIETH-CENTURY SOCIAL SCIENCE ASSUMPTIONS AND PRACTICES, JUDICIAL DECISIONS, AND THEIR IMPLICATIONS FOR THE NET VULNERABILITY OF DIVERSE YOUTH

As a basis for providing alternative and inclusive human development theorizing relevant to diverse youth, we described the benefits of PVEST. A major rationale supporting the framework's use is its applicability to all individuals irrespective of group demographics (e.g., economic status, race, ethnicity, nativity, and immigration status). The framework's inclusive character represents an important benefit because the literature narrowly and frequently infers deviance, pathology, and problems for those categorized as different (i.e., from the accepted and nonstigmatizing norm of being Caucasian and middle income). As described, the early research on Black children was conceptually flawed in multiple ways (see Spencer, 2005). And at the same time, traditional and widely disseminated child development research efforts assumed the findings to be representative of all youths' experiences (i.e., diversity within-group is generally not inferred). Specifically, the operating perspective suggests that European American experiences represent the normative standard for all. For the most part, process-oriented developmental analyses have been restricted to middle income people or European Americans. Conversely, problem- or pathology-oriented outcome-focused studies have primarily been assumed as representing the experiences of minorities in the social science literatures generally but continue to characterize the developmental sciences specifically.

Inferences, Assumptions, and What *Brown v. Board of Education* Should Have Considered: Contemporary Implications for Research, Practice, and Theorizing

The pattern of published research suggests specific assumptions such as an unacknowledged status of privilege for some (i.e., and who represent what is thought of as normal for all), and an inferred homogenous experience of atypicality for most others. Inferable from the developmental sciences is that normal remains the provenance of European Americans and middle-income people. At the opposite end of the spectrum, marginalized group members are conceptualized as the other. Erroneously, their experiences are assumed to be *homogenous as the minority case,* and as suggested, they are most frequently represented in the literature under categories of deviance, difference, problems, pathology, and deficit (see Spencer, Brookins, & Allen, 1985). Moreover, the two juxtapositions frequently ignore the multiple contributions of the social and physical ecology: Except for *crediting* diverse youth of color for the character of the context, and thus, the source for the group's high vulnerability (higher risks than available protective factors).

Unfortunately, as such, this latter perspective continues to the disadvantage of some youth (i.e., immigrants, low-income families, and youth of color) because it communicates the penchant that individuals are solely responsible for their own social situations. The working notion reinforces the stereotype that the problem or major sources of risk reside in individuals who deterministically create their own environments. Thus, the assumption is that they are responsible for their own disadvantaged situation. The stereotypes reinforced by narrow and under-representative scientific efforts have failed to contribute to inclusive theorizing, proactive research traditions, or culturally authentic programmatic applications that adequately address and enhance human development stage-specific outcomes for diverse groups. As a process-oriented, culturally sensitive and identity-focused framework that addresses the "how" (which is important for application), PVEST aids in filling the long-term void described by S. H. White (1996), Cole (1996), Lee et al. (2003), and others.

S. H. White's (1996) chronicling of the history and cultural shortcomings of contemporary research suggests a significant lack of inclusive thinking. The ICE perspective provided by PVEST in response, given S. H. White's critique, brings attention to the patterned *lack of cultural competence and generally inadequate research perspectives* (including acknowledgment of the broad diversity both within and between groups). Infrequently acknowledged, except to occasionally lament their existence, the problematic conduct, character, and interpretation of such programs of research remain endemic to the social sciences and have been highlighted more recently as "outcome disparities," particularly in the education and health literatures. As a consequence, given the shortcomings noted, *social policies* themselves have *provided neither the conceptual leadership nor the social and psychological protective* functions usually intended or inferred from good social policy.

At the same time, the broad privileges associated with middle and high socioeconomic status and European American group membership continue to be underappreciated and more frequently generally ignored (see McIntosh, 1989). Luthar's (2003) program of research with affluent Caucasian suburban youth provides the potential for new beginnings for understanding the special character of vulnerability experienced by privileged youths. Similar to Roediger's (2002) analysis, equally relevant is Moore's (2002 and documentary, http://www.bowlingforcolumbine.com) perspective concerning school-based mass killings such as the one at Columbine High School. Given his analysis, evidence for a downside of privilege begs attention. Generally speaking, questions concerning the relationships between privilege and underdeveloped coping skills are needed for the design and implementation of intervention and prevention strategies. Inadequate coping responses to many common but painful adolescent or childhood stressors, such as teasing and marginalization, are inadequately addressed in the literature, particularly as they relate to privilege, coping strategies, and completed suicide rates. This oversight in the child and adolescent literatures is especially troubling, given that White males on average have the highest completed suicide rate among adolescents and individuals in middle adulthood (see Carroll & Tyler, under review). On average, however, they are also expected to obtain the highest life course earnings and complete the most years of education. Accordingly, high suicide rates among White males in adolescence and middle adulthood (see Carroll & Tyler, under review) appears inconsistent with other indicators of mean successes accrued. This disparity suggests the need for intervention/prevention strategies and analyses that differ from those assumed for marginalized youths and particularly males.

Speculations about the challenges faced by youth of color and low socioeconomic-resourced youth may be more readily associated with *the lack of opportunity,* economic difficulties, and underserviced neighborhoods. Irrespective of the many challenges and the media exploitation of obvious coping failures, the majority of young people successfully tackle the developmental tasks described by Havighurst (1953). Their successes are generally underacknowledged; in fact, their resiliency amidst persistent challenges suggests that many demonstrate carefully honed adaptive coping skills. Resilient outcomes, however, are not solely dependent on environmental influence. The variability of coping success and failure often occurs in the same family, where environmental influence may be similar across siblings (one son becomes a medical professional and a second becomes an inmate in jail). A particular strength of PVEST is its capacity for understanding the unique experiences of each sibling by including the consideration of phenomenology. Youths' meaning-making can be totally different even if, for example, brothers are believed to be exposed to the same parental messages, ecolevel structural conditions including the character of neighborhood resources and challenges.

Additionally, explicit experiences of cultural socialization and carefully developed strategies of parental monitoring predict positively to healthy emergent identities and developmental stage-specific coping products (e.g., completing school, obtaining employment, living a healthy lifestyle; Spencer, 1983, 1990; Spencer et al., 1996). Thus, given the variability possible, context-linked challenges confronted, and coping processes evoked (i.e., independent of shared demographics, child-rearing, and schooling environments), both within- and between-group diversity of outcomes is possible. Inclusive conceptual frameworks should be amenable to and effective in explaining the "how" of (a) youths' unique meaning-making processes that govern coping and identity processes, (b) their active usage or self-restraint of opportunity structures (e.g., optimizing or pushing back from educational options provided through public schooling), and (c) children's broad range of within-group behavioral variation. The wide spectrum of adaptive coping prospects are not independent of the fact that youths, as they transition across time and place, may be burdened with stereotyping encounters or stigmatizing imagery (i.e., of themselves or their referent group) and limitations of proactive or adaptive coping experiences given assumptions frequently associated with privilege, or its absence. Moreover, youths' ensuing social epistemologies that result (i.e., given stage-specific developmental variations in youths' perceptual processes and phenomenology) promote further variability in coping strategies available and outcome options.

As inferred from Chestang (1972), the persistent encounters with hostile environments are often based solely on group-linked stigma such as race, gender, low socioeconomic resources, skin pigmentation, ethnicity, and immigration status. We suggest that how young people make meaning and cope with challenges require dynamic, recursive, and culturally sensitive interpretive frameworks. These conceptual advantages promote the

design, determination, and construction of the most appropriate and effective prevention/intervention supports. PVEST serves as an effective conceptual tool for describing the range of coping strategies possible and aids in determining the character of coping options that an individual might use in the moment. Some responsive strategies might evoke jail-time sentencing decisions by the judicial system (e.g., see Stevenson, 1997) or precipitate effectance motivation that can lead to youths' high levels of success and competence (e.g., see R. White, 1959, 1960). The *range of reactive coping responses possible* may result in resiliency for some (i.e., positive outcomes in the face of inordinate challenge) or produce unfortunate labeling and unproductive coping products that lead to the oft-reported group disparities for a particular characteristic (e.g., academic underperformance, health status, special education placement, and disproportionate sentencing to the criminal justice system).

In contrast, the several mass school shootings over the last decades, most recently that at Columbine High School (Moore, 2002 and documentary, http://bowlingforcolumbine.com), certainly make the point of privileged youths' understudied but apparent vulnerability, which is consistent with the patterned suicide rates for White males. Although generally lacking parallel media coverage, which is frequently reserved for mishaps committed by low-resource youth, particularly youth of color, these unfortunate situations also fall into the category of *unproductive coping processes and outcomes.* Their patterned quality for privileged youth suggests a particular level and character of vulnerability. Although not generally discussed, these themes deserve theory-driven scholarly analyses for informing intervention and prevention efforts. As most evidenced by stereotyping of marginalized youth, there is a potential downside to bringing attention to a specific need because the resulting stigma increases individuals' experiences of risk and underscores the need for additional protective factors.

For example, the media acknowledges and highlights particular disparities, which further stigmatizes referent group members and can lead to situations of stereotype threat (Steele, 1997, 2004; Steele & Aronson, 1995). Accordingly, a theoretical perspective relevant to *diverse youth* (i.e., both privileged and those inordinately challenged) should accommodate the exacerbating impact of (a) maturation-linked complexity (e.g., early versus late physiologic maturation; Spencer, Dupree, Swanson, & Cunningham, 1998), (b) transactional-determined dynamism (i.e., individual-context interactions; e.g., awareness of bias; Spencer, 1985, 1999b, 2001), and (c) cultural embeddedness (e.g., Lee et al., 2003). The efficacy of a theory as a process-oriented conceptual tool should aid in explaining the "how" of outcomes, given the breadth of experiences possible and the persistence and character of situations under which many children struggle and have little control. For example, the traditional literature on service learning and volunteerism positively acknowledges and credits supports provided by youth only if provided to others or nonrelated groups. For some children, the garnering of official approval, support, and recognition for *service learning provided to their immediate or extended family system and community* is equally important and should earn equivalent psycho-social benefits and academic reward to youth when compared against service provided to unknown others (Spencer & Cassidy, 2004).

Given the salient role of *context,* PVEST satisfies criteria for good theory as suggested by S. H. White (1996). Specifically, it accommodates the consideration of traditional externally based information about study subject(s) such as *neighborhood and community characteristics and assessments.* These are frequently obtained through "windshield" observations of context or similar strategies. This information resource is particularly relevant for studies of older middle childhood youth and especially adolescents who transition across neighborhoods as an aspect of the developmental task requiring the establishment of broader social relationships. Parental reports and other interview data sources are also useful context-based information in answering the "how" question from a PVEST perspective. Achievement testing process and outcome data represent an additional context-linked data source on par with teacher ratings. Considered together, PVEST provides an analysis, which includes the individual's own view as well as the transactional contributions of the context; thus, it provides an ICE perspective that represents a valuing and recognition of the individual's own perspective or phenomenology considered from within the cultural context.

The varied meaning-making, coping processes, and emergent identities of youth may be associated with several possible levels of environmental hostility or racism, which are contributed to by social infusions of what Steele and colleagues (Steele, 2004; Steele & Aronson, 1995) characterize as "stereotype threat" or inferred hostility (see Chestang, 1972). Further, when considered developmentally, the responsive coping

styles may be highly heterogeneous in character and do not necessarily include the internalization of negative affect assumed by the larger society given the group's social placement and denial of rights (see Spencer, 1990; Spencer & Markstrom-Adams, 1990; Swanson, Spencer, Harpalani, Noll, Seaton, et al., 2003). From a policy perspective, the nuanced and developmental-sensitive perspectives published in the past 25 years were not in place when the Courts determined *Brown v. Board of Education* in 1954 (see Cross, 1991). *As a major historical event, the decision's salience and aftermath greatly influenced social and educational policy, practice, and legal decisions. Most important, the decision continues having significant relevance today—50 years post*-Brown.

Shortcomings of Mid-Twentieth-Century Social Science Contributions to the Brown *Decision*

The research efforts of Kenneth and Mamie Clark (1939, 1940) were cited as a footnote in the U.S. Supreme Court's landmark *Brown v. Board of Education* decision (see Lal, 2002). The published scholarship and known programs of research available at the time were used to support the notion that Black children developed a low self-esteem due to segregation, and that integration was necessary to mitigate feelings of inferiority. The 50th anniversary of that decision suggests an appropriate point to integrate, revisit, and reanalyze the legislation's impact for youth development but particularly for marginalized youths' academic experiences and outcomes in U.S. school settings. The power of better theory for interpreting the Clark's research without either castigating the researchers or pathologizing the children is overdue. The case enlightens both the importance of training diverse investigators and having authentically inclusive human development theory for interpreting findings and enhancing the efficacy of policy decisions for the common good.

Jack Balkin's (2001) edited volume, *What Brown versus Board of Education Should Have Said,* reports on his request of a group of constitutional scholars to rewrite the opinion in *Brown v. Board of Education.* He asked the specific question, "How would you have written the Brown opinion in 1954, if you knew then what you know now about the subsequent history of the country and the progress of race relations in the past half century?" (Balkin, 2001, p. ix; Note: It should be acknowledged that the opinion called *Brown* is actually based on three opinions: *Brown I,* May 17, 1954; *Brown II,* May 31, 1955; and *Bolling v. Sharpe,* May 17, 1954.) Balkin (2001) instructed participants to draft an opinion (a majority opinion, concurrence, or dissent) *based on the material available in 1954.* The contributors addressed three sets of issues. Given feedback and overall case analysis, Balkin argues that *Brown* is one of the most recognized and treasured court decisions in history. He states:

> The civil rights policy of the United States in the last half century has been premised on the correctness of *Brown,* even if people often disagree (and disagree heatedly) about what the opinion stands for. No federal judicial nominee and no mainstream politician today would dare suggest that Brown was wrongly decided. At most they might suggest that the opinion was inartfully written, that it depended too much on social science literature, that it did not go far enough, or that it has been misinterpreted by legal and political actors to promote an unjust political agenda. The use made of *Brown* is often criticized, but the idea of *Brown* remains largely sacred in American political culture. (Balkin, 2001, p. 4)

However, as recently analyzed (see Spencer, 2005), the sentiment described was clearly not evident in the first decade following the decision; indeed, there was much upheaval over the decision. Many opponents argued that it was more a sociological rendering than a legal decision, claiming that it ignored history and legal precedent. The South raised massive resistance claiming that *Brown* was an abuse of judicial power. However, *Brown* has gradually come to be highly esteemed. Balkin (2001) claims that the decision falls in line with the U.S. "Great Progressive Narrative," which states that the United States through its Constitution and through history is gradually reaching its social justice goals and that the United States is essentially a just society and that through struggle and history these goals will be realized. The fame of *Brown* is ironic, in that today, many public schools remain segregated by race and are often taught by teachers who have difficulty educating certain children, particularly those with whom they lack history (see Ladson-Billings, 1994). During the 1970s and 1980s, southern schools were rapidly desegregated turning the south into one of the most integrated parts of the country. However, more recently there has been resegregation of schools based primarily on differential resources structured demographically along the poverty line, and the penchant has visible racial consequences.

The pace of desegregation slowed in the middle 1970s, in part, because of Supreme Court decisions that failed to regulate desegregation across primarily White suburb and minority inner city boundaries. For example, *Milliken v. Bradley,* 1974, in Detroit, "freed white suburban districts from any legal obligation to participate in metropolitan desegregation efforts" (p. 6). Despite these court implications, desegregation actually continues into the 1980s. As chronicled by Balkin (2000), during the 1990s, however, the Supreme Court actively restricted their supervision of school districts with:

- 1991, *Board of Education v. Dowell:* The Supreme Court held that "courts could end desegregation orders in school districts that had attempted in good faith to comply, even if this would result in immediate resegregation" (p. 6). The replacement of Justice Thurgood Marshal (major civil rights supporter) with Justice Clarence Thomas in 1991 gave further impetus to this trend of restricting court supervision.
- 1992, *Freeman v. Pitts:* The Supreme Court held that "courts could end some aspects of school desegregation orders even if other aspects had never been fully complied with" (p. 7).
- 1995, *Missouri v. Jenkins:* The Supreme Court "overturned an ambitious plan for magnet schools in Kansas City designed to attract white students back into inner city schools" (p. 7).

Two salient implications and consequences of these Supreme Court rulings ensued: (1) The federal court's desegregation orders have been largely stopped, and (2) districts technically subject to court orders face no enforcement activity. Thus, in the 1990s, there has been a tendency to resegregate. An implication is that schools can be segregated by race as long as the status is not due to direct government impetus. In his analysis, Balkins (2001) states that "racial segregation today is the result of a complicated mix of social, political, legal, and economic factors, rather than the result of direct state commands ordering racial separation . . . it remains overwhelmingly the case that minority children in central cities are educated in virtually all-minority schools with decidedly inferior facilities and educational opportunities" (p. 7). *Evident is that Brown called for the importance of equal educational opportunity; however, it is evident that minority students do not receive an equal education compared to that provided by public schools in wealthier, Whiter suburban districts.* As a major and consistent source of risk, the schooling contexts are not equivalent for youth of color versus privileged youth. However, achievement gap language implies that it is an individual's own performance inadequacy that is the culprit rather than sets of *policy determined, constructed, and supported social inequities.* Accordingly, inclusive and sensitive theorizing matters for producing the most beneficial policies and practices.

Traditional Assumptions, Beliefs, and Values: The Conceptual Benefits of a Phenomenological Variant of Ecological Systems Theory Framework

Given the process-emphasizing rendering of PVEST in Figure 15.12, good developmental theory appears important because it explains *how* youth respond to externally imposed inequities and cope with adverse ecological conditions or what Chestang (1972) refers to as character development efforts pursued in persistently challenging environments. *Brown* has come to mean different things to different people: It has also been used in diverse ways by different groups. *Brown* was implemented to support public equity in buses, pools, restaurants, and retail outlets (i.e., all important contexts of socialization and youth development) and has become a symbol of equality generally, beyond racial equality. This is both interesting and informative given the intent of the originating cases.

Brown opposed *Plessy v. Ferguson,* 1896, which allowed for segregation of public spaces and gave justification to Jim Crow. The only Justice to oppose this decision was John Marshall Harlan who maintained that this country should not support a caste society and that it should be color-blind. His words have been applauded by civil rights supporters. However, more recently, the differences between *anti-classification* and *anti-subordination* have become more apparent and are exceedingly important for youths' developmental opportunities and experiences. As one example, there are those who support classification in affirmative action to promote Black equality (see Balkan, 2001).

According to the anti-subordination approach, the question is not whether the law classifies by race, but rather whether the law is *doing anything to remedy subordination or whether it is doing something to enhance it.* Anti-classification, because the law does not currently

directly impose classification, actually *tends to work to perpetuate Black inequality because it fails to acknowledge the differential ways in which Blacks have suffered cumulative effects and continue to be burdened by social and economic subordination.* Thus, this tends to sanctify the many *indirect practices that subordinate Blacks,* without directly classifying: "It encourages people to explain persistent black inequality as the result of private choices, cultural differences, or black inferiority rather than at least partially as the result of facially neutral legal policies that help preserve social stratification" (Balkin, 2001, p. 13). *The New York Times* (Rimer & Arenson, 2004, June 24, Sec. A, P1) described analyses by two Harvard researchers, Skip Gates and Lani Guanier. The researchers suggest that selective school attendance by Blacks represent immigrant Blacks and not indigenous Blacks for whom the *Brown* decision was targeted. The admissions profile favoring immigrants imply efforts to satisfy the law without considering its spirit and the variability of experience by ethnicity and immigration status *within race.* The admissions profile and its implementation by respective selective college's admissions office provides a powerful illustration of the broad manipulation of opportunity thus suggesting that supports are not always supportive to those actually intended to benefit. Selective postsecondary schools of higher education such as Harvard, Yale, and Princeton communicate a solid track record of admitting Blacks. However, the admissions procedures in practice at select schools, in fact, admit Blacks of first- or second-generation immigrant status whose academic record and schooling experiences lack the cumulative intergenerational effects of long-term U.S. race-based hostilities, which the *Brown* decision sought to remedy.

The broad controversy between color-blindness and equal citizenship extends into every part of anti-discrimination law and policy. Each side substantiates their claims in *Brown.* Balkin's (2001) analysis of the feedback suggests an important role for the politicized views of the moment. Actually, the Balkin perspective underscores the powerful role of the political-ecology and contends that the Court rulings coincide very smoothly with the political climate and are not, as some have argued, free from this context. Even *Brown* was not revolutionary in an isolated sense. From a global and broad psycho-historical perspective, it was relevant to the Cold War climate and the image U.S. leaders wanted to present abroad to diminish criticism of Jim Crow: Using Chestang's (1972) analysis of the ecology, the goal was to suggest a less hostile context of development for those suffering under Jim Crow practices. *Brown made sense as a blow to communism and to demonstrate the democratic tenets of our constitution and the ways the United States upholds these despite its lived societal inconsistencies.* Considered from a PVEST perspective, the penchant produces a level of official deniability relative to responsibility for diverse youths' life course coping patterns, processes, and outcomes.

Many critics maintain that the view of the Supreme Court as brave and a progressive, counter-majoritarian institution is largely a myth and that is does not work to favor minorities in the face of majority opposition. As Derrick Bell (cited in Balkin, 2001) maintains, *Brown* is congruent with his "interest convergence thesis," which maintains that advancement for Blacks will only occur if these advancements are in White interests. Bell argues, "ending Jim Crow—at least formally—was in the interests of northern whites and the foreign policy establishment. However, the convergence of interests between blacks and white elites did not mean that whites had an interest in full social and economic equality for blacks, and the limited convergence of interests that did exist did not last. Actual desegregation remedies were a long time in coming and fell far short of providing genuinely equal educational opportunities for blacks" (see Balkin, 2001, p. 22). From a child development and parental socialization perspective, an understanding of such nuanced analyses is required and itself represents an unfair burden for minority group and disenfranchised parents. Appropriate use of the legal insights requires an ability to translate complex policy-relevant information into particular parenting strategies: For parenting of European American or well-resourced youth, a goal would be to counteract easily inferred privilege assumptions by young people. For poor and marginalized youth, the goal would be to monitor and support youth development in ways that would reinforce effectance motivation and model adaptive coping strategies needed for responding to socially unacknowledged, unfair, and ethnicity-linked challenges.

Critics maintain that *Brown* is a symbol of how ineffective the Supreme Court is at promoting social change. They argue that the lack of implementation and the reversal in the 1990s demonstrates the ineffectiveness of judicial change. For example and as reported by Balkin (2001), Rosenberg in his 1991 book, *The Hollow Hope:*

Can Courts Bring about Social Change? argues that *Brown*'s role in promoting equality has been overstated. Rosenberg suggests that enforcement did not proceed until the Civil Rights Act of 1964 and rather that *Brown* instigated a forceful resistance from southern Democrats. Also, critics oppose the view that *Brown* initiated the civil rights movement, naming the many grass-roots efforts that proceeded *Brown.* Balkin (2001) claims that legal precedent such as Brown is important in that it structures the discourse that can ensue. *Brown* provided a symbol, linking the Constitution and rule of law to civil rights and racial equality. Balkin maintains that *Brown* is currently very important and the argument is not over whether it was correct, but rather, contesting its meanings and implications. Interestingly, 50 years later, the argument is whether the underlying principle of constitutional equality provided by *Brown* is *anti-classification* or *anti-subordination.* "Is the real evil of Plessy the classification of persons by race or is it the subordination of one race by another?" (Balkin, 2001, p. 55). Following the *Brown* decision, there were no provisions for equalization and true integration, rather the specified legal doctrine noted that states could not assign pupils based on race alone. Many states adopted choice plans and the use of private schools to avoid directly contesting *Brown.* Balkin states, "Indeed, because the schools were technically 'desegregated' once overt assignments by race ended, one could argue that there was no continuing obligation to equalize facilities between schools; he notes that the situation might be even worse than it was before Plessy" (p. 65). Importantly, there has been little discussion in the youth-focusing social sciences about the impact of these events on the psychological context of child development *research,* on everyday coping experiences in the daily lives of children, or on the myriad levels of youths' socialization contexts.

In the 1990s, significant disillusionment surrounded *Brown,* given that a majority of Blacks still receive substandard education in deteriorating schools and that the push for desegregation for the most part has been rejected. In particular, public schools in urban areas continue to be mostly Black: "In 1998–1999, 90% of the public school students in Chicago were African American or Latino; 83% lived in poverty-stricken households. In Detroit, 90% of public schools students were black and 70% were poor enough to qualify for free school lunches; more than one-half of the city's students did not graduate from high school" (Balkin, 2001, pp. 211). In addition, many large school districts, including Cleveland, Dallas, Denver, Minneapolis, and so on, "were allowed by judges in the late 1990s to phase out or terminate court supervision" (p. 212). Hence, integration of schools vastly declined in the late 1990s.

Several court decisions in the late 1990s ended efforts to desegregate (e.g., busing) and also ended race-based decision-making in many schools, thus canceling affirmative action practices. Data indicate that gaps between Black and White achievements are increasing again in the 1990s after slightly decreasing in the 1970s and 1980s. However, the data also suggest that the gaps remain even in districts that are integrated and of a higher economic status. Family structure, income level, and educational level did not seem to alter these gaps.

Cross-Disciplinary Contributions from Legal Studies

Like Balkin, Sarat (1997) argues that *Brown* challenged legal precedent and rearranged the ways in which the law could work toward progressive change in society. Sarat states: "*Brown* was at once a turning point and a source of resistance, a point of pride and an object of vilification. Its legacy, like the legacy of all great historical events, is, even today, contested and uncertain" (p. 5). Although not acknowledged, it is evident that a strong legal position continues to be the problem of subordination: Racism, stereotypes, and low expectations continue to haunt particularly Hispanic and Black children as an integral and persistent aspect of their social ecologies. Importantly, *theories of development that guide the training of teachers in pre-kindergarten through 12th grade and beyond neither adequately nor authentically represent the individual-context experiences of diverse youth.* Parents frequently appear equally handicapped in providing the necessary supports as counteractions against race-linked challenges. Teachers and administrators not only miss adequate training information about youth of color but also are frequently not accountable for analyzing their own internalization of subordination beliefs. Except for the scholarly thrust of the CRT initiatives, Whiteness studies (in general), and White-privilege perspectives (specifically), there remains a strong pattern in social science and developmental science to inadequately consider race or to attempt to minimize or to statistically control for its impact on youths' coping processes.

Critical Race Theory (CRT): Contributions and Limitations

Another important development in scholarship on racism, CRT (Delgado & Stefancic, 2001), draws its origins from legal studies and represents another historically important innovation. CRT began as a critique of liberal post-civil rights ideology that de-emphasized the role of race in U.S. society. The CRT movement has drawn attention in a variety of academic disciplines, including education, the humanities, and the social sciences. In parallel with sociological theorizing, CRT highlights racism as a normal component of society, not an aberration, and examines the subtle racial interests and tangible consequences of legal decision-making and policy in a society marked by racial hierarchy. Additionally, CRT scholars often use rhetorical devices and narrative storytelling, often autobiographical, to illustrate everyday manifestations of racism and their connection to broader, structural forces. As a representation of a phenomenological perspective, CRT begins to link individual experiences with societal theories of racialization, integrating the structural, ideological, and material expressions of racism in the routine course of daily life.

Critical Race Theory: Tenets, Analytic Applications, and Theoretical Renderings of Race. As a movement that is both theoretical and activist oriented, CRT arose from the discipline of legal studies. CRT departs from many other disciplinary regimes as it attempts to name the inequities in our current social structure and then re-envision the categories and assumptions that we as society use to frame our world. Formally begun in the mid-1970s through the founding work of Derrick Bell (e.g., Bell, 1995, 2000a, 2000b) and Alan Freeman (e.g., Freeman, 1995), CRT poses critiques that disrupt the blinders that social systems create in an attempt to *make racism invisible.* The perspective forces an acknowledgment of the ways in which discourse and social structure cooperate in the realization of inequities and racism.

The CRT approach was situated in a particular historical period and arose primarily as a dialogue with and in response to the civil rights movement. The theorists were critical of the changes brought about by this movement, in particular, the lack of steady advancement in racial reform in the United States. Regarding the more recent retrogression of progress that have been made since earlier legal gains (Delgado & Stefancic, 2000), Bell (1999a) indicates that "statistics on poverty, unemployment and income support the growing concern that the slow racial advances of the 1960s and 1970s have ended, and retrogression is well under way" (Bell, 1999a, p. 2).

CRT, as a discipline, is based on the foundations laid by critical legal studies and feminism and its intellectual ties extend back to U.S. thinkers, such as W. E. B. Du Bois, and European theorists such as Gramsci and Derrida (Delgado & Stefancic, 2000, 2001). From a PVEST perspective, it delineates the role of race for vulnerability and demonstrates the countless ways in which race for youth of color increases net stress level through its manifestation of subtle and explicit daily challenges borne by youth and their families. CRT questions the very foundations of legal reasoning, and although CRT still predominantly produces new legal discourse, analysis is now applied more broadly in fields, such as education, where the tenets of CRT are used to understand tracking, curriculum, and the history of IQ and achievement testing (Delgado & Stefancic, 2001). Thus, from the child and adolescent development perspective of the social sciences, CRT provides an important and generally overlooked *contextual perspective* by defining it in race-linked terms. CRT is inherently nondevelopmental; however, it provides lenses for articulating the influence of racism and stigma as a presence and potential impact on normative developmental tasks pursued by youths. Its inclusion and or consideration represents a significant variation from traditional child development approaches that attempt to clarify the salience of race through statistical strategies that categorically defines the impact of race for hypothesized outcomes. Further, as a statement about everyday practice as supported by the law, CRT specifies the differential character of race-based practices as experienced by marginalized youth. When considered from a PVEST perspective, CRT provides a service to the social sciences by fully specifying the varied contributions to vulnerability level as experienced by diverse youth. As supported from legal studies, the perspective specifies the contributions to the high-risk context of development as experienced by youth of color and, at the same time, specifies the implicit protective character of racial group membership particularly for European American children.

CRT incorporates two main concepts from the field of critical legal studies. First, *legal indeterminacy* acknowledges the subjectivity of legal outcomes and maintains that "not every legal case has one correct outcome"

(Delgado & Stefacic, 2001, p. 5). *The legal outcome depends on whose interpretation is privileged, which is dictated by the power and authority of various interpretations.* Second, *favorable precedents* tend to erode over time due to the ways in which lower courts interpret precedents using narrower definitions and because of the general lack of enforcement of legal doctrine (Delgado & Stefacic, 2001).

CRT also incorporates concepts and terminology from feminism. Specifically, it applies theoretical feminist views on power, the construction of social roles in society, and its use of hegemony. As reported by Hall (2000), the concept of *hegemony* was developed by Gramsci and is defined as "total social authority" acquired through the combination of *coercion* and *consent* at the economic, political, ideological, intellectual, and moral levels. CRT also works in the feminist premise that legal and social theory have practical consequences in society and that these consequences must be addressed (Armour, 2000; Delgado & Stefacic, 2001).

Delgado and Stefancic (2000, 2001) summarize four underlying tenets of CRT. The first tenet maintains that "[R]acism is normal, not aberrant, in American Society" (Delgado & Stefancic, 2000, p. xvi). As opposed to being relegated to the undifferentiated level of the ecology described by Bronfenbrenner as the macrosystem, instead, racism is conceptualized as an intricate part of the everyday life experiences in the United States and is woven into all institutions and social interactions. It is an ingrained aspect of our society to such an extent that racist practices and interactions are deemed as normal. Most important, as understood in the social sciences generally and child research specifically, the roots of these injustices are ignored or frequently not perceived. Formal equal opportunity rules and laws target extreme, overt injustices but do not in any way address these microlevel everyday expressions of racism. For example, legal doctrine requires the demonstration of *intent* of racist action to litigate. However, this intent is often difficult to prove and racism is frequently built into the fabric of U.S. social structures and institutions such that a specific intent is not immediately apparent. From our perspective, legal doctrine has no precedent for addressing these forms of racism.

The second tenet assumes a critique of liberalism. According to Delgado and Stefancic (2000, 2001), liberals uphold the neutrality of the law and view it as objective and morally accurate. However, CRT questions these assumptions and the liberal notion of change in the law through the process of gradualism. As alluded to previously in this chapter, CRT draws on a term created by Derrick Bell, *interest convergence,* which describes a phenomenon in which Whites will only support Black advances if these advances serve White interests. Building on this concept, critical race theorists contend that the civil rights movement and the current legal structure do not foster structural change and that only through drastic alterations to systems, structures, and ideological foundations can true racial progress and equity ensue. These linkages are too infrequently considered both in the design and conduct of child and adolescent research, theory, and policy and in their interpretation in the social sciences.

Critical race theorists maintain that "structural determinism" in society impedes racial reform through a variety of means. Freeman argues that civil rights law enforces racial progress at a slow rate, creating a social control mechanism that insures enough change to prevent civil uprising while not actually altering the status quo (Delgado & Stefancic, 2001). The awareness of this may have implications for differences in cultural socialization practices, thus also an implication for youths' cultural identity formation, manifestations as part of reactive coping strategies for some, and implications for youths' degree of individual-contextual fit (e.g., see Swanson et al. 1998).

One of the tenets of CRT establishes that race is a product of social construction. Their analysis suggests that prevalent definitions and assumptions in society are never innocent of the inequities shaped by power relations. Youths' social-cognitive maturation makes the awareness of inequities difficult to articulate but remain unavoidably experienced as either a source of risk or a contributor of a protective factor. Thus, from a developmental perspective given maturing perceptions, CRT increases our understanding of youths' vulnerability level, coping processes, and stage-specific coping outcomes, given the several developmental tasks requiring mastery.

As an important conceptual contribution to child development scholarship, CRT acknowledges the importance of context and uses legal studies to further specify its impact. For example, the legal system functions based on the premises of generalizability and essentialized notions of right and wrong. These premises do not provide the legal space for consideration of the ways in which individuals are inequitably influenced and shaped

by their specific contextual factors. CRT uses the term *intersectionality* to acknowledge the complex, contradicting, and cumulative ways in which race, gender, class, and sexual orientation affect an individual's positioning in larger social structures. CRT contends that racism exists and continues in our society because the mind-set of the majority of people in the United States has not changed, despite the civil rights movement. This lack of change in mind-set introduces an entrenched conundrum: Although unacknowledged, its impact is inclusive of those individuals responsible for funding, designing, implementing, publishing, and interpreting social science research both for children of color and European American youth. Its use in the training of professionals and their modeling of the content (e.g., in youth and family service delivery and education practice) further contributes to its entrenched character, formidability, and persistence.

Encompassed under the umbrella of CRT are other subsidiary studies including critical White, Asian, and Latino studies and feminist and gay critical studies. Asian studies look critically at the *model minority stereotype,* while feminist and gay studies look at *intersectionality.* Critical White studies examine the ways in which Whiteness is *socially constructed* and how groups have historically moved in and out of this category. For example, certain ethnic populations in the United States such as Jews, Italians, and Irish have moved into the category of White, after being labeled as non-White during their early history in the United States. Such studies also explore the ways in which privileges associated with this label structure power relations and how discourse through literature and cultural forms powerfully reinforces stereotypes and the values associated with Whiteness in contrast to color (Delgado & Stefancic, 2001).

In sum, unlike the traditional approach to child developmental research, critical White studies contribute by affording an opportunity to deconstruct and specify the process of normal human development experienced in context for members of diverse groups. Roediger (2002) looks at the social construction of Whiteness and maintains that, historically, this category has been ignored. This continues to be the case particularly in the adolescent and child development literatures. Roediger cites Fusco who contends that to ignore this category tends to "redouble its hegemony by naturalizing it" (Roediger, 2001, p. 327), thus Whiteness becomes further ingrained as the normative standard. Roediger explores the historical process by which immigrants earned their status as White. The process of Americanizing European immigrants ("White ethnics") allowed them to be accepted as White rather than Irish or Polish. Underlying premises of CRT are instituted to critique the justice system, the educational system and policy affecting the broader society.

CRT has also been useful to analyze the implications of various educational legal reforms including integration and affirmative action (which affects a broad range of institutions including the educational system). Derrick Bell (2000b), in *Serving Two Masters,* looks at the outcomes of integration mandates and asks an important question: Is racial balance in the schools enough to provide educational equity? Bell contends that historically, since the 1930s, the approach of the National Association for the Advancement of Colored People (NAACP) has been to eliminate racial segregation across society. This approach took precedence in the education system, particularly, with the passing of *Brown* in 1954. The subsequent lack of compliance with the legal precedent set by *Brown* led to a series of school litigation cases being filed. For some theorists, the lack of compliance has not been unexpected and, again, reaffirms the salience of history for contemporary and entrenched practices.

W. E. B. Du Bois named the educational dilemma for our society in 1935 and his concerns remain prevalent even today and, although infrequently acknowledged, are particularly relevant in the field of child development. Integration has not proved to be the silver bullet for educational equity in our society, as predicted by Du Bois, and more comprehensive changes need to be made in society before educational equity can be a reality. Du Bois states:

> [T]he Negro needs neither segregated schools nor mixed schools. What he needs is Education. What he must remember is that there is no magic, either in mixed schools or segregated schools. A mixed school with poor and unsympathetic teachers, with hostile public opinion, and no teaching of truth concerning black folk, is bad. A segregated school with ignorant placeholders, inadequate equipment, poor salaries, and wretched housing is equally bad. Other things being equal, the mixed school is the broader, more natural basis for the education of all youth. It gives wider contacts; it inspires greater self-confidence; and suppresses the inferiority complex. But other things seldom are equal, and in that case, Sympathy, Knowledge,

> and the Truth, outweigh all that the mixed school can offer. (Bell, 2000b, p. 243)

Critiques of Critical Race Theory and Their Implications for Child Development Research. It is important to note that CRT has not been without its share of critiques. Delgado and Stefancic (2001) relay general critiques of the CRT approach, and some scholars in the broader discipline of legal studies have critiqued the CRT's use of storytelling in the law. Their critique rests on several premises, which are not unlike the standard research tensions between the use of quantitative versus qualitative research approaches in child development research: (a) These stories may not represent the typical experience of members of the larger group of individuals of color, (b) narratives lack analytical rigor, and (c) stories told by individuals of color stifle wider discussion due to the general belief that these individuals have a superior understanding of race. Some scholars critique the perspective held by critical race theorists that truth is a social construct created to further the position of those in power.

Another critique of CRT is that it focuses on changing discourse and cultural forms of racism and does not speak to the deeply ingrained structural/material racism, more strongly affecting the poor. This critique maintains that CRT focuses primarily on issues of identity and does not incorporate a thorough enough class analysis. Even in the discipline of CRT, theorists voice a need to develop further theories that look at the intersection between race and class. Also, critical race theorists express the need to develop a broader global analysis of race, looking at the connections of sweatshop concerns—the oppression of people of color abroad working low-wage jobs—and the unemployment of people of color in the United States (Delgado & Stefancic, 2001).

When considered together, Whiteness studies delineating the impact of racism and privilege along with CRT increase our understanding of proximal processes experienced by America's diverse youth post-*Brown*. Unfortunately, the links are seldom acknowledged and the oversight has important implications for the continuing dissemination of stigma and unquestioned assumptions concerning privilege. As elaborated, there are few demonstrations of the interaction of these themes than in the acting White myth associated with African American youth achievement and coping patterns (see Spencer, Cross, et al., 2003, pp. 276–287).

AN EXAMPLE OF AFRICAN AMERICANS AND THE ACHIEVEMENT GAP: AN INTERFACE OF STIGMATIZING CONTEXT, REACTIVE COPING RESPONSES, AND THE "ACTING WHITE" MYTH

In their analysis and critique of the acting White myth, Spencer and Harpalani (under review) describe Fordham and Ogbu's (1986) position that one of the main reasons that Black students do so poorly in school is that "they experience inordinate ambivalence and affective dissonance in regard to academic efforts and success" (Fordham & Ogbu, 1986, p. 177). Fordham and Ogbu further state that the cultural orientation in the Black community is that learning is equated to "acting White." Although roundly critiqued by Bronfenbrenner (1985), their three-group classification describes "autonomous" minorities as those who are minorities primarily in the numerical sense, "immigrant" minorities as those who arrived voluntarily with hopes of improving their lives, and "castelike," or involuntary minorities (e.g., Blacks, Native Americans, and Chicanos) as those who came to America involuntarily through slavery or conquest (Fordham & Ogbu, 1986; Ogbu, 1986).

Focusing on the castelike group, specifically Blacks, they purport to examine the expressive dimension of the relationship between minorities and the dominant culture. In exploring the African American and European American relationship, they focus on twin phenomena: oppositional cultural identity and oppositional frame of reference (Ogbu, 1990). Their analysis concludes that African Americans develop a sense of identity in opposition to the social identity of Whites due to their treatment in both the political and economic domains. Fordham and Ogbu's (1986) analysis suggests that an oppositional frame of reference is used as a protective device as a strategy to promote Black identity and foster the maintenance of Black/White cultural boundaries, thus development of protective devices is aimed at promoting Black identity. They posit that the setting and maintenance of boundaries reinforces solidarity and unity, suggesting that slavery reinforced this tendency through the creation of traditions such as beliefs concerning duty-bound relationships that extended beyond family relations (e.g., fictive kin networks).

They suggest an emphasis on group loyalty in situations involving conflict and competition with the majority group. Fordham and Ogbu (1986) suggest that these ideas influence children's perception of their potential

for success (see also Fordham, 1988, 1996). As analyzed by Spencer, Cross, et al. (2003), Fordham and Ogbu's contention is that, accordingly, Black students, especially adolescents, attending both integrated and predominantly Black schools face the burden of acting White. This line of reasoning suggests that Black youths' academic prowess and success are controlled by external and within-group factors. Thus, according to Fordham and Ogbu, "Apparently, Black children's general perception that academic pursuit is 'acting White' is learned in the Black community. The ideology of the community in regard to the cultural meaning of schooling is, therefore, implicated and needs to be reexamined" (p. 203). Overall, Fordham and Ogbu conclude that Blacks have not historically valued education and define academic achievement as a White cultural attribute. There is major shortsightedness in the conceptualization of this work, which is consistent with the flaws noted initially concerning the need for new theory. The first flaw is the absence of historical accuracy.

Historical Overview of African American Achievement Motivation

It is commonly assumed that slavery made achievement motivation impossible. As described, critiqued, and analyzed by Spencer, Cross, et al. (2003), the view suggests that from slavery forward, Blacks struggled not only with external sources of oppression but also with the effects of slavery, such as family dysfunctionality, psychological hatred, high rates of criminality, and low achievement motivation: the pattern is inferred by some to indicate a "mark of oppression" (see Kardiner & Ovesey, 1951, as the classic illustration of the deficit assumption). However, historical evidence traces the evolution of Black achievement motivation. The record shows that from the end of slavery and well into the twentieth century, Blacks, as individuals and as a social group, evidenced high achievement motivation, and we are hard-pressed to think of any White ethnic group, including Eastern European Jews, who evidenced a higher regard for achievement motivation for the period from the end of the Civil War to the early 1930s. The insufficiency of efforts to translate such high achievement motivation into social mobility was not linked to the legacy of slavery but to the larger society's failure to cultivate, compliment, reinforce, and authenticate the numerous manifestations of Black achievement motivation.

At the start of the twentieth century, Carter G. Woodson was surprised at the copious evidence concerning Black education (Woodson, 1919) that resulted in his 454 page scholarly text. In thinking about freedom for slaves, in a theoretical sense, certain owners became curious as to whether emancipated Blacks could handle freedom and the level of education demanded by the status as a free person; consequently, certain individual slaves were turned into test cases. Bullock (1967) describes how John Chavis of North Carolina was selected as an experimental case and sent to Princeton. Chavis not only passed his tests with flying colors but also returned to North Carolina to become a leading teacher for the children of the planter class. Both Bullock (1967) and Woodson (1919) underscore that the atmosphere of the revolutionary period stimulated a certain degree of leniency concerning the formal education of Blacks, and the curiosities and whims of the planters resulted in highly educated slaves. A few became part of the popular culture of the times, including Phyllis Wheatley, the Black poet, and Benjamin Banneker, the Black mathematician and author of the first Farmer's Almanac ever written in the United States. It is during the revolutionary period that the manumission of individual slaves helped produce large clusters of free Blacks in Atlanta, Charleston, and other major cities across the South; and as these clusters of free Blacks formed communities, the development of formal educational structures became an immediate enterprise.

Another ripple effect was the birth of the abolitionist movement. White leaders of this movement took the likes of Frederick Douglass, assisted in his formal education, and turned him loose, as an icon for their movement. Beyond assisting individuals, the movement helped found colleges where scores of Blacks could obtain a higher education. For those Whites who could not fathom a nation that included Blacks, but whose moral compass required that Blacks be educated, manumitted, and, then, sent back to Africa (colonization), also created educational opportunities for Blacks, including the construction of schools.

Black Response to Freedom: A Social Movement for Education

As delineated by Spencer, Cross, et al. (2003) as a historical overview, the Black community enjoyed a critical mass of educated leaders, teachers, and potential educational administrators. Du Bois estimated that 150,000 of

the 4 million slaves were able to read and write, and literacy was commonplace among free Blacks (Du Bois, 1935; p. 638). Thus, the source of the social movement suggests ex-slaves themselves because they seemed to carry educational designs in their ragged pockets as they crossed over into freedom. After the Civil War, educated Blacks and their White allies were dumfounded and even mildly shocked at the level of educational demands the ex-slaves immediately made on themselves and their leaders (Anderson, 1988): "A teacher at Port Royal declared that he could not set forth, in anything like adequate terms, the eagerness and determination with which the Black freedmen apply themselves, young and old, to the task of learning the alphabet [Another teacher was greeted by] a motley assemblage [who were] cold, dirty and half naked but eager to learn; [she found them less concerned with food and clothing] but anxious to feel sure that they would have the privilege of coming to school everyday" (Butchart, 1980, p. 169). Available research reported by Spencer, Cross, et al. (2003) indicate that the hunger for education came not simply from the eyes of children as "many teachers conducted night school as well as day schools to accommodate the aspirations of [adult] workers" (Butchart, 1980; p. 170). In sum, the drive for Black education was organic: It came from the ex-slaves themselves.

Just after the Civil War, John W. Alvord was appointed the national superintendent of schools for the Freedman's Bureau, and in 1866 he reported that Black-controlled schools numbered 500 and were to be found all over the South. Just 3 years later, in 1869, Black schools, now often associated with evolving Black churches, totaled 1,512, with 6,146 teachers and 107,109 pupils. The demand for education and the desire to be taught by Black teachers quickly strained the teaching force that first greeted the ex-slaves and their children. To meet the demands being made by the ex-slaves, educated Blacks, Northern societies, and the federal government helped to launch such new entities as Howard University and other Black colleges (Anderson, 1988; Bullock, 1967; Du Bois, 1935). Spencer, Cross, et al. (2003) suggest that the drive toward Black education, after the Civil War, can only be given its due if framed as a social movement—not a trend, not a drift, and not a contrivance imposed by White allies from the North. While educated free Blacks and White allies where crucial elements, the sheer scope of the educational demands and depth of ex-slaves revealed a deep seated *achievement motivation* that had its origins in slavery itself. As Anderson noted, "[B]lacks emerged from slavery with a strong belief in the desirability of learning to read and write. This belief was expressed in the pride with which they talked of the other ex-slaves who learned to read or write in slavery and in the esteem in which they held literate Blacks. It was expressed in the intensity and frequency of their anger at slavery for keeping them illiterate" (Anderson, 1988; p. 5).

W. E. B. Du Bois noted that the ex-slaves' immediate drive for education was one of the most amazing stories in the annals of Western history and culture (Du Bois, 1935). Had this drive and achievement motivation been positively received, cultivated, protected, and sustained by the larger society, within 100 years Blacks would have outstripped the social mobility patterns of all groups in modern American society, including Eastern European Jews. As noted by Spencer, Cross, et al. (2003), one is hard-pressed to think of any White ethnic group who entered the United States at the turn of the twentieth century with a collective achievement motivation that could match that exhibited by the ex-slaves on the heels of the Civil War. They suggest that those who would try to draw a straight line connecting contemporary problems in Black education with the legacy of slavery, such as Fordham and Ogbu (1986), are ignorant of this resilient history.

Reconstruction did not bring the ex-slaves land redistribution, education, protection, liberty, the right to vote, or social justice. During the bleak period between 1900 to 1930, historians have recorded that Blacks would often double and triple tax themselves to build and sustain schools, despite not receiving a fair share of tax dollars already paid.

In effect, Black citizens of Mississippi, Georgia, North Carolina and South Carolina, and other southern states reached deep into their grinding poverty and found the wherewithal—the achievement motivation—which propelled them to support the education of their children. History does not support Fordham and Ogbu's (1986) contention that Black communities have not valued education and that this devaluation is a reaction to White racism. The assumptions of Fordham and Ogbu (1986) are woefully negligent of the resilience that many African Americans displayed in the face of virulent institutionalized oppression. Their shortsighted perspectives have contributed to what Claude Steele (2004) refers to as social and identity contingencies that

reinforce social stigma and dissonance in the individual-context match.

Developmental Considerations for Research on Black Academic Achievement

As analyzed by Spencer, Cross, et al. (2003), in addition to neglecting the resilient history of Black achievement motivation, the acting White myth also makes large conceptual errors in its analysis of racial identity and cultural influences on human development. For example, the acting White hypothesis can be criticized on several grounds. It draws psychological inferences from sociohistorical data (Trueba, 1988), neglects within-group variation, and fails to understand and capture the psychological and developmental processes that lead to academic achievement and other outcomes. As noted by Obidah (2001), Ogbu (1990) does not account for variation in the so-called involuntary or castelike minorities and fails to note that some members of the majority group demonstrate characteristics he associates with involuntary minorities (MacLeod, 1987). Further, when considering Bronfenbrenner's (1989) ecological systems theory, it is apparent that Ogbu (1987; Fordham & Ogbu, 1986) limits much of his analysis at the level of the macrosystem, narrowly focusing on the social and historical conditions impacting African American academic achievement. He neglects the micro- and mesosystems, thereby failing to understand how these larger conditions play out in everyday lives. The previous section that reviewed the history of Black achievement motivation illustrates well how Ogbu's macrolevel analysis falls short in its inferences about the attitudes and motivation of African Americans toward education.

Further, as reported by Spencer, Cross, et al. (2003), Ford, Harris, Webb, and Jones (1994) note that Fordham (1988) neglects the phenomenon of "code switching"—demonstrating different modes of cultural communication and style in different settings—and that Black students can become bicultural rather than "raceless" and maintain their ethnic identities. Bicultural identity is one of the different modes of the Internalization stage that Cross (1995) has described in his model. It also represents a particular emergent identity in the PVEST framework, one that is not represented in Fordham's (1988, 1996) or Fordham and Ogbu's (1986) work. Other coping options also sensitive to diverse youth more generally are described by Datnow and Cooper (1996), which illustrate adaptive coping in the school context and show how peers of the same race in different contexts interpret the same phenomena differently. As noted earlier, such within-group variation is also largely neglected by Fordham and Ogbu (1986).

In a study of 562 Black adolescents, aged 11 to 16 from a southeastern U.S. city, Spencer, Noll, Stolzfus, and Harpalani (2001) found that individuals with a Eurocentric orientation, as indicated by a high score in Cross's (1971, 1991) Pre-Encounter stage, exhibit lower academic achievement and lower self-esteem than those individuals who have a proactive Afrocentric orientation—the Internalization stage. While individuals with a reactive Afrocentric orientation (Immersion-Emersion stage) performed poorly, the study indicates that a strong, proactive sense of Black cultural identity is associated with positive academic achievement for Black youth. The study by Spencer et al. (2001) illustrates the importance of considering both adaptive and maladaptive coping outcomes and shows how Black racial identity can be related to both. It also contradicts the claims of Fordham and Ogbu (1986) and Fordham (1988, 1996), who contend that Blacks must distance themselves from Black culture to achieve. As reviewed by Spencer, Cross, et al. (2003), it is interesting to note that Fordham and Ogbu's (1986) paper was not the first academic article to use the phrase "acting White." The earliest reference we found was a 1970 article by McArdle and Young entitled "Classroom Discussion of Racial Identity or How Can We Make It Without 'Acting White?'" The very question posed by McArdle and Young (1970) implies that it is possible to make it without acting White, an idea denied by Fordham (1988) and Fordham and Ogbu (1986).

Adolescents of all ethnicities engage in identity searching and strive for acceptance and approval. Cross's (1971; Cross et al., 1991) Immersion-Emersion identity stage may be characterized by anti-White attitudes. While this can be maladaptive, it is not an abnormal initial reaction to devaluation, particularly at this salient developmental period. If Black youth perceive a classroom, school, or other setting as a context where they are devalued, they may cope by defining the expectations of this context as acting White. However, this is reflective of normative identity development processes rather than a cultural devaluation of education. As Spencer et al. (2001) note, "acting White has so many potential variations based on multiple contextual

realities" (p. 28). The acting White phenomenon is not responsible for Black academic underachievement, nor is it reflective of a broad cultural frame of reference, as Fordham and Ogbu (1986) suggest. It is simply one of many coping responses to feeling devalued. Curiously, and acknowledged by Ogbu (1985), when describing high academically performing, first-generation South Asian immigrants, this high achievement has never been described as acting White. As noted by Trueba (1988), culturally based assumptions that represent sociohistorical assumptions are at best troubling. At worst, they serve as an additional source of stress and challenge to Black academic achievement and youths' effectance motivation.

As reviewed by Harpalani and Spencer (2005), irrespective of whether racism functions as product of economic relations, sociological relations, or as a consequence of some configuration between the social and economic race is defined by Omi and Winant (2002) as a "concept which signifies and symbolizes social conflicts and interests by referring to different types of bodies" (p. 123). Stoler (2002) complicates this notion of race by contending that there is a historical divergence between racism as overt, biologically based, and psychologically based and the new racism as insidious, cultural, and complex. There is a historical divergence in capturing racism as a difference between the seen and the unseen, on noticeable differences or on more subtle cultural differences. The selection of biological traits and/or cultural qualities for classification is a social and historical process, not rooted as a biological given. Over time, different groups of individuals have moved in and out of racial categories as economic and social conditions have changed. Hence, one can locate a plurality of racisms constructed as a result of the complex relationship between specific social, cultural, and economic factors (Hall, 2002; Omi & Winant, 2002; Stoler, 2002). Omi and Winant (2002) characterize "racial formation" as the "sociohistorical process by which racial categories are created, inhabited, transformed and destroyed" (p. 124).

Another historical way of categorizing racisms is articulated by Omi and Winant (2002) who explain the ways in which definitions and understandings have become more complex only recently. They contend that racism, before the 1960s, was understood using a rather limited lens—expressed through interpersonal relations and extending from individual prejudices. During the 1960s, our understanding of racism expanded to explore broader forms of discrimination and the ways in which racism is institutionally sanctioned and produced through structural inequities.

Essed (2002) develops an understanding of racism that synthesizes the ways in which microaggression works in conjunction with and through systemic inequities. Essed defines "everyday racism" as:

> a process in which (1) socialized racist notions are integrated into meanings that make practices immediately definable and manageable, (2) practices with racist implications become in themselves familiar and repetitive, and (3) underlying racial and ethnic relations are actualized and reinforced through these routine or familiar practices in everyday situations. (p. 190)

Furthermore, everyday racism is not necessarily communicated through direct interactions with people of color. For example, journalists produce their everyday products that perpetuate racist discourse and policymakers produce programs that can inadvertently perpetuate inequities. Essed maintains that "when racist notions and actions infiltrate everyday life and become part of the reproduction of the system, the system reproduces everyday racism" (2002, p. 188). Hence, macro and micro forms of racism are extensions of one another as microaggressions while racists are not always founded by intentional prejudice.

Omi and Winant (2002) refer to a "common sense" understanding, which they contend is a normative system of ideas and practices—perpetuated through education, the media, policy, and so on. Similar to Essed's characterization of everyday racism, racial inequities are perpetuated through these commonsense ways of relating and being in such a way that they are more insidiously woven into the fabric of society rather than expressions of direct racial prejudice. However, the existence of this form of racism in society does not eliminate more direct forms of prejudice. Rather, Omi and Winant maintain that our understanding of racism has broadened such that we now understand it to exist in plural forms that function through diverse contexts and power dynamics.

It is through the development of this normative system that hegemony operates. Hegemony defines the ways in which relations of power frame the shape of racism. This form of racism, as discussed previously in this review, is related to the historical and temporal context. This context is also shaped through power relations, and the form of racial inequity is molded through the

ways in which hegemony functions through coercion and particularly, through consent. Omi and Winant (2002) argue that as racial rule transitions in many societies from dictatorship to democracy, rule is based more directly on processes of consent rather than coercion, and beliefs concerning racial superiority and inferiority are a part of the discourse.

Cornel West (2002) has sought to locate the foundation of the idea of Black racial inferiority in Western culture. His efforts include an attempt to characterize the genealogy of modern racism, looking specifically at the cultural discourse. He makes links between the discourse associated with modernity and the ways in which White supremacy became substantiated as a dominant discourse. West contends that modern discourse of the late-seventeenth and eighteenth centuries in Western Europe and during the Enlightenment was structured such that the discourse of Black beauty and intelligence as equivalent to White standards was silenced. The modernity discourse of science and rationality fostered the observation, comparison, ranking, and ordering of physical characteristics of human bodies. The intellectual ordering and co-option of classical norms of beauty and culture made the equality of Black beauty and intelligence not only unreasonable but also barbaric. West (2002) argues that White supremacy is connected not only to economic relations and psychological needs of the White ruling class but also to the ways in which discourse is structured. Only certain notions of race are conceivable based on the structuring of the dominant modern discourse.

Goldberg (2002) complicates West's analysis through linking historical conceptions of moral subjectivity, the creation of racial exclusion, and modernity. He maintains that only in the second half of the twentieth century has the concept of rights been claimed as "vested and borne by the subject" (p. 298). This conception of rights has fueled the critical attack on racial discourse. However, Goldberg cites MacIntyre's characterization of "rights as a moral fiction," which claims to rest justifications on objective notions of morality but in actuality the moral order is based on subjective standards that shift over time and space. Goldberg points out the subjectivity of the moral order and how historically, morality has been used in diverse ways to both justify and critique the racial order. Moral categories are derived from the social structure and moral construction discourages *certain racist expressions while failing to recognize and discourage other forms.* Goldberg (2002) contends: "The rights others as a matter of course enjoy are yet denied people of color because black, *Brown,* red and yellow subjectivities continue to be disvalued; and the devaluation of these subjectivities delimits at least the applicability of rights or restricts their scope of application that people of color might otherwise properly claim" (p. 299). Thus, the progressive subtlety and subjective character of racial beliefs and their impacts concerning perceived inferiority and superiority of particular societal members is not independent of developmental factors. According, as a final theme and as reviewed by Harpalani and Spencer (2005), when considered especially for children and adolescents, it is important to detail the impact of denied rights as subjectively experienced in the course of human development.

RACISM AND HUMAN DEVELOPMENT

As described elsewhere (see Harpalani & Spencer, 2005) and inferred from the integration and analysis presented, racism is an insidious and omnipresent phenomenon that is translated through multiple levels of social, cultural, and historical contexts and affects a large impact on human lives. The traditional definition of racism as simply discrimination based on race does not cover the vast range of ways in which this phenomenon is manifested. As experienced by youth, racism is signified not only by discriminatory behavior but also by structural relationships, political ideologies, and institutional practices, all of which are often viewed as normative components of our society and a critical aspect of every day life for all. These structural and ideological components are highly institutionalized, thus affecting individual experiences and life trajectories, not only by disadvantaging people of color but also by privileging White people. To help understand how racism operates, we integrate various theoretical traditions here, examining social, political, and cultural forces that shape history and society and the ways in which these forces impact individuals' identities and everyday lives.

Classical opinions about racism, while acknowledging its damaging impact, tended to view this phenomenon as a set of aberrant attitudes and behaviors resulting from mistaken beliefs or *mis*education. Newer theories have critiqued this approach and provided a broader, systemic delineation of racial hierarchy in

societies. To understand the salience of racism for human development and life-stage specific outcomes, it is first necessary to examine its broad, systemic character. However, a societal approach to racism by itself is not sufficient for developmental science; it is also necessary to examine the different ways that youth cope with experiences of racism that present many challenges for youth of color and unrecognized privileges for White youth. To accomplish this end, both sociological theories of racism and contextually sensitive frameworks for human development are useful, and these can be integrated to understand how systemic racism impacts the lives of youth.

Among the most widely cited works on the sociohistorical formation of racism is Omi and Winant's (1994) treatise, *Racial Formation in the United States.* This text outlines the various paradigms that sociologists in the twentieth century have employed to understand race and racism. The authors highlight the social construction of race: Racial groups do not reflect discrete biological categories, but are social and political divisions based on superficial physical features—divisions that are created primarily for the purpose of economic and political subordination (i.e., racism). Omi and Winant (1994) note that in sociological theorizing, analyses of race and racism have often been subsumed under other paradigms, including *ethnicity* (with an emphasis on culture and assimilation processes), *class* (with a Marxist orientation underscoring economic and labor divisions), and *nation* (with a focus on anti-colonial struggles and collective consciousness formed in response to these struggles). Omi and Winant's (1994) perspective centers on *racial formation,* which they define as, "the sociohistorical process by which racial categories are created, inhabited, transformed, and destroyed" (p. 55). Racial formation emphasizes the intersection of various influences in this process of racialization and recognizes racial formation as a phenomenon that occurs at multiple levels, with macrolevel structural manifestations that translate into individual everyday experiences at the microlevel. Omi and Winant (1994) discuss racial formation in terms of "historically situated, racial projects," which are posited interpretations and explanations of the racial dynamics in a society and serve to reallocate resources to various racial groups. Racism is constituted by those racial projects that "create or reproduce structures of domination based on essentialist categories of race" (p. 194).

Building on Omi and Winant's (1994) ideological notions of racial formation, Bonilla-Silva (2001) outlines a theory of racism that is both structural and process-oriented: the *racialized social systems* framework. In this framework, racialized social systems are societies that allocate material and social rewards differentially by race, and such societies develop a particular *racial structure:* the set of social relations, cultural practices, and tacit and explicit assumptions, based on physical distinctions that govern the social construction of racial groups in the society.

Inclusive theories of human development, in conjunction with systemic analyses of racism often found in CRT, can help elucidate how racism impacts developmental outcomes. For example, Bronfenbrenner's (1989) ecological systems theory provides an effective framework to analyze the role of social, cultural, and historical context in human development, and thus to illustrate the impact of racism at multiple levels. As reviewed by Harpalani and Spencer (2005), in its role as a process oriented theoretical tool, ecological systems theory offers mediating points between larger structural processes and the immediate settings where racism is encountered in everyday life. A final step for developmental scientists interested in the effects of racism is to employ an identity-focused, contextually sensitive, theory of human development that can illustrate how bias (e.g., racism) impacts experiences, coping, identity formation, and outcomes from a developmental perspective—through all stages of the life course. We posit that PVEST (Spencer, 1995) provides such a framework (see Figure 15.12).

As suggested, PVEST links context and experience with individual meaning-making and identity formation, all from the perspective of human development. While ecological systems theory provides a *means for describing hierarchical levels of context,* PVEST directly illustrates life-course human development as influenced by these multiple levels of context. PVEST serves as a model to examine normative developmental processes—framed through the interaction of identity, lived cultural experiences, and tangible manifestations of racism, including White privilege, for youth of all ethnicities. In doing so, it takes into account individual differences in experience, perception, and negotiations of stress and dissonance. PVEST demonstrates a recycling through the life span, as individuals encounter new risks and protective factors, experience new stressors (potentially

offset by supports), establish more expansive coping strategies, and redefine how they view themselves, which also impacts how others view them. Thus, as elaborated in Harpalani and Spencer (2005), PVEST is a temporally contingent model; it illustrates how outcomes in prior stages impact developmental challenges that individuals encounter and resolve in current situations. Many researchers have examined the relationship of systemic racism to outcomes; however, PVEST highlights the mediating processes between race, as a risk factor, and tangible outcomes. As suggested by Figure 15.20, essentially, it allows us to examine "how" different individuals cope with racism throughout their life-course development.

Future research on racism, along with social, political, and legal attempts to mitigate its impact, should take into account both the subtle, normative expressions of this phenomenon and the different levels at which it is manifested. Individual level interventions are necessary, but transformation of institutions and their practices will also be vital in the long run. The theories noted along with many others, afford varying insights on the nature of racism and its broad impacts on human lives. Developmental scientists have the option to draw on these frameworks in the production of better science, which allows all youth, regardless of race, to achieve their full potential.

In summary, it is apparent that the several themes pursued have important implications for the content of the invariable linear or deterministic thinking that continues to serve as shorthand analyses of youths' life-course coping efforts. Accordingly, it is obvious that context, cultural traditions and normative human developmental processes matter and interact while humans transition across time and place. Utilizing PVEST as an organizing framework, this final section provides helpful heuristic devices for inferring more sensitive and valid conclusions about expected outcomes. The strategy should diminish the dissemination of stigma and stereotypes in the conduct of developmental science: Interpretive frameworks representing models, which afford best inferences concerning *both dual* aspects *implicit in* youths' Net Vulnerability (i.e., levels of risks ***and*** protective factors)—*given the experience of net stress and coping processes*—that may be anticipated for a particular *stage-specific coping outcomes* (i.e., unproductive versus productive options).

CONCLUSIONS AND PHENOMENOLOGICAL VARIANT OF ECOLOGICAL SYSTEMS THEORY INFLUENCED INTERPRETATIONS OF YOUTHS' STAGE-SPECIFIC COPING OUTCOMES AS A FUNCTION OF NET VULNERABILITY

One major certainty to be concluded from the multidisciplinary literatures integrated and analyses provided in demonstrating the benefits of PVEST is that any *inclusive theory of human development* should bear a particular burden. Specifically, *not only* should the framework acknowledge and incorporate the major objectively identifiable expressions of human variation (e.g., race, gender, and unique life-course placement—an infant versus an elder) that may differentially interface with context, *but also* provide an adequate explanation of the "how" of human development processes that leads to the "what" or particularly patterned outcomes (see Figure 15.20).

The uniquely structured and experienced processes of human development are inextricably linked to the tensions produced between nuanced developmental tasks pursued by the individual given context character and influences of the psychohistorical moment, along with expectations for competence. However, unavoidable tensions are also produced as a function of children's characteristics such as group membership and context quality; although infrequently noted, the latter continues to be linked to structural conditions associated with race, racism, and White privilege. As indicated in the synthesis statement, this unchanging dilemma is overlooked in the child psychology literature except for a priori assumptions of deviance, psychopathology, or problems associated with youth of color. Further, this situation, experienced as stigmatization, is linked to historical conditions and includes their perpetuation as values, beliefs, attitudes, contextual inequalities, and psychosocial experiences. Considered together, they serve neither to perpetuate risks nor to promulgate protective factors as net stress is experienced, reactive coping responses evoked, and emergent identities enacted. Thus, recursively structured, they become associated with particular stage-specific outcomes as young lives unfold given particular cultural traditions. Accordingly, our introduction of PVEST as an ICE perspective suggests that the unfolding coping processes and consequent coping products experienced at one stage serves as the

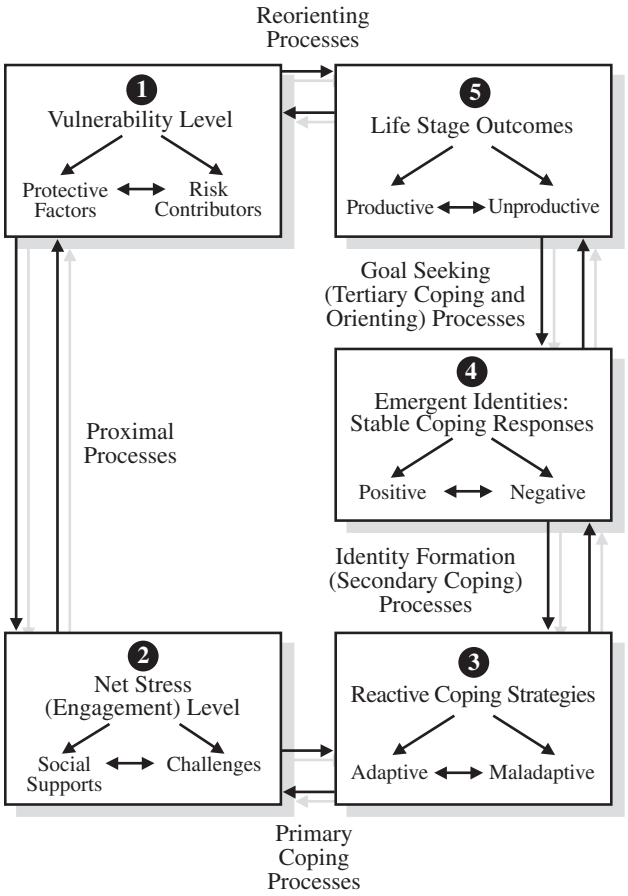

Figure 15.20 Processes Emphasizing Phenomenological Variant of Ecological Systems Theory (PVEST). *Source:* From Spencer & Harpalani, 2004.

major source of the individual's net vulnerability at the next stage given the ongoing experiences of individual-context interface. Thus, as a dynamic recursive theoretical framework, PVEST moves beyond narrow deterministic perspectives of human development.

Conceptual Advantages of Phenomenological Variant of Ecological Systems Theory as a Dual Axis Coping Outcome Interpretational Framework of Human Development: Traditional and Limited Dual Axis Perspectives

As illustrated in Figure 15.21, in general, traditional and limited views of human development may consider risk level and protective factor intensity for understanding human vulnerability. However, the approach is still generally underdeveloped when considering the experiences of diverse youth of color.

As suggested by the literatures reviewed and synthesized, high risk assessments without the consideration of available protective factors have generally represented the analyses of youth of color. At the same time, unacknowledged White privileging views about European Americans are generally not associated with estimates of vulnerability (i.e., only protective factors such as social class are considered). As suggested and more problematic, the high performance often associated with middle-income European Americans is assumed to be the expected norm for all youth; outliers are considered deviant or atypical. As illustrated, two groups are usually compared when conducting research with diverse youth; middle-income Whites are invariably compared with a group or groups of low-resource marginalized group youth. This lack of equivalent sample comparisons, as described in an early section of the paper, remains a significant problem in the developmental literature on child development. However, as illustrated in Figure 15.21 and when compared against Figure 15.22, there remain conceptual shortcomings and simplistic assumptions when dual analyses of vulnerability are provided.

As suggested, as a dual axis model of vulnerability, too frequently Quadrant I is assumed to be poor and mi-

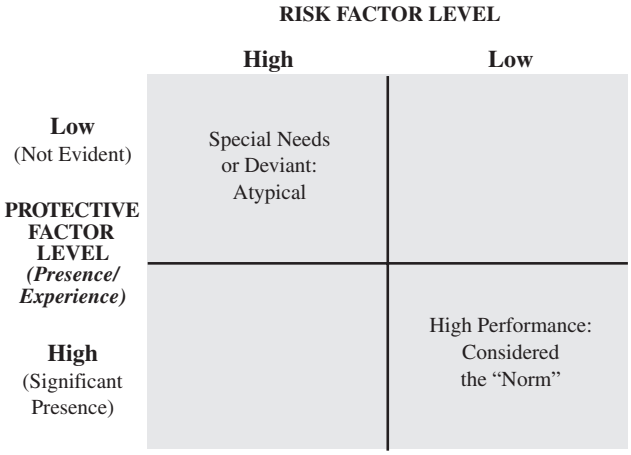

Figure 15.21 Traditional and limiting dual axis Perspective: This view narrowly compares extremes. *Source:* From "What Does 'Acting White' Actually Mean?: Racial Identity, Adolescent Development, and Academic Achievement among African American Youth," by M. nority, on the one hand, and Quadrant IV is assumed to be youth of middle-income and nonminority (or model minority) status; on the other hand. Quadrant II is generally ignored in the literature except for recent efforts by Luthar (2003) with extremely affluent suburban European Americans. Alternatively, when considering Quadrant III, the major publication patterns in child psychology have overwhelmingly ignored this high risk and high protective factor level group or assumed that it does not exist. There are a few theorists that explore protective factors such as parental monitoring, cultural socialization, specific achievement enhancing programming, and reference group identity as protective factors (e.g., Spencer, 1983; Spencer, Fegley, & Harpalani, 2003; Spencer, Noll, et al., 2001; Swanson et al., 2002; Youngblood & Spencer, 2002). When considered together, it appears that as a specific outcome oriented perspective of the PVEST framework, Figure 15.23 provides important implications for interpreting resiliency particularly as conceptualized by Anthony (1987).

Predicting Positive Outcomes in the Face of Challenge

One of the many strengths of James Anthony's (1974) formulation of resiliency is its acknowledgment of the simultaneous interfacing of protective factors with risk. He defines resiliency as the attainment of positive outcomes in the face of risk. Inferred from his definition is that one can only be resilient given the presence of high risk and its net-balancing with protective factors. Thus, as described in Figure 15.23, lacking a high level of protective factors, Quadrant I youth can be labeled highly vulnerable; however, Quadrant II youth are low on risk factor level although generally lacking high levels of protective factors; accordingly, Figure 15.23 describes them as lacking in significant symptomatology but show overall "masked vulnerability."

As indicated, Quadrant IV youth are generally those who have high levels of protective factors and low or no discernible risks; problematically, they are often used as the standard or norm for all; however, as indicated, they are described as "untested" or actually possessing "undetermined vulnerability" as depicted in Figure 15.23 as the PVEST-linked vulnerability level and resiliency prediction dual axis coping outcome model. Considered carefully from the theoretical perspective of James Anthony, as a major contributor to the PVEST framework, "resiliency" can only be expected for Quadrant III Group because, as defined by Anthony, resiliency is associated with those experiencing significant levels of risk but concomitantly have access to high levels of protective factors. As indicated, we believe that this dual axis model provides a clarifying heuristic device for understanding levels of vulnerability and resiliency prediction estimates without engaging in unfair and stigmatizing analyses.

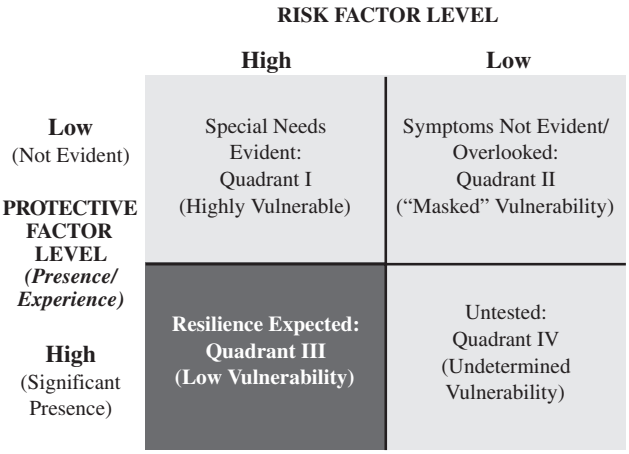

Figure 15.23 PVEST-linked vulnerability level and resiliency predicting dual axis coping outcome model. *Source:* Adapted from "Introduction: The Syndrome of the Psychologically Vulnerable Child" (pp. 3–10), by E. J. Anthony, in *The Child in His Family: Children at Psychiatric Risk,* E. J. Anthony and C. Koupernik (Eds.), 1974, New York: Wiley.

Unfortunately, this is not the orientation of most theories of human development that consider the experiences of diverse youth. Importantly, PVEST is not only applicable to identifiable diverse young people and sensitive to their unique cultural and contextual niches but also serves as a broad life-course theory of human development, which analyzes the systemic relationships between vulnerability, stress level, coping processes (i.e., reactive, stable coping as emergent identities), and stage-specific coping outcomes as lives unfolds across the life course irrespective of group membership (including privilege) and its socially structured social standing.

In sum, considered together, PVEST and its dual axis coping outcome model of human development provide conceptual tools and heuristic devices for accounting for the diverse expressions of human development in cultural context.

CHAPTER 16

Positive Youth Development: Theory, Research, and Applications

PETER L. BENSON, PETER C. SCALES, STEPHEN F. HAMILTON, and ARTURO SESMA JR.

Positive youth development is simultaneously a field of research and an arena of practice. Linked more by shared ideals than by formal membership or credentials, positive youth development includes a growing number of programs, agencies, foundations, federal grant programs, policy initiatives, researchers, and youth-serving professionals committed to promoting competent, healthy, and successful youth. Collectively, they have generated ideas, data, and resources. At the same time, they have unleashed a wave of energy and action not unlike that of a social movement, with a multitude of community actors connecting to a broad set of principles, concepts, and strategies for increasing youth access to the kinds of relationships, programs, settings, and activities known (or assumed) to promote healthy development.

Positive youth development is an umbrella term that covers many streams of work. It is variously a field of interdisciplinary research, a policy approach, a philosophy, an academic major, a program description, and a professional identity (e.g., youth development worker). The "idea" of positive youth development reaches into a number of fields, including child and adolescent developmental psychology, public health, health promotion, prevention, sociology, social work, medicine, and education. Within the past few years, positive youth development has been a focal topic in a wide range of scholarly journals, including *The Annals of the American Academy of Political and Social Science* (January, 2004), *Prevention and Treatment* (June, 2002), *The Prevention Researcher* (April, 2004), and the *American Journal of Health Behavior* (July, 2003). Two established research journals, *Applied Developmental Science* and *New Directions in Youth Development,* help to ground the field.

Undergirding positive youth development is an important and growing line of scientific inquiry, including theory, research, and a set of conceptual models and frameworks that both guide and emerge from the

The writing of this chapter was supported by a grant to Search Institute from The Lilly Endowment.

research. This chapter: (a) defines the concept of positive youth development; (b) presents a broad theory of this sphere of human development; (c) examines empirical support for a series of theory-driven hypotheses; and (d) proposes implications for theory reformulation, future research, and applications.

DEFINING POSITIVE YOUTH DEVELOPMENT

As noted, the field of positive youth development encompasses a vast territory of disciplines, concepts, and strategies. One recent review of positive youth development (Benson & Pittman, 2001a) suggests four distinguishing features of this field. It is *comprehensive* in its scope, linking a variety of: (1) ecological contexts (e.g., relationships, programs, families, schools, neighborhoods, congregations, communities) to (2) the production of experiences, supports, and opportunities known to (3) enhance positive developmental outcomes. Its primary organizing principle is *promotion* (of youth access to positive experiences, resources and opportunities, and of developmental outcomes useful to both self and society). It is, as the term implies, *developmental,* with emphasis on growth and an increasing recognition that youth can (and should be) deliberate actors in the production of positive development. And it is *symbiotic,* drawing into its orbit ideas, strategies, and practices from many lines of inquiry (e.g., resiliency, prevention, public health, community organizing, developmental psychology).

Damon (2004; Damon & Gregory, 2003) argues that positive youth development represents a sea change in psychological theory and research, with observable consequences for a variety of fields including education and social policy. Three central themes are noted here. In Damon's view, positive youth development takes a strength-based approach to defining and understanding the developmental process. More precisely, it "emphasizes the manifest potentialities rather than the supposed incapacities of young people . . ." (2004, p. 15). There is more to this statement than initially meets the eye. It connotes a significant critique of mainstream psychological inquiry that is quite ubiquitous in the positive youth development literature. This critique is that understandings of child and adolescent development have been so dominated by the exploration and remediation of pathology and deficit that we have an incomplete—if not distorted—view of how organisms develop. This ongoing debate is addressed in more detail in the next section.

Second, Damon, like many other positive youth development advocates, holds up the centrality of community as both an incubator of positive development as well as a multifaceted setting in which young people can exercise agency and inform the settings, places, people, and policies that in turn impact their development. Finally, Damon notes that positive youth development, in its efforts to identify the positive attitudes and competencies that energize healthy developmental trajectories, is not afraid to identify values, moral perspectives, and religious worldviews as constructive developmental resources even though this "flies in the face of our predominantly secular social-science traditions" (2004, p. 21).

Several other accents or themes are increasingly prominent in the youth development literature. Two are particularly germane for positioning this field in intellectual and scientific space. A number of scholars argue that the definition of developmental success most deeply entrenched in public policy and practice conceives of health as the absence of disease or pathology. In recent decades, the dominant framework driving federal, state, and local interventions with youth has been that of risk behaviors, including alcohol use, tobacco use, other drug use, nonmarital pregnancy, suicide, antisocial behavior, violence, and school drop out (Benson, 1997; Hein, 2003; National Research Council & Institute of Medicine [NRCIM], 2002; Takanishi, 1993). While positive youth development advocates readily accept that reductions in these health-compromising behaviors are important markers of developmental success, there is simultaneously a growing interest in defining "the other side of the coin"—that is, the attributes, skills, competencies, and potentials needed to succeed in the spheres of work, family, and civic life. This dichotomy is well captured in the youth development mantra "problem free" is not fully prepared (Pittman & Fleming, 1991). Accordingly, an important aspect of current positive youth development science is the conceptualization and measurement of dimensions of positive developmental success. Among these areas of work are efforts to define indicators of child well-being (Moore, 1997; Moore, Lippman, & Brown, 2004), thriving (Benson, 2003a; Lerner, 2004; Lerner et al., in press; Scales & Benson, 2004; Theokas et al., 2004), and flourishing (Keyes,

2003). Within this inquiry on positive markers of success, an emerging issue has to do with expanding the conceptualization of developmental success to include not only what promotes individual well-being but also what promotes the social good (Benson & Leffert, 2001; Benson, Mannes, Pittman, & Ferber, 2004; Damon, 1997; Lerner, 2004).

In turn, this interest in positive indicators covaries with an emerging accent on reconceptualizing the population target for improving the lives of children and youth. This is the debate about "at-risk youth" versus "all youth." In the early stages of the term's emergence, positive youth development tended to be positioned as a strategy—complementary to reducing risks—for preventing high-risk behaviors, particularly among that subset of youth particularly susceptible to the potential harm of poverty and dysfunctional families and/or communities. As work moves forward to expand the notions of health, well-being, and developmental success, and as these ideas merge with historical and sociological insights about pervasive societal changes, the positive youth development field increasingly calls for strategic national and community investments to strengthen the developmental landscape more generally (Bumbarger & Greenberg, 2002; Lerner, 2000; Lorion & Sokoloff, 2003). Ultimately, we might characterize this issue as whether the national priority should be to promote "good enough" development or to promote optimal development. In more poetic language, Lorion and Sokoloff (2003) offer that this choice is between "fixing" troubled youth and the view that "all soil can be enriched and all moisture and sunlight maximally used to nourish all flowers" (p. 137).

Several attempts have been made to articulate the core concepts and principles in the positive youth development field (Benson & Pittman, 2001a, 2001b; Catalano, Berglund, Ryan, Lonczak, & Hawkins, 1999; Hamilton, Hamilton, & Pittman, 2004; NRCIM, 2002). A synthesis of these reviews suggests considerable consensus on these six principles:

1. All youth have the inherent capacity for positive growth and development.
2. A positive developmental trajectory is enabled when youth are embedded in relationships, contexts, and ecologies that nurture their development.
3. The promotion of positive development is further enabled when youth participate in multiple, nutrient-rich relationships, contexts, and ecologies.
4. All youth benefit from these relationships, contexts, and ecologies. Support, empowerment, and engagement are, for example, important developmental assets for all youth, generalizing across race, ethnicity, gender, and family income. However, the strategies and tactics for promoting these developmental assets can vary considerably as a function of social location.
5. Community is a viable and critical "delivery system" for positive youth development.
6. Youth are major actors in their own development and are significant (and underutilized) resources for creating the kinds of relationships, contexts, ecologies, and communities that enable positive youth development.

There are many published definitions of positive youth development. Indeed, most reviewers of the literature and many authors of positive youth development research articles generate new definitions. This proliferation of many definitions—as well as concomitant lack of consensus on a particular definition—reflects both the relative newness of the field as well as its profoundly interdisciplinary nature. Each definition focuses on some combination (and the interactions among them) of the core constructs displayed in Figure 16.1.

Figure 16.1 suggests that the core ideas in positive youth development include (A) developmental contexts (i.e., places, settings, ecologies, and relationships with the potential to generate supports, opportunities, and resources); (B) the nature of the child with accents on inherent capacity to grow and thrive (and actively engage with supportive contexts); (C) developmental strengths (attributes of the person, including skills, competencies, values, and dispositions important for successful engagement in the world); and two complimentary conceptualizations of developmental success; (D) the reduction of high-risk behavior; and (E) the promotion of thriving. The bidirectional arrows intend to convey the dynamic nature of person-ecology interactions prominent in recent expositions of positive youth development (Lerner, 2003, 2004).

We know of no definition that encompasses all of this conceptual territory. But the fullness of these constructs is evident when integrating a representative sample of published definitions. Several accent the nature of the child (B). Damon (2004), for example, offers that "the positive youth development perspective emphasizes the manifest potentialities rather than the supposed incapacities of young people—including young people from the most disadvantaged backgrounds and those with the most troubled histories" (p. 17).

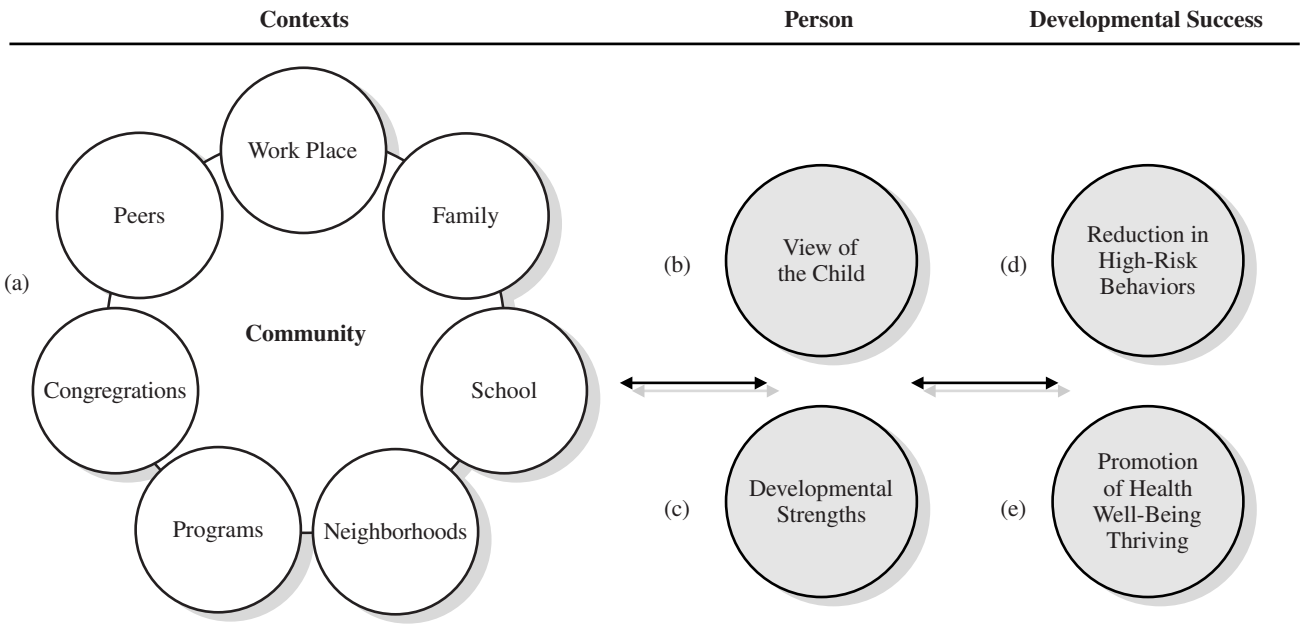

Figure 16.1 Core positive youth development constructs.

Hamilton (1999; Hamilton et al., 2004) noted that the term has been used in three ways. His first definition reflects, like Damon, an articulation of the nature of the child (B in Figure 16.1): "youth development has traditionally been and is still most widely used to mean a natural process: the growing capacity of a young person to understand and act on the environment" (Hamilton et al., 2004, p. 3). His second definition picks up the role of contexts (A in Figure 16.1) in the development of strengths (C): "in the 1990s the term youth development came to be applied to a set of principles, a philosophy or approach emphasizing active support for the growing capacity of young people by individuals, organizations and institutions, especially at the community level" (Hamilton et al., 2004, p. 4). Finally, youth development also refers to a "planned set of practices, or activities, that foster the developmental process in young people" (Hamilton et al., 2004, p. 4). These practices occur within the context portion (A) of Figure 16.1 and can be delivered via programs, organizations, or community initiatives.

Catalano et al. (1999, 2004) conducted a major review of the positive youth development field with support from the National Institute of Child Health and Human Development (NICHD). Among its purposes were to "research and establish both theoretical and empirical definitions of positive youth development" (Catalano et al., 1999, p. ii). Arguing that no comprehensive definition of the term could be found, they created a definition that named the objectives of positive youth development approaches. Hence, positive youth development seeks to promote one or more of the following: bonding, resilience, social competence, emotional competence, cognitive competence, behavioral competence, moral competence, self-determination, spirituality, self-efficacy, positive identity, belief in the future, recognition for positive behavior, opportunities for prosocial involvement, and prosocial norms. This definition, then, focuses on describing the territories of (C) developmental strengths and (E) well-being in Figure 16.1.

In 2002, the National Research Council and Institute of Medicine released the influential report, *Community Programs to Promote Youth Development* (NRCIM, 2002). Though this report did not offer a clear definition of the term, its focus was on defining (and advocating for) two of the constructs in Figure 16.1: "the personal and social assets" young people need "to function well during adolescence and adulthood" (p. 3) and the features of positive developmental settings. These two represent constructs C and A in Figure 16.1.

Larson (2000) contrasts positive youth development with developmental psychopathology and suggests the former is about "how things go right" while the latter focuses on "how things go wrong." Hence, his focus is on positive youth development as a line of inquiry regarding "the pathways whereby children and adolescents become motivated, directed, socially competent,

compassionate and psycholocally vigorous adults" (p. 170). The pathways organically link contexts (A), developmental strengths (C) and developmental success (D and E). In a similar vein, Lerner's definition (Lerner, Fisher, & Weinberg, 2000) contrasts pathology—reducing and asset-building approaches. "Preventing the actualization of youth risk behaviors is not the same thing as taking actions to promote positive youth development (e.g., the inculcation of attributes such as caring/compassion, competence, character, connection, and confidence). Similarly, programs and policies that prevent youth problems do not necessarily prepare youth to contribute to civil society" (p. 12).

Some recent definitions place additional accent on the processes and dynamics of designing and mobilizing developmental contexts (A in Figure 16.1) to enhance C, D, E, and their intersection. Benson and Saito (2001), for example, suggested that "youth development mobilizes programs, organizations, systems and communities to build developmental strengths in order to promote health and well-being" (p. 144). Finally, Small and Memmo (2004) identify a variant on positive youth development that places an important accent on mobilizing youth to shape their contexts and communities. Called Community Youth Development (Hughes & Curnan, 2000; Perkins, Borden, & Villarruel, 2001; Perkins, Borden, Keith, Hoppe-Rooney, & Villarruel, 2003), this approach takes seriously the bidirectional arrow in Figure 16.1 connecting A with B and C. As we will see in the section on the theory of youth development, this bidirectionality is a central feature of developmental systems theory and in particular, Lerner's application of this theory to positive youth development (Lerner, 2003, 2004; Lerner, Brentano, Dowling, & Anderson, 2002).

POSITIVE YOUTH DEVELOPMENT IN HISTORICAL AND SOCIAL CONTEXT

Early uses of the term *youth development* can be found in the literature on juvenile delinquency. In 1947, the Texas State Development Council was formed following a report from a blue-ribbon commission charging that the state-run schools for delinquent children were failing. Embedded in the report was the suggestion that the causes of delinquency included environmental factors with the implication that well-entrenched models of changing behavior by "fixing the child" were insufficient. This new understanding of the contextual backdrop to individual development gained further momentum in a series of monographs from the University of Chicago's experimental Community Youth Development Program, an initiative designed to identify and organize community resources to better serve youth with "special problems" or "special abilities" (Havighurst, 1953).

Federal agencies dealing with juvenile delinquency expanded on their earlier efforts and took another important conceptual step. In 1970, the Youth Development and Delinquency Prevention Administration (housed in what was then the Department of Health, Education, and Welfare) developed a delinquency prevention program based on what keeps "good kids on track" rather than the more prevalent question of the day ("why do kids get into trouble?"; West, 1974). The federal answer to the question of why some youth succeed had four components: a sense of competence, a sense of usefulness, a sense of belonging, and a sense of power (U.S. Department of Health and Human Services Administration for Children and Families, 1996, p. 4).

In these state and federal approaches to addressing "troubled and troubling youth," we see the early signs of two cornerstones of contemporary youth development approaches: the primacy of context for shaping development and development understood in terms of strength rather than deficit. Though such ideas hardly seem like intellectual advances now, it is important to note how these ideas came to challenge historical and deeply entrenched therapeutic models.

Subsequently, a number of prominent foundations entered the picture. In addition to major youth development grant programs at the Kellogg Foundation, the Lilly Endowment, and the Kauffman Foundation, the Carnegie Corporation of New York and the William T. Grant Foundation sponsored and broadly disseminated pivotal reports on the developmental trajectories of American youth. Moving beyond the question of how society best deals with its so-called "at-risk youth," these influential reports began to document more persistent and pervasive issues about health and well-being of American youth. To some extent, the reports expanded the need for enhancing developmental supports and opportunities to include most young people.

In 1985, the Carnegie Corporation launched the Carnegie Council on Adolescent Development. The concluding report, *Great Transitions: Preparing Adolescents for a New Century,* sought to focus the national spotlight on adolescence (Carnegie Council on Adolescent Development, 1995). The report, like many before it, lamented not only the high rates of high risk behaviors (e.g., alcohol use, illicit drug use, teen pregnancy)

and exposure to developmental threats (e.g., physical and sexual abuse) among adolescents, but the emergence of alarming rates for these phenomena among 10- to 15-year-olds. Unlike other reports on the health of youth, however, the Carnegie Council proposed solutions based less on services to and treatment of youth and more on altering the formative contexts of families, schools, community organizations, and the media. Among key recommendations were reengaging families with their adolescent children, designing developmentally attentive schools, and transforming the media into a socially constructive resource. And in a reaffirmation of the Carnegie Council's early report, *A Matter of Time: Risk and Opportunity in the Non School Hours* (Carnegie Corporation of New York, 1992), this 1995 report called for community investment in and expansion of "safe, growth-promoting settings during the high-risk, after school time when parents are often not able to supervise their children and adolescents" (Hamburg & Takanishi, 1996, p. 387).

Several years earlier, the William T. Grant Foundation released *The Forgotten Half: Pathways to Success for America's Youth and Young Families* (1988). Its focus was on ages 16 to 24 and the transition from adolescence to adulthood. In its words, "half of our youth are in danger of being caught in a massive bind that can deny them full participation in our society and the full benefit of their own talents" (p. 1). Like the Carnegie Council report, *The Forgotten Half* focused its recommendations on changing community and societal contexts. Among its specific recommendations: closer adult-youth relationships, opportunities to participate in the life of community in activities valued by adults (including community service), and quality work experiences that provide skill-building pathways to sustainable work.

In combination, these two highly visible reports challenged the common assumption that the "youth problem" was confined to a small percentage of youth needing special and targeted services to redeem them. Instead, portraits of youth emerge which suggested that the developmental journey was fragile for a much larger percentage of youth. And both reports made bold calls for systemic change in how communities and their socialization systems connect with young people.

By the 1990s, three ideas generally important in the youth development field were gaining momentum. These are: identifying positive, developmental "building blocks" which help youth stay on a successful developmental trajectory; attributing causality for "youth problems" more to environments and contexts than youth themselves, with a concomitant call for reforming and/or transforming contexts; and mainstreaming the need for change (i.e., the percentage of youth needing change goes far beyond the notion of "at-risk" youth). A corollary to these three strands is the oft-repeated idea that youth are resources to be utilized rather than problems to be fixed.

Several additional events have added direction and momentum to the positive youth development movement. The first was a symbolic and galvanizing historical moment—the gathering of five living U.S. presidents (Carter, G. H. W. Bush, Clinton, Ford, and Reagan, represented by Nancy Reagan) with hundreds of influential delegates—for the President's Summit on Youth in Philadelphia. This April, 1997 event offered an accessible language of positive development—and a passionate call to action—around five fundamental development resources (or promises). These were: caring adults, safe places and structured activities, community service, education for marketable skills, and a healthy start. This 1997 event became institutionalized with the formation of America's Promise, a not-for-profit community mobilization organization initially led by (Ret.) General Colin Powell.

While this and other mobilization efforts gave impetus to the principles of positive youth development, a series of publications gave greater intellectual and scientific attention to the youth development idea. In 1998, the Youth Development Directions Project (YDDP) was conceived by the Youth Development Funders Group at a meeting held at the Ewing Marian Kauffman Foundation in Kansas City. The purpose was to take stock of the youth development field and lay out suggested direction for strengthening science, practice and policy. A number of organizations, including the Academy for Educational Development (Center for Youth Development and Research), Chapin Hall Center for Children at the University of Chicago, The Forum for Youth Investment at the International Youth Foundation, Public/Private Ventures, and Search Institute participated in a 2-year learning and writing project, culminating in one of the first efforts to capture the breadth and status of the field (Benson & Pittman, 2001b; Public/Private Ventures, 2000).

Moreover, as already noted, influential federal reports had reviewed the field of positive youth development. Both focused on the slice of youth development having to do with the creation of developmentally attentive programs. One, initiated by the Board on Children,

Youth and Families of the National Research Council, created a Committee on Community-Level Programs for Youth that evaluated and synthesized the science of adolescent development with research on the quality and efficiency of community programs designed to promote healthy development, and resulted in the influential report, *Community Programs to Promote Youth Development* (NRCIM, 2002). The second was the comprehensive review of positive youth development programs evaluations commissioned by the National Institute for Child Health and Human Development (Catalano et al., 1999).

The rise of positive youth development as a field of science and practice has been fueled by two types of social analysis. The first documents a series of pervasive societal changes that inform and shape the processes of child and adolescent socialization. It is common in published treatises on positive youth development strategies to pinpoint the role of rapid social change in altering youth access to developmental resources. In this extensive literature, social changes hypothesized to undermine the capacity of family and community to generate developmental resources include: increasing parental absence as a result of changes in the nature of work and the dramatic increase in out-of home employment of mothers; the rise of civic disengagement; the loss of shared ideals about the goals of development; the growing privatization of recreation; increases in age segregation; the decrease in neighborhood cohesion; teenagers' disconnection from structured programming; the prevalence of negative stereotypes about youth; and the explosion in media access by youth (see, e.g., Benson, 1997; Benson, Leffert, Scales, & Blyth, 1998; Damon, 1997; Dryfoos, 1990; Furstenberg, 2000; Garbarino, 1995; Lerner, 1995; Mortimer & Larson, 2002; Scales, 1991, 2001). In a particularly cogent analysis of these trends, Bronfenbrenner and Morris (1998) offered this summary:

> The research findings presented here reveal growing chaos in the lives of families, in child care settings, schools, peer groups, youth programs, neighborhoods, workplaces, and other everyday environments in which human beings live their lives. Such chaos, in turn, interrupts and undermines the formation and stability of relationships and activities that are necessary for psychological growth. (p. 1022)

The second social analysis common in the youth development literature is a critique of deficit models prominent in the service professions, policy, and research. Indeed, it is a somewhat common refrain that models focused primarily on reducing risk behaviors, for example, are inadequate both theoretically and strategically. Furthermore, models driven by risk, deficit, and pathology may unintentionally become part of the problem (e.g., by negatively labeling youth and/or fueling unfavorable stereotypes of youth). These ideas have been discussed in a wide range of positive youth development publications (Catalano et al., 1999; Lerner, 2004; Pittman, Irby, & Ferber, 2001; Roth & Brooks-Gunn, 2000; Villarruel, Perkins, Borden, & Keith, 2003). In one particularly important analysis, Larson (2000) suggests that developmental psychology has spawned a much stronger tradition for understanding and treating psychopathology than for understanding and promoting pathways to developmental success. In this regard, positive youth development advocates are sympathetic to positive psychology's critique of the dominance of pathology-oriented research and practice within mainstream psychology (Seligman & Csikszentmihalyi, 2000).

The premise that positive youth development represents a categorically different approach than so-called deficit, pathology, and risk models deserves deeper exploration. There is consensus that adolescent psychology, and applied youth areas have been dominated, in recent decades, by explorations of "youth problems." The social historian, Francis Fukuyama (1999), attributes this, in part, to a logical outgrowth of rapid social change. When social institutions become less stable—as in the United States beginning in the 1960s—governments, he noted, inevitably begin to create and measure indicators of social upheaval, and craft policy and programs to minimize social and personal problems assumed to emerge from social change (e.g., violence, alcohol, and other drug use).

Sociologist Frank Furstenberg (2000; Furstenberg, Modell, & Herschberg, 1976), argues that adolescence becomes culturally defined as a lifestage when schooling replaces work as the major activity during youth. This, he suggests, occurred in the United States near the middle of the twentieth century. The advent of full-time education "establishes a youth-based social world that is age segregated, partially buffered from adult control, and relatively turned in on itself" (2000, p. 897). Not surprisingly, societies interpret the consequences of this upheaval in terms of "youth problems." Consequently, and in line with Fukuyama's analysis, cultural authorities focus major attention on behaviors and styles that contradict established social norms. And not surpris-

ingly, social scientific studies of youth follow suit, with a disproportionate focus on problem behaviors (Dryfoos, 1998; Larson, 2000; Roth & Brooks-Gunn, 2000; Steinberg & Lerner, 2004). This dominating theme in youth research likely reflects the dual consequence of the cultural zeitgeist and the longer term hospitality in mainline psychology to the study of pathology (Larson, 2000; Moore et al., 2004; Peterson, 2004). Furstenberg (2000) provided a cogent description of the implications of these social and scientific trends for the broader public perception of youth:

> Such an approach inevitably treats successful adolescents and young adults as escape artists who manage to dodge the hazards of growing up, rather than focusing on the ways that young people acquire and master skills, construct positive identities, and learn how to negotiate social roles simultaneously in the youth culture and adult world. (p. 900)

At first glance, it would appear that positive youth development represents a theoretical, research and practice "paradigm shift" from the prevention field—a multidisciplinary area of inquiry, programming, policy, and practice with a substantial American history (Wandersman & Florin, 2003; Weissberg, Kumpfer, & Seligman, 2003). However, a considerable debate is underway about the conceptual overlap between prevention and positive youth development (Benson et al., 2004; Bumbarger & Greenberg, 2002; Catalano & Hawkins, 2002; Roth & Brooks-Gunn, 2003; Sesma, Mannes, & Scales, in press; Small & Memmo, 2004).

Prevention and prevention science are deeply rooted in public health and epidemiological approaches to disease prevention (Bloom, 1996; Small & Memmo, 2004), with a particular focus on crafting interventions before the onset of significant problems, and with a focus on populations known to be at risk for such onset (Durlak, 1998; Munóz, Mrazek, & Haggerty, 1996). This form of prevention has been called primary prevention, in contrast to secondary and tertiary prevention (Caplan, 1964), or in more contemporary parlance, universal prevention in contrast to targeted prevention (Weissberg et al., 2003). At the center of current prevention research are the concepts of risk factors and protective factors (Jessor, 1993; Jessor, Turbin, & Costa, 1998; Rutter, 1987). Risk factors are individual and/or environmental markers which increase the probability of a negative outcome. Protective factors are safeguards identified in epidemiological research that help individuals cope successfully with risk. As noted by Rutter (1987), protective factors operate only when risk is present.

There are important points of overlap and of difference when comparing positive youth development with this major risk and protective factor approach to prevention. The two approaches partially agree on developmental goals. That is, both are dedicated to reducing problem behaviors and negative outcomes. At the same time, however, positive youth development tends to place as much or more focus on promoting additional approaches to health, including thriving skill-building and competency (Bumbarger & Greenberg, 2002; Pittman & Fleming, 1991). There is also some overlap in understanding the processes and mechanisms involved in the production of successful development. Some of the so-called protective factors that buffer risk and reduce negative outcomes also play a role in the production of positive outcomes (Catalano, Hawkins, Berglund, Pollard, & Arthur, 2002). Alternatively, positive youth development research also identifies a series of additional supports, opportunities, and developmental assets whose identification emerges from investigations of environmental and individual factors that promote competence, achievement, growth, and thriving (Benson, 2003a; Lerner, 2004; Scales, Benson, Leffert, & Blyth, 2000). Hence, protective factors and the broader range of developmental resources central to positive youth development are not isomorphic.

At another level, however, prevention and positive youth development are grounded in quite different theoretical orientations and—though yoked by common interest in the health of youth—spring forth from quite different visions of youth potential and the developmental, ecological, and social processes at play (Damon & Gregory, 2003; Lerner, 2004).

THE THEORY OF POSITIVE YOUTH DEVELOPMENT

A grand theory of positive youth development requires the integration of multiple theoretical orientations. In part, this is because positive youth development is a "bridging" field that touches multiple academic disciplines and spheres of practice. Three theoretical strands central to positive youth development are discussed in this section, with primary emphasis on the first. These three are: human development, community organization and development, and social and community change.

Human Development

Central to positive youth development theory is a series of questions rooted squarely in the discipline of developmental psychology. The overarching goals of this theory are to explain: the capacity of youth to change and to change in a direction that fosters both individual well-being and the social good; how and under what conditions contextual and ecological factors contribute to this change (and how these factors are informed or influenced by the developing person); and, the principles and mechanisms that are at play in maximizing the dynamic and developmentally constructive interplay of context and individual.

The articulation of a *developmental* theory of positive youth development is itself an ongoing and dynamic process emerging several decades after the birthing of positive youth development as a field of practice (Benson & Saito, 2001; Hamilton & Hamilton, 2004; Larson, 2000; Zeldin, 2000). Zeldin (2000) provides an important analysis of how the science of youth development emerged:

> [I]n hindsight, it is clear that positive youth development, as a philosophy of service and as a field of study was initiated and grounded in the expertise of practitioners, primarily those working in nonprofit, community-based, youth-serving organizations. Research was used primarily to offer "empirical justification" for exemplary practice that was already occurring in communities. (p. 3)

An important step in growing the science of positive youth development was a "call to action" made by a team of researchers and leaders of youth development organizations (Zeldin, 1995). Facilitated by the Academy for Educational Development, this 1995 document challenged academicians—particularly those engaged in the study of adolescence—to focus research on strength-based models of adolescent development, identify and study positive youth outcomes, and identify "the day-to-day developmental opportunities and supports that allow young people to become competent and compassionate individuals connected to their communities" (Zeldin, 2000, p. 3).

The "golden age" of positive youth development research began in the mid-1990s, with burgeoning literatures on topics such as civic engagement, service learning, connectedness, generosity, purpose, empowerment, and leadership. In the past few years, work positing the theoretical foundations of positive youth development has begun. This historical progression of practice, to research, to theory may not be the idealized scientific progression, but it is important here to identify how this evolutionary pattern critiques the heretofore irrelevance of developmental psychology to the massive number of people and organizations trying to innovate strength-based youth work in the United States. As Larson (2000) put it, youth development evolved separately from development psychology "partly because we psychologists have had little to offer" (p. 171). Alternatively, this progression may be an exemplar of the kind of citizen-scholar partnership needed to promote civil society (Lerner et al., 2000).

Essential to positive youth development theory is a generous view of human capacity and potential. Grounded initially in the views and values of professionals and practitioners working with youth, this vision of human nature identified the possibility of active and constructive contribution to the development of self, community, and society. As noted earlier in this chapter, such a view is often characterized in youth development circles by describing young people as resources to be nurtured versus problems to be managed. This view is an important starting point for a theory of positive youth development, for it brings to the fore the notion that the individual—and not just the environment—is a prime actor in the shaping of positive developmental trajectories.

Damon (2004), in an important essay titled "What Is Positive Youth Development" argues that this positive vision of youth potential has implications for research, education, and social policy. He also sees this human nature assumption supported by three relatively recent lines of inquiry: the research on resilience (Garmezy, 1983); the capacity of newborns to demonstrate empathy (Eisenberg & Fabes, 1998; Hoffman, 2000); and the universal capacity for moral awareness and prosocial behavior (Feshbach, 1983; Madsen, 1971). Damon also asserts that this human capacity for competence and contribution is at play when seeking to explain how young people "learn and thrive in the diverse settings where they live."

The essence of positive youth development theory is explaining how such potentiality expresses itself. The theory requires an appreciation of the dynamic interplay of person and context. Accordingly, the theory is most at home in a family of theoretical approaches constituting the large metatheory known as developmental systems theory (Ford & Lerner, 1992; Gottlieb, 1997).

This metatheory includes several crucial assumptions and components that, in combination, positions human development in relational and contextual space, and that stand in contrast to earlier developmental theories that split development into such polarities as nature-nurture, biology-culture and individual—society (Lerner, 1998; Overton, 1998).

Although positive youth development theory is predicated on key concepts in developmental systems theory, it includes several other core ideas having to do with the orchestration of bidirectional context-person relationships in order to maximize growth and development. While positive youth development can happen naturally (as in the adage that "positive youth development is what happens when families have a good day"), such adaptive development regulations (Lerner, 1998, 2004) can be encouraged and engineered by the ways contexts are designed and the ways youth are engaged in that design.

Central to the theory of positive youth development are conceptions of the developing person, the contexts in which the person is embedded and the dynamic interaction between the two. Following Lerner's lead (1984, 1998, 2002, 2003), all of the multiple levels of organizations engaged in human development—from biology and personality disposition to relationships, social institutions, culture, and history—are fused into an integrated system. Development has to do with changes in the relations among and between these multiple levels of organizations. Consonant with systems thinking in biology, persons—through their dynamic interaction with developmental contexts—experience pattern and order via the process of self-organizing. This key dynamic of self-organization means that "pattern and order emerge from the interactions of the components of a complex system without explicit instructions, either in the organization itself or from the environment. Self-organization—processes that by their own activities change themselves—is a fundamental property of living things" (Thelen & Smith, 1998, p. 564). At one level, this proposed dynamic interaction of nature and nurture is a dramatic departure from earlier models of human development which created a split between the two (Lorenz, 1965; Skinner, 1938). At another level, however, the concept of self-organization introduces, as Lerner suggested (1976, 2003) a "third source" of development: the organism itself. Schneirla's (1957, 1959) concepts of circular functions and self-stimulation were important illustrations of the organism's centrality and active participation in development.

An articulation of this point suggests that individual development cannot be explained by heredity or environment alone (Gottlieb, Wahlsten, & Lickliter, 1998). Evidence for this comes from studies where "genetically identical individuals are reared in unusually uniform environments but nonetheless differ markedly in phenotypic types" (Gottlieb et al., p. 253). While individual differences—stemming presumably from neither genes nor contexts—can be a nuisance to theorists preferring reductionist understandings of development, such so-called "noise" or "randomness" points to the "third source" of development central in developmental system theories.

Positive youth development theory includes another dynamic feature of the organism that is consonant with the process of self-organization but not readily inferred from it. And this is the concept of how persons act on their contexts. Indeed, one of the core tenets in developmental systems theory is the bidirectional nature of influences on development. That is, the "individual is both the active producer and the product of his or her ontogeny . . ." (Brandtstädter, 1998, p. 800). Action theories of human development seek to explain these dual developmental regulation processes of the action of contexts on individuals and the action of individuals on their contexts. This process by which organisms engage, interact with, and alter their developmental contexts (e.g., peer group, family, school, and neighborhood) is not only a pivotal theoretical notion for positive youth development, but is also "the essential intellectual challenge for developmental science" (Lerner, 2003, p. 228).

What processes guide how youth engage and act on their contexts? There are a series of developmental processes particularly salient during adolescence. Among these are identify formation and allied issues around self-appraisal, meaning-making, and autonomy. Because of the centrality of these issues during adolescence, positive youth development theory argues that adolescents bring particular energy to their relational and social world. Their activity—as "co-producers" of their development—is guided by three intertwined processes, each of which is rooted in theoretical traditions from within the broader "family" of developmental systems theories. Indeed, we think of these three as prime features of the "engine" of development. And in combination, the three make possible a purposeful search for positive (i.e., developmentally rich) contexts.

Brandtstädter's action theory of development emphasizes the role of *intentionality* in guiding and regulating

one's engagement with social and symbolic environments (1998, 1999). His assumption is that persons reflect on, learn from, and use feedback from their social engagements creating behavioral intentions that guide subsequent behavior. While this proposed dynamic has currency across the life span, it is a hallmark of adolescence. There are a range of possible constraints on how the person self-regulates internal engagements with her or his social and symbolic worlds. As Brandtstädter suggests "these constraints lie partly or even completely outsides one's span of control, but they decisively structure the range of behavioral and developmental options" (1998, p. 808).

In addition to *intentionality,* there are *selection* and *optimization* processes that also inform how persons interact with their environments. Aligned with Baltes and his colleagues (Baltes & Baltes, 1990; Baltes, Dittmann-Kohli, & Dixon, 1984; Baltes, Lindenberger, & Staudinger, 1998), positive youth development theory posits that youth select from a range of developmental supports and opportunities a subset that has psychological and social advantage for prioritized personal goals. Selection, then, has to do with both one's preferences (e.g., to learn to play the flute, to find friends, to experiment with drama) and the ecologies one chooses to be the primary crucibles for development. Optimization is "the process of acquiring, refining, coordinating, and applying goal-relevant means or resources" toward the selected targets (Lerner, 2002, p. 224). Critical issues in the applied youth development world include: how well communities provide meaningful opportunities for optimization; and how well communities make it possible for youth to create optimization opportunities (e.g., to begin a new sports or arts program, or to attach oneself to an appropriate mentor).

The self-regulation of context engagement—even when buoyed with an internal press guided by intentionality, selection, and optimization—creates something of a conundrum for those on whom the constraints on action appear sizable. These constraints, which are well articulated in a number of life span and life course theories (e.g., Elder, 1974, 1980, 1998, 1999; Nesselroade, 1977; Schaie, 1965), can have strong salience during adolescence. Youth, after all, both seek control and are controlled, with many agents in their lives who, by virtue of position and power, can either suppress or encourage exploration, selection, and optimization. Among this army of socialization agents are parents, neighbors, teachers, youth workers, coaches, clergy, employees, and peers. Positive youth development theory posits that adolescents will strive to find and/or create optimizing settings even when their degrees of freedom are limited. These settings may be countercultural and/or deemed by society to be out-of-bounds. This axiom is supported by the work of Heckhausen and her colleagues (Heckhausen, 1999; Heckhausen & Krueger, 1993; Heckhausen & Schulz, 1995). As in the model of selection, optimization, and compensation (Baltes & Baltes, 1990), she is concerned with the dialectic between possibility (i.e., plasticity) and constraint. She argues that "primary control" (or the process of acting on the environment in order to make it more congruent with ones needs) is a dominating human striving, particularly during adolescence and young adulthood.

Lerner (1998, 2002, 2003, 2004; Lerner, Anderson, Balsano, Dowling, & Bobek, 2003; Lerner et al., 2002) has been particularly productive and influential in connecting core ideas in developmental systems theories to the emerging field of positive youth development. His overarching view is that "changes across the life span are seen as propelled by the dynamic relations between the individual and the multiple levels of the ecology of human development (family, peer group, school, community, culture), all changing interdependently across time (history)" (Lerner et al., 2002, pp. 13–14). His thinking about three core concepts—temporal embeddedness, plasticity, and developmental regulation—is central to the formation of positive youth development theory and deepens the assumptions of person-context interactions described earlier.

Temporal embeddedness refers to the potentiality, across the entire life span, for change in person-context relations. This potentiality—yoked with our earlier discussion of the principles of self-organization and the active participation by the individual in shaping one's contexts—liberates us from the idea that biology, environment, or the combination of the two, is destiny. Positive youth development—as theory and practice—works in the optimistic arena offered by temporal embeddedness and by the *relative plasticity* (i.e., the potential for systemic change) that derives from it. That is, temporality and relative plasticity mean that, "the potential to enhance human life" always exists (Lerner et al., 2002, p. 14).

Finally, Lerner links the concept of developmental regulation to the promise of positive youth development. By so doing, he gives the theory a way to understand how individuals manage or shape their relations with

multiple contexts. Developmental systems theories derive concepts of developmental regulation from the idea of relative plasticity. As persons actively regulate their development, developmental change occurs in the mutual exchange between person and context. *Adaptive* (healthy) *developmental regulation* occurs when there is a balance between individual capacity or strengths and the "growth-promoting influences of the social world" (Lerner, 2004, p. 44).

Positive youth development, then, occurs in the fusion of an active, engaged, and competent person with receptive, supportive, and nurturing ecologies. The consequences of these balanced interactions—particularly when they are frequent and sustained—can be seen at both the individual and social level. Among these hypotheses are the advancement of individual thriving and the reduction of health-compromising behaviors (Benson, 1997; Benson et al., 1998; Lerner, 2004; Lerner & Benson, 2003; Scales, Benson, et al., 2000). A common vocabulary in positive youth development for describing these effects is the five Cs: competence, confidence, connection, character, and caring (or compassion; NRCIM, 2002; Lerner, 2004; Lerner et al., 2000; Roth & Brooks-Gunn, 2003) has written extensively about a "6th C" fueled by adaptive developmental regulations: contribution. In his frame, the six Cs are essential not only for individual well-being but also for the creation of healthy and civil society.

Several recent lines of inquiry are congruent with this thinking. The goodness-of-fit model, for example, demonstrates the adaptive consequences of good matches between individual competencies and needs with the demands, features, and responsiveness of developmental settings, such as families and schools (Bogenschneider, Small, & Tsay, 1997; Chess & Thomas, 1999; Galambos & Turner, 1999; Thomas & Chess, 1977). Similarly, Eccles and her colleagues (Eccles, 1997; Eccles & Harold, 1996), employing a stage-environment fit model, demonstrate how embeddedness in developmentally appropriate environments such as schools influences motivation and academic achievement.

As we note later in this chapter, the issue of diversity is central to positive youth development. Spencer and her colleagues (Spencer, 1995, 1999; Spencer, Dupree, & Hartmann, 1997) provide a particularly important refinement and extension of the kinds of ecological and systems dynamics shaping the theory of youth development. Central to her phenomenological variant of ecological systems theory (PVEST), Spencer uses the concept of identity formation and of how self-appraisal processes regarding one's standing in multiple contexts (e.g., schools) inform the processing of bidirectional person-context transactions. Phenomenological variant of ecological systems th, then, integrates issues of historical and cultural context (e.g., race and gender stereotypes, minority status) into normative developmental processes. This theory has been extensively utilized to understand the development of African American youth. New work is underway to understand the historical and cultural contexts informing the development of Latino/Latina youth (Rodriguez & Morrobel, 2004).

Conceptual Models of Positive Development

A series of conceptual models have emerged to identify the positive developmental experiences that enhance the fusion of person and context. A rich vocabulary has developed to describe these development-enhancing ingredients. Among these are supports, opportunities, developmental nutrients, developmental strengths, and developmental assets.

One important research-based tradition informing these conceptualizations is that of resilience. Formal inquiry into resilience, or the development of positive adaptation in the context of significant adversity (Masten, 2001), took root during the 1960s and 1970s. In an effort to better understand maladaptive behavior, psychologists and psychiatrists studied children believed to be at risk for pathology (e.g., children of a parent with schizophrenia), and observed that some children were developing normally (Masten & Coatsworth, 1998). These early efforts at understanding "invulnerables" (Werner & Smith, 1989) focused on personal qualities of the child, such as self-esteem or high intelligence (Anthony, 1974). Eventually researchers came to understand that resilience was not a trait inherent in the child, but rather was a function of the child? environment interaction. This more ecological approach led to the identification of three broad sets of protective factors implicated in fostering resilience: (1) those within a child (cognitive abilities, easy temperament); (2) within the family (organized family environment, close parent-child relationships); and (3) within the broader social ecology (effective schools, relationship with a caring adult; Luthar, Cicchetti, & Becker, 2000; Masten & Garmezy, 1985).

The primary mechanism through which resilience approaches attempt to facilitate positive development is via intervention and prevention programs. One exemplar of

this approach is Hawkins' social development model (Hawkins & Catalano, 1996). This model asserts that children who experience developmentally appropriate opportunities for active involvement in their families, schools, and communities, *and* are recognized for their efforts are more likely to form positive bonds and attachments that inhibit deviant or problem behavior (Catalano et al., 2003). According to these authors, the following salient protective factors are necessary for prevention:

Community Protective Factors

- Opportunities for prosocial community involvement
- Rewards for prosocial community involvement

School Protective Factors

- Opportunities for prosocial school involvement
- Rewards for prosocial school involvement

Family Protective Factors

- Opportunities for prosocial family involvement
- Rewards for prosocial family involvement
- Family attachment

Peer and Individual Protective Factors

- Religiosity
- Belief in a moral order
- Social Skills
- Prosocial Peer Attachment
- Resilient Temperament
- Sociability

Within the community of scholars self-identifying as youth development researchers, considerable attention has been given to defining and conceptualizing development-enhancing processes, with a growing number of publications dedicated to synthesizing the many frameworks (Benson & Saito, 2001; NRCIM, 2002; Roth & Brooks-Gunn, 2000; Small & Memmo, 2004). Several publications have been influential in guiding practice and policy. Pittman and her colleagues (Pittman, Irby, & Ferber, 2000; Pittman, Irby, Tolman, Yohalem, & Ferber, 2001) identified seven essential developmental resources: stable programs; basic care and services; healthy relationships with peers and adults; high expectations and standards; role models, resources and networks; challenging experiences and opportunities to participate and contribute; and high-quality instruction and training. Connell, Gambone, and Smith (2001) posit three major developmental resources: the ability to be productive, the ability to connect, and the ability to navigate. Zeldin (1995; Zeldin, Kimball, & Price, 1995) identifies access to safe places, challenging experiences, and caring people.

The concept of developmental assets emerged in 1990 (Benson, 1990, 1997, 2002, 2003a) and has triggered considerable research and a community change process used in 700 cities in the United States and Canada. The framework of developmental assets (see Table 16.1) is a theory-based model linking features of ecologies (external assets) with personal skills and capacities (internal assets), guided by the hypothesis that external and internal assts are dynamically interconnected "building blocks" that, in combination, prevent high risk health behaviors and enhance many forms of developmental success (i.e., thriving).

As described in a series of publications (Benson, 1997, 2002; Benson et al., 1998), the framework establishes a set of developmental experiences and supports that are hypothesized to have import for all young people during the 2nd decade of life. However, it has also been hypothesized that developmental assets reflect developmental processes that have age-related parallels in infancy and childhood (Leffert, Benson, & Roehlkepartain, 1997; Mannes, Benson, Kretzmann, & Norris, 2003; Scales, Sesma, & Bolstrom, 2004).

The framework synthesizes research in a number of fields with the goal of selecting for inclusion those developmental resources that: (a) have been demonstrated to prevent high risk behavior (e.g., substance use, violence, dropping out of school), enhance thriving, or build resilience; (b) have evidence of generalizability across social locations; (c) contribute balance to the overall framework (i.e., of ecological and individual-level factors); and (d) for which it can be demonstrated that communities have the capacity to effect their acquisition.

Because the model, in addition to its theoretical and research purposes, "is also intended to have practical significance for mobilizing communities" (Benson, 2002, p. 127), the assets are placed in categories that have conceptual integrity and that can be described easily to the people of a community. They are grouped into 20 external assets (health-promoting features of the environment) and 20 that are internal (skills, values, competencies, and self-perceptions). The external assets are grouped into four categories: (1) support, (2) empowerment, (3) boundaries and expectations, and (4) constructive use of time. The

TABLE 16.1 The Framework of Developmental Assets

Category	External Assets	Definition
Support	1. Family support	Family life provides high levels of love and support.
	2. Positive family communication	Young person and her or his parent(s) communicate positively, and young person is willing to seek advice and counsel from parents.
	3. Other adult relationships	Young person receives support from three or more nonparent adults.
	4. Caring neighborhood	Young person experiences caring neighbors.
	5. Caring school climate	School provides a caring, encouraging environment.
	6. Parent involvement in schooling	Parent(s) are actively involved in helping young person succeed in school.
Empowerment	7. Community values youth	Young person perceives that adults in the community value youth.
	8. Youth as resources	Young people are given useful roles in the community.
	9. Service to others	Young person serves in the community one hour or more per week.
	10. Safety	Young person feels safe at home, school, and in the neighborhood.
Boundaries and expectations	11. Family boundaries	Family has clear rules and consequences and monitors the young person's whereabouts.
	12. School boundaries	School provides clear rules and consequences.
	13. Neighborhood boundaries	Neighbors take responsibility for monitoring young people's behavior.
	14. Adult role models	Parent(s) and other adults model positive, responsible behavior.
	15. Positive peer influence	Young person's best friends model responsible behavior.
	16. High expectations	Both parent(s) and teachers encourage the young person to do well.
Category	**Internal Assets**	**Definition**
Commitment to learning	21. Achievement motivation	Young person is motivated to do well in school.
	22. School engagement	Young person is actively engaged in learning.
	23. Homework	Young person reports doing at least one hour of homework every school day.
	24. Bonding to school	Young person cares about her or his school.
	25. Reading for pleasure	Young person reads for pleasure three or more hours per week.
Positive values	26. Caring	Young person places high value on helping other people.
	27. Equality and social justice	Young person places high value on promoting equality and reducing hunger and poverty.
	28. Integrity	Young person acts on convictions and stands up for her or his beliefs.
	29. Honesty	Young person "tells the truth even when it is not easy."
	30. Responsibility	Young person accepts and takes personal responsibility.
	31. Restraint	Young person believes it is important not to be sexually active or to use alcohol or other drugs.
Social competencies	32. Planning and decision making	Young person knows how to plan ahead and make choices.
	33. Interpersonal competence	Young person has empathy, sensitivity, and friendship skills.
	34. Cultural competence	Young person has knowledge of and comfort with people of different cultural/racial/ethnic backgrounds.
	35. Resistance skills	Young person can resist negative peer pressure and dangerous situations.
	36. Peaceful conflict resolution	Young person seeks to resolve conflict nonviolently.

(continued)

TABLE 16.1 *Continued*

Category	External Assets	Definition
Positive identity	37. Personal power	Young person feels he or she has control over "things that happen to me."
	38. Self-esteem	Young person reports having high self-esteem.
	39. Sense of purpose	Young person reports that "my life has a purpose."
	40. Positive view of personal future	Young person is optimistic about her or his personal future.

internal assets are placed in four categories: (1) commitment to learning, (2) positive values, (3) social competencies, and (4) positive identity. The scientific foundations for the eight categories and each of the 40 assets are described in a series of publications (Scales & Leffert, 1999, 2004; Scales et al., 2004).

The 2002 report from The National Research Council and Institute of Medicine, *Community Programs to Promote Positive youth Development* (NRCIM, 2002), used the concept of assets to describe the experiences, supports, and opportunities "which facilitate both successful passage through" adolescence and "optimal transition into the next phase of life—adulthood" (p. 67). Parallel to Search Institute's distinction between external and internal assets, this national report used the language of "personal" and "social" assets. The authors used three types of empirical studies to identify assets: "studies linking the personal and social assets to indicators of positive current development, studies linking these characteristics to indicators of future positive adult development, and experimental studies designed to change the asset under study" (p. 82).

The committee of scholars charged with creating this report then identified 28 personal and social assets. Unlike Search Institute's developmental asset taxonomy, the 28 indicators are all personological in nature and do not include the same balance of contextual factors and individual-level factors. Nonetheless, there is considerable overlap between the two taxonomies. Table 16.2 displays the NRCIM taxonomy of personal and social assets. It should be noted, however, that the committee also created a conceptual model of the "features of positive developmental settings." These provide some parallel thinking to the concept of external assets. These "features" will be discussed in the next section.

Embedded in both the developmental asset model and the National Research Council report are three explicit hypotheses, each of which will be evaluated later in this chapter. The first has to do with the additive or cumulative nature of the elements called assets. The assumption is that "the more assets, the better." The National Research Council Report frames it this way: "adolescents with more personal and social assets . . . have a greater chance of both current well-being and future success" (NRCIM, 2002, p. 42). Benson and his colleagues (Benson, 2003a; Benson et al., 1998; Benson, Scales, & Mannes, 2003) refer to the longitudinal expression of this principle as the "vertical pile up" of assets. Both streams of thought also contend that this principle of accumulated assets generalizes to multiple forms of behavior—from prevention of high risk behavior to the enhancement of positive outcomes such as school success (Benson et al., 2003; NRCIM, 2002; Scales & Roehlkepartain, 2003).

Closely related is the idea of the "pile up" of supportive contexts. That is, positive development is also enhanced when many settings collaborate—whether intentional or not—in generating the kinds of supports and opportunities known to promote assets. In the words of the National Research Council (2002),

> Research shows that the more settings that adolescents experience reflecting these features, the more likely they are to acquire the personal and social assets linked to both current and future well-being. (p. 43)

Scales and Roehlkepartain (2004) have recently called this the principle of "horizontal pile up." This concept is similar to the idea of developmental redundancy (Benson, 1997; Benson et al., 1998). Recent work in the sociology of adolescence also speaks to this dynamic (Furstenberg, 2000).

A second hypothesis addresses the nature of assets as relevant universally, although often experienced or expressed differently across diversities. Among youth development scholars, it is commonly assumed that the elements in the conceptual models of nutrients/

TABLE 16.2 Personal and Social Assets That Facilitate Positive Youth Development

Physical development:
- –Good health habits
- –Good health risk management skills

Intellectual development:
- –Knowledge of essential life skills
- –Knowledge of essential vocational skills
- –School success
- –Rational habits of mind—critical thinking and reasoning skills
- –In-depth knowledge of more than one culture
- –Good decision-making skills
- –Knowledge of skills needed to navigate through multiple cultural contexts

Psychological and emotional development:
- –Good mental health including positive self-regard
- –Good emotional self-regulation skills
- –Good coping skills
- –Good conflict resolution skills
- –Mastery motivation and positive achievement motivation
- –Confidence in one's personal efficacy
- –"Planfulness"—planning for the future and future life events
- –Sense of personal autonomy/responsibility for self
- –Optimism coupled with realism
- –Coherent and positive personal and social identity
- –Prosocial and culturally sensitive values
- –Spirituality or a sense of a "larger" purpose in life
- –Strong moral character
- –A commitment to good use of time

Social development:
- –Connectedness—perceived good relationships and trust with parents, peers, and some other adults
- –Sense of social plane/integration—being connected and valued by larger social networks
- –Attachment to prosocial/conventional institutions, such as school, church, nonschool youth programs
- –Ability to navigate in multiple cultural contexts
- –Commitment to civic engagement

Gootman (Eds), Board on Children, Youth and Families, Division of Behavioral and Social Sciences and Education, 2002, Washington, DC: National Academy Press.

resources/assets have currency for youth in all social locations. This claim is particularly clear in both the National Research Council report and the research undergirding the developmental asset model. At the same time, however, both models testify to the diversity of methods and procedures for promoting assets, and to the importance of creating strategies of asset-building that are crafted with deep sensitivity to the experience, wisdom and capacity of people within particular racial, ethnic, religious, and economic groups (Hamilton et al., 2004).

The third assumption is one that arguably is the strongest point of theoretical consensus across scholars, research programs, and practitioners within the positive youth development field. This is the belief that assets are enhanced when contexts and settings are configured

and organized in specific ways. Context matters and contexts can be changed. This principle can be succinctly stated as:

> personal and social assets are enhanced by positive developmental settings. (NRCIM, 2002, p. 43)

Not surprisingly, then, there is a considerable research tradition on how, and under what conditions, contexts and ecologies promote positive development. This body of work shifts the unit of analysis from the person to contexts, environments, and communities. Accordingly, it draws us into a number of fields beyond developmental psychology in which such inquiry is more at home. We suggest that a theory of person, context, and their intersection such as suggested earlier in this chapter is a necessary but not sufficient set of ideas for delineating the territory, scope, and uniqueness of positive youth development. The major lacuna in our discussion to this point is the idea of intentional change. At the heart of positive youth development thinking and research is the question of how the healthy/balanced/adaptive fusion of person and context can be enhanced. It is this idea—this possibility of creating change—that has fueled practice for several decades and, more recently, is fueling research and policy.

A theory of positive youth development, then, is incomplete without incorporating the concept of intentional change. Without doing so, we have a theory of adolescent development—not positive youth development. Intentional change is the purposeful effort to enhance the fusion of person and context in a healthy direction. Because of the dynamic bidirectionality of this interaction, there are three major points of potential intervention. The three of these, in combination, increase the probability of adaptive developmental regulation. These are:

1. *Increasing the developmental-attentiveness of contexts* (to increase their capacity to nurture, support, and constructively challenge the developing person).
2. *Enhancing the skills and competencies of youth* (to further enable their "natural" capacity to engage with, connect, change, and learn from their social contexts).
3. *Creating processes and opportunities to invite youth to actively exercise and utilize their capacity* to engage with and change their social contexts. In practice and research, this form of intentional change travels under such concepts as youth leadership, service learning, youth empowerment, and youth engagement.

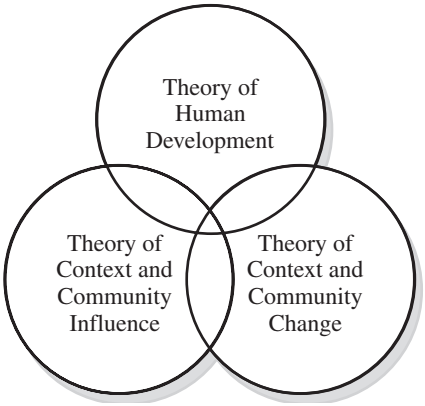

Figure 16.2 A comprehensive theory of positive youth development.

A comprehensive approach to positive youth-development requires the integration of three theories: of human development (which is the primary focus of this chapter), of context and community influence, and of how contexts and communities change. These three are displayed in Figure 16.2.

The Theory of Context and Community Influence

There is an extensive and growing literature on the features and dynamics of developmentally supportive contexts. It is here that we reference the major contributions of Bronfenbrenner (1979; Bronfenbrenner & Morris, 1998). His ecological theory of development has been instrumental in shaping the theory, research, and practice of positive youth development. If we were to posit the canon of youth development, the list would begin with *The Ecology of Human Development* (1979). In this work, he provides a highly influential definition that not only supports a critical notion in current developmental systems theory but also shaped a generation of scholarship. In his words:

> The ecology of human development involves the scientific study of progressive, mutual accommodation between an active, growing human being and the changing properties of the immediate settings in which the developing person lives, as this process is affected by relations between these settings, and by the larger contexts in which the settings are embedded. (p. 21)

Among Bronfenbrenner's many contributions is his conceptual formulation of the nature and dynamics of developmental contexts. He portrays the nested systems that influence development as interdependent; their influence is interactive; none stands or has its effects alone. What happens in a microsystem, such as a classroom, is influenced by tax policies and by the media, but those elements of the macrosystem are themselves interpreted through and influenced by microsystems. An important implication for youth development is that effective efforts to enhance assets must change more than one system and level of system. Changing schools or even families will be less effective than changing multiple systems (or settings).

Wynn (1997) and her colleagues conceive of the community institutions influencing youth development as "sectors" and focus on "primary supports" as a strong but under-appreciated influence. Primary supports are voluntary; youth choose to participate and make choices about what they will do and how. Primary supports afford young people opportunities to take initiative and to participate actively, in contrast to the passivity characterizing the role of student. Exemplars of primary supports include "arts and after school programs; organized sports; community service and youth entrepreneurship opportunities; and the offerings of parks, libraries, museums, and community centers" (p. 1).

Consistent with Bronfenbrenner's idea of the importance of links among systems, Wynn (1997) claims that primary supports function best when they reinforce and link other sectors, especially families, schools, healthcare, and other services. Critical to effective primary supports are: high expectations; group problem solving; concrete products and performances; prospects for advancement and expanded opportunities; adults acting as caregivers, catalysts and coaches; membership; availability and continuity; respect and reciprocity; and adult investment (pp. 5–7).

There are a growing number of such conceptual models for identifying developmental contexts that are potential sources for positive youth development (see, e.g., Benson & Saito, 2001; Benson et al., 2003; Gambone, Klem, & Connell, 2002; Hamilton & Hamilton, 2004; Pittman et al., 2000). An important line of theory and research is also emerging to explain how, and under what conditions, such contexts inform positive development. Several themes are particularly central to positive youth development theory. Bronfenbrenner and Morris (1998) identify two of these themes. Development occurs as a person interacts with "people, objects and symbols" in what they call "proximal processes," which are "the primary engines of development" (p. 996). Caring relationships are critical, not only in the family, but in all the settings youth occupy. Likewise, youth need a range of challenging activities in multiple settings. Both the people and the activities foster development best when they provide an optimum balance of challenge and support. According to Bronfenbrenner and Morris, the most powerful activities and relationships are predictable and enduring.

The classic account of how relationships promote development and learning is Vygotsky's (1978) "zone of proximal development." According to Vygotsky, development, in the sense of growing competence, occurs when the developing person is assisted by someone who is already competent in accomplishing tasks she or he cannot do unaided. With experience, this assistance becomes unnecessary and the person can perform independently. Several cognitive scientists have elaborated this notion, using the metaphor of "scaffolding" that is gradually withdrawn (e.g., Bruner, 1983; Rogoff, 1990). Although the metaphor is faulty (implying that scaffolding holds up a building until it is capable of standing on its own), the idea is sound: the assistance of someone who is more advanced enables youth to gain competence, especially if that person is skilled at knowing when to help and when not to. Bronfenbrenner (1979), acknowledging Vygotsky, hypothesized that:

> Learning and development are facilitated by the participation of the developing person in progressively more complex patterns of reciprocal activity with someone with whom that person has developed a strong and enduring emotional attachment and when the balance of power gradually shifts in favor of the developing person. (p. 60)

Benson et al. (2003) enumerated five aspects of relationships germane to positive youth development. First, supportive relationships with both immediate and extended family members have been shown, in multiple studies and multiple demographic settings, to enhance developmental strengths and provide a protective buffer against risk (Rhodes & Roffman, 2003). Second, supportive relationships with nonparental adults can be equally compelling in advancing positive development, particularly during adolescence (Scales, Benson, & Mannes, 2002; Scales & Leffert, 2004; Scales, Leffert, & Vraa, 2003). Third, the number of supportive adult relationships may provide an additive impact: As the

number of nurturing relationships increase, probabilities for the presence of developmental strengths such as caring values, self-esteem, and a positive view of one's future also may increase (Benson, 1997). An additional axiom about nonparental adults has to do with the sustainability of relationships. It is reasonable to hypothesize that the strength-building capacity of nonparental adult connections increases proportionately with the length of the relationship.

Fourth, exposure to positive peer influence—defined, for example, as peer modeling of prosocial and achievement values—can both advance developmental strengths and inhibit risk behaviors (Leffert et al., 1998; Scales, Benson, et al., 2000). Finally, the developmental advantage of relationships is enhanced by three factors: their quality, their quantity, and their sustainability.

The second theme identified by Bronfenbrenner and Morris (1998) has to do with the importance and certainty of activity. Csikszentmihalyi (1990) has compellingly made the case that certain kinds of activities instigate development in his work on "flow" or "the psychology of optimal performance." Csikszentmihalyi has documented the phenomenon of flow in people like rock climbers, dancers, and others who engage in highly challenging activities that reward them with a sense of successfully negotiating challenges that require intense concentration. This work helps to explain why some activities contribute more to building youths' assets than others. Activities such as playing chess, playing a musical instrument, or planning and carrying out a community service project build developmental assets more than watching television or gossiping with friends.

In another important statement of how activity contributes to positive development, Larson (2000) posits that the development of initiative is critical. Combining intrinsic motivation and deep attention, initiative can emerge from well-designed structured activities within sports, arts, and related youth development programs.

The themes of relationships and developmentally appropriate activity are "front and center" in most conceptual models seeking to describe the essential features of positive developmental contexts (Gambone & Arbreton, 1997; McLaughlin, Irby, & Langman, 1994; Quinn, 1999; Roth & Brooks-Gunn, 2000, 2003). In a synthesis of this research, NRCIM (2002) identified eight features of programs, hypothesized to "expand the opportunities for youth to acquire personal and social assets" (p. 8). These are listed in Table 16.3. As noted earlier, these

TABLE 16.3 Features of Positive Developmental Settings

Feature	Descriptors
Physical and psychological safety	Safe and health-promoting facilities, practice that increases safe peer group interaction and decreases unsafe or confrontational peer interactions
Appropriate structure	Limit setting, clear and consistent rules and expectations, firm-enough control, continuity and predictability, clear boundaries, and age-appropriate monitoring
Supportive relationships	Warmth, closeness, connectedness, good communication, caring, support, guidance, secure attachment, and responsiveness.
Opportunities to belong	Opportunities for meaningful inclusion, regardless of one's gender, ethnicity, sexual orientation or disabilities; social inclusion, social engagement and integration; opportunities for sociocultural identity formation; and support for cultural and bicultural competence
Positive social norms	Rules of behavior, expectations, injunctions, ways of doing things, values and morals, and obligations for service
Support for efficacy and mattering	Youth-based, empowerment practices that support autonomy, making a real difference in one's community, and being taken seriously; practices that include enabling, responsibility granting, and meaningful challenge; practices that focus on improvement rather than on relative current performance levels
Opportunity for skill building	Opportunities to learn physical, intellectual, psychological, emotional, and social skills; exposure to intentional learning experiences; opportunities to learn cultural literacies, media literacy, communication skills, and good habits of mind; preparation for adult employment and opportunities to develop social and cultural capital
Integration of family, school, and community efforts	Concordance; coordination and synergy among family, school and community.

Source: From *Community Programs to Promote Youth Development: Committee on Community-Level Programs for Youth,* by the National Research Council and Institute of Medicine, J. Eccles and J. A. Gootman (Eds), Board on Children, Youth and Families, Division of Behavioral and Social Sciences and Education, 2002, Washington, DC: National Academy Press.

eight features of positive development settings have some conceptual overlap with the external assets in the developmental asset framework (Benson, 1997; Benson et al., 2003; Scales & Leffert, 1999, 2004).

The theory of positive youth development posits that development is enhanced when contexts are configured and organized in ways consonant with these developmental principles. As already suggested, closely aligned with the "contexts can be changed" axiom is the principle of "horizontal pile-up." This latter concept refers to the reinforcing, simultaneous experience of ecological assets across the different context of a young person's total ecology, such as family, neighborhood, school, peer group, after-school programs, and other co-curricular organizations. As suggested by Benson et al. (2003):

> Such multiple and redundant exposure to developmentally rich ecologies fortifies the social space within which young people can perceive themselves to be safe, supported and capable. Young people who experience such redundancy ought to be even more likely than young people without such a horizontal pile-up of assets to enjoy protection from risk and to thrive. (p. 387)

This idea of "developmental redundancy" helps to fuel an additional and important concept in positive youth development: the viability of community as a setting for generating both ecological and internal assets. This question of how communities inform development has become a vibrant area of inquiry (Benson et al., 1998; Blyth, 2001; Booth & Crouter, 2001; Comer, 1980; Comer, Haynes, Joyner, & Ben-Avie, 1996; Connell et al., 2001; Earls & Carlson, 2001; Hughes & Curnan, 2000; Kretzmann & McKnight, 1993; Mannes et al., 2003; Sampson, 2001; Spencer, 2001).

Using community as a unit of analysis, researchers have posited a number of community processes and dynamics inferred to be important for creating the kinds of relationships and developmentally rich contexts that promote positive development. Scales and his colleagues (Scales et al., 2001, 2002, 2003) identify pro-child social norms in which engagement with children and adolescents is expected and supported. Some theorists posit the viability of shared ideals and expectations that unite multiple socializing systems in common purpose (Benson, 1997; Damon, 1997). Zeldin (2002) points to the role of adults' sense of community as an important precursor to engagement with youth. And several identify the role of strategic alignment among community services delivery systems (Dorgan & Ferguson, 2004; Dryfoos, 1990; Mannes et al., 2003).

The construct of social capital elucidates why community mobilization is important and points to some avenues for action. Coleman (1990, p. 304) describes social capital as contained in human relationships. Human capital includes a person's competencies. Just like human capital and financial capital, social capital makes it possible for people to be productive, to accomplish tasks. Coleman points out that social capital is greater in social networks with a high degree of "closure," meaning that many people know each other, communicate, and trust each other (pp. 319–320).

Sampson and his colleagues (Sampson, 2001; Sampson, Morenoff, & Earls, 1999; Sampson, Raudenbush, & Earls, 1997) have identified community mechanisms that facilitate the generation of social capital. Chief among these is the idea of collective efficacy, which signifies "an emphasis on shared beliefs in a neighborhood's conjoint capability for action to achieve an intended effect, and hence an active sense of engagement on the part of residents" (Sampson, 2001, p. 10). Benson and his colleagues (Benson, 1997; Benson et al., 1998) have suggested that one important source of collective efficacy is a shared community vocabulary of developmental assets aligned with a publicly shared understanding of the capacity of social contexts to effect their acquisition.

The Theory of Context and Community Change

The third formulation in a comprehensive theory of positive youth-development focuses on the processes, strategies, and tactics that can directly or indirectly alter contexts and community. This is the least developed of the three theoretical foundations of the theory we envision. One recent review of the science on "how change occurs" has argued that a compelling question emerging from new discoveries about the dynamic and bidirectional sources of positive development has to do with:

> the processes and procedures of increasing access to developmental nutrients/assets on a rather massive scale. And truth be told, though all architects of developmental nutrient models are deeply interested in application, the science of how change occurs is in its infancy. We have invested much more intellectual and research energy in naming the positive building blocks of development and demonstrating their predictive utility for enhancing health and academic outcomes than in studying the complex

> array of strategies and procedures for moving the developmental needle forward. (Benson, 2003b, p. 214)

Thinking about such change is a complex enterprise. Because positive youth-development has a pronounced interest in application, a comprehensive theory of change is needed to guide both research and the change-making efforts already underway in hundreds of communities, organizations, and systems. Tying this theory and research agenda to the previous section on context and community influences suggests some of the concepts hypothesized to be central to this inquiry. Among these are building shared vision; activating collective and personal efficacy; promoting social trust; reframing how citizens view youth; mobilizing adult-youth relationships; creating effective cross-sector collaborations; and enhancing relationships and developmentally appropriate activities within socializing systems and programs.

Many points of entry into this complex arena of change have been proposed. Among these are social policy (Blum & Ellen, 2002; Halfon, 2003); social norms (Scales et al., 2003); community building (Hyman, 2002; Mannes et al., 2003); schools (Gambone et al., 2002); neighborhoods (Sampson, 2001); families (Simpson & Roehlkepartain, 2003); the mobilization of adults as change activists (Rhodes & Roffman, 2003); and the mobilization of youth as change activists (Earls & Carlson, 2002).

Recently, two conceptual frames have been proposed to help guide theory and research on change. First, Granger (2002) suggested two overarching constructs: intervention strategies to enhance the *will* to change and intervention strategies to enhance the *capacity* to change. For the latter, he posits five key strategies: human capital creation, redistribution strategies, investment strategies, social capital creation, and efficiency strategies.

Second, Benson et al. (2003) proposed five interlocking spheres of intervention. Grounded in organizational systems theory, this model suggests that change in any one sphere impacts each of the others. This assertion bears theoretical affinity with core tenets in developmental systems theory. This five-fold model is in the service, theoretically, of creating a "developmentally attentive community" (p. 389). Such a community is envisioned as one that marshals and activates the asset-building capacity of its residents (both adults and youth), and sectors (family, neighborhoods, schools, youth organizations, laces of work, congregations). A developmentally attentive community is also characterized by indirect influences that support and sustain these more direct resident and sector influences. These influences include policy, financial resources, and social norms that promote adult engagement with the young (Scales et al., 2001, 2003).

In turn, Benson et al. (2003) propose that the strategic targets for such communities are *vertical pileup* (in which youth develop many developmental assets), *horizontal pileup* (in which youth experience asset-building in multiple contexts), and *developmental breadth* (extending, by purpose and design, the reach of asset-building energy to *all* children and adolescents, not only those judged to be at "risk" and served by traditional "prevention" programs).

Accordingly, the five synergistic strategies they posit for community change are:

1. *Engage adults:* Community adults build sustained, asset-building relationships with children and youth, both within and beyond family.
2. *Mobilize youth engagement:* Adolescents use their asset-building capacities with peers and with younger children and in activities that help enhance the quality of their community.
3. *Activate sectors:* Families, neighborhoods, schools, congregations, and youth organizations activate their asset-building potential.
4. *Invigorate programs:* A community infrastructure of quality early childhood, after-school, weekend, and summer programs is available and used by children and youth.
5. *Influence civic decisions:* Financial, leadership, media, and policy resources are mobilized to support and sustain the transformation needed for areas 1, 2, 3, and 4 to emerge.

RESEARCH SUPPORT FOR KEY POSITIVE YOUTH DEVELOPMENT HYPOTHESES

The theory and practice of positive youth development suggests several of key hypotheses. Later in this section, we introduce and examine empirical support for seven hypotheses, and offer perspectives on the implications of these principles both for understanding and promoting positive youth development. Here, however, it is important to provide an overview of the nature and power of the research base pertinent to these hypotheses.

Overview of Positive Youth Development Research

The research base supporting these hypotheses is plentiful, although uneven. The literature measuring developmental resources is typified by variable-centered methods, a focus on isolated variables, use of cross-sectional samples, and linear-additive theory and analytic strategies. What is needed are person-centered methods, a focus on patterns or clusters of variables, use of longitudinal samples, and dynamic nonlinear theory and analytic strategies (Lerner, Lerner, De Stefanis, & Apfel, 2001).

Developmental outcomes for youth also encompass processes that are as important as if not more important than outcomes reflecting status points in time (e.g., current use of alcohol, how much community service one contributes). Processes include reorganization (Sroufe, 1979), being able to permanently make transitions (Baltes & Freund, 2003), and being on a path to a hopeful future (Lerner et al., 2002; Scales & Benson, 2004). Status outcomes may not adequately capture the nested interactions of person and contexts over time, for example, person-family and family community (Lerner, Freund, De Stefanis, & Habermas, 2001).

Further, the literature says relatively little about the interaction of the combination of nutrients or resources young people experience. Most studies focus on just a handful of assets (especially parental/family assets and school orientation assets, with some emphasis on peers, and more recently, on extracurricular and positive youth development program activities), and at best, how this handful may interact.

We illuminate the research support for the positive youth development hypotheses by focusing on a small number of outcomes for which positive youth development theory is best explicated, and that appear to have strong research bases and broad constituencies of researchers, practitioners, and policymakers dealing with them: Alcohol and other drug use; violence/anti-social behavior; school success; and civic engagement. Much but not all of the research cited herein pertains to those four exemplar outcomes.

How Much Explanatory Power Is Reasonable to Expect?

Hundreds of studies, cited in this chapter and in comprehensive reviews (Scales & Leffert, 2004; Scales et al., 2004), provide *persuasive* evidence (Miller & Thoresen, 2003) for the broad theoretical connection between developmental assets and developmental outcomes, both concurrently and longitudinally. This is especially true when considering as an independent variable the cumulative number of assets young people experience, or comparing those young people with relatively higher and lower levels of assets.

There is relative persuasiveness and consistency of positive findings in the literature on the explanatory power of positive youth development concepts. But what level of explanation is reasonable to expect developmental assets or nutrients to provide for complex outcomes? Luthar et al. (2000), for example, observe that studies whose findings rest on main effects often report effects of 10% to 20% for individual protective factors. When interaction effects are necessary to explain the workings of such assets, effect sizes are far smaller, in the 2% to 5% range. With both advocacy and empirical work in recent years reflecting a shift from merely documenting the impact of developmental nutrients to studying the processes and interactions that suggest *how* those nutrients contribute to outcomes (Collins, Maccoby, Steinberg, Heatherington, & Bornstein, 2000; Davey, Eaker, & Walters, 2003; Luthar et al., 2000), it may be expected that the size of many reported effects will be disappointingly, but understandably, limited.

Ecological and developmental systems theory have become the predominant frames of theoretical reference for the study of child and adolescent development (Lerner et al., 2002). Moreover, individual development and broader community and social change processes increasingly are linked in positive youth development frameworks (Benson et al., 1998, 2003; Connell & Kubisch, 2001; Hawkins & Catalano, 1996). These theoretical formulations imply that effects derived from studies shaped by those theories and frameworks may be quite modest, a conclusion supported in a recent review by Wandersman and Florin (2003). All these factors make it quite challenging scientifically to capture broad community change in the service of positive youth development (Berkowitz, 2001).

With the preceding comments providing perspective on the state-of-the-art in positive youth development research, we turn now to illustrating the evidence for each of the major positive youth development hypotheses, we can derive from our prior discussion of the theoretical and practitioner bases of the concept of positive youth development.

Hypothesis One

The first hypothesis is termed the contextual change hypothesis, and consists of two assumptions. First, contexts can be intentionally altered to enhance developmental success. And second, changes in these contexts change the person.

There is abundant evidence that ecological contexts can be changed to promote positive youth development, as well as a wealth of data about why such approaches have those positive effects. In most of this research, researchers have documented (usually, but not always) the efficacy of intervention or prevention programs in providing youth with experiences that facilitate developmental outcomes. For example, from their review of 60 evaluations of youth development programs, Roth, Brooks-Gunn, Murray, and Foster (1998) concluded:

> [Y]outh development programs are best characterized by their approach to youth as resources to be developed rather than as problems to be managed, and their efforts to help youth become healthy, happy, and productive by increasing youths' exposure to the external assets, opportunities and supports. (p. 427)

The Social Development Research Group at the University of Washington conducted one of the most wide-ranging reviews of positive youth development programs (Catalano et al., 2004). They identified 161 programs and discussed in detail 25 that were well-evaluated and showed significant effects on behavioral outcomes. The programs had to have one or more of the following objectives about building developmental assets or nutrients: Promote bonding; foster resilience; promote social competence; promote emotional competence; promote cognitive competence; promote behavioral competence; promote moral competence; foster self-determination; foster spirituality; foster self-efficacy; foster clear and positive identity; foster belief in the future; provide recognition for positive behavior; provide opportunities for prosocial involvement; and foster prosocial norms. In addition, the programs had to address either multiple assets, or a single nutrient but across the multiple social domains of family, school, or community. Programs that addressed only a single asset in a single domain were excluded. Competence, self-efficacy, and prosocial norms were addressed in all 25 programs, and most programs dealt with at least 8 of the 15 nutrients. Most programs used positive outcome measures as well as reduction of problem behavior in their evaluations. Nineteen of the 25 programs demonstrated significant effects on positive youth development outcomes, including improvements in interpersonal skills, quality of peer and adult relationships, self-control, problem solving, cognitive competence, self-efficacy, commitment to school, and academic achievement. In addition, 24 of the 25 showed significant reductions in problem behaviors such as alcohol and other drug use, school problems, aggressive behavior, violence, and risky sexual behavior.

In a review of more than 1,200 studies of outcomes in prevention programs for children and adolescents, Durlak (1998) identified eight common protective factors across programs successful in preventing behavior problems, school failure, poor physical health, and pregnancy among young people: Social support; personal and social skills; self-efficacy; good parent-child relationships; positive peer modeling; high quality schools; effective social policies; and positive social norms. The resilience literature also suggests from the finding of "synchronous evidence" from multiple studies using differing measurements, that there are three critical kinds of protective factors: Close relationships with caring, supportive adults, often in primary care-giving roles; effective schools; and positive relationships with prosocial adults in the wider community (Luthar et al., 2000).

In a meta-analysis of 177 primary prevention programs designed to prevent behavioral and mental health problems among children and adolescents, Durlak and Wells (1997) reported that most kinds of primary prevention programs (whether person- or environment-centered, and whether universal or targeted) contributed both to reducing problems and increasing competencies. However, only 15% of these programs attempted to change children's environments, despite the emphasis of context in the major developmental systems and ecological theories that are the foundation of the positive youth development field.

Developmental theories suggest that, because of the fusion of person and context, variations or alterations in developmental context should be associated with variations or alterations in developmental outcomes. For example, theories regarding the development of anti-social behavior and violence typically posit several differing trajectories. Children who are chronically high in anti-social behavior from childhood through adolescence, for example, are seen as having biological or genetic vulnerabilities that manifest themselves in attention and concentration problems, which are associated both with early school failure and peer rejection (Moffitt, 1993). Poor parenting may also contribute to this pathway.

Those developing higher levels of antisocial behavior later in childhood or adolescence are seen as being influenced more by association with deviant peers (Dishion, Andrews, & Crosby, 1995; Patterson, Reid, & Dishion, 1992). A study of several hundred urban, mostly African American males followed from first grade through seventh grade found evidence supporting such differing pathways (Schaeffer, Petras, Ialongo, Poduska, & Kellam, 2003). Theoretically then, it is plausible that early efforts to improve family related assets, social competencies, and school success all could have an ameliorative effect on the development of antisocial behavior trajectories. Indeed, Furlong, Paige, and Osher (2003) note such evidence findings linking violence prevention with children's connection to caring adults, social/emotional skills, and appropriate instruction and academic supports that promote a sense of competence and school success.

Similarly, in a study of school success, Gutman, Sameroff, and Eccles (2002) showed that developmental assets may have both a promotive (helpful for all youth) and a protective function (helpful for some youth under conditions of risk). In their study of more than 800 seventh-grade African American students, these researchers found that consistent discipline and parental school involvement were related to higher GPAs and better attendance for all youth, but not to math test scores. Peer support was a helpful resource, but only for math test scores, and then only for students who also were exposed to multiple risks such as low maternal education and family income. Parent promotion of democratic decision making was related to higher GPAs and math test scores for students who experienced multiple risks, but it was high-risk students whose parents did *not* promote democratic decision making who had the greater school success. The researchers reasoned that parents adapt their parenting practices to the risk level of the environment, with greater parental control more beneficial when children are living in high-risk environments.

In a study of high school students, McLellan and Youniss (2003) used the framework of identity development theory to describe the developmental role played by different kinds of community service, that is, differing service contexts. In their view, service provides access to different "transcendent systems of meaning" that enable young people to connect themselves with historical, religious, ethnic, or political traditions "of which they can legitimately feel a part" (p. 57). Young people were more likely to volunteer if they were in networks in which their parents and friends did service, and if they were connected to youth organizations and religious institutions. That is, service was less an individual and spontaneous act and more the result of a web of asset-building relationships and norms that together elevated service to a shared social expectation.

One of the most impressive studies illustrating the power of changed contexts on personal change and developmental success is the evaluation of Big Brothers/Big Sisters conducted by Public/Private Ventures (Tierney, Grossman, & Resch, 1995). The investigators fashioned a true experiment by randomly assigning half of those awaiting placement to a delayed-treatment control group while seeking placements for the other half. Those in the treatment group demonstrated several advantages over the control group, including lower likelihood of beginning to use drugs and alcohol or to have hit another person, along with better attitudes toward school, better grades, and attendance. In addition, they reported improved relations with family and peers. The causal pathway of mentoring's effects on school performance appears to have been through improved relations with parents (Rhodes, Grossman, & Resch, 2000).

In summary, intentional efforts to change contexts to improve developmental success among young people largely have been shown to be effective. A cluster of intervention components including strengthened adult-youth relationships, social norms around desired behavior, development of social competencies, and provision of youth opportunities appears especially critical.

Hypothesis Two

The youth action hypothesis is the second hypothesis. The three components that comprise it are: (1) Youth action impacts contexts and the person. When youth take action to improve the contexts in which they live, the impact is enhanced because such action (properly guided and including reflection) is developmentally enhancing and, when successful, makes the target context(s) more beneficial to the actors and to other youth; (2) The impact is cumulative because youth who take action are more likely than those who do not to take action in the future, which again enhances their personal development and the contexts they have changed; their example also encourages other youth to take action; and (3) Processes for strengthening youth impact on context and self—youth participation and leadership—can be designed and implemented.

Systems and ecological models of development hold that individuals are both the products and producers of

their environments, and that it is the *relation* between the individual and environment that influences development (Bronfenbrenner & Morris, 1998; Hamilton et al., 2004; Lerner, 2002; Zeldin, 2004). As Hamilton et al. (2004, p. 15) note: "Human beings develop through active engagement with their environment; by making choices and shaping that environment, they also direct their own development." Two related processes may be at work. Young people's engagement may in fact alter how other people relate to them, and young people taking action to improve their contexts may subjectively appraise those contexts more favorably.

Youth engagement extends beyond merely providing opportunities for youth, but is rather a part of an intricate dialectic that itself characterizes positive outcomes, or thriving (Lerner, Dowling, & Anderson, 2003). Lerner hypothesizes that when this bidirectional process occurs under conditions of "building a civil society"—that is, when the ideals of equity, democracy, social justice, and personal freedoms are supported—and when youth see themselves as part of an activity or issue that is larger than themselves, this in turn impels both healthy individual development as well as salutary effects for the community (Lerner, Dowling, et al., 2003; see also Nakamura, 2001; Pancer, Rose-Krasnor, & Loiselle, 2002).

'Youth engagement' is a multidimensional term, and loosely refers to activities and constructs such as positive citizenship, volunteering, prosocial acts in the community, involvement, participation, community service, and youth voice (O'Donoghue, Kirshner, & McLaughlin, 2002; Zaff & Michelsen, 2002). Central to all of these terms is meaningful participation in an activity that links the individual, through action and commitment, to the broader context (Nakamura, 2001; Pancer et al., 2002). It is this last component—where the individual "transcends self-interest" (Lerner, Dowling, et al., 2003; p. 176)—that separates youth engagement from other extracurricular activities in which the youth may partake.

The interplay of person and context means not only that change in context changes the person, but that young people's actions inevitably alter the developmental contexts they experience, with related consequences, positively or negatively, for their developmental well-being (and as well, the positive development of their *community*—see below). For example, exploring the theoretical importance of "engagement" in living, Hunter and Csikszentmihalyi (2003) studied a diverse national sample of 6th, 8th, 10th, and 12th graders. They compared adolescents who were "chronically interested" as they went about their lives, versus adolescents who reported being habitually bored. The interested, engaged adolescents had significantly higher global self-esteem, internal locus of control, and optimism about their future, and significantly less pessimism than the bored adolescents.

Hunter and Csikszentmihalyi (2003) reasoned that, over time, engaged adolescents will develop more internal resources of confidence and enthusiasm—more "psychological capital"—than their disengaged peers, because they view themselves as more effective agents in constructing the flow of their lives. Moreover, their openness and interested connection to their experiences may both partly arise from their social capital in the form of adults' enhancing and guiding their interests, and also help create further social capital, as their very interested nature attracts others to them. Ryff and Singer (1998) also ascribe high importance to the effect that individuals' perceptions of events or circumstances have on psychological coping and how "physiological cascades unfold" (p. 13) based on perceptions.

These theoretical descriptions of social and psychological capital, and the processes that link them, are quite analogous to Benson et al.'s (1998) formulation of "external" and "internal" developmental assets being key "building blocks of success." Similar too is Lerner, Wertlieb, and Jacobs (2003) elaboration of the reciprocal individual-context relations that are the heart of developmental systems theory.

Dworkin, Larsen, and Hansen (2003) also provide a theoretical explanation of how youth participation in one kind of developmental context—extracurricular or community-based activities—might positively influence development through young people's actions. They postulated that such activities facilitate six different developmental processes: Identity exploration; the development of initiative ("the capacity to direct attention and effort over time toward a challenging goal," p. 18) and goal-directed behavior; growth in emotional competencies; formation of new and varied peer network connections; development of social skills; and the acquisition of social capital through developing relationships with nonfamily adults. Dworkin et al. concluded that a common thread connecting these processes is that the young people participating in youth programs were developing a sense of agency and seeing themselves as producers of their own development. This empirical conclusion provides support for

one of the basic tenets of both ecological and especially developmental systems theory, that children and youth help to construct their contexts and do not simply "interact" with them (Lerner, 2002).

Masten et al. (1999) used multiple methods to follow a group of 200 urban 8- to 12-year-olds for 10 years, investigating pathways to resilience. Individuals were resilient if they were adequately competent in academic achievement, conduct, and peer relations even when experiencing high adversity. They experienced positive adaptational systems much like those of low adversity and competent peers, namely, adequate IQ, high parenting quality, high self-worth, and a cheerful, energetic outlook. Consistent with positive youth development Hypothesis 2, competence in childhood longitudinally predicted positive changes in parenting quality during adolescence, and parenting quality in childhood longitudinally contributed to positive changes in peer social competence during adolescence. Children's own behaviors changed the kind of family context they experienced, as reflected in parenting, and through that path altered another developmental context, that of later peer relations.

When youth provide community service, they participate in an activity that explicitly is intended to alter both person and context. For example, Metz, McLellan, and Youniss (2003) studied 367 mostly European American, middle-class, public high school students in Boston, examining how different kinds of community service facilitated civic development (e.g., concern with poverty, intention to vote, demonstrating for a cause, future volunteering) over the course of a school year. Both social cause service (remedying a social problem) and standard service (from coaching to raking leaves) were associated with greater future intentions to serve than was not participating in service. However, social cause service during the school year was associated with greater concern for social issues and unconventional civic involvement than was standard service or no service.

Eccles and Barber (1999) examined the effects of 10th-grade prosocial activity involvement (church involvement and/or participating in volunteer and community service) on concurrent and future (2 years later) risk behaviors and academic outcomes. Students engaged in prosocial activities drank alcohol and used marijuana less at both time points than did students not engaged in these activities. In addition, involved students also had higher concurrent and future grade point averages than did their noninvolved peers, even after controlling for initial levels of outcome.

Scales, Blyth, Berkas, and Kielsmeier (2000) compared, over the course of a school year, social responsibility and academic success among middle-school students engaged in service-learning projects and a control group of students. Youth action had significant effects on young people's social contexts: Youth in service-learning projects were more likely to maintain concern for others' welfare than were control students. Moreover, service-learning students, especially girls, also declined significantly less then did control students in their frequency of talking with parents about school, a contextual effect (parent involvement) related to positive academic achievement.

In a study by Allen, Philliber, Herrling, and Kuperminc (1997), almost 700 high school students were randomly assigned to a treatment group, which consisted of structured volunteer community service time as well as a related classroom-based curriculum, or to a control group. Students involved in volunteer activities had significantly lower rates of course failure, school suspensions, and rates of pregnancy (ever been for females, responsible for pregnancy for males) than did the control group.

In a study of 972 urban, predominantly non-European American seventh and eightg graders, O'Donnell and colleagues (1999) found that students who participated in community service reported significantly less violence than did control students, after controlling for initial levels of violence, gender, ethnicity, and socially desirable responses. Students who had only a violence-prevention curriculum did not differ from controls at the 6-month follow-up, suggesting that participation in community service was critical to the changes in behavior.

These studies illustrate the significance of different kinds of youth engagement on *changes* in developmental outcomes over time. In particular, given that in many cases these effects held after controlling for potential selection-effect confounds (Atkins & Hart, 2003), these results suggest that all youth, regardless of background, can benefit from these kinds of experiences.

Youniss and colleagues (Yates & Youniss, 1996; Youniss, McLellan, & Yates, 1997) offer a more specific model for how youth participation actively facilitates not only a sense of identity, but specifically, civic identity. They argue that "participatory action" during adolescent identity formation infuses one's sense of self with a civic component; this civic component then

becomes an inextricable part of how an adolescent sees himself or herself (Youniss et al., 1997).

Youniss proposes three related consequences of youth engagement that work to influence identity formation. First, participating in community activities "allows youth to see society as a construction of human actors with political and moral goals rather than as a distant, preformed object" (Youniss et al., 1997). Second, by virtue of engaging in these kinds of activities, youth build a sense of agency regarding their own abilities to influence their surrounding contexts. Third, community involvement instills in youth a sense of responsibility for welfare of the community and its members (see also Lerner, Dowling, et al., 2003). These processes have lifelong effects on the attitudes individuals hold and the actions they take. Support for this hypothesis is provided in Youniss et al. (1997). Retrospective accounts indicated that participation in youth organizations during adolescence increased the likelihood of civic behaviors (e.g., membership in local civic, church, service, and professional groups) 15 years later in adulthood. This is interpreted as indicating that youth engagement acts as a gateway to future civic involvement (Tolman & Pittman, 2001).

The research thus shows the positive impact that youth action has on both person—young people themselves—and social context. However, most of this research concerns community service or service-learning programs, which represent only one kind of "youth action" or leadership. One review of more than 800 studies concluded that youth "empowerment," broadly construed, is a relatively less represented area of research in positive youth development (Scales & Leffert, 2004).

Hypothesis Three

The covariation hypothesis states that the Person factors (e.g., achievement motivation) and context factors (e.g., caring school climate or school boundaries) covary and are mutually reinforcing. That is, ecological factors and individual attributes tend to be directly related. Increasing assets of one kind tends to increase the other.

Developmental theory posits that person and context truly are mutually interactive. Thus, developmental assets "in" the person, such as social competencies or positive identity, should be found operating together with developmental assets "outside" the person in their various contexts (e.g., family, schools, peers, community) to promote developmental well-being and thriving. In support of this hypothesis, studies consistently find constellations of developmental nutrients, including both internal and external factors, to be associated with various outcomes. For example, Dukes and Stein (2001) measured several protective factors, including: self-esteem, positive school attitudes, prosocial activities (homework, clubs, service), purpose in life, and prosocial bonds (attitudes toward police officers). Outcomes included drug use, delinquency, and weapons possession. A second-order factor comprising the assets predicted significantly fewer of those problem behaviors among a sample of 13,000 6th to 12th grade students in Colorado. Similarly, in the Add Health study, lower levels of violence were significantly predicted by parent-family connectedness, parental expectations for education (weakly), and school connectedness. However, parent-adolescent activities or self-esteem did not predict lower levels of violence (Resnick et al., 1997).

Leffert et al. (1998) studied a sample of nearly 100,000 youth from more than 200 U.S. communities. They reported that a cluster of four assets—positive peer influence, peaceful conflict resolution, school engagement, and safety—added 30% to the explained variance of engagement in violence, compared to the 8% explained by demographics.

Crosnoe, Erickson, and Dornbusch (2002) studied a diverse sample of adolescents from nine California and Wisconsin high schools. They reported that "protection" against delinquency and substance use existed among adolescents who experienced warm relations with parents, came from relatively well-organized households, valued academic achievement, were engaged at school, felt close to teachers, and performed well in school.

Catterall (1998) analyzed subsamples from the National Educational Longitudinal Study of 1988 to explore the concepts of commitment resilience and academic resilience among 8th graders followed through 10th grade. Commitment resilience was the recovery by 10th grade of confidence in graduating among those who in 8th grade had "any degree of doubt" about graduating. Academic resilience was the significantly better performance in English of 10th-grade students who in 8th grade had C or lower grades in that subject. Both kinds of resilience were fostered by a similar constellation of positive assets. These assets included family involvement in and supports for schooling (e.g., books in the home, a place for studying, rules about TV watching [for academic resilience only]), teacher responsiveness (listening and being interested in students), fairness of

school discipline policies, and student involvement in school and extracurricular activities.

These studies illustrate the commonly observed linkage of both person and context factors in positive youth development. Some assets, such as school bonding, also well exemplify the often tenuous distinction between "internal" and "external" resources. School bonding is a particularly important developmental asset, having been linked to positive outcomes such as reduced substance use, antisocial behavior, risky behaviors such as early sexual initiation, delinquency and, most substantially, academic performance. Four dimensions of school bonding have been identified: Attachment to school (youth care about their school), attachment to personnel (connection to school adults), school commitment (the priority of school for youth), and school involvement (participation in school activities). In the social development model, involvement is seen more as a contributor to school bonding than a result of it (Maddox & Prinz, 2003), but that the construct comprises *both* internal and external dimensions underscores the covariation of person and context influences on development.

Hypothesis Four

The fourth hypothesis, termed the "pile-up" hypothesis, states that the total number of positive experiences (i.e., a pile-up of assets) is concurrently related to both positive and negative outcomes. Moreover, assets are functionally equivalent; it is the number of assets that matters, not specific assets or combinations of assets, because context-person fusion creates an infinite diversity of combinations of assets that "matter most." Research provides considerable support for the first part of this hypothesis, the "pile-up" effect associated with greater numbers of assets. But there is also considerable evidence that specific assets or clusters of assets matter more or less for specific youth (see also below under the universality/diversity hypothesis), and depending on the developmental outcome the assets are hypothesized to predict.

The accumulation of developmental strengths repeatedly has been shown to add value over the positive effects of a lesser number of strengths. As discussed in Benson et al. (2003) there are two manifestations of this pile-up, horizontal and vertical. Horizontal pile-up is reflected in cross-sectional studies that document an increased association of assets and outcomes at a single point in time when the young person experiences greater numbers of those assets. Horizontal pile-up also implies contextual breadth, if not synergy, in the experience of assets, as when the accumulation of assets experienced in multiple ecological contexts (e.g., family, school, community, peer) is more strongly associated with positive outcomes than are assets experienced in only one context.

Jessor, Van Den Bos, Vanderryn, Costa, and Turbin's (1995) longitudinal study of seventh to ninth graders was one of the first to demonstrate, not only that an accumulation of risk factors was associated with greater problem behavior, but that a greater accumulation of protective factors was associated with fewer problem behavior. Implicit in their Protective Factor Index was the representation of multiple contexts, including school, friends, family, and community elements. Gutman and Midgely (2000) documented the multiplicative effects of developmental assets on the academic achievement of African American students living in poverty and making the transition to middle school. Students with either family (high parental involvement) or school protective factors (perceived teacher support, or feelings of school belonging) had higher GPAs in sixth grade than classmates who did not experience those nutrients. But students who had both family and school assets had higher GPAs than students who had only family or school assets but not both.

In a sample of more than 100,000 youth, Benson, Scales, Leffert, and Roehlkepartain (1999) found that each successive increase in a young person's quartile asset level, from asset-depleted (0 to 10 assets) to asset-rich (31 to 40 assets) was associated with significantly more adolescent thriving (e.g., school success, overcoming adversity) and significantly less risk behavior (e.g., problem alcohol use, early sexual intercourse).

A subsequent analysis of a more diverse sample of 217,000 middle and high school students from more than 300 U.S. communities revealed the same evidence of horizontal pile-up (*Developmental assets,* 2001). Young people with 0 to 10 assets report an average of 4.1 high-risk behavior patterns; those with 11 to 20 assets report 2.3 risk patterns; those with 21 to 30 assets report an asset of just 1 high-risk behavior pattern; and asset-rich youth, and with 31 to 40 assets, report an average of just .3 high-risk patterns.

Hollister-Wagner, Foshee, and Jackson (2001) studied how developmental assets (protective factors in their terminology) might promote resilience to aggression among adolescents. In their study of rural eighth and

ninth graders, the protective factors investigated were importance of religion, self-esteem, closeness to one adult, relationship competence, constructive communication skills, and constructive anger response. For females, but not for males, the researchers found that with each increase in the simple number of protective factors, the relationship between risk factors (e.g., having been hit, witnessing parental violence) and reports of beating up one's peers weakened. Eighth and ninth-grade girls who had all six protective factors were about three times less likely as girls with only two, and four times less likely as girls with no protective factors, to report beating up someone.

Relationships with adults in school and community settings also provide valuable sources of protection from risk. For example, in the National Longitudinal Study on Adolescent Health, Resnick et al. (1997) reported that young people who experienced closer connections to their families and schools were significantly less likely than other adolescents to engage in a variety of risk-taking behaviors. Each of the contexts (family and school) by itself explained relatively modest portions (5% to 18%) of the variance across outcomes such as emotional distress, violence, and substance use. But when the effects of the other context (family or school) and assets in still other contexts (e.g., religious involvement) were included, the contribution of these assets to outcome variance increased by more than 50%.

In another report utilizing the Add Health data (U.S. Department of Health and Human Services, 1999), the extent of several positive behaviors among 7th to 12th graders was noted, such as getting B or higher averages, involvement in extracurricular activities, and religious involvement once a month or more. The more positive behaviors in which students engaged, the fewer the number of risk behaviors in which they engaged.

Cumulative environmental risk has been shown to be predictive of internalizing and externalizing problems, not only as the absolute number of risks increases, but as the number of social domains (e.g., family, peer, school, neighborhood) being high-risk increases (Gerard & Buehler, 2004). Sanders's (1998) study of more than 800 urban African American students in the eighth grade lends further support to the hypothesis that, analogous to the findings for risk, *strengths* piling up *across* ecological domains magnify the protective and thriving effects of positive experiences in single contexts.

He reported that when all three support contexts—family, school, and church—were combined, the effect on academic self-concept (which most strongly predicted actual achievement) and achievement ideology were stronger than the unique effects of any of the individual contexts (the combined effect on school conduct was comparable to the individual effect from teacher support). This finding suggested that "when students receive support from the family, church, and school simultaneously, the effects on their attitudes about self and the importance of schooling are magnified" (Sanders, 1998, p. 402).

The effects of positive experience across multiple contexts can be seen as well in Scales, Benson, et al.'s (2000) study of the relations among developmental assets and thriving indicators. For example, among European American 6th to 12th graders, achievement motivation alone explained 19% of the variance in school success (self-reported grades). But school engagement, time in youth programs, time at home, planning and decision making, parent involvement in school, and self-esteem added another 12% of variance (Scales, Benson, et al., 2000). The Search Institute findings are consistent with those reported by Eccles, Early, Frasier, Belansky, and McCarthy (1997). In their study of middle school students, the explained variance of adolescent outcomes was "substantially increased" when all the contexts studied (family, school, and peers) were added into regressions, leading the researchers to conclude that positive experiences across contexts add "linearly and independently" to contribute to positive development.

Brody, Dorsey, Forehand, and Armistead (2002) studied the contribution of supportive parenting and classroom processes to the psychological adjustment of African American elementary and middle school students living in poverty in the South. For both grade cohorts, they found that students experiencing high parenting (high monitoring and a supportive, involved mother-child relationship) or classroom quality (high levels of organization, clarity of rules, and involvement of students) had better adjustment than students experiencing low quality in both contexts. However, students experiencing high quality in *both* contexts had the best adjustment, as reflected in the highest self-regulation scores, and lowest externalization and depression scores.

Similar findings, among fifth and sixth graders, are reported by Paulson, Marchant, and Rothlisberg (1998) in a study of the effect of children having assets across contexts. Children with the highest achievement perceived a consistency and congruence of parenting and teaching styles, accompanied by high parental involvement in school and a caring school climate. The assets provided by family and school enabled those children to

enjoy more positive outcomes than children who experienced assets in only one of those contexts.

A test of the social development model (Catalano & Kosterman, 1996) found an acceptable fit to predicting drug use among 590 17- and 18-year-olds on the basis of variables measuring prosocial and antisocial influences from fifth grade through middle school. In addition to prior drug use, the model includes such protective factors as: perceived opportunities and rewards for prosocial involvement (knowing where to go to join clubs, participating in family decisions, having lots of chances for extracurricular activities), reported involvement in prosocial activities (including church attendance and membership in community groups), social competencies, attachment and bonding to prosocial others, and belief in the moral order (e.g., importance of telling the truth, whether it is okay to cheat). All the path coefficients for protective factors to drug use were significant and in the expected direction.

In a study of 12,500 9th to 12th graders from the original Add Health study pool of 7th to 12th graders, Zweig, Phillips, and Lindberg (2002) reported that students with higher levels of protective factors (e.g., decision-making skills, participation in physical activities) consistently had significantly lower levels of behaviors such as sexual activity, alcohol use, binge drinking, other drug use, fighting, and suicidal behaviors.

Similarly, Jessor et al. (1998) examined risk and protection especially among disadvantaged students, with disadvantage defined by low parental occupational status, low parental education, and single-parent family structure. The outcome variables of interest were school engagement, low problem behavior, and a composite of the two, labeled "Making It." They reported that a protective factor index contributed about as much to variance in the successful outcomes as did a risk factor index. For example, risk contributed 32% to the composite measure of Making It, compared to 26% for protection.

Benson and Roehlkepartain (2004) studied the relation of assets to substance use among a cross-sectional sample of more than 217,000 6th to 12th graders. They reported that young people with low levels of developmental assets (0 to 10 of the 40 assets) were from 2.4 to 4.4 times more likely to engage in different kinds of alcohol, tobacco, and other drug use than were students at average or higher levels of assets (21 or more assets). The effects of assets were stronger than that of SES or living in a single-parent family.

The pile-up effect is seen for other outcomes as well. For example, the overall level of evidence (Miller & Thoresen, 2003) for the theoretical connection between assets and greater school success appears to be *persuasive,* supported by scores of peer-reviewed studies. However, this conclusion pertains only when a number of assets and other factors (e.g., teachers' collective efficacy) are operating together; rarely do single assets or other factors (excepting near tautologies such as previous grades predicting future grades) account for considerable variance in school success outcomes (Wang, Hartel, & Walberg, 1990). Benson et al. (1999), for example, reported that in a sample of nearly 100,000 6th to 12th graders, each quartile increase in students' levels of 40 developmental assets (i.e., from 0 to 10, 11 to 20) was associated with a significant improvement in self-reported grades.

Similarly, Scales and Benson (2004) created a prosocial orientation measure by combining several items tapping adolescents' attitudes toward helping others, and several items asking about intentions to help those in need, working to improve their school, or tutoring or coaching younger children over the next year. They then examined the concurrent relation to prosocial orientation and the number of developmental assets adolescents reported. In a racially/ethnically diverse sample of more than 5,000 6th to 12th graders, they found that each increase in the quartile level of the asset domains studied (0 to 2, 3 to 5, 6 to 8, or 9 to 12 assets) was associated with a significant increase in the mean score on prosocial orientation. They also found that, controlling for grade in school, race/ethnicity, and parental education, both boys and girls with above average levels of prosocial orientation were nearly four times more likely to report actual volunteer service of at least 1 hour per week in the past year.

Overall, the empirical evidence is consistent and strong for the theoretical relation between the number of assets that adolescents experience and the positive developmental outcomes of both greater thriving and lessened risk behaviors.

Hypothesis Five

The longitudinal hypothesis is defined as the fusion of context/person dynamics in the presence of high levels of developmental assets results *over time* in (a) lessened risk behaviors; (b) increased academic achievement; (c) increased contribution; and (d) higher levels of other thriving indicators.

Numerous studies have demonstrated the contribution that developmental assets make to positive youth

outcomes not only concurrently but also over time. For example, more than 30 longitudinal studies showing these relations are cited in comprehensive reviews of research on developmental assets in adolescence (Scales & Leffert, 2004) and middle childhood (Scales et al., 2004). Although in all cases, the studies focus on only one or a small number of assets, not the entire range of 40 assets identified by Search Institute, the results are nevertheless consistent: The experience of developmental assets contributes significantly to the likelihood of subsequent protection from high-risk behaviors and promotion of thriving.

For example, Moore and Glei (1995) found that young people who as children and adolescents participated significantly more than their peers in school clubs were especially likely to report positive outcomes *in young adulthood* (ages 18 to 22). Outcomes included closer relationships with their parents, and greater involvement in community affairs or volunteer work.

In a small ($N = 100$) sample of racially/ethnically diverse adolescents from low-income families, Way and Robinson (2003) found, as predicted, that the asset of positive school climate contributed to higher levels of self esteem at 2 years later, over and above the positive effects of family and friend support. Masten et al. (1999) followed a sample of urban 8- to 12-year-olds for 10 years. They showed that even after controlling for IQ and socioeconomic status (SES), the quality of parenting in mid-adolescence predicted academic, conduct, and social competence in late adolescence. Perhaps more striking, the quality of parenting in childhood predicted social competence 10 years later in late adolescence.

Pettit, Bates, and Dodge (1997) reported similar longitudinal results in their 7-year study of more than 500 Tennessee and Indiana families with kindergartners. The quality of supportive parenting children received as kindergartners (e.g., parental warmth and involvement, proactive teaching, calm discussion) contributed a small (1% to 3%) but unique amount of variance to the prediction of their functioning in both kindergarten and grade six, including whether they exhibited problem behaviors, were socially skillful, and performed well in school. This study was notable for showing that the presence of positive parenting, not merely the absence of harsh parenting, plays an important role in contributing to child well-being in both the short- and longer-term.

Moreover, as for studies reflecting horizontal pile-up, experiencing assets in multiple contexts also is developmentally advantageous over time. Cook, Herman, Phillips, and Settersten (2002) reported in their study of changes in early adolescent development that the effects of *individual* contexts on development were generally quite modest. However, the *additive* effects of adolescents' multiple positive contexts were considerable, a result in alignment with other research showing the value of young people experiencing "redundancy" of developmental assets across their ecologies (Benson et al., 2003).

Ultimately, the most important "outcome" of positive development is more postive development. The findings of the Iowa Youth and Families Project are illustrative. The researchers (Conger & Conger, 2002) reported that the assets of nurturant and involved parenting experienced in seventh grade helped young people have fewer emotional and behavioral problems and function more competently during adolescence, even when dealing with family economic adversity. But young people who experienced those family assets during adolescence also were themselves more competent parents and more successful in their romantic relationships years later in *early adulthood* (5 years posthigh school).

Gambone et al. (2002) created indices to measure several optimal adolescent developmental outcomes (young people are productive, connected, and can navigate through their worlds effectively), and several optimal young adult outcomes (individuals are on a path to economic self-sufficiency, have healthy family and social relationships, and are involved in the community). About half of youth were doing well overall in young adulthood, but 69% of those with optimal developmental milestones in high school subsequently did very well, with a 41% greater chance of experiencing such optimal young adult outcomes. Moreover, young people who had optimal levels of the developmental nutrients *early* in high school were much more likely to have the positive developmental milestones later in high school. For example, youth who had supportive relationships with parents, teachers, and friends early in high school were 100% more likely to have optimal developmental outcomes later in high school.

Analysis by Search Institute (2004) of a longitudinal sample of 370 students in St. Louis Park, Minnesota, from when they were in 7th to 9th grades to when they were in 10th to 12th grades, showed that, in general, the more assets students reported in 1998, the less they reported risk-taking behavior patterns (e.g., driving and alcohol problems, school problems) and the more they reported indicators of thriving (e.g., delayed gratifica-

tion, physical health) in 2001 (unpublished analyses for this chapter; for study details see Scales, Benson, Roehlkepartain, Sesma, & van Dulmen, in press; Scales & Roehlkepartain, 2003). These results were largely maintained even when controlling for earlier levels of the outcome variables. Additional perspective came from using a more person-centered analysis. Students who stayed stable or went up .5 SD in their assets over those 3 years had significantly fewer problem alcohol use or school problems, and more informal helping, leadership, overcoming adversity, and school success than students who declined .5 SD in their assets.

Moreover, both concurrently and longitudinally, each quartile increase in assets was associated with significantly higher GPA, and the longitudinal relations held even when controlling for the effects of earlier GPA (Scales & Roehlkepartain, 2003). The difference in mean GPA between asset-rich students (31 to 40 assets) and asset-depleted students (0 to 10 assets) was equivalent to the difference between a B+ and a C average. In addition, growth curve analysis showed a small but significant relationship between increase in assets and increase in GPA, such that mean GPA increased about ⅕th of a grade point over time for each increase of one asset.

In a small study of 95 inner-city sixth to eighth graders (about 60% non-European American), Dubow, Arnett, Smith, and Ippolito (2001) reported that the asset of positive expectations for the future, as assessed in September, significantly predicted lower levels of a problem behavior index in June, including using alcohol. In addition, higher initial levels of perceived problem-solving efficacy and family support predicted increases over the school year in positive expectations for the future. In another example, the social development model was applied to promote children's bonding to school in Seattle. Children who received a program in Grade 5 emphasizing the development of social competencies and bonding to school experienced, by age 21, significantly more responsible sexual behavior, including fewer partners and less sexually transmitted diseases, than peers not exposed to the program (Lonczak, Abbott, Hawkins, Kosterman, & Catalano, 2002).

Benson and Roehlkepartain (2004) also conducted longitudinal analyses on a sample of middle school students who reported abstaining from alcohol, tobacco, or drug (ATOD) use in 1997. Those who continued to abstain in high school 4 years later, compared to those who began ATOD use, had significantly higher levels of assets in both 1997 and 2001, especially in the categories of support, and boundaries and expectations. These results offer an additional provocative suggestion of the role of developmental assets in protecting young people from ATOD risks.

Participation in youth programs was found in both the Scales, Benson, et al. (2000) and Scales and Roehlkepartain (2003) Search Institute studies to be linked to school success. In a study focusing on the role of such extracurricular programs on posthigh school educational achievement, Mahoney, Cairns, and Farmer (2003) utilized the Carolina Longitudinal Study to follow nearly 700 students annually from 4th grade through 12th grade, interviewing them again when the young people were 20. They found that consistency of extracurricular participation was significantly associated with both interpersonal competence over time, as well as with educational aspirations in late adolescence, and both of those factors were linked to educational status (whether in postsecondary education or not) at age 20. The researchers explained the theoretical basis for such results by noting that the peer and adult relationships and skills associated with sustained extracurricular activity participation promote social acceptance, positive social identity development, less depressed mood and anti-social behavior, school engagement, and higher educational expectations.

In an analysis of several waves of data from the National Education Longitudinal Study of 1988, Zaff, Moore, Papillo, and Williams (2003) reported that volunteering 2 years after high school was significantly more likely among students who enjoyed key developmental assets from grades 8 to 12, such as having high levels of parental support and monitoring, positive peer influences, and attendance at religious services. Moreover, if students consistently participated in extracurricular activities during grades 8 to 12—regardless of whether those activities were sports, schools clubs, or community clubs—they were twice as likely to volunteer and to have voted in local or national elections 2 years after high school as students with only occasional extracurricular participation.

The overall pattern of these results suggests that developmental strengths provide some unique proportion of influence over time in addition to their much more substantial impact on concurrent developmental outcomes. In both their strong concurrent relations and small to moderate longitudinal relations, they provide support for the theoretical proposition that developmental assets positively affect developmental trajectories.

Hypothesis Six

The Community Hypothesis is based on the notion that community is a viable focus for understanding and promoting dynamics crucial for maximizing context/person relationships. By analogy to public health, the largest improvements in positive youth development will occur in response to interventions/initiatives that are aimed at changing communities more so than those aimed at individuals. How the community is defined depends on the target(s) of the intervention/initiative.

The inadequacy of individual treatment is related to the principles of public health and prevention. Despite dramatic improvements in medical treatment, Kreipe, Ryan, and Seibold-Simpson (2004, p. 104) point out that "Improved sanitation, work environments, and immunization programs as well as safety measures . . . have done more to improve health than one-to-one medical treatment."

Similarly, community mobilization to promote positive youth development must address not only formal organizations and programs but also informal norms and relationships. Studies show that youth do better in communities where adults share some basic values, norms, and expectations, including understandings about what kind of behavior is acceptable and what to do when someone crosses the line (Damon, 1997; Sampson et al., 1997).

In this section, we refer to community as the interlocking systems of contexts, ecologies, and settings that moderate developmental growth. Accordingly, there are within this broad conception a wide range of influences on development, including family, neighborhood, school, playground, and congregation, the relationships inside and beyond these settings, and the policy, business and economic infrastructure of a community.

Tolan, Gorman-Smith, and Henry (2003) conducted a 6-year longitudinal study of several hundred African American and Latino adolescent males and their primary caretakers. As predicted by bioecological theory (Bronfenbrenner & Morris, 1998), they reported a complex relationship among community structural characteristics, neighborhood processes, parenting practices, and youths' violent behavior. Neighborhood concentrated poverty and high crime levels were found to predict the extent of perceived neighborhood problems and neighborliness, as well as directly to predict parenting practices, such that high poverty and crime were related to more restrictive parenting, which reduced violence by limiting youths' gang involvement.

Scales and Roehlkepartain (2003) found that for every point higher students scored in 1998 on a developmental assets factor reflecting connection to community, they were three times more likely than other students to be in the high GPA group (B+ or higher) in 2001. Assets in that factor included youth programs, religious community, service to others, creative activities, reading for pleasure, other adult relationships, and adult role models. The results of this study are provocative in suggesting how a multiplicity of assets reflecting the developmental attentiveness of "community" may favorably affect young people's school success.

Similarly, Greenberg et al. (2003) reviewed a wide range of evidence that suggests the most effective school-based prevention and youth development data are those that "enhance students' personal and social assets" and improve the school-community environment (p. 467). The focus of effective approaches is not on narrow programs addressing a single issue—programs that often may be disruptive more than beneficial—but comprehensive efforts that try simultaneously to build students' health, character, citizenship and community connection, school orientation, and academic performance. The American Psychological Association's Task Force on Prevention, Promoting Strength Resilience, and Health in Young People, also endorses a broad approach that coordinates problem-prevention with efforts to build young people's competence, relationships with others, and contributions to the community (Weissberg et al., 2003).

Echoing the research presented earlier as relevant to the first positive youth development hypothesis (i.e., that contexts are modifiable, and that these changes in contexts have consequences for youths' developmental outcomes), a core of strategies repeatedly appears in reports of successful efforts. These include: building students' social-emotional learning repertoire, providing frequent opportunities for student participation, such as through community service, fostering caring, supportive relationships among students, teachers, and parents, and consistently rewarding positive social, health, and academic behaviors through school-parent-community collaborations.

Much of the source for the impact of community comes from adults outside young people's own families. Recent research has documented clearly the value of formal mentoring relationships for young people (DuBois, Holloway, Valentine, & Cooper, 2002; Rhodes et al., 2000). The more global influence of "other adult assets" that occur quite naturally in young people's

lives, such as with neighbors, is potentially more far-reaching but has been less well studied. The limited evidence suggests that only 15% of young people report experiencing a "rich" level of relationships with adults other than parents (Scales, 2003; Scales et al., 2002).

But the climate of social expectations is crucial. Sixty-two percent of U.S. adults with *strong* social expectations for involvement are highly engaged with other people's children, versus 41% for those who feel only moderate expectations, 22% for those with mild expectations, and just 9% for those with weak social expectations for involvement (Scales, 2003). Consequently, although studies regularly demonstrate the effect of "community" as a source of developmental assets, potentiation of the full range of possible positive community impact on youth development requires attention to changing existing social norms about adult-youth engagement.

Some of the more ambitious efforts to intervene at the level of community have been initiated by national foundations. The Kellogg Youth Initiative Partnerships (KYIP) were launched in 1987 to assist three Michigan communities in expanding beyond investment in "fixing young people's problems" to community collaborations engaged in promoting youth potential. Combining service integration with youth development principles and a focus on school reform, the Annie E. Casey Foundation in 1987 launched New Futures, a 5-year demonstration project in five cities with high percentages of high-risk youth. In 1995, with funding from a consortium of foundations, Public/Private Ventures (P/PV) launched its Community Change for Youth Development Initiative (CCYD). The CCYD provided communities with a set of research-based core principles and with strategies for implementing them. Among the principles were adult support and guidance and structured activities during nonschool hours.

None of these initiatives reported large and consistent effects in terms of outcomes for youth. However, new programs, organizations, and leaders demonstrated enduring impact. For example, 5 years after New Futures funding was ended, investigators (Hahn & Lanspery, 2001) attributed "change that abides" to the "ripeness" of the communities for change, including leadership, a widespread recognition of problems, and utilization of other resources and initiatives with compatible goals.

In a similar vein, a report from the Kellogg Foundation (n.d.) after the 1st decade of KYIP stressed the critical importance of engaging the community. Such engagement critically includes youth themselves. And from the lessons of CCYD, Gambone et al. (2002) have articulated and demonstrated a convincing rationale for evaluating the *opportunities* such an initiative creates for youth rather than focusing solely on impact or outcomes for individual youth. The "community action framework for youth development" (Connell et al., 2001) embeds such opportunities in a theory of change that can be theoretically and empirically linked to desired outcomes, some intermediate-term and some long-term.

In a particularly useful analysis of community initiatives, Dorgan and Ferguson (2004) examined factors critical to the success (or lack of it) in the New Futures initiative and the New York City Beacons project (community centers operating in public school buildings). Though the two initiatives had similar aspirations, they were directed by quite different theories of change and implementation strategies. The authors credit the particular success of the Beacons project to a clear, understandable, and politically compelling emphasis on co-locating services, supports and opportunities in neighborhood schools to create "safe havens" for youth. In addition, the Beacons' focus on professionals working directly with youth and on the grassroots support of volunteers, parents, and neighborhood residents led to faster achievement of goals than the New Futures approach of creating collaboratives to plan and coordinate youth services and programs city-wide.

A somewhat different theory of change undergirds Search Institute's national Healthy Community • Healthy Youth movement. With 600 communities currently engaged (Benson, 2003a), this change strategy invites communities to create multiple innovative "experiments" to transform contexts and ecologies with a particular eye to mobilizing asset-building adult and peer relationships. A number of studies are completed or ongoing in capturing both how transformative change is made and the connection of these changes to adolescent health and well-being (Mannes, Lewis, Hintz, Foster, & Nakkula, 2002; Whitlock & Hamiltion, 2003). A longitudinal study in St. Louis Park, Minnesota provides suggestive evidence that sustained community-wide engagement with asset-building has population-level effects on several measures of well-being (Roehlkepartain, Benson, & Sesma, 2003).

These studies generally support the broad hypothesis that describes "community" as an important focus of positive youth development efforts. However, much research is needed to better understand how specific conceptualizations of "community" operate to positively influence

young people, and how those effects may vary as a function of varying realities of person-context fusion.

Hypothesis Seven

The Universality/Diversity Hypothesis proposed that there are developmental supports and opportunities that enhance developmental success for all youth; strategies and tactics for promoting them vary. Moreover, because all youth need developmental assets, many community-level interventions will benefit all or almost all youth. However, youth with few or no assets may require interventions targeted to them and their specific needs. One of the functions of those extraordinary interventions is to enable those youth to benefit from more universal interventions.

There are likely variations in the degree to which developmental assets can explain developmental outcomes, and in which assets may be most critical in promoting specific outcomes, depending on differences among young people's contexts and developmental histories. But studies (e.g., reviews in Montemayor, Adams, & Gullotta, 2000; Scales et al., 2004; Scales & Leffert, 2004) suggest significant theoretical and practical insights relevant for most if not all groups of young people in looking at their development through a strength-based lens.

However, compared to the literature on developmental strengths and young people of differing gender, age, racial/ethnic groups, and socioeconomic status, there is a dearth of empirical work on relating developmental strengths to other dimensions of diversity, such as sexual orientation, family background, or differing exposure to violence. Goldfried and Bell (2003), for example, describe literature on sexual minorities as essentially "ignored" in mainstream psychology and adolescent development. The available evidence suggests that at least some developmental strengths, such as self-esteem and, particularly, family support, seem to diminish or eliminate differences in mental or behavioral health problems among both sexual majority and minority youth (Blum, Beuhring, & Rinehart, 2000).

YOUTH DEVELOPMENT RESEARCH

We next briefly describe illustrative research pertaining to positive youth development as reflected across gender, age, SES, and race/ethnicity.

Gender

Studies consistently find that females report higher levels of most developmental assets than do males, with the exception of self-esteem (see reviews by Scales & Leffert, 2004; Scales et al., 2004). The consistency of such findings across studies and measures provides evidence for the validity of this basic conclusion. However, these systematic differences may be produced by a lack of measures tapping potential assets that may be more common among young men (e.g., assertiveness, competitiveness). Reported gender differences in some assets also may be a result of systematic response biases from young people responding in gender-typed ways (e.g., girls' greater reporting of prosocial attitudes and behaviors—Eisenberg & Fabes, 1998). Apart from frequency differences, however, numerous studies suggest that assets may operate somewhat differently for males and females.

Huebner and Betts (2002) used social control theory to frame a study of 911 7th to 12th graders from a mining community in the southwest. They found that both attachment bonds (connections to parents, unrelated adults, and peers) and involvement bonds (time in school and nonschool activities, including time in religious activities, volunteering, and clubs or organizations) predicted less delinquency and greater academic achievement (self-reported grades). Involvement bonds predicted delinquency more for males than females, and attachment bonds predicted grades more for females than for males.

Hollister-Wagner et al. (2001) studied resiliency with regard to aggression (beating up a peer). In a large sample of rural eighth and ninth graders, they found support for the role of protective factors in reducing violence for females, but not males. The researchers reasoned that exposure to aggressive models, and social reinforcement for aggression, is sufficiently stronger for males that protective factors, although still positive, have a weaker influence on them.

Age

High school students consistently are found to report fewer developmental assets than do middle school students. For example, in a cross-sectional sample of more than 217,000 6th to 12th graders, whose average number of 40 assets was 19.3, 6th graders reported 23.1 assets, 8th graders reported 19.6, and 10th graders reported

17.8 (Benson, 2001). Asset levels were somewhat higher among 11th and 12th graders (to 18.1 and 18.3 assets, respectively), but still remained lower than asset levels among the younger students. Similarly, in a study of more than 5,000 6th to 12th graders in a mid-sized Western city, Scales, Leffert, et al. (2003) reported that 6th to 8th graders reported significantly more exposure than 9th to 12th grade students to most assets, including positive relationships with unrelated adults and consistency of expectations for behavior. In a longitudinal study of 370 students, Roehlkepartain et al. (2003) reported that asset levels declined sharply across 6th to 8th grade, bottomed out between 9th to 11th grades, and evidenced a slight rebound in the 12th grade. In another analysis of the same longitudinal sample, Scales and Roehlkepartain (2003) reported that 41% of these students decreased at least .5 standard deviations in their assets from middle school through high school. Another 34% stayed relatively stable, and only 24% increased at least .5 standard deviations in asset levels over the middle school to high school period.

Similarly, Scales et al. (2004) found that fourth and fifth graders reported more assets than did sixth graders (26.6. and 26, respectively, versus 24.7 for sixth graders). Only for safety did sixth graders report higher levels than fourth to fifth graders. Although longitudinal data are not yet available to confirm that those grade differences result from declining assets as cohorts age, the longitudinal results for older youth suggest that this interpretation is warranted.

Race/Ethnicity and SES

Drawing on seven national, state, and local studies with racially/ethnically diverse adolescent samples, Rowe, Vazsonyi, and Flannery (1994) argued that developmental processes appeared similar across racial/ethnic categories in effects on outcomes such as IQ, achievement, and social adjustment. The variables investigated included parental involvement and monitoring, self-efficacy, school self-esteem, parents' school encouragement, family communication, and attachment to teachers. The covariance matrices of the associations between these developmental influences and outcomes had significant and similar goodness-of-fit indexes across African American, Asian, Hispanic, and European American adolescents. The degree of similarity between racial/ethnic groups was no less than the degree of similarity found in comparing covariance matrices of random halves of a single racial/ethnic group, which would be expected to be highly similar.

Rowe et al. (1994) did not investigate precisely *how* assets and outcomes were related across racial/ethnic groups. Although developmental assets in general appear to have comparable positive relations with developmental outcomes for most groups of youth, how particular assets function to promote positive outcomes may well vary depending on which dimensions of diversity are examined. For example, Bean, Bush, McKenry, and Wilson (2003) studied the relation of components of authoritative parenting to academic achievement (self-reported grades) among 155 African American and European American high school students. They found that parental support, behavioral control, and psychological control had significantly different relations with grades, depending on parents' race and gender. For African American students, maternal support was significantly related to academic achievement, but the other components were not, and none of the parenting components was significant for African American fathers. But for neither European American mothers nor fathers was support a significant contributor to achievement. For European American students, fathers use of greater behavioral control, and mothers use of greater behavioral control and less psychological control, were significant predictors of academic success.

Sesma and Roehlkepartain (2003) examined developmental assets and outcomes among 217,277 6th- through 12th-grade students (including 69,731 youth of color) surveyed in 318 U.S. communities during the 1999/2000 school year. Across all racial/ethnic groups, greater numbers of developmental assets were associated with fewer risk behavior patterns and more thriving indicators. These relations held even after controlling for socioeconomic status. For example, across all racial/ethnic groups, young people who engaged in none of 10 high-risk behavior patterns averaged experiencing about 23 assets, whereas those who reported engaging in 5 or more of the 10 risk patterns said they experienced 15 or fewer of the developmental assets.

At the same time, there were racial/ethnic differences. For example, boundaries and expectations assets (e.g., family rules, neighborhood social controls, and adult role models) were important for all youth in helping them avoid anti-social behavior, but were found to have especially strong preventive associations for American Indian, Multiracial, and European American youth (Sesma & Roehlkepartain, 2003).

Scales, Benson, et al. (2000) also reported that specific clusters of assets could explain from 19% to 32% of the variance in self-reported grades, over and above demographics, among six different racial/ethnic groups of students. The assets of achievement motivation, school engagement, time in youth programs, time at home, and personal power meaningfully contributed to variance in grades for three or more of the six racial/ethnic groups.

In an interview study with 45 male African American gang members and 50 similar youth connected to community organizations, Taylor et al. (2003) found that the nongang youth reported significantly more positive developmental experiences. However, across nine categories of positive attributes that reflect developmental assets, an average of 28% of the gang members scored above the mean for the nongang youth, suggesting that a reservoir of developmental strengths may exist among even "deviant" youth assets that supports their positive growth. For example, more than one-third of the gang youth had more positive relations with family and with school or education than the nongang youth, and a fifth had more positive role models than did nongang youth. In a 1-year longitudinal analyses of this sample, Taylor et al. (2002) also reported a sizeable correlation (.67, $p \leq .01$) between change in developmental assets from Time 1 to Time 2, and changes in individual growth in positive personal and social functioning. These findings point to two tentative conclusions: (1) that the developmental assets that support positive outcomes are not entirely absent even for young people who currently are "embedded in a behavioral and social milieu marked by risks (e.g., gang violence, drugs, and poor familial support) [and] . . . ambient problems of poverty and racism" (p. 513), and (2) that enhancing developmental assets may facilitate positive trajectories for a subset of such challenged youth.

In another study of several hundred gang and nongang adolescents, Li et al. (2002) also found, as expected, that gang members on average reported fewer resilience factors in their lives. But like Taylor et al. (2003), Li et al. also reported that gang and nongang youth were not significantly different on a number of those contributors to resilience, including social problem-solving skills, self-esteem, physical activity, and academic performance. That is, both these studies suggest that individual and ecological characteristics that promote health and thriving exist among a substantial proportion of seemingly "lost" young people, representing a potentially valuable target of community actions to build better developmental paths for all young people.

There is little research on developmental assets among mixed-race or multiracial adolescents. A recent report drawing on the national Add Health dataset focused solely on risk behaviors, and concluded that mixed-race adolescents, regardless of which racial/ethnic groups were combined, tended to have higher incidences of health and behavioral risks than single race youth. Although impossible to confirm with those data, the researchers speculated that the results were consistent with a theoretical explanation pointing to mixed-race status increasing the stress those young people faced (Udry, Li, & Hendrickson-Smith, 2003).

In one study of positive development that included self-described Multiracial youth, Scales, Benson, et al. (2000) reported that clusters of developmental assets had significant explanatory power for concurrent indicators of thriving among 6,000 middle and high school youth across racial/ethnic groups (American Indian, African American, Asian, Hispanic, Multiracial, and European American). For example, aggregating the indicators into an index of thriving, clusters of the assets explained from 47% of variance among American Indian youth to 54% among Multiracial youth, over and above gender, grade, and level of maternal education. There were some differences across groups. For example, experiencing supportive relationships with adults other than parents was an important contributor to the thriving index for Multiracial, American Indian, and European American youth, but reading for pleasure was more important among African American and Hispanic youth. However, a core of assets was important across groups. Time spent in youth programs, cultural competence, self esteem, personal power (a construct akin to self-efficacy), achievement motivation, and planning and decision-making skills each meaningfully contributed to variance for at least two of seven thriving indicators across at least three out of six racial/ethnic groups.

DIRECTIONS FOR FUTURE RESEARCH

Although the past 10 years have seen a proliferation of conceptual models seeking to articulate the necessary ingredients for positive development and subsequent empirical tests of these models, on balance the state of our knowledge is disproportionately low compared with the state of our unknowns. Our knowledge-base is relatively strong in the following areas:

- Taxonomies of factors that are correlated with positive outcomes.
- Cross-sectional research results affirming associations among relationships, opportunities, social norms, and positive developmental outcomes.
- Knowledge that effective programs have the capacity to promote short-term changes in youth behaviors.

Lacunae in our knowledge base regarding developmental assets include the following:

- Theories of change that articulate *how* youths, adults, and community systems move toward greater developmental attentiveness.
- Explorations of the transactional nature of community-youth change; that is, examinations of both how community efforts (both informal and programmatic) affect youth, as well as how youth in turn affect and help shape their ecology.
- Empirical understanding of the significance of "informal, natural, and nonprogrammatic capacity of community" (Benson & Saito, 2001, p. 146).
- Understanding of the variability in the delivery of developmental assets across diverse communities and groups of people. While we can specify the necessary ingredients, we still do not well understand how those ingredients "work" in culturally diverse settings.
- Understanding of how broad, expansive models of community involvement and engagement interact with more focused programmatic approaches (i.e., does the presence of the former moderate the efficacy of the latter?).

In addition, the empirical literature offers to date only limited answers to the following more specific theoretical questions:

- How is the theory connecting assets to thriving outcomes the same as that linking assets to risk reduction outcomes, and how is it different? Relatedly, are "internal" asset categories such as positive values or positive identity more properly thought of as indicators of well-being, that is, as outcomes?
- Is the role of developmental assets global, or dependent on the outcome of interest?
- Is the effect of assets invariant across contexts, or does social domain make a difference in how assets affect outcomes? For example, do the same assets that explain delay of gratification in the school domain also explain delay of gratification in the peer domain?
- Is there such a thing as too much of particular developmental assets, such that they no longer are assets and even become deficits or risk factors (e.g., family support becoming enmeshment, or high expectations becoming a factor that lessens perceived feelings of competence)?
- Are there ceiling effects not yet revealed in the research? For example, a close relationship with at least one caring adult is clearly important, and probably having that with several adults is better, but what does a dozen such relationships add that five or six does not? Whitlock (2003) reported, for instance, that youth reporting 9 or 10 of 10 possible developmental supports did not have greater school connectedness than youth reporting 7 or 8 of those supports. But developmental supports showed a continued linear relationship with *community* connectedness, that is, a ceiling effect was not observed for community connectedness.
- If all assets are not equal in their promotive and protective valence, then what are the bases on which some assets are considered more important than others, if not for all young people, then for some youth in some situations for some outcomes?
- Do some assets function as "gateways" more than others, making it more likely that young people will experience additional assets that collectively promote positive developmental outcomes? Scales and Roehlkepartain (2004), for example, found that students who provided community service in middle school were significantly more likely to be "asset-rich" in high school than were students who did not contribute service.
- Are some assets more critical for healthy development at differing developmental points or stages? For example, are high expectations from teachers and parents more critical in middle school and early adolescence, when increases in challenges to competency beliefs are common, than in later adolescence? Similarly, does the asset of cultural competence become *more* important as children age and encounter increasingly more diverse peers and adults?
- In a related sense, do some assets have more impact during key developmental transitions than at other times? For example, are young people feeling valued and that they have useful roles more important assets during the transition from elementary to middle

school and the transition from middle school to high school than they are at other times during early and later adolescence?
- How many of developmental assets does one need, over what period of time, to contribute meaningfully toward particular desired outcomes?

In addition to these questions, there exist issues regarding the design of research within which the questions may be addressed. Approaches such as the theory of change strategy for evaluating comprehensive positive youth development initiatives have been discussed for some time (see Connell & Kubisch, 2001; Connell, Kubisch, Schorr, & Weiss, 1995). But only a limited number of examples show such technology actually being applied, and a broad consensus does not exist about what reasonable outcomes for community initiatives may be (Berkowitz, 2001; Spilka, 2004).

Moreover, although the research to date shows promising results, the existing literature focuses almost exclusively on assessing the effects of community interventions on adolescent problem behaviors such as alcohol and other drug use, adolescent pregnancy, and antisocial behavior. Few positive outcomes other than academic success tend to be measured in *community,* as contrasted with program, initiatives (Greenberg et al., 2003; Wandersman & Florin, 2003).

MacDonald and Valdivieso (2001) also observed that deficit-oriented measures prevail in national tracking systems. They described numerous possible positive constructs and measures that are being or could be applied in gathering data across four critical domains: young people themselves, parent and nonparent adults, organizations that serve young people, and community-level data on policies, resources, and services.

Weissberg et al. (2003) also note that despite an impressive literature now suggesting the effectiveness of strength-based approaches to prevention and youth development, there is a continuing need for evaluations of multiyear, comprehensive youth development initiatives that target multiple outcomes. Especially needed are investigations of the mediating and moderating influences on program or initiative effects, and how strength-based approaches work similarly or differently across diversities of geography and circumstance. Finally, they noted the need for more standardized measures of core youth development outcomes, so that results across different studies can more readily be compared.

The lack of common positive measures of development decried by Weissberg et al. (2003) is not unique to youth development. Ryff and Singer (1998) struck a similar chord in talking about research on "health" among older adults. Such research, they argued, routinely defines health by emphasizing the absence of negatives, such as being unable to dress and feed oneself, at the expense of inquiring about the positive indicators of purpose and engagement in life that actually may better predict health outcomes. To more accurately understand health, they argued, questions should be asked about what persons did today "that was meaningful or fulfilling," or whether they "love and care for others" (p. 21).

Several recent efforts have emerged in response to both the relative lack of emphasis on measuring positive outcomes, and the lack of a common core of measures to be used across positive youth development studies. For example, Search Institute, the Institute for Applied Research in Youth Development at Tufts University, and the Fuller Theological Seminary, with strategic consultation from Stanford University and the Thrive Foundation for Youth, recently embarked on a multiyear "Thriving Indicator Project" with the goal of producing effective measurement tools and resources on thriving that would be widely used and developed from a foundation of deep science.

Initial activities have included a comprehensive review of the literature on thriving and related concepts, and interviews with scholars, positive youth development practitioners, youth, and their parents that elicited their views on what describes a thriving youth (King et al., in press). A group of core dimensions of thriving is emerging (e.g., Theokas et al., in press) that will then serve as a lens to help focus development of thriving measurement tools to be used in clinical, programmatic, community change, and national tracking applications.

A similar effort, with the goal of developing and embedding common measures of positive youth development outcomes in state and federal data tracking systems, is being led by Child Trends. Scholars and policymakers are recommending reliable, valid, and relatively brief measures in areas such as prosocial orientation, religiosity, and social competencies (Moore & Lippman, 2004) that could help track developmental strengths and contribute to a long-term re-shaping of child and youth policy.

CONCLUSIONS

Despite differences in terminology and comprehensiveness, the similarities across models of positive youth development are apparent, and a substantial body of research supports the hypotheses emerging from the

melding of positive youth development practice and a variety of developmental and other theories. Positive youth development is both caused and indicated by whether a young person experiences adequate supports and opportunities. Doing so consistently and in multiple settings is particularly important. These experiences help them develop key competencies, skills, values, and self-perceptions that adaptively self-regulating persons need in order to successfully shape and navigate life over time.

There are multiple sources of those developmental nutrients or assets, including the proactive influence of young people on their own environments. Not just genetic heritage, not just family, not just schools, congregations, peers, or any other influence create a young person's developmental path, but all do so operating together, interactively, to form a system larger than the sum of those parts. In practical terms, the research findings that support this conclusion lead to two inevitable implications.

First, isolated programs working to change individual youth without changing the environments in which they live may have some limited, short-term success, but cannot be expected to support significant long-term positive development, or especially, to radically alter the developmental path of particularly vulnerable young people. Multiple contexts of young people's lives need to be strengthened simultaneously to promote the systemic supports needed for sustained and widespread positive development among all youth.

Second, the nesting of young people in families and schools within neighborhoods and communities and wider society means that a long-term commitment to significant community mobilization around common norms, values, and goals related to positive youth development is essential. No less an effort will attain the breadth, depth, and permeation of culture with both formal and informal daily life to profoundly change the developmental odds for a critical mass of America's young people.

Though research supports the efficacy of positive youth development as an approach for changing these developmental odds, it is also clear that other approaches are necessary. Poverty, family violence, and abuse are among a litany of risks that jeopardize development. It is likely that reducing risks and promoting assets can be complimentary strategies for enhancing positive developmental outcomes. Theory and research is needed to better understand the interplay of risks and assets. In addition, it is important to identify how combinations of risk reduction and asset-building intervention strategies work for youth in various social locations.

One of the major contributions of positive youth development theory and research is the identification of the multiple contexts and settings that inform developmental trajectories. As an applied field, positive youth development and its advocates face crucial decision points about how and where to create intentional change. Though the development of and/or enrichment of programs is the primary locus of intervention, theory and research also identify a much wider range of possibilities. Access to developmental assets could also be advanced by, for example, transforming socializing systems (e.g., schools and neighborhoods) or mobilizing adults to create sustained relationships with community youth.

It is here in this complex space of community and societal change where new thinking is particularly needed. As noted at several points in this chapter, the least developed part of positive youth development theory is that having to do with how intentional change can best be understood (and practiced). The complexity of this issue (as well as the societal importance of promoting positive development) requires an interdisciplinary approach, integrating multiple fields in common pursuit of how to enhance the dynamic fusion of ecological- and individual-level strengths.

This interdisciplinary research agenda should initially focus on developmental contexts as the unit of analysis with inquiry into the strategies that enhance the capacity and will of schools, neighborhoods, families, and congregations to nurture developmental strengths. And such inquiry will necessarily lead to important research issues regarding the orchestration of change at multiple levels, including the strategies for creating developmentally attentive communities. Consonant with the theory of positive development, we hypothesize that the most successful transformation in contexts and community will occur when youth are at the forefront in planning and implementing the change initiative.

CHAPTER 17

Religious and Spiritual Development throughout the Life Span

FRITZ K. OSER, W. GEORGE SCARLETT, and ANTON BUCHER

A young man meets his former professor and relates that he has recently fallen in love. He says he believes his falling in love is a matter of destiny, a gift given by chance. The older man listens intently and then suggests this experience cannot have happened by chance, that it is indeed a gift, a gift given by the two people involved *and* by God. He also suggests that a development such as this always has a hidden, transcendent meaning.

In this sketch of a conversation, we are confronted with judgments about the meaning of an important life event—falling in love. One judgment seems to have no connection to religion or spirituality, while the other seems to be very much connected to religion. It is judgments such as these that theories of religious development must explain, and in such a way that we understand individual change, transformations, pro-

The authors would like to thank Kathryn Tabone, Mitchael Steorts, and Alexis Gerber for their help in preparing the manuscript.

Preparation of this chapter was supported by a grant from the Templeton Foundation.

gression, and regression as well as commonalities across persons, groups, and ages.

Thirty years ago, theories of religious development avoided explaining issues expressed in our scene—issues about faith and transcendence. Rather, theories of religious development applied a cognitive, Piagetian approach to concepts and knowledge—for example, in explaining how children understand the concept of God (Goldman, 1964).

Religious thinking was seen as an application of general cognitive structures, such that lower levels of religious thinking were taken as expressions of immature, magical, and egocentric thinking. In doing so, researchers on religious and spiritual development gave no value to lower stage constructions of meaning. They saw nothing in the way lower stages can provide for a growing religious and spiritual rationality. In this chapter, we explore theories providing explanations of religious and spiritual development quite different from that provided by Piagetian stage theory.

Here is another story to help define our area of inquiry: On arrival at a birthday party, a young woman notices candles in front of every invited guest. After a while, the host asks everyone present to concentrate on the candles, to become quiet, to close their eyes and then to share a good wish for the birthday person. The room is silent, and then, when wishes are shared, every word is valued. What happens here is a form of going into as well as beyond oneself—which is what many take to be something spiritual.

As with religious development, spiritual development is also related to change and transformation, to progression and regression. However, if separated from religious development, the contents of spiritual development seem less fixed, and the steps toward higher, more complex levels seem less evident. There is today no theory of pure spiritual development. That is why in this chapter, we explore alternative theories of spiritual growth, and why we use *religious* and *spiritual* as highly overlapping entities, which can be taken mostly together.

We believe that religious and spiritual development is a normative task. As such, developing religiously and/or spiritually is important because it transforms narrow-minded religious behavior and thinking into open, fully integrated religiosity and spirituality, thus avoiding central problems, including religious fundamentalism, intolerance, and war. However, being mindful of the challenges faced by any normative approach, we emphasize especially the challenge presented by alternative conceptions of endpoints of development—including the alternative of no definite endpoint.

Thus, this chapter aims to examine the emergence and growth of religious *and* spiritual development from a variety of perspectives, but with a special emphasis on those with a transformative view. It does so using two overarching paradigms or frameworks. The first is the organismic or cognitive—structural paradigm associated with the stage theories of Piaget, Werner, and Kohlberg. The second is the developmental systems paradigm that has gained interest over the past 2 decades (Lerner, 2002). In one sense, the developmental systems paradigm includes the organismic paradigm such that they operate on different conceptual levels. In theory the two are compatible, and we use them in this way, as theoretically compatible. However, in practice, those adopting a developmental systems paradigm have often settled on simple definitions of religious and spiritual development. The strength and contribution of the organismic paradigm is that it forces attention on the problem of definition. This is a major reason for introducing the concept of stage. We use the organismic paradigm to better define religious and spiritual development—and later on, use mostly a developmental systems paradigm to discuss the literature on *contexts, situatedness influences, supports, outcomes,* and *effects.*

The chapter examines the following major questions in particular:

- How should we define religious and spiritual development?
- What is universal and what is culturally situated with respect to religious and spiritual development?
- What triggers, causes, and supports religious and spiritual development?
- What evidence is there for religious and spiritual development promoting character development, avoiding risky behavior, and fostering thriving in general?
- What evidence do we have for religious and spiritual development promoting physically and psychologically unhealthy behavior?

A DEVELOPMENTAL APPROACH

To explain religious and spiritual development requires explaining the antecedents and consequences of religious

and spiritual content and belief, religious and spiritual practical life, and religious and spiritual structure (Baltes, Lindenberger, & Staudinger, 1998). It also requires explaining how an existential experience can be interpreted differently at different times in life and with different complexity, styles, and meaning-making capacities. Finally, it means explaining how religious and spiritual development elucidates growth and change in ways of being in the world that need not contradict the general enlightening process of modern and postmodern society. Our approach is individual centered in that religious and spiritual behavior is seen as rooted in the person who is immersed in and influenced by life events, learning, and culture.

The question of how apparently simple levels of development are transformed into complex forms is central (Case, 1985; Fischer & Bidell, 1997; Fischer & Rose, 1999; Pascual-Leone, 1983). We adhere to the discontinuous approach to development, but, in so doing, we differentiate highly according to lifestyles, denominations, cultures, situations, intelligence, and ethnographic experiences. We offer no stereotypic portraits of stages. Rather, we describe and explain how individuals in modern societies transform their religious attitudes, judgments, and feelings in the life span. Development is the focus—so much so that general discussions about the psychology and sociology of religion (Brown, 1987; Durkheim, 1915/1995; Grom, 1992; Hood, Spilka, Hunsberger, & Gorsuch, 1996; Wulff, 1991) are avoided.

Taking a developmental approach to religiousness and spirituality has serious implications for designing interventions to help. When religiousness and spirituality make life uncontrollable and bound to blind faith, they can easily become sources for inhuman behavior, intolerance, and painful dependency on dysfunctional groups. But when real development occurs, religiousness and spirituality can be compared to any other developmental transformation producing losses and gains in a flexible and complex human personality.

Thus, religious and spiritual development contains the growth of the personality and identity in the broadest sense. Religious and spiritual knowledge, feelings, belonging, self-efficacy, and identity—all are part of development and change and must—to the extent that research is available—be part of our overall developmental frame.

In this chapter, we defend the thesis that religious and spiritual thoughts, acts, and feelings can neither be derived from nor reduced to something else. They have their own meaning, roots, and core—like morality, mathematics, and music. Later on, we speak about religiousness as having a fundamental mother structure, which is generated, in part, from the universal experience that life is fragile. Even at early ages, children ask questions about the meaning of death, about arbitrariness and contingency, and about why there is misfortune and evil. This questioning reveals the religious mother structure, and it provides one expression of and impetus for spiritual development.

IS RELIGIOUS AND SPIRITUAL DEVELOPMENT RESISTANT TO THE POSTMODERN PATH?

In 1791, Condorcet (1789/1976), the French Minister of Education, predicted that as the human intellect progressed, religion would be dispensed with in a culture largely dominated by science. In the nineteenth and twentieth centuries, leading thinkers agreed, among them Karl Marx, Sigmund Freud, and James Leuba. Marx dismissed religion as the "opium of the people" because he thought religion alienated people and legitimized the exploitation of the proletariat. Freud regarded religion as an obsessional neurosis, an infantile illusion that humanity would have to overcome by moving in the direction of "God as logos." Leuba, one of the founding fathers of the psychology of religion, considered religiousness to be negatively correlated with rationality, implying that religiousness is something to be overcome.

However, at the beginning of the third millennium, research tells us that Condorcet's prognosis has not been fulfilled. The opposite has happened. The classic secularization thesis, which claims there is a successive weakening of religiousness in the postmodern age, has been refuted. In the United States, 96% of the population professes to believe in God (Gallup, 1995) and 75% of U.S. adolescents say they try to follow the teachings of their religion (P. King & C. Boyatzis, 2004). In most European countries, the numbers are markedly smaller, but even in a country such as France, with its distinct lay history, there are still approximately 67% who believe in God (Denz, 2002, p. 40).

In Europe, in general, we see that persons in the new millennium are less apt to belong to a denomination but still feel themselves to be religious and/or spiritual.

For example, in a large sociological study in Austria, Zulehner, Hager, and Polak (2001) found that 94% of the people in their sample felt strongly religious despite only 27% saying they are Christians, 30% saying they have a patchwork religiosity, 30% saying they are humanists, 13% saying they are atheists, and only a small number saying they participate in active church life. In addition, the correlation between social engagement and religiosity was very high, a finding consistent with findings from the research of many, which shows that willingness to perform volunteer service is positively associated with stable or upward religious developmental trajectories (Donnelly, Matsuba, Hart, & Atkins, 2005; Youniss, McLellan, Su, & Yates, 1999).

If anything, the postmodern era manifests tendencies to become more religious, not less. New religious movements, often of a fundamentalist nature, are motivating millions. More and more religious groups are succeeding, among them totalitarian sects. And with regard to forms of spirituality, the enormous variety suggests that we are today in the midst of a spirituality "boom."

The evidence for their being a spirituality boom comes from several sources. There are the many new books on spirituality with titles such as *Heart and Home. Embracing the Spiritual in Everyday Life* (Benish, 2001) and *The Way. Using the Wisdom of Kabbalah for Spiritual Transformation and Fulfillment* (Berg, 2001). There are also now psychological journals devoting special issues to spiritual topics, for example, the *Journal of Individual Psychology* (2000, Vol. 3) and the journal, *Applied Developmental Science* (2004, Vol. 8). And even a cursory search on the Internet indicates tremendous interest in spirituality and spiritual development. For example, launching a search for "spiritual development" in databases such as *PsycInfo* will produce more hits than "religious development."

The variety and boom are, no doubt, related to the fact that religious freedom has been established as a constitutional right in the developed world so that religious and spiritual beliefs and affiliations can no longer be imposed or prescribed. Connected with this is the way in which spirituality has been released from the power of religious communities. As a result, many now are developing their own religious ideas and practices. These ideas and practices can be rejected as "religion à la carte," but they can also be seen positively as the result of a patchwork religiousness and spirituality that has emerged under the influence of postmodernism.

Furthermore, in academia we now find a renewed interest in religion and spirituality as well as new theories putting religion and spirituality at the very heart of what it means to be human. We see this renewed interest especially in the psychology of religion, which long ago cast off ties restricting it to church religiousness and, in recent times, turned to discussing diverse forms of spirituality (Argyle, 2000; Beit-Hallahmi & Argyle, 1997; Hood, 1995; Hood et al., 1996; Wulff, 1991). And we see that many scientists want to connect religious life and the natural sciences through speculative reflection (Reich, 2004). As for the new theories, we see them suggesting religious and spiritual development is indispensable to human functioning. For example, today, sociobiologists claim religiousness is determined genetically and that religion was and still is an important factor in evolutionary survival (Burkert, 1996; Daecke & Schnakenberg, 2000; Wilson, 1998). Religion, they argue, offers advantages of selection; sects especially serve as examples—since they achieve selection by strengthening group cohesiveness and because they foster aggression toward threatening entities outside the group.

Thus renowned psychologists of religion (Hood et al., 1996, p. 44) have asked, "Is religion in our genes?" In so doing, they are thinking not about specific religions, which are always marked and shaped in sociocultural ways, but about a basic religious disposition, which according to Oerter (1980, p. 293), is activated when young children become conscious of their temporally restricted existence, an experience that leads to a preoccupation, determined by nature, with religious and metaphysical problems. Spirituality, too, has been seen as humanity's answer to its own finite nature (Socha, 1999).

Modern, scientifically based theories of religion and spirituality have explained religious and spiritual development as a means of satisfying the human need to exercise control, indeed, control over and above the mere immanence of the here-and-now and into the great transcendent realm beyond (Flammer, 1994).

Throughout human evolution, belief in the divine has worked because it has helped humans cope with threatening and difficult situations. In addition, religion has legitimized authority and created security—through oaths, for example, but also through the expectation of reciprocity between sacrifice and reward (Burkert, 1996).

As another example of new theories giving a positive view of religious and spiritual development, Huntington (1998, p. 61) has theorized that every culture is based

on a religion, which, in the nature of a latent disposition, retains its power to grow and spread even after it has been subjected to waves of secularization. Furthermore, cultural anthropologists point out that every culture produces a system of religious symbols, which govern individuals' relations with transcendence and provide the ultimate systems of authority. This means "religion can be viewed as a precondition of culture, or as springing from the same roots as culture" (Ohlig 2002, p. 101).

However, *discontinuity, boom, genetic issues,* and *new developments* are not the only terms to use to explain why Condorcet's prognosis has been proven wrong. Today, there are continuities with the past in the way religiosity and spirituality are experienced. Children and young people continue, as they did in the past, to encounter religious phenomena such as church buildings, saffron robed monks, religious sisters, veiled Islamic schoolgirls, orthodox Jews with yarmulkes and side locks, soccer players making the sign of the cross, and people praying at a funeral. Furthermore, places of spirituality are still represented by monasteries and convents, houses of retreat for spiritual exercises, and remote places for tranquility and prayer. Spirituality also includes traditional ideas—negative ideas having to do with suffering and asceticism but also positive ideas having to do with affirming life, being health conscious, and seeking happiness.

In sum, religion and spirituality are alive and thriving both in traditional ways and in ways not even imagined by Condorcet. Now, more than ever, we need to understand this widespread and varied human phenomenon—especially by understanding its development.

A HISTORICAL PERSPECTIVE

The scientific study of religious development dates back to 1882, the year that G. Stanley Hall, in the context of his "Child Study," investigated children's religious imagination (see Huxel, 2000, 95 f). However, the concept of religious development has a much longer history. The books of the dead in ancient Egypt and Tibet described steps leading to the gods and Nirvana respectively. In the Bible, the Apostle Paul noted children's qualitatively different ways of being in the world when he wrote, "When I was a child, I spoke as a child, I understood as a child, I thought as a child; when I became an adult, I put away childish ways" (1 Corinthians 13:11, New Revised Standard Version).

In the Christian faith tradition, the concepts of development and stage have been used frequently to define the religious and spiritual life—so frequently that one might suspect that current stage developmental theory is rooted in the mind-set of this Western tradition. There are many examples. Ambrosias, one of the early church fathers (dec. 379), described four stages in the ascent to God, and Benedict of Nursia (dec. 547) described normatively 12 stages of humility.

Mysticism has also played a central role in developing the concept of religious and spiritual development, and, in recent times, some of the more famous stage models of mystics have been compared to stage models of modern theorists. Thus, M. J. Meadow (1992) showed impressive parallels between Teresa of Avila's seven stages leading to mystical union and Jane Loevinger's model of ego development. Steele (1994) reconstructed John of the Cross's stages of spiritual development in the light of transpersonal psychology, and Oser (2002) compared the steps of the mystical path in both Meister Eckhart and Margerethe Porete to the stages of religious judgment as presented by Oser and Gmünder (1991).

These prescientific descriptions of stages provide no systematic theory or description of age changes. Rather, they define an ideal for the *total* religious life. Nevertheless, they show that, early on, religious leaders made frequent use of the metaphors of stage and step to give their own developmental accounts.

The phenomenon of religious development was also obvious to Jean-Jacques Rousseau (1712–1768). In *Emile* (1762/1979), his novel on education, Rousseau observed younger children's propensity to imagine God as a person as well as their not understanding the abstract language of catechism. From these observations, Rousseau advised that children be kept from religious instruction until they reach adolescence. Centuries later, Ronald Goldman would give similar advice but from a Piagetian theoretical perspective.

In the field of religious education, classical writers such as Salzmann, Basedow, Jean Paul, and Jean Calvin were finely attuned to children's religious development (Schweitzer, 1992). For example, Jean Calvin (1834, p. 200) assigned the Old Testament to children and the New Testament to adolescents, a practice that anticipated G. Stanley Hall's advice at the turn of the twentieth century (Hall, 1900, 1908). Calvin assumed that the vivid stories of the Old Testament matched the interests and mental capacities of children just as the ab-

stract messages of the New Testament did the same for adolescents.

By the turn of the twentieth century, when psychological exploration of religious development began in earnest, the three main paradigms for explaining religious and spiritual development had already been well established as:

1. Religious and spiritual development as maturing
2. Religious and spiritual development as coping
3. Religious and spiritual development as perfecting

In the first paradigm, maturity, loosely defined, is the telos toward which religious and spiritual development tends. Maturity is a value-laden concept, but the values made explicit in this paradigm are attainable by most. In this paradigm, to mature religiously and spiritually is not to become a saint. Rather, it is to become an adult in whatever ways being an adult is culturally defined.

In the second paradigm, maturity is also a telos, but the emphasis is more on the primitive and immature—so that maturity means coping with personal limitations. Here, we see a functional approach—with religious and spiritual development functioning to help us cope. We also see *health* and *maturity* being used almost interchangeably. Nowhere is this paradigm used more extensively than in psychoanalytic theory—so we concentrate on psychoanalytic theory when discussing this paradigm.

The third paradigm explicitly embraces perfection as the goal of development. The telos here is entirely conceptual—though occasionally the talk is of religious or spiritual exemplars. But even in the exemplars, the assumption of this paradigm is not that the exemplar is perfect but that the exemplar points to what perfection consists of, to the standard or ideal that defines development, and allows us to evaluate and explain levels or stages of development as approximations to perfection.

These three paradigms are used to organize the remainder of this section.

Religious and Spiritual Development as Maturing

Research into religious development reached its first highpoint in the beginning decades of the twentieth century, partly as a result of the work of American pioneers in the psychology of religion, in particular, Hall, Leuba, and Starbuck (see Huxel, 2000; Wulff, 1991, pp. 41–53). This era also produced extensive work in Germany, by practical theologians hoping that knowledge derived from the psychology of religion would optimize religious instruction.

These early researchers and practical theologians investigated children's concepts of heaven (Barth, 1911), God (Nobiling, 1929), religious doubt (Wunderle, 1932), and religious ideas in general (Voss, 1926). Their central focus was on describing age differences rather than on constructing theories. For most of these early investigators, religious development was a maturational process (Gesell, 1977; Kroh, 1965). Nowhere do we see this more clearly than in the stage theory of G. Stanley Hall.

G. Stanley Hall

Hall (1904, 1923) argued that individual religious development recapitulates the religious development of the species. So, religious development begins with unconsciousness and is followed by a stage of fetishism and nature worship—the very features that define both ancient idolatrous religions and the religious concepts of school children with their concrete and anthropomorphic images of God.

Hall also argued that children need to work through these earlier (i.e., historically earlier) ways of being religious before they can adopt more advanced, recently acquired ways. So, as mentioned previously, he suggested that the religious education of children should focus on the Old Testament with its concrete images and stories, and later on, during adolescence, on the New Testament with its abstract principles and values.

Hall's influence and contribution was also in his promoting careful, empirical work as well as in his explaining that adolescence is a significant time for spiritual transformation.

Hall's linking individual and phylogenetic religious development has been critiqued and refuted (Gould, 2003a). However, his influence on the psychology of religious development has been enormous, not only because he got others to think developmentally, but also because he demonstrated that religious development is a domain that should be studied scientifically. Hall's phylogenetic theory was a maturationist theory in that it assumed religious development unfolded in ways heavily influenced by biology. This maturationist understanding and emphasis continued long after Hall—even into the second half of the twentieth century.

Gordon W. Allport

The third example of religious and spiritual development as a process of maturing is the work of

G. W. Allport. In *The Individual and His Religion* (Allport, 1950), Allport described two types of religiousness, which form a developmental sequence. The first type is the "self-interested" religiousness of younger children who see prayers as a means of getting material things. Children also imagine God in a concrete, anthropomorphic manner. Thus, we have the precursor of the well-established concept, "extrinsic religiousness."

In the years preceding puberty, children's egocentric religiousness leads to disappointment (e.g., initiated by denial of material goods, experiences of theodicy). Subsequently, children form new and more abstract religious concepts and shape a mature and self-disinterested type of religiousness. In the best case, religion becomes part of an adolescent's own personality and fulfils the criterion of functional autonomy: religiousness becomes "intrinsic religiousness."

In the following decades, the distinction between extrinsic and intrinsic religiousness became one of the most powerful distinctions in the psychology of religion. Hundreds of studies showed that intrinsic religiousness is positively correlated with a variety of desirable outcomes, such as a sense of well-being, whereas extrinsic religiousness is positively correlated with undesirable outcomes such as being prejudiced (see the overview by Wulff, 1991, pp. 217–242; see also Hood et al., 1996).

In discussing earlier works using this first paradigm, we see how religious and spiritual maturity can represent an achievable and worthwhile end. Furthermore, we see how maturity has to do with individuals functioning well in their cultures and contributing to their societies. These early works using this first paradigm can be seen as the forerunners of present-day research on religious maturity (Benson, Donahue, & Erickson, 1993). Furthermore, they can be seen as the forerunners of present-day research on resilience and positive youth development as they relate to religious and spiritual development (Lerner, Dowling, & Anderson, 2003). Later on, we have more to say about present-day research continuing in this tradition of thinking about religious and spiritual development as a maturing process.

Religious and Spiritual Development as Coping: Psychoanalytic Theory

Psychoanalytic theory is—if developmental—essentially a theory of motivation. More precisely, it is a collection of related theories connected by their sharing a common focus on unconscious, intrapsychic conflicts. Psychoanalytic theory has played a central role in defining religious and spiritual development and its functions. It has done so in both controversial and contradictory ways—with theorists from the same psychoanalytic community often reaching opposite conclusions based on common starting points. Nowhere do we see this more clearly than in the competing theories of Freud and Jung and in the radically different ways that Freudian, ego analytic, and object relations theorists have evaluated religion and religious development.

Sigmund Freud

Sigmund Freud took issue repeatedly and in an influential way with religiousness. In so doing, he stimulated thousands of psychoanalytic studies of religion (Beit-Hallahmi, 1996a; see also Shafranske, 1995; Wulff, 1991, pp. 253–316). As early as 1907, he characterized religiousness as an obsessional neurosis. For Freud, religious concepts are illusions that provide comfort and security to those threatened by the forces of nature, the inevitability of old age and death, and the hostility of others. Their origins can be traced to protective persons with whom the child has close contact in early childhood.

The most important protective person was, for Freud, the father, toward whom boys have hostile feelings during the Oedipal phase, resulting in the father image being projected into the transcendent realm. In his later writings, Freud put his theory of the psychic origins of God as follows: "To begin with, we know that God is a father-substitute; or, more correctly, that he is a copy of a father as he is seen and experienced in childhood—by individuals in their own childhood . . ." (Freud, 1923a, p. 85).

However, in classic Freudian psychoanalysis, religious development is not merely a matter of projection but also of sublimating sexual libido. In an early paper titled, "Obsessive Actions and Religious Practices," Freud (1907) claimed that religiousness arose as a "renunciation of certain impulses . . . within which . . . a sexual element cannot normally be excluded." Freud's student, Schroedter (1908), drew from this the general conclusion that the origin of religiousness, in particular, emotive and mystical forms of religiousness, resides in the repression of erotic instincts. What is repressed, he argued, reappears in a distorted form, as in acts of piety that border on hysteria.

Pfister (1911), one of the first theologians familiar with Freudian theory, used Freudian theory to explain the religious development of Margarethe Ebner, a mystic of the high Middle Ages. Ebner had the habit of lying next to a crucifix and experiencing the "sweetest" sensations—for Pfister, evidence of the sublimation of unsatisfied sexuality. Pfister (1925) applied the same kind of analysis to Count Ludwig von Zinzendorf (1700–1760), founder of the Moravian Church. When he was forty, Von Zinzendorf began worshipping the wound in the side of Jesus—evidence, according to Pfister, for the sublimation of homosexual feelings.

The constellation of unresolved Oedipal feelings, homoerotic inclinations, sublimation, repression, and neurosis in general was subsequently interpreted into dozens of biographies of prominent religious personalities (see reviews by Bucher, 2004; Hitschmann, 1947; Zeligs, 1974, on the religious development of biblical figures).

Not surprisingly, the classical Freudian view of religious development drew criticism on a massive scale (see reviews by Beit-Hallahmi, 1996a; Meissner, 1984). For example, Greve and Roos (1996) questioned the universal applicability of the Oedipus complex and argued that the Oedipus story is, after all, a myth, not an accurate representation of a universal phenomenon. Freud's reducing God to an earthly father also came under attack. For example, on the basis of clinical case studies, Schjelderup and Schjelderup (1932) described how people develop their own mother religions, especially in Eastern contexts. However, possibly the most damning criticism of Freud's psychology of religious development has been the criticism that there is no way to disprove Freud's claims because when claims cannot be disproved, they fall outside the domain of science.

Carl Jung

For Carl Gustav Jung, the son of a protestant minister, religion played a positive role in both his theory and personal life. Still in the psychoanalytic tradition, Jung provided a quite different focus than Freud's—with his concept of individuation (1968). The concept of individuation explains individual development as a gradual integration of psychic structures, creating a self where conscious and unconscious are fully integrated and compatible.

As for his theory's connection to religious and spiritual development, Jung spoke about a "personal unconscious" or hidden psychic realm that he referred to as the "shadow." According to Jung, every individual has to cope with what is suppressed, ignored, and neglected in personal life. In doing so, individuals develop toward wholeness, becoming a wholly integrated self. For this process of becoming an integrated self (*individuation)*, religion plays a central role.

The goal of the individual is to balance the demands of reality with personal needs. This balancing is achieved with the help of inherited archetypes in a collective unconscious that is a part of every individual's heritage. Numinous archetypes are structuring principles that are produced through dreams and cannot be produced by mind and reflection. Religions play a central role by effecting this balance in the way they relate to the archetypes. Because religious myths are projections of the archetypes, the messages of the soul and the messages of religions are of similar form and can be translated each to the other. In doing so, individuals cope better by coming to terms with their shadow.

Therefore, whereas for Freud development consists of putting religion behind us, for Jung, development consists of embracing and using religion to support development.

Erik Erikson

Erikson represents a third variation on the psychoanalytic theme with respect to religious and spiritual development. As did Freud and Jung, Erikson focused on unconscious intrapsychic conflicts to explain what fuels development. However, Erikson's emphasis was much more on how intrapsychic conflict reflects not only familial themes but also societal-cultural themes. In many ways, Erikson fits more comfortably into present-day discussions about context, culture, and development.

With respect to Erikson and religious and spiritual development, the two main concepts are "basic trust" and "identity." Developing basic trust was, for Erikson, the central religious issue—not only trust in God but also trust in a universe that offers enough to make life worth living.

However, for Erikson, it is the struggle to achieve a personal identity that warranted special attention. For Erikson, religion offered one of several ways in which individuals achieve identity. Nowhere is this better illustrated than in Erikson's (1958) influential book, *Young Man Luther,* in which he shows how Luther used religion to shape and construct his identity.

In *Young Man Luther,* Erikson demonstrated how religious ideology and religious institutions provide ways for

youth to separate themselves from old identifications with parents to achieve a new identity better suited to weather the storms of adulthood and better suited to render them able to contribute to society. In *Young Man Luther,* Erikson shows how Luther's choice to become a monk, his obsessional behavior as a young monk, and, his becoming a great reformer, all reveal his inner struggle to remain identified with his father and his church while, at the same time, to distance himself to become his own person with his own convictions and purpose in life.

Object Relations Theorists

For the past several decades, neo-analytic psychology has focused more and more on the quality of interpersonal relations and on how interpersonal relations are affected by internalized images of self and significant others. Nowhere do we see this more clearly than in the work of those who identify themselves as object relations theorists. Their central focus is on imagination and illusion-making.

While continuing Freud's practice of calling religious imaginings *illusions,* object relations theorists have given illusion-making a positive spin, which treats imagining as a wedge between impulse and objective reality, a wedge that guards against the dangers of impulses and autistic thinking, on the one hand, and the slings and arrows of misfortune and a stultifying status quo, on the other. In Paul Pruyser's (1991) words:

> Illusion is not hallucination or delusion but can deteriorate into them. Illusion formation is . . . a unique process that derives from the imagination. It need not be captive to the autistic process and cannot be locked into the reality testing procedures described by common sense. (p. 176)

Object relations theorists define imagining as a transitional phenomenon, where the boundaries between subjective and objective become blurred. The partial differentiation between what is inside and outside allows individuals to not only creatively manage but also to creatively transform. Pruyser (1991) provides the example of Martin Luther King Jr. and his "I have a dream" speech to illustrate what is meant by religious imagining being a transitional phenomenon that creatively manages and transforms. He writes:

> That speech straddled both the world of ideas and the world of facts; it introduced a new paradigm after showing the bankruptcy of an older one; it combined Yahwistic wrath with the benevolence of a God-in-Christ. But for all his patent creativity, what reliance King had on the great illusionistic traditions of the Bible, black preaching, and Gandhian nonviolence! Absorption in these traditions had become to him a sacred playing—with one sideways glance at the brutal facts of the realistic world and another keen glance at the ever-present explosive turbulence of the autistic world. (p. 179)

The example of King provides insight into the analytic concept of religious and spiritual maturity and the role of religious-spiritual imagining in realizing maturity. Pruyser implies that King's religious imagining grasped something true, though not something true in the sense of scientific truth. Truth in this context is obviously not about propositions that are either true or false. Presumably, truth in this sense has more to do with living lives that are "true."

What is missing, though, is just how to evaluate a religious illusion as true. We are left wondering if Pruyser means to suggest it is universal truths that are revealed in religious imaginings or simply truths that are specific to particular groups and individuals. The following personal story suggests perhaps it is both. Pruyser (1991) writes,

> I attended a denominational school . . . that stood for much greater Calvinist orthodoxy than did my family. Thus, home and school presented me with two different religious and emotional worlds. The first was mellow, optimistic, and forgiving; the second strict, somber and punitive—both equally taking recourse to scripture. . . . There is nothing like such an upbringing to convince a young boy that religion is what you make it, that all of it is what I now call "illusionistic." Fortunately, home won over school, undoubtedly because of its deeper roots in my childhood practicing of the transitional sphere. The hand of God, much talked about in school, was closer to my mother's tender-and-firm hand than to the threatening and often slapping extremities of my teachers. (p. 180)

In other words, for Pruyser—and for many trained in the object relations tradition—the decisive step in religious and spiritual development is choosing between alternative imaginings. For Pruyser, the truth or value of imagining lies not so much in its structure as in its content, and in the value of its content for supporting healthy psychological development. The gentler, nurturing im-

agery promoted in Pruyser's home life seemed healthier to Pruyser than the more punitive imagery promoted in his school life.

But what exactly should one mean by "healthier," and is healthier to be equated with mature? Pruyser and object relations theory in general are not specific with regard to how the concepts of healthy and religious-spiritual development relate—and perhaps for good reason. Health is not to be reified, turned into a "thing"; rather, it is to be used to assess functioning, and functioning is a matter of fit between person and context.

Object relations theory has also contributed by broadening our understanding of the origins of the God concept. For example, Rizzuto (1979) argued that Freud picked too late a period in dating the beginnings of the representation of God in the Oedipal phase. She located the origin of the representation of God in early childhood. Regardless of whether they are raised in a religious manner, children form a representation of God or sacred figures such as the Buddha. These representations or images may derive from the mother, father, or combinations of significant others. Furthermore, the quality of the relationships depicted in these images depends on the quality of early human relationships. These representations or images provide, at best, protection. Later on, they may be held onto, updated, or discarded—to conform to official doctrines or to contradict them.

In sum, classic and neo-psychoanalytic theory provides a variety of examples of work done in the paradigm of coping. Furthermore, these examples are among the forerunners of present-day studies, which also operate in the paradigm of coping. We will have more to say about present-day studies working in the paradigm of coping, such as the case studies of Susan Kwilecki (1999).

Religious and Spiritual Development as Perfecting

> [I]n contradistinction to the process of mere change (development) is a movement toward perfection, as variously as that idea may be constructed. (Kaplan, 1983a)

In describing religious and spiritual development, the previous two paradigms stay close to tangible reality. Persons develop, and some mature, but development and maturity are not remarkable. In contrast, this third paradigm defines and assesses religious and spiritual development in terms of what is remarkable, so remarkable that one may never actually witness an example of someone who reaches the endpoint, someone who is fully developed.

At first glance, this third paradigm seems to revert back to prescientific days when religious and spiritual development meant climbing toward some state of mystical union. However, the paradigm leads in a quite different direction. It leads in the direction of offering specific criteria for defining and evaluating development and for making explicit the often implicit or hidden values in all developmental models. Later on, there will be extended examples to show how this paradigm works. Here, and for the purpose of providing a historical perspective, we concentrate on a single example, namely, the example of William James and his monumental work, *The Varieties of Religious Experience* (1902).

The *Varieties* is arguably the single most influential book in the psychology of religion. Even after a century since it was written, readers find in it insights that are directly relevant to our times (Taylor, 2002). However, the *Varieties* is not normally thought of as a text on religious and spiritual development. For one thing, there is hardly any mention of children. For another, it gives us religious types, but the types themselves seem ordered more along a horizontal plane than along a vertical, developmental one. This seems especially true of James's two major types: "The Healthy-Minded" or "once-born" and the "Sick Soul" or those who feel themselves in need of being "twice-born."

Nevertheless, a closer reading of the *Varieties* shows James to be very much a developmentalist as defined by the third paradigm. In particular, James saw the sick soul as having a more mature grasp of reality than that seen in the healthy minded—and a greater potential for developing spiritually. He shows this developmental ordering of the two types when he turns from writing about the once-born, healthy-minded to writing about the sick soul in need of being twice-born:

> Let us then resolutely turn our backs on the once-born and their sky-blue optimistic gospel; let us not simply cry out, in spite of all appearances, "Hurrah for the Universe!—God's in his Heaven, all's right with the world." Let us see rather whether pity, pain, and fear, and the sentiment of human helplessness may not open a profounder view and put into our hands a more complicated key to the meaning of the situation. (James, 1902, pp. 135–136)

In short, the sick soul has a better grasp of reality and so is in a better position to develop further.

And what might that development consist of? Later on, James tells us when he discusses saintliness. After a second (spiritual) birth, the previously sick soul is more sensitive to the world's contingencies. This is essential to growth, which shows how James can be seen as a developmentalist in the tradition of the third paradigm.

Saintliness is James's way of providing a telos, an ideal endpoint needed to define, evaluate, and explain religious and spiritual development. He makes this clear by characterizing his picture of saintliness as a composite picture, an ideal type, rather than as a picture of specific individuals. In short, James's saint is a standard of perfection that helps define what it means to develop religiously and spiritually.

James's concept of saintliness is not the everyday concept of a moral exemplar who uses religious language. Rather, James's concept of saintliness is essentially religious or spiritual, not moral. In his words, to be a saint is to have "a feeling of being in a wider life than that of this world's selfish little interests; and a conviction, not merely intellectual, but as it were sensible, of the existence of an Ideal Power" (p. 272). He follows this description with the added comment that the saint has "a sense of the friendly continuity of the ideal power with our own life, and a willing self-surrender to its control" (p. 273). For James, religious and spiritual emotions are central. Morality is a by-product.

In the *Varieties,* the saint is an ideal type defining the endpoint of religious and spiritual development. For James, the experience of being a divided self, a self in need of being saved, a lost or sick soul was instrumental for developing toward saintliness. To develop religiously or spiritually meant that things might get worse, not better—at least for a while. For James, simply becoming mature and coping are not, by themselves, enough to define what can ultimately develop when we speak of religious and spiritual development. For James and anyone else working in this third paradigm, it matters little whether anyone actually reaches sainthood and perfection. What matters is that we can conceive of sainthood and perfection and in so conceiving, we can become better able to define, evaluate, and explain religious and spiritual development.

Just as the work of previous writers working in the other two paradigms forecast current research, so, too, the work of James forecast current research and theory using this third paradigm. In particular, James's ideal type, saintliness, forecasts current stage theories, which also use perfection as a telos, particularly the theories of Fowler (1981) and Oser and Gmünder (1991). Later on, we have more to say about these more current theories operating in the paradigm of religious and spiritual development as perfecting.

From the point of view of today's research, these three paradigms for thinking about religious development operate in all discussions taking identity formation as the main goal of development. As King (2003) states, ". . . identity development that emerges . . . within religion is an identity that transcends the self and can promote a sense of commitment that not only fosters individual well-being but promotes the good of society as well" (p. 197). These three paradigms thus are holistic approaches to religious and spiritual development, a point we return to repeatedly throughout the remainder of the chapter.

DEFINING RELIGIOUS AND SPIRITUAL DEVELOPMENT

In Goethe's (1974) *Faust,* when Gretchen asked Faust about his attitude toward religion, she was thinking of faith in the church, salvation of souls, and fear of hell. Presumably, so was Faust. Were she to ask her question today, she would have to imagine quotation marks around "religion" and do her best to interpret which of several meanings was embedded in Faust's response. Today, one of the central problems in the psychology of religious and spiritual development—as mentioned in the beginning—is the problem of defining religious and spiritual.

This problem of defining is nothing new. Almost a century ago, James Leuba (1912, p. 341) listed 48 different definitions of religion, which led him to conclude that attempts to define *religion* precisely border on megalomania. Since, the situation has become still more difficult because *spirituality* also needs definition and because the religious-spiritual landscape has become more pluralistic. Generally accepted definitions do not exist (Beile, 1998, p. 24), and the search for a common definition can proceed almost indefinitely (Brown, 1987, p. 17). For this reason authoritative textbooks on the psychology of religion generally avoid providing a working or operational definition (Beit-Hallahmi, 1989, p. 11; Beit-Hallahmi & Argyle, 1997, p. 5; Hood et al., 1996, p. 7).

Nevertheless, even though there is no commonly accepted definition, there are commonly accepted distinctions that help define religious and spiritual development. In particular, there are the commonly accepted distinctions between *religion* and *religiousness,* between *religiousness* and *spiritual,* and between *content, form,* and *function.* We discuss each of these distinctions to address the problem of definition. In addition, we discuss the concepts of *structure* and *stage* as indispensable means for defining and explaining the religious and spiritual development of persons and not just of acts, thoughts, and feelings considered separately.

Religion, Religiousness, and Spirituality

Religion refers to institutions and systems consisting of organizational structures, codes of behavior, and symbol systems defining assumptions and beliefs designed to create in people powerful, comprehensive, and enduring world views and attitudes. As such, religion is primarily susceptible to sociological analysis.

Religiousness refers to *subjective* modes of experiencing and interpreting, making religiousness primarily susceptible to psychological analysis. One and the same religion can be reconstructed and experienced in quite different ways leading to quite different types of religiousness. The Catholic Church, for example, can be a source of fastidious anxieties for one person and a secure, maternal home for another. Therefore, it is ultimately the individual who determines religiousness on the basis of his or her subjective experience: "Events or feelings are only 'religious' if a person defines them as such" (Stark, 1965, p. 99). Religiousness refers to much more than religious practice such as attending religious services and joining religious institutions. Many regard themselves as being religious even though they have left or avoided religious institutions and religious practice.

Nor is it any less difficult to arrive at a definition of spirituality. For a good many experts, when it comes to spirituality, the problems of defining are even more difficult (Hood et al., 1996, p. 115). However, there is no way to evade the issue given the fact that at the present time, there is scarcely a discussion of faith and scarcely a book on religion that does not use *spirituality.* Indeed, the term *spirituality* is visibly eclipsing the term *religiousness.* The increased use of spirituality derives to a large extent from the loss of relevance of religious institutions and traditions. Many feel themselves bound by spiritual ideals even as they feel themselves not bound by religious tradition (see story on p. 943).

In order not to exclude these people, Utsch (1998, p. 97) argued in favor of converting spirituality into an autonomous research subject separated from the subject of religion. In his view, such a separation is justified since religion can exist without spirituality when it "consists only of rules of behavior, of theology not related to experience, and of rites which have not been understood" (p, 99). Spirituality is thus named *ex negativo* and defined as a *subjective experience* of what is existentially relevant for human beings.

However, a good many scholars retain the historical connection between religion and spirituality by linking spirituality to the experience of transcendence. For example, Pargament (1997) defined spirituality as "a highly individualized search for the sense of connectedness with a transcendent force" (p. 38). McFadden (1996) also included a religious element in her definition when she designated spirituality as a "motivational-emotional phenomenon associated with a sense of meaningful integration within the self, with other persons and the world, and with the Divine" (p. 387). Miller and Martin (1988) did something similar in saying, "Spirituality entails the acknowledgment of a transcendent being, power, or reality greater than ourselves" (p. 14).

In sum, spirituality can be identical with religiousness by its constituting a relationship to a divine or transcendent power, or it can be independent of religiousness by its stressing a more philosophical orientation. Put another way, spirituality can refer to actions, which rekindle religiousness or to actions without religious reference such as relaxation exercises practiced by self-professed atheists. Religiousness and spirituality are therefore not to be seen as in contrast to each other but rather as overlapping (Reich, Oser, & Scarlett, 1999, see also p. 943).

This view of religiousness and spirituality as being both independent and overlapping has been supported by several recent studies. For example, Dowling et al. (2004) used factor analytic and structural equation modeling to separate out spirituality from religiosity factors contained in the questionnaire results of Search Institute's database. They did so by equating spirituality with self-transcendence evidenced in the way individuals become civic-minded and concerned about contributing to society.

In another study, Zinnbauer et al. (1997) asked a sample of 350 persons whether they understand themselves as:

- Spiritual and religious (74%)
- Spiritual but not religious (19%)
- Religious but not spiritual (4%)
- Neither spiritual nor religious (3%)

From these data, we see that the overwhelming majority understood themselves as being both spiritual *and* religious (74%). Only 19% understood themselves as being exclusively spiritual. Still, despite there being a relatively small percentage that understood themselves to be exclusively spiritual, spiritual development is a potentially powerful resource for positive human development (Benson, Roehlkepartain, & Rude, 2003, p. 205). It is, however, an understudied, complex, and multifaceted concept, one that overlaps with many aspects of religious development, and one that is shaped by both individual capacities and ecological influences—as we discuss later.

It is the relatively small group that considers itself to be spiritual but not religious, which furnishes the popular stereotype that religion is antiquated for being institutional and dogmatic, whereas spirituality is central for being personal and open. The wide-spread acceptance of this stereotype has led Hill (2000) to warn against polarizing religiousness as bad and spirituality as good—because virtually all religions promote spirituality, and virtually all spiritual practices have at one time or another been promoted in religious traditions.

In the social sciences, the effort to distinguish religiousness from spirituality has not been matched by an equal effort to specify what they have in common. Outside the social sciences, there has been more said about this issue. The work of Wilfred Cantwell Smith on faith has been most influential (Smith, 1998a, 1998b).

Smith, the historian and long-time dean of comparative religious studies, has argued that faith is the central category in both religiousness and nonreligious spirituality. As explained by him, faith refers to a person's involvement in the symbols of a faith tradition rather than to the symbols themselves. Faith is more a verb than a noun. It is more about action and living a certain way than it is about something static such as a dogma, belief, or symbol. Smith points out that this meaning of faith is much older than the newer meaning of faith as belief (Smith, 1998a). It was the Enlightenment that spawned the newer meaning and reduced religion to matters of belief or to its alternative, feeling.

The picture Smith (1998a) paints of faith-filled lives emphasizes how individuals, by participating in the symbols of their faith traditions have been transformed:

> To live religiously is not merely to live in the presence of certain symbols, but to be involved with them or through them in a quite special way, a way that may lead far beyond the symbols, that may demand of a person's response, and may affect one's relations not only to them but to everything else: to oneself, to one's neighbor and to the stars. (p. 3)

But the main point here is that faith is about participation and response, not about belief. "One does not believe a symbol. Rather, one responds to it." (Smith, 1998a, p. 146).

The consequences of conflating faith and belief have been to marginalize religion and to dismiss spirituality as something less than rational:

> Belief became . . . the category of thought by which skeptics, reducing others' faith to manageability, translated that faith into mundane terms. They substituted for an interest in it as faith an interest rather in the exotic mental processes and conceptual framework of those whose lives had been sustained and enriched by it. . . . What had been a relation between the human and something external and higher . . . was transformed by the new thinking into a self-subsistent, mundane operation of the mind. . . . To imagine that religious persons "believe" this or that is a way of dominating intellectually, and comfortably, what in fact one does not truly discern. (W. C. Smith, 1998a, p. 144)

With regard to the religious-spiritual distinction: Faith need not refer to religious faith. Faith as involvement in a symbol system meant to define and support the good life, such faith can be entirely secular faith. For example, one legacy of classical Greece and Rome has been a secular faith, which is, says Smith:

> a living tradition with its own metaphysical underpinning, its own great champions and even martyrs, its own institutions, its own apprehension of or by transcendence, and, . . . its own type of faith. (1998a, p. 134)

Using Smith's conception of faith, we gain one way of understanding what religiousness and spirituality have in common: They are both grounded in faith.

Content, Form, and Function

The last set of commonly accepted distinctions is the most difficult to explain, yet it may be the most crucial for defining religious and spiritual development. Our goal here is not simply to define what content, form, and function mean with regard to religious and spiritual development. Rather, our goal is also to define how these three, taken together, point us in the direction of adopting a structural definition and explanation of religious and spiritual development as development of *persons.* While there is general agreement over what we should mean by content, form, and function, there is no such agreement over what we should mean by structure and structural development. Beginning with what we can agree on may help clarify what we should mean by religious and spiritual structural development.

To illustrate distinctions between content, form, and function, we use the phenomenon of personal prayer (Scarlett & Perriello, 1991). Personal prayer, as distinct from the generally impersonal group prayers said during religious services, offers a reasonable way to illustrate distinctions, because personal prayer is both widespread and clearly religious in nature—particularly when individuals invest their prayers with feeling. Furthermore, with age, personal prayers not only change but also develop. We focus mostly on petitionary personal prayers because, of the various types of prayers, they are by far the most common.

Prayer's content refers to the specific themes, ideas, and beliefs contained in prayer. Prayer may be about healing, avoiding danger, hoping for success—almost anything and everything. It may be about gods, ancestors, or patron saints. It may be about something as small and petty as finding a parking space or as large and noble as achieving world peace.

The variety of contents found in phenomena such as personal prayer points to both the value and limitations of understanding religious and spiritual development in terms of its content only. On the one hand, content provides a window on special circumstances, on what is on an individual's mind, and on how an individual may be thinking in ways characteristic of his or her family, community, and culture. On the other hand, the infinite variety in content limits its value for defining development in terms of content only. How, for example, should we distinguish developmentally between prayer directed to a single divinity and prayer directed to gods or ancestors? Given that there are no agreed on criteria, we should not.

Nevertheless, content figures into analysis of religious and spiritual development in general and the development of prayer in particular—both to the extent that content occasionally supports criteria for defining religious and spiritual maturity (e.g., acting in self-disinterested ways, pursuing noble purposes) and to the extent that content reveals something about the overall structuring of content, form, and function. So, for example, when the content of petitionary prayer includes statements such as "If it be your will . . .," then the content makes explicit that the praying individual sees the possibility of there being alternative perspectives or wills—a measure of decentering and therefore of development. It is reasonable to treat petitionary prayers that make this possibility explicit as being more developed than petitionary prayers that do not, all other things being equal.

A better indicator of developmental differences has been, generally, differences in *form.* With respect to prayer, there are the differences in types—petitionary, confessional, thanksgiving, and so on—and presumably development has something to do with recognizing, understanding, and being able to use each type. However, in each type, there are different forms that have different developmental meanings. For example, two confessional type prayers may each contain specifications of the same transgression, say, lying. However, only one of the two may specify a plan for becoming honest. Adding the plan is more than adding content. It is making confessional prayer into a more developed form, a form that is more differentiated with respect to its parts. With the example of prayer containing "If it be your will . . .," the added content is not clearly an added part making the prayer into a more differentiated whole. The added content is, rather, an indicator of an underlying attitude and understanding of the relationship between person and the agency to which the prayer is directed.

With regard to *functions,* prayer also provides examples. By definition, petitionary prayers serve the explicit function of making requests. However, a closer inspection reveals petitionary prayers sometimes serve additional functions as well. Furthermore, these additional functions can sometimes help define development. For example, a child and an adult may both pray for a sick relative to get well. However, the adult may add something

about not knowing what to do if things turn out for the worse, if the sick relative dies. This little addition suggests prayer serves the added function of helping the praying individual to figure out, puzzle, or search for ways to understand or frame a crisis. This searching function is hardly ever found in children's prayers and may only occasionally be found in the prayers of adults—which tips us off to its being a function that can help define development.

Therefore, by analyzing and evaluating separately the content, form, and functions of religious and spiritual phenomena, such as prayer, we often gain a better understanding of religious and spiritual development. However, in doing so, we still are not able to define and explain how individual persons develop. For this we need the concepts of *stage* and *structure*.

Stage and Structure

The concepts of stage and structure offer indispensable means for defining and explaining the religious and spiritual development of persons. They do so first in the way they organize content, form, and function to reveal the full meaning of the religious and spiritual life. Attending to content, form, and function separately or in sequence can lead to overlooking the central characteristics that distinguish mature from immature—the hidden structure that allows us to not only evaluate individual acts but also to evaluate the development of persons.

Stage and structure also offer means to explain the dynamic nature of religious and spiritual development. In the previously cited example of adding functions to petitionary prayer, we see a transformation in the self's structured way of being in the world—from being in the world as a self depending on some divine power to resolve crises to being in the world as a self acting in concert with a divine power. The change from one to the other is neither arbitrary nor random. Rather, the change has profound meaning for adaptation—which is a major reason why we judge the second way of structuring to be more developed.

This view of stage and structure differs markedly from the views of current critics of stage theory—including critics of religious and spiritual stage theories. Post-Piagetian critics have dismissed stage-structural theory primarily for not providing an adequate account of variability and not accounting for transition processes. However, recently, a number of theorists have answered the critics and in so doing, have revitalized stage-structural theory. David Henry Feldman's (in press) discussion bears special mention.

After outlining each of the main criticisms of Piaget's stage-structural theory, D. H. Feldman proposes ways to answer the criticisms and retain stage as a useful, even indispensable explanatory concept. His main suggestions include the following two, which we take to be the most central.

The first major criticism of stage-structural theories such as Piaget's is that they do not account for the wide variation in behavior one finds in any given stage. D. H. Feldman answers this criticism by suggesting we think of a stage as consisting of two substages—with the first substage devoted to constructing the stage and with the second devoted to extending and applying the stage's system as widely as possible. Stages are marked by their midpoints.

Using this way of thinking, stages emerge only gradually and are only gradually replaced as the effort to extend and apply begins to fail. In other words, stages need not be thought of as structured wholes, which snap into place at particular moments in development. There is an ebb and flow to their development, and variability in behavior or patterns of behavior, rather than undermining the notion of stages, is another indicator of their development.

The second major criticism of stage-structural theories is that they do not provide adequate accounts of transition mechanisms. In the case of Piaget's stage theory, equilibration as a transition mechanism bears too much of the burden for explaining transitions. D. H. Feldman answers this criticism by suggesting we keep Piaget's equilibration mechanism but give more emphasis to other mechanisms to explain transitions—including maturation and learning.

Suggestions such as D. H. Feldman's (in press) allow us to hold on to the concepts of stage and structure to define and explain religious and spiritual development. Once again, we find there is no reason to throw out the baby with the bath water.

In sum, content, form, and function are commonly accepted concepts and distinctions used for defining and evaluating religious and spiritual development. However, when used by themselves, they do not adequately account for the development of persons. Stage and structure are less commonly accepted concepts. However, if used in ways that address the main criticisms of stage-structural theories, stage and structure

become indispensable concepts for defining and explaining the religious and spiritual development of persons.

The neo-Kantian philosopher, Ernst Cassirer, provides an example of how stage-structural analysis can be indispensable in defining, evaluating, and explaining the religious and spiritual development of persons. For Cassirer, at the lower stages of religious and spiritual development, individuals live in a mytho-poetic world where symbol and referent are fused and where there is no distinction between meaning and existence (Cassirer, 1955). Cassirer distinguishes between mythical and religious consciousness with the latter being more developed. However, myth (a tradition's imagination) and religion are inseparable. Cassirer writes:

> If we attempt to isolate and remove the basic mythical components from religious belief, we no longer have religion in its real, objectively historical manifestation; all that remains is a shadow of it, an empty abstraction. Yet, although the contents of myth and religion are inextricably interwoven, their form is not the same. And the particularity of the religious form is disclosed in the changed attitude which consciousness here assumes toward the mythical image world. It cannot do without this world, it cannot immediately reject it; but seen through the medium of the religious attitude this world gradually takes on a new meaning.
>
> The new ideality, the new spiritual dimension, that is opened up through religion not only lends myth a new signification but actually introduces the opposition between "meaning" and "existence" into the realm of myth. Religion takes the decisive step that is essentially alien to myth: in its use of sensuous images and signs it recognizes them as such—a means of expression which, though they reveal a determinate meaning, must necessarily remain inadequate to it, which "point" to this meaning but never wholly exhaust it. (p. 239)

In Cassirer's account, we see how important structural differences can be for defining what is essential in religious and spiritual development. For Cassirer, it is the transformation from living in a mytho-poetic world to living in a world where the myths and poetry of faith traditions become symbols pointing to truths to live by. Others who engage in stage-structural analysis find different ways to characterize what is essential. Whatever the ways, the effort is the same, explaining not only the development of acts, thoughts, and feelings but also explaining the development of persons. In general, critics forget that stages and structures are heuristic instruments for understanding this development: They are frames of mind and heuristics of beliefs, not tangible realities.

Having explained the rationale for using the concepts of stage and structure, we turn now to discussing specific stage-structural theories of religious and spiritual development.

STAGE-STRUCTURAL THEORIES

The stage-structural theories to be discussed here are all in the constructivist tradition associated with the work of Jean Piaget. Because Piaget's theory focused on epistemology and cognitive development, stage-structural models of religious and spiritual development are often criticized for being too cognitive. Critics assume that any off-shoot of Piaget's theory is also bound to be too cognitive.

It is ironic that few know about Piaget's early reflections on religious and spiritual development—what is generally understood to be a Piagetian approach to religious and spiritual development is not at all Piagetian. We begin with a brief summary of Piaget's actual approach to religious and spiritual development to better frame the discussion of stage-structural theories.

From his late teens until his early 30s, Piaget preoccupied himself with the question of how one can believe in God and remain objective (Reich, 2005). His questioning led to a significant development in his thinking: to his distinguishing between a transcendent and immanent God. For Piaget, God initially meant the God of conservative theology—a transcendent and mysterious God whose laws must be followed slavishly. Over time and in the context of actively debating and discussing, Piaget developed a very different meaning of God so that eventually God, for him, went inward. In rejecting transcendence in favor of immanence, Piaget came to identify God with the heart, with the norms of reason, and with the internalized example of Jesus.

Piaget's model of religious development centered around a transformation from transcendent to immanent meanings of divinity. This transformation was far more than a cognitive transformation and certainly more than developing faith in reason. To be sure, reason was there in his model but also the heart and a faith tradition. He makes this clear in a lecture he gave in 1929, to members of the Swiss Christian Students Association:

> if, beyond men, one examines the currents of thought that propagate from generation to generation, immanentism appears as the continuation of the impulse of spiritualization that characterizes the history of the notion of divinity. The same progress is accomplished from the transcendental God endowed with supernatural causality to the purely spiritual God of immanent experience, as from the semi-material God of primitive religions to the metaphysical God. Now—and this is the essential point—to this progress in the realm of intelligence corresponds a moral and social progress, that is, ultimately an emancipation of inner life. (Vidal, p. 287)

Piaget never developed a research program to test out his developmental theory of religious and spiritual development. Whatever the reasons may be for Piaget's abandoning his public reflections on religious and spiritual development, his early discussions clearly indicate that a true Piagetian approach to religious and spiritual development demands much more than attending to cognition and reasoning.

However, in the early 1960s, when Piaget's cognitive developmental theory was eclipsing all other theories of cognitive development, Piaget's early reflections were virtually forgotten. The result was an application of Piaget that was not at all Piagetian and that was indeed overly cognitive. The clearest example is the work of Ronald Goldman.

Cognitive-Stage Theories: Ronald Goldman

Goldman's (1964) classic study "Religious Thinking from Childhood to Adolescence" is a landmark in the research on religious development. The main concern of the book is ultimately derived from the pedagogy of religion: "To know what a child is able to grasp intellectually is a surer foundation for education than to know only what adults feel the child ought to grasp" (p. xi). Goldman referred to the decisive work of Jean Piaget—not so much to Piaget's early work, "The Child's Conception of the World" (1929), which investigated children's theories—and the stages of cognitive development. In so doing, Goldman adopted the position that, "Religious thinking is not different in mode and method from nonreligious thinking. Religious thinking is . . . the activity of thinking toward religion" (p. 3).

Unlike earlier studies in the psychology of religion, which merely described children's religious concepts without explaining them, Goldman's approach had the advantage of treating diverse impressions of children in a theoretically based sequence. Goldman asked children and young people about their religious conceptions such as "God's omnipotence," "the Bible," and "Jesus." He also asked children about their interpretations of three biblical stories: Moses and the burning bush, the crossing of the Red Sea, and the temptation of Christ. He assigned children's interpretations to three stages of religious cognition and matched them to Piaget's stages of cognitive development—as indicated in Table 17.1.

From this summary table, we see that Goldman conceptualized mature religious thought moving beyond the "childish and immature religious ideas of children" (p. 67) to be capable of seeing the symbolic-metaphorical structure of religious language in general and biblical language in particular. Using the findings of his research, Goldman drew provocative consequences for the peda-

TABLE 17.1 Stages of Piaget and Goldman Compared

Piaget	Goldman
Preoperational	Intuitive Religious Thought Religious contents comprehended unsystematically, fragmentarily, frequently in a magical way, God represented anthropomorphously; frquent transductive conclusions: "Why did Moses not go to the bush?" "Because there was a sign saying 'Keep off the Grass.'"
Concrete operational	Concrete Religious Thought Magical and animistic elements receding; religious concepts presented in a more coherent and objective way—though their symbolic-metaphorical nature not yet apprehended: "The burning bush had a fire behind it, it only seemed to be burning."
Formal operational	Abstract Religious Thought Religious contents now reflected in a hypothetical-deductive manner with symbols recognized as symbols: "The burning bush is a symbol that God is there."

gogy of religion, notably that children should no longer be confronted with the Bible because they glaringly misunderstand biblical texts.

Goldman inspired an abundance of studies replicating his work (see reviews by Hyde, 1990, p. 15–63; Slee, 1986a). Peatling's (1974) multiple-choice test and his devised "Thinking about the Bible Test" became widely known and used. Other psychologists of religion made use of the semi-clinical interview (Elkind, 1964), and they also applied Piaget's cognitive stages to religious concepts. The overall picture painted was that, with increasing age, concrete modes of thinking recede and are replaced by more abstract religious thinking (e.g., Tamminnen, 1976).

However, even while Goldman inspired others to apply Piagetian stage analysis to religious material, he also drew widespread criticism. His work was criticized for its faulty methods (Langdon, 1969; Slee, 1986a, 1986b). For example, religious semantics can be more appropriately based on word choice procedures than on interview questions foreign to children's natural ways of thinking (Murphy, 1978). Furthermore, research showed that abstract religious thought coincides positively not with the acceptance of religious, particularly biblical, contents but with rejection of that content (Hoge & Petrillo, 1978), and children's understanding of biblical content is more adequately explained by other stage-structural theories such as Oser and Gmünder's (Bucher, 1991).

More recently, cognitive scientists informed by research on "theory of mind" as well as by cognitive anthropology, have questioned Goldman's work for overstating differences between children's and adult's ways of thinking about religion. On the one hand, children's thinking about counterintuitive religious concepts, such as the concept of an all-seeing God, must be judged in the context of children's intuitive psychology and in the context of what adults teach children about religious concepts. When so judged, children's thinking appears far more reasonable and sophisticated than Goldman's theory leads us to believe (Boyer & Walker, 2000; Harris, 2000). On the other hand, adults often give theologically correct answers to questions about religious concepts, but, in their own personal lives, they function with religious concepts not altogether different than what Goldman ascribed to children (J. Barrett & Keil, 1996). We have more to say about this line of criticism when discussing research on children's religious concepts.

By far, the most common criticism of Goldman's work has been directed at Goldman's essentially narrow cognitive focus. Critics have pointed out that religious consciousness includes far more than what is implied in Goldman's research, particularly with regard to the use of religious symbols (Godin, 1968b). A special problem is that Goldman did not deal with the development of religiousness, *sui generis,* but rather with cognitive structures to the extent that they rub off on religious content.

Probably as a reaction to Goldman's overestimation of cognitive processes, the first empirically based theory of religious and spiritual development of the 1980s was holistic in nature and included social, moral, religious, spiritual, and identity formation parts and treated faith as having a much broader meaning than belief. It is this theory of James Fowler that we discuss next.

Faith Developmental Theory: James Fowler

Fowler's focus is broad because his view of faith is broad. Following the lead of theologians Paul Tillich, H. Richard Niebuhr, and Wilfred Cantwell Smith, Fowler (1981) defines faith as a universal quality of persons, a quality defined by the way persons orient themselves in the cosmos and, at higher stages, in an ideal, yet-to-be-achieved or experienced ultimate environment. In Judeo-Christian thinking, this ultimate environment is defined as the "kingdom of God," the endpoint of human history. Faith so defined is reflected in how individuals make or find meaning, how they define centers of value and power, and how they adopt symbols and stories to reveal or express their faith. For Fowler, faith is far more than belief or reasoning.

Fowler's (1981) focus is also broad because faith developmental theory is intent on capturing the overall psychological development of persons. His theory borrows heavily from Erikson, Piaget, and Kohlberg, and to a lesser extent from Sullivan, Stern, Rizzuto, and Kegan. His stages take into consideration an individual's development with respect to major developmental tasks including identity achievement, cognitive development, moral judgment, symbol formation, social perspective taking, and locus of control. For Fowler, the development of faith and the development of persons are so intertwined as to be, to a large extent, one in the same.

At the heart of Fowler's (1981) view of faith development is the issue of individuation in a pluralistic society.

From this view, the central dilemma for individuals is that of being true to ourselves, our feelings, intuitions, beliefs, and understandings, while, at the same time, maintaining or constructing ethical, positive relationships with increasingly diverse communities.

At first, this dilemma is played out in the family and with one's inherited extra-familial community and faith tradition, then with self-consciously adopted communities and faith traditions, and, ultimately, with the community of humankind. As with Oser and Gmünder's (1991) stage theory, Fowler's faith developmental theory is meant to define an ideal sequence (paradigm of perfection). Only a few reach the highest stage.

Fowler's way of construing faith and human development shows in the descriptions of his stages of faith development. Table 17.2 provides a brief overview of those stages (Fowler, 1981).

Fowler's stage model was applied to transcripts made following two-hour interviews with over 350 subjects. The interviews made use of a "Faith Development Instrument" designed to elicit and support discussion directly relevant to getting at subjects faith, as faith was defined by Fowler.

The results of Fowler's (1981) own research indicated that almost all of the preschoolers in the sample had an intuitive-projective faith; almost three quarters of the elementary school children had a mythic-literal faith, and almost half of the adolescents interviewed had a synthetic-conventional faith. Among adults, the variance was greater, with 40% younger than 30 having an individuative-reflective type of faith and 18% having a synthetic-conventional type. Conjunctive faith was rare and occurred only after age 40. There was only one subject categorized as having a universalizing type faith.

There have been at least 11 empirical studies replicating Fowler's original study, and 26 others using the faith development interview technique (Streib, 2001). Several cross-cultural studies provide inconclusive evidence about the suitability of Fowler's stages for studying faith development in non-Western cultures. Part of the difficulty has been in using the faith development interview method. Attempts to devise a shorter method to measure faith development have not been successful.

Since conducting his study in the 1970s, Fowler (1981) has focused more on making faith developmental theory useful for practitioners, particularly in the fields of pastoral counseling and religious education. However, he has continued to modify the theory in response to criticisms. Concerning gender bias and overemphasis on

TABLE 17.2 Fowler's Stages of Faith Development

Stage One: Primal Faith (Infancy)
Prelinguistic faith defined by the trust developing between infants and their caregivers and by the psychological bonds created through affect attunement.
Stage Two: Intuitive-Projective Faith (Early Childhood)
Faith defined by the images created to represent both threatening and protective powers, by representations of God that derive from experience with significant caregivers, by the awakening of moral standards, and by continued reliance on and referencing to caregivers.
Stage Three: Mythic-Literal Faith (Elementary School Years)
Faith defined by widening sources of authority to include those outside the family so as to create a community of like-minded, by the appreciation of myths and narratives taken literally and valued for their ability to explain and express faith, and by anthropomorphic images/conceptions of God.
Stage Four: Synthetic-Conventional Faith (Adolescence and Adulthood)
Faith defined by the development of a worldview derived from conventionally or consensually sanctioned authorities, by self-identity forming a synthesis of the perceptions of others so that identity is defined in terms of belonging (to family, ethnic group, sex role, religion) and/or possessing, and by undeveloped ability to understand and identify with groups with worldviews different from one's own.
Stage Five: Individuative-Reflective Faith (Late Adolescence to Adulthood)
Faith defined by the self-conscious, explicit examination of commitments, beliefs, and values leading to critical examination of the individual's faith heritage and a self-conscious choosing of the faith tradition and community to which the individual belongs. Faith at this stage indicates the individual takes charge of his/or life in defining self and commitments – often limiting the individual's ability to connect to faith-based groups and faith traditions and to take the perspective of alternative groups.
Stage Six: Conjunctive Faith: (Average Age: About 30)
Faith defined as self-conscious commitment to ethical action based on fully internalized principles and to a vision of meaning, coherence, and value that fully accepts the limitations of the self to understand fully and act purely. Faith at this stage is maintained without the props of external authority and may be described as paradoxical faith inasmuch as commitments are made in the context of self-doubt and despair that allows for appreciation of alternative perspectives but threatens passivity and inability to act.
Stage Seven: Universalizing Faith: (Average Age: Minimum about 40)
Faith defined as overcoming paradox through identifying with the ultimate conditions of existence ("kingdom of God"). Faith at Stage Seven often appears to be simple compared to faith at Stages Five and Six. Self and other are, at Stage Seven, viewed and understood from a cosmic, transcendent perspective which allows for the feeling of unity and meaning.

autonomy issues at stage four, Fowler has placed more emphasis on relational knowing to characterize faith at stage four, and in response to criticisms concerning cultural bias, Fowler has placed greater emphasis on the deconstructing power of specific cultural contexts, which call for more emphasis on faith development being viewed in the context of culture and needing specific conditions for development to proceed beyond the lower stages.

More recent stage-structural theories of development refer again to Piaget's and Kohlberg's conceptions of growth; however, instead of considering religious and spiritual experiences only as they reflect general stages of logical thinking and cognition, these newer theories consider genuine religious experience, feelings, and convictions as they reflect religious judgment, reasoning, and cognition. Clear examples occur in the research of Oser, Gmünder, and Reich—which we discuss next.

Stages of Religious Judgment and Reasoning: Fritz Oser and Paul Gmünder

Goldman's research was on judgment and reasoning about religious content and concepts. Oser and Gmünder's research is on religious judgment and reasoning about unspecified content (Oser & Gmünder, 1991). The distinction is important. In Goldman's case, judgment and reasoning was the issue and religion was the content. In Oser and Gmünder's case, religiousness is the issue and judgment and reasoning is a means to understanding religiousness. In Goldman's case, the focus is on the cognitive domain. In Oser and Gmünder's case, the focus is on the religious domain. Here, we see religious judgment and reasoning treated as a "mother structure" or way of thinking that cannot be reduced to some other way of thinking.

However, because religious judgment and reasoning constitute judgment and reasoning about something, the question arises as to what religious judgment and reasoning are about. For Oser and Gmünder (1991), religious judgment and reasoning are not about meaning-making of all life, but from a measurement point of view are most apt to be about resolving ambiguities elicited in particular kinds of situations, here described as *contingency* situations.

Contingency situations elicit religious judgment and reasoning primarily because they raise questions about who or what is ultimately in control and also about a variety of conflicts having to do with a person's relationship to an ultimate being or reality. With contingency situations, there is ambiguity, which can be resolved through a special kind of interpreting that Oser and Gmünder (1991) identify as being religious or spiritual in nature. This chapter opened with such an example—the example of one person interpreting another's good fortune as having a religious meaning. Other examples include interpretations of misfortune. Therefore, studying reactions to contingency situations offers one way to understand the development of religious judgment and reasoning.

Oser and Gmünder's (1991) focus was on the qualitatively different ways that individuals reason religiously about the conflicts elicited by existential contingency situations. Contingency situations are not controllable in human life. They stimulate the beginning of religiousness, but they also stimulate conflicts in persons, which are defined as polar opposites needing to be differentiated and coordinated. Each polar opposite defines some issue that may be brought to bear when interpreting a contingency situation. As noted in Table 17.3, Oser and Gmünder list several polar opposites as central.

These polar opposites can be used to reason about how best to interpret and react to contingency situations. They function in ways similar to the Kantian categories of thinking (time, space, causality, etc.) needed to organize thinking in general.

From a genetic point of view, at lower stages of development, individuals choose only one of the polar opposites. Either they are dependent, or they are free. Either they are in a holy space or in a profane space—and so forth. By adolescence, individuals usually consider both polar opposites simultaneously. There is trust and mistrust, transcendence and immanence, and so on. Furthermore, each polar opposite is seen as having meaning in life. Here is transcendence, and there is immanence, and both can be at the same time. Later, at higher stages of development, one polar opposite can be taken as a

TABLE 17.3 Polar Opposites to Be Coordinated for Religious Judgment and Reasoning

Freedom versus dependence
Transcendence versus immanence
Hope versus absurdity
Transparency versus opacity
Eternal versus ephemeral
Trust versus mistrust
Holy versus profane

fundamental condition for the other, so, for example, the experience of absurdity can become a condition for experiencing hope, and freedom can become a prerequisite for experiencing healthy dependency.

But what exactly does reasoning with the aid of seven polar opposites organize and accomplish? Oser and Gmünder's (1991) answer is that it helps define how individuals understand their relationship to God or to whatever individuals owe a commitment. Because some faith traditions speak of a collection of personal agencies (gods, ancestors, etc.) while others speak of an impersonal force or reality (dharma, Tao), Oser and Gmünder referred to the person-"Ultimate" relationship—with ultimate referring to that which one owes commitment to ultimately. For example, devote Buddhists often treat dharma (cosmic law) as an Ultimate reality to which one owes commitment (W. C. Smith, 1998a).

A clear example of how the polar opposites figure into reasoning about the person-Ultimate relationship occurs when individuals, faced with contingency situations, reason about how free and/or how dependent they are with respect to a higher power or reality. Contingency situations are, after all, situations that raise questions about control. The main assumption here is that reasoning well about the person-Ultimate relationship leads to more adaptive ways of living that serve not only the individual but also those around the individual.

This does not mean that less developed ways are necessarily less adaptive—because adaptation is always a matter of the match between person and context. A child's way of reasoning may be perfectly matched to his or her protective surroundings. The theory suggests that it is adaptive for children to reason religiously as if there are no apparent conflicts created by the presence of evil, tragedy, and injustice. However, it is not adaptive for adults to reason without taking into account these and other conflicts. In short, for adults, the standards for adaptive behavior are higher.

Furthermore, saying development is about adapting does not mean that immature ways need to be discouraged. On the contrary, the model suggests that most of the time, religious reasoning is directed toward adapting and is open to being modified and transformed as the need arises. Refer back to the previous section's comments about consolidating and expanding phases in stages as well as to transition mechanisms, and Oser and Gmünder's stage approach becomes clearer.

What development of religious reasoning means is that, with development, individuals are more able to adapt to a wide variety of contexts or situations—not just to the narrow set of contexts and situations experienced in, say, childhood. Furthermore, development here is assumed to help prevent negative dependency, dogmatic positions, intolerant behavior, and aggressive forms of religious expressions.

What development and adaptation mean differs according to theoretical perspective, as we see in the next section. Here, development is defined as structural development and approximations to an ideal endpoint (paradigm of perfection). In other theories, development may be defined more as content, intensity, and adaptation to specific circumstances (paradigm of coping).

Two further comments to clarify the stage theory of religious judgment: First, though the focus here is on contingency situations, the theory suggests that religious judgment and reasoning may occur in a wide variety of situations, not just contingency situations. William James' saints were, after all, continually judging and reasoning religiously. Second, though the theory refers to religious judgment and reasoning, the term *spiritual judgment* and reasoning could work just

TABLE 17.4 Stages of Religious Judgment in the Oser and Gmünder (1991) Model

Stage 1: Orientation of Religious Heteronomy—Deus ex Machina
God (the Ultimate) is understood as active and as intervening unexpectedly in the affairs of the world; persons are conceived as mostly reactive to God's (the Ultimate's) power and interventions.
Stage 2: Orientation of Do et Des—"Give so you may receive"
God (the Ultimate) is understood to be external, all-powerful, and intervening, however, God (the Ultimate) now can be influenced through promises, prayers, and deeds.
Stage 3: Orientation of Ego Autonomy and One-Sided Responsibility
The influence of God (the Ultimate) is consciously reduced. The individual is conceived of as responsible for his or her own life. The Ultimate Being (if accepted as real) has a separate and hidden existence and responsibility/function.
Stage 4: Orientation of Mediated Autonomy
God (the Ultimate) is mediated through immanence—as in developing faith in a divine plan and living life accordingly. Social engagement becomes a form of religious/spiritual expression.
Stage 5: Orientation of Unconditional Religiosity
The individual feels that he or she is always and unconditionally related to the Ultimate Being—so that each moment is or can have a religious/spiritual dimension. Religious and spiritual reasoning displays complete differentiation and coordination of the seven polar opposites.

as well—especially given the fact that certain kinds of atheism and agnosticism retain notions of a person-Ultimate relationship.

This brings us, at last, to the heart of the theory: to how the polar opposites become increasingly differentiated and coordinated and created stages defining how individuals understand their relationship with an Ultimate being. Table 17.4 lists the stages and provides brief descriptions.

Again, independent of the religious denomination (jewish, catholics, protestants):

- At the lower stages, there is little or no effort to coordinate the polar opposites. Either God (the Ultimate Being) intervenes, or He (It) does not intervene. Either we feel hopeful, or we do not feel hopeful. Either an event reveals God's (the Ultimate Being's) will or that will remains inscrutable. And so it goes with the rest of the polar opposites, as individuals continue to think in "Either . . . or . . ." terms.
- At middle stages, polar opposites become differentiated and opposed to one another—without there being a way to coordinate or balance them. For example, at a middle stage, individuals may see themselves as free to make their own choices while, at the same time, they may feel that God (or the Ultimate Being) is simultaneously doing the same, possibly in opposition to what they are doing.
- At higher stages, the polar opposites interpenetrate one another so that, for example, freedom is achieved through remaining dependent on God (the Ultimate Being); transcendence emerges indirectly through concrete actions so that immanence and transcendence are intertwined, and transparency and opacity become integrated as indicated by phrases such as, "We see, but through a glass darkly." (1 Corinthians 13:12, New Revised Standard Version). With respect to the polar opposites, what were originally experienced as conflicting opposites come to be experienced as integrated dualities that define religious and spiritual experience.

Oser and Gmünder's (1991) stage theory of religious judgment was developed, tested, and validated using a semistructured clinical interview method that asked subjects to respond to hypothetical contingency situations. The best known of these situations is the "Paul dilemma." Subjects are first told the story of a young man caught in a plane about to crash. The young man promises God that, if he survives the crash, he will forego a promising career and serve humanity in a third world country. Paul survives, and subjects are asked to respond to a series of questions to elicit reasoning about Paul's promise, whether he should keep his promise toward God, what will happen if he doesn't, and how, in general, he should think and behave in reaction to his surviving the crash.

A coding manual allowed subjects' responses to the Paul dilemma and to other hypothetical dilemmas to be evaluated in terms of the seven polar dimensions—and allowed for subjects to be assigned to a particular stage of religious judgment. Here are typical responses to the question of whether Paul should keep his promise:

Stage One: "Paul has to keep his promise, otherwise God will give him a stomach ache."

Stage Two: "God helped Paul so Paul now has to do some good." Or, "If Paul does not keep his promise, he has to do something else. He has to pray so that he won't be punished."

Stage Three: "This has nothing to do with God. Paul has to make his own decision. God, if he exists, has other problems."

Stage Four: "Whatever decision Paul makes, he will likely use his faith in God to act responsibly—because acting responsibly is really what is God's will. And, in the end, things will be okay."

Stage Five: "Whether he goes (to serve in a third world country) or does not go is unimportant; what is important is that Paul fulfills the larger promise to meet the many challenges he will face throughout life, in the light of what he gathers to be God's will. God is present in every human communication and so it does not matter where exactly Paul ends up."

Again, no single answer or response was enough to assign a subject to a particular stage. It was the collective response that determined how subjects were assigned to stages.

The results of the original and subsequent studies have proven the usefulness of this stage model for (a) describing age changes, (b) understanding religious behavior, (c) looking at conversion experiences, and (d) establishing the value and significance of developing religious judgment and reasoning.

With respect to age changes, significant age trends were established with European samples, not only in cross-sectional studies (Oser & Gmünder, 1991), but

also in longitudinal studies as well (Di Loreto & Oser, 1996). Together, the cross-sectional and longitudinal studies suggest that children and adolescents normally progress through the first three stages of religious judgment. After adolescence, the majority of adults remain at stage 3. This finding may be explained, in part, by cognitive development being the prime transition mechanism at lower stages (e.g., developing capacity to reason about contradictions) while emotional development figures more in the transitions at higher stages (Beile, 1998).

These findings were replicated in sociocultural contexts as different as India (Hindu and Buddhist), Tibet and Rhwanda (ancestor worship; Dick, 1981). Another finding is that in adolescence, girls score higher than boys—though the differences are small and disappear with the transition to adulthood (Reich, 1997; Schweitzer, 1992).

As for the usefulness of the stages for understanding religious behavior, the stages shed light on individual differences in (a) involvement in religious communities, (b) interpretations of religious texts, and (c) self-effectiveness in religious beliefs.

With respect to involvement in religious communities, individuals at stages 1 and 2 are more likely to prefer religious communities that require unconditional subservience from members, but individuals at higher stages are more likely to prefer liberal communities (Zondag & Belzen, 1999). Furthermore, individuals at stage 2 are more likely to have stronger ties to religious institutions, attach greater importance to sacraments, and expect more support from religion (Kager, 1995). Finally, with respect to religious communities, persons at lower stages are more likely to prefer religious bonding relationships analogous to the mother-child relationship, but persons at higher stages are more likely to prefer such relationships to take the form of cooperating friends (Kager, 1995).

With respect to interpretation of religious texts, individuals at stages 1 and 2 tend to understand religious language literally rather than metaphorically or symbolically (Zondag & Belzen, 1999)—and in a manner consistent with their *do ut des* orientation. So, for example, individuals at stage 2 tend to interpret miracles reported in the Bible as pay-back for biblical figures being good, and parables such as the parable of the workers in the vineyard who received a full day's pay for working only an hour were interpreted as showing that God rewards good work (Bucher, 1991).

With respect to conversion experiences, conversions into open, but not into closed, narrow religious groups are associated with stage development (Wenger Jindra, 2004).

With respect to self-effectiveness in religious beliefs (SEB), individuals at stage 3 show considerably less SEB than do individuals at lower and higher stages (Rollett & Kager, 1999). SEB is strongest at stage 2, which is consistent with the overall stage 2 orientation emphasizing the influence that individuals can have on God or the Ultimate Being.

As for the value and significance of developing religious judgment, three studies suggest that stages may influence how individuals cope with adversity and come to think positively. In one study of parents with either Down syndrome or autistic children, parents at higher stages were more likely to use social support than were parents at stage 3 (Gnos, 2003). In a similar vein, another study provided evidence that widows were overcoming sadness at a higher stage level than non-widows, suggesting that, for at least some widows, stage development may occur to cope with the death of a spouse (Zenklusen, 2003). Finally, in one study, stimulating the development of thinking about content with spiritual meaning had direct effects on social consciousness and on well-being (Blakeney & Blakeney, 2005).

Therefore, Oser and Gmünder's (1991) stage theory has proven useful and in a number of ways. In particular, the theory has proven useful for understanding how religious judgment and reasoning figure into overall religious development.

Fowler and Oser and Gmünder's Theories Compared

The similarities between the theories of Fowler (1981) and Oser and Gmünder (1991) are evident. Both are indebted to genetic structuralism. Both are in the tradition of the Enlightenment. Both describe a development that leads from the particular to the universal and from heteronomy to autonomy. Both establish significant age trends, and the stages from both theories, to a certain extent, parallel one another. For example, in a direct comparative study by Tamminnen (1994), results showed that in the adult age group, most subjects were at stage 3 in Oser and Gmünder's scheme and at the parallel stage 4 in Fowler's. Notwithstanding these similarities, there are differences (for a fuller discussion, see Nipkow, Schweitzer, & Fowler, 1988).

First, Fowler (1981) incorporates into his scheme of stages many different kinds of psychological elements, including moral and social elements, the development of

self-hood and self-identity, type of thinking, and comprehension of symbols. In contrast, Oser and Gmünder (1991) concentrate on religious matters only to the extent they can be used to cope with life in the face of the Absolute or Divine.

Fowler speaks of faith in a very general sense, which has attracted the criticism that we are dealing here with an "everything and nothing view of faith" (Fernhout, 1986, p. 66). In contrast, Oser and Gmünder (1991) speak of religious judgment for establishing control in a situation of life through a person's regulating the relationship (bounding) between him- or herself and the Absolute.

Fowler (1981) views the normative goal of religious education in terms of the biblical metaphor of the kingdom of God (or "reigning of God"), whereas Oser and Gmünder (1991) view this goal as not determining the characteristics of stages.

While Fowler's (1981) approach may be more suitable for raising questions related to life history and existential themes, Oser and Gmünder's (1991) approach is more about the transformation dynamics of cognitive structures. Fowler is more interested in the implications of his stage theory for supporting pastoral care, while Oser and Gmünder are more interested in scientific issues such as the issue of validating stages.

Approaches have their own history and their own advantages and drawbacks. Oser and Gmünder's (1991) approach is admittedly less explanatory and more sharply focused on God-man connectedness, but this could be interpreted as a strength. Fowler's (1981) approach is more faith related and thus more holistic, and this, too, can be seen as strength. Therefore, to a certain extent, these approaches or theories serve complementary roles for understanding religious and spiritual development.

The Relational and Contextual Model of Development: Helmut Reich

There are numerous religious phenomena calling for more specialized reasoning than that explained in the Oser and Gmünder's (1991) stage model. In particular, there are religious dogmas and religious conflicts that raise intellectual challenges for any believer who feels obligated to think logically and scientifically. These more specific challenges call for the development of a specialized way of reasoning that Reich (1993) has named relational and contextual reasoning (RCR).

RCR reasoning is useful in situations involving competing, bona fide explanations. It is useful because of its underlying trivalent logic, which can lead to categorizing competing explanations as being compatible, incompatible, or noncompatible. Noncompatible refers to instances when competing explanations are both (all) correct, *depending on context.*

Using the construct of RCR and working in the framework established by Oser and Gmünder (1991), Reich's (1993) research has focused on how individuals develop ways to resolve apparent contradictions having religious meaning. Examples include the problem of evil (How can there be a just and all-powerful God when there is evil and tragedy?) and the contrasting biblical and scientific accounts of how the universe came to be.

Reich's (1993) research has demonstrated how individuals, with age and with development, resolve these apparent religious contradictions using RCR reasoning. Development is described in the following stages:

Stage One: Only one competing explanation is recognized.

Stage Two: One or more competing explanations are recognized.

Stage Three: Competing explanations are seen as needed for full understanding.

Stage Four: The relation between competing explanations is analyzed, and the situation specificity of the relative contributions of each is at least intimated.

Stage Five: An overarching theory or synopsis is constructed to specify the complex and mutual relationships between competing explanations, and the situation specificity of their explanatory weight.

So, for example, stage 5 responses to the biblical versus scientific explanations of the origins of the universe and humankind might emphasize God's setting in motion Darwinian evolution and/or the essentially moral-spiritual meaning explained in biblical accounts versus the essentially material-physical meaning explained in scientific accounts.

At the end of this focus on relational judgment and reasoning as they both define religious and spiritual development, we admit that they do not need to lead to reducing religious and spiritual development to general (e.g., Piagetian) stages of cognitive development. Furthermore, we see that adopting such a focus allows for precision in measuring and explaining.

STAGE-STRUCTURAL THEORIES: CONCERNS

Stage-structural theories of development in general and religious and spiritual development in particular have come under attack for several reasons. The main reasons have to do with (a) the linear and normative treatment of development, (b) the emphasis on cognition, judgment, and reasoning, (c) the emphasis on presumed universals to the exclusion of individual and cultural differences, and (d) the mostly positive/optimistic view of structural development that overlooks pathology among those at higher stages. A fair assessment of stage-structural theories must address these concerns—which we do in the next section on alternative approaches to religious and spiritual development.

Those who object to the linear and normative nature of stage-structural theories generally equate development with change over time. They may also place greater emphasis than do stage-structural theorists on the short-term functions that faith plays in individuals' lives. Together, these two ways of thinking about religiousness and spirituality lead us to note that stage-structural theories fail to capture the changes and consistencies in individuals' ways of being religious and/or spiritual (Wulff, 1993).

This criticism that stage-structural theories are too linear and normative may even be found as an implied criticism by the authors of stage-structural models. For example, Oser and Gmünder (1991), as well as Fowler (1981), report that using their stages to describe age changes reveals patterns that are decidedly nonlinear—especially among adults.

However, if the concept of development is distinguished from the concept of change over time, as we think it should be, then the linear nature of stage-structural models can be seen for its essential worth: for contributing to the *definition* of religious and spiritual development and for contributing to our ability to *evaluate* any given pattern of faith. A linear model is needed for the purposes of defining and evaluating, and age changes need not be linear for stage-structural models to be validated or useful (Kaplan, 1983b).

As for the criticism that stage-structural theories overemphasize the role of cognition, judgment, and reasoning in religious and spiritual development, several points apply. First, as we have seen, Goldman's (1964) theory and all other stage-structural theories that treat religious and spiritual development as being merely an application of universal cognitive structures do indeed go beyond the evidence to overemphasize the role of cognition.

However, overemphasis on cognition is not intrinsic to stage-structural theories. Indeed, Oser and Gmünder's (1991) theory as well as Fowler's (1981) include in their descriptions of stages many issues, conflicts, and concerns that are obviously social and emotional in nature. For example, both theories place at the center of religious and spiritual development, not the ability to think logically, but the ability to coordinate conflicts between individuation and making positive connections to God (the Ultimate) and to communities of diverse believers. Furthermore, and as Rest (1983) and Oser (1988) have argued, it is impossible to disentangle emotion from cognition because there is no such thing as reasoning without feeling. Finally, and following Piaget's lead, stage theorists such as Oser and Fowler assume that emotion provides a functional "motor" for the transition from one stage to another. Indeed, this seems to be particularly the case for transitions between the upper stages (Rollett & Kager, 1999).

The third concern and criticism has to do with stage-structural theories' emphasizing universals to the exclusion of cultural differences. As we see in the next section, the focus on nonuniversals and on cultural (communication) differences has become a main focus in recent times, often to the point of excluding discussion of universals.

However, the choice to focus on universals is a legitimate research focus. We need to focus on universals to adequately define human development. We also need to focus on those norms that need not be embodied but that form indispensable means for defining what development means, or should mean. Stage-structural theories do just that: By focusing on structural development rather than on content, we gain understanding of what we should mean by "developing" and whether any norms for defining development can be said to be universal. Furthermore, and as cross-cultural studies have shown, there is at least enough empirical research to suggest that, when it comes to religious and spiritual development, there are universals.

But does content not matter? This raises the last concern that stage-structural models are overly positive/optimistic. Our own view is that this concern is justified—despite the fact that there are discussions noting the potential for problems even at the higher stages (Kohlberg, 1981). However, the main point here is about content, not structure. Content matters, particularly

with respect to whether an individual's or group's images and beliefs support or undermine an ethical life. Individuals functioning at lower stages in stage-structural models may show more compassion and be more sensitive to issues of justice than many functioning at higher stages as defined by structural criteria only. Put another way, there are spiritual problems at all stages—as we discuss later in the final section dealing with problems of a religious and/or spiritual nature, such as the problem of religiously inspired terrorism. There is a need for research in this area, to document and explain the nature of problems at different stages of religious and spiritual development.

Having provided a stage-structural framework for thinking about religious and spiritual development, we can move on to evaluating current empirical approaches in the light of this framework. Because this framework has to do with norms for defining the maturing of faith and of persons, the discussion of current approaches is in terms of their not being about faith or persons, or about development defined by norms.

ALTERNATIVES TO STAGE-STRUCTURAL THEORIES

Is religious and spiritual development to be conceived of as a march toward a single, albeit complex and universal endpoint, thus following norms that push, pull, or define where individuals are to head if they are to develop? Or is religious and spiritual development to be conceived of as water flooding a hillside, as a branching bush, or as some other metaphor that characterizes development in terms of multiple pathways leading to multiple endpoints?

Development conceived of as an upward climb toward perfection is defined by approximations to perfection. Development conceived of as multidirectional pathways leading to multiple endpoints is defined by what happens to individuals as they react to unexpected moments and as they participate in particular contexts and cultures.

These two conceptions of development lead to quite different goals for the social scientist bent on explaining religious and spiritual development. Using a normative conception of development, explanation tends to be about the structural development that underlies or defines "lower" and "higher," "immature" and "mature," and about universals. Using a nonnormative conception of development, explanation tends to be closer to describing change over time, not only or mainly in the individual but also in the individual's transactions and participation in contexts and cultures to function and adapt.

We look at four quite different approaches that share a common understanding that religious and spiritual development need not and should not be thought of in terms of stages and universal endpoints. Each criticizes normative, stage-structural models for failing to explain the nonlinear changes that often occur in how religiousness and spirituality get expressed from birth to death. Each also criticizes stage-structural models for not capturing the diverse ways that individuals express themselves religiously and spiritually, for being overly optimistic about the fruits of structural development, and for putting western, liberal values above all others. David Wulff (1993) sums up these criticisms this way:

> The positing of religious development, especially in the form of progressive and irreversible stages, requires the assumption of religion-specific dispositions or structures as well as of particular end-states representing the fullest realization of the inborn potential. It is difficult to say, however, of what these rarely observed end-states consist. Furthermore, the construction of these states requires the imposition of certain philosophical and theological views, thus undermining any claims for universality. (p. 182)

We review the contributions of these current approaches to religious and spiritual development and their specific, as well as general, criticisms of normative, stage-structural theories, even if they are in part speculative. We begin with the contributions and criticisms of Susan Kwilecki's substantive-functional approach (Kwilecki, 1999), which follows in the tradition of religious studies.

Susan Kwilecki's Substantive-Functional Approach

Kwilecki's work is with adults, not children, because, in her view, "childhood is not the period of consummate religious expression." (1999, p. 264). She is, therefore, critical of current research on religious and spiritual development, which she says, "meticulously explains the differences in . . . the religious conceptualization of a 5- and a 9-year-old, but does not address the spectacular variety of adult religious perspectives"

(p. 264). Because of this variety, Kwilecki defines religious and spiritual development by quantitative measures. She writes,

> Growth or development in personal religion occurs . . . when ideas and experiences of the supernatural become increasingly salient and functional to the individual. . . . My criterion of religious development—the scope, depth, and pervasiveness of supernaturalism in life—is essentially quantitative. (pp. 32–33)

For Kwilecki, what grows or develops has to do with imagination more than with perception and reason:

> Becoming religious . . . means realizing, and increasingly acting upon the realization, that ultimately our fate lies with forces that transcend our generally most effective tools of adaptation—the senses and reason. Attempting to monitor critical but elusive powers, the religious are daily thrown upon the imagination, a faculty difficult to discipline and trust. Ongoing negotiations with unseen beings strain even the hominid capacity for symbolization. Not everyone becomes religious to the same degree. (p. 31)

As lives lived imaginatively, the religious, for Kwilecki, are not to be evaluated using the cognitive-developmental schemes derived from Piaget and Kohlberg.

With respect to defining religious and spiritual development, Kwilecki's (1999) work reminds us that the focus needs to be on whole persons functioning in complex and ever-changing circumstances. To capture religious and spiritual development, we cannot rely solely on general description systems such as those found in stage-structural theories. We need to know the details of individuals' lives, the challenges they face as well as their inner thoughts, fantasies, and feelings.

Kwilecki's (1999) work also shows us the value of certain forms of thinking and behaving that often are explicitly or implicitly denigrated by stage-structural theories. For example, in her case study of "Jack McCullers," a mechanic who reported he once received a divine command to purchase a head gasket for a Toyota, when he did not own a Toyota or know anybody who did. Kwilecki's response to the religious imaginings of McCullers was: "What could be sillier than thinking that the ruler of the universe would waste time on interventions and messages such as these? What could be lovelier than thinking that the ruler of the universe is so intimate and playful?" (personal communication; Kwilecki, September 2003). In short, in Kwilecki's approach, we see the inherent ambiguity in religious imagining that is often missing in normative, stage-structural approaches.

Kwilecki's (1999) approach corrects deficiencies found in normative, stage-structural approaches. But is her way of defining development entirely quantitative and without norms? In her writing, we can occasionally detect a normative and qualitative definition of development, one that seems sensible if not inevitable. Throughout her writing, Kwilecki goes back and forth between describing the ordinary individuals that are the focus of her case studies and extraordinary religious and spiritual exemplars. In her admiration of ordinary examples of faith but especially in her admiration of exemplars, one can detect an implicit developmental approach defined by qualitative differences. Whether writing about Mother Teresa, Black Elk, or the Zen nun Satori Myods, Kwilecki admires the faithful's ability to pursue noble purposes, especially in the face of adversity—and always she is taken with the faithful's ability to imagine realities beyond appearances, their ability to remain optimistic, and their ability to use imagination to adapt. Her person-centered approach can, therefore, lay the foundation for a normative developmental approach that is sensitive to culture, circumstances, and individual personalities.

Kwilecki's (1999) work focuses on adults because she believes that it is in the adult years that faith takes on its varied and sometimes magnificent forms. Her approach is nonnormative in the way she defines religious and spiritual development in quantitative terms, as faith gaining strength. Her approach gives us development without explicit norms, even if empirically not yet fully validated. The next example is of a current approach focusing on children because it claims that stage-structural models have overlooked children's rich and varied spiritual experience. The focus here is on assessing children's spirituality but without development.

The Spiritual Child Movement

In recent years, a number of psychologists and educators have been writing about "the spiritual child" (Coles, 1990; Hart, 2005; Hay & Nye, 1998; Reimer & Furrow, 2003), so many that we can discern a spiritual child movement that is, in part, a reaction to stage-structural theories of religious and spiritual development, which are generally seen as following along the lines set down by Goldman. As such, one of the main criticisms put forth by this group is that stage-structural theories are

too cognitive. For example, David Hay (Hay & Nye, 1998) writes:

> the cumulative feeling I am left with after reviewing what we know about childhood spirituality is an uneasiness about the adequacy of developmental theory (meaning stage-structural theories) to give an account of it. . . . The major problem (with stage theories) is their narrowness, coming near to dissolving religion into reason and therefore childhood spirituality into nothing more than a form of immaturity or inadequacy. (pp. 50, 51)

The idea that children are spiritual is not new. Throughout history, faith traditions have, at some time or another, found an innate spirituality in children—as demonstrated in the passage from Mark 10:15 (New Revised Standard Version), "Whosoever shall not receive the kingdom of God as a little child, he shall not enter therein"; in the reincarnation beliefs surrounding the search for a new Dalai Lama (Thurman, 1991); and in the treatment of babies by the Beng of Ivory Coast (Gottlieb, 2005). At various times, children have been seen as having a natural and uncritical faith, a natural wisdom and capacity for discerning the way things really are, and a spirituality that comes from being old souls. Therefore, what is new in the current spiritual child movement is not the idea of children being spiritual but the arguments attacking stage-structural theories for being too cognitive.

The spiritual child movement is a movement based on the idea that spirituality is rooted in personal experience, feeling, and biology. Those leading the movement do acknowledge there is a cognitive element to what they refer to as "spiritual experience." To experience spiritually requires at least the cognitive ability to step back and be aware—of the larger picture, of the mystery of life, of there being something more than what is given by the senses. But this ability is present at very young ages, as young as four by some accounts, but certainly by six.

The capacity for spiritual awareness is present at young ages because, says this group, humans have evolved in ways that provide for this capacity (Hart, 2005; Hay & Nye, 1998). Spiritual capacity is inherited capacity, a product of brain development. It is given to children by biology rather than by parents, teachers, or culture—though for spirituality to develop, children need lots of encouragement and support. In sum, the spiritual child movement is bent on getting across one main idea, namely, that children have the capacity for rich and varied spiritual experiences that form (or should form through being encouraged and supported) the foundation of their religious, ethical, and spiritual development.

What is the evidence supporting this claim that children have the capacity for experiences that are essentially spiritual? The evidence there is comes from interview studies of children, from retrospective paper and pencil studies of adults, and from collections of anecdotes.

Members of this group have been the first to point out that their methods and the available evidence do not meet rigorous scientific standards. Even with regard to the issue of how to define children's spirituality, they admit that it is difficult, at best, and perhaps impossible to pin down children's spirituality by means of definition. There is, says this group, an inevitable subjectivity to discerning children's spirituality. For example, Rebecca Nye (1999) writes that what she observed as moments when the children she interviewed were relating their spiritual experiences were moments not captured by the words appearing in transcripts. Those moments were singled out because, during them, children "seemed to shift into another gear" (Nye, 1999, p. 62) when speaking about their experiences.

Given the current evidence and methods, it might be easy to dismiss this movement on the grounds that it is not grounded in solid scientific research. However, doing so ignores the real phenomena being discussed. The main question is not whether the phenomena discussed are real but whether they warrant the designation of spiritual. Other terms work equally well, terms used by the leaders of this movement themselves—*wonder, awe, wisdom,* and *relational consciousness.* Adding the term *spiritual* runs the risk of adding a gratuitous interpretation.

Furthermore, by calling attention to children's "spiritual experiences," the group promoting the spiritual-child movement has self-consciously de-emphasized the role of judgment and reasoning and thinking in general, to the point of sometimes adopting an opposite extreme to that of Goldman. The previous quote by David Hay might serve as an example.

Finally, this group's approach may be questioned for how development is conceived (or not conceived, as the case may be). It is one thing to point out moments of awe, wonder, and wisdom in the lives of children and another to define faith and its development. Of the two enterprises, the second seems more significant. Moments of awe, wonder, wisdom, and relational consciousness are not likely to shoulder much of the work of establishing a foundation for religious and spiritual development.

At least, research has yet to show they do. And even if it is not the moments themselves that are important but rather the innate capacities they point to, we are still left with the question of how these innate capacities develop into mature patterns of faith. Granted that what develops has to do with wonder, awe, and wisdom, we are left still with the task of figuring out the qualitative differences between the wonder, awe, and wisdom of a child and that of, say, John Muir speaking of mountains as "God's cathedrals" (Cronon, 1997) and Gandhi demonstrating the wisdom of the Gujarati precept, "Return good for evil" (Gandhi, 1993).

In the following discussion of the next approach, we also find an appreciation for how much children understand—as well as an appreciation for the influence of elders and culture. However, unlike the previous two approaches, the next approach is grounded in experimental research done in post-Piagetian and postrationalist, cognitive-developmental psychology—with its focus on domain specific development and cultural diversity.

Cognitive-Cultural Theories

Stage-structural theories posit norms for defining development, which make them susceptible to being insensitive to cultural diversity. The wealth of information now obtained from new disciplines such as cognitive anthropology suggests that no stage-structural theory can do justice to the rich variety of thinking and acting that is found in and among cultures. Rather than adopt the stairway to maturity model, today's cognitive developmental psychologists, like Darwin before them, have adopted the model of an ever-branching bush.

Current cognitive-cultural theories (e.g., Johnson & Boyatzis, 2005) search for competencies specific to nonuniversal domains rather than search only for competencies that cut across domains (e.g., object permanence). This search has provided a more nuanced view of intellectual development. The word *domain* can have as its reference something quite broad, such as the domain of physics, or something quite narrow such as the domains of baseball and knock-knock jokes (Feldman, 1980). It is the broad sense of domain that is used in current cognitive studies—and three broad domains in particular have been the focus of research on children's cognitive development: the physical, biological, and psychological (theory of mind) domains. Throughout their early years, children are seen as developing intuitive knowledge in these three domains so that by age 4, most children have a fairly well developed intuitive ontology (Boyer & Walker, 2000; Harris, 2000).

This view of young children having a fairly well developed intuitive ontology directly contradicts the older Piagetian view, which characterizes young children's thinking as being prelogical. In this newer view, young children come off as neither rational nor irrational. Rather, they come off as adept at handling different systems of thinking about reality. For our purposes, two systems are central.

The first system is for thinking about everyday events. This is the default system. It rests on direct observation and on an innate push to find patterns and causal connections. It is not a system that looks for magic and the counterintuitive. On the contrary, it is a system that is thoroughly empirical. Preschoolers may pretend, but in doing so, they call their pretense "make-believe." And when not pretending, if their causal inferences seem irrational, it is more because they lack information and experience than because their thought processes are inherently irrational.

The other system is for thinking about the counterintuitive. It comes into play more because of culture and testimony of trusted caregivers than it does because of children's reflections on reality. Early on, children are exposed to counterintuitive ideas and counterintuitive worlds that make up their culture's religious heritage, and, remarkably, they have little difficulty taking on these ideas and worlds and making them their own (Harris, 2003).

They do so for a number of reasons. First, they trust their caregivers and mentors—those giving testimony to the reality of the counterintuitive (Harris, 2000). Second, because religious ideas are both counterintuitive and presented as true, children find them arresting and memorable (Atran & Norenzayan, 2005). Third, children are able to keep a kind of double booking—with intuitive ontology employed most of the time, and their newly acquired counterintuitive ontology employed when the occasion fits (Harris, 2003). Fourth, even when assimilating counterintuitive religious belief systems, children borrow from their intuitive ontology—making it possible to draw inferences from the counterintuitive world to the everyday and vice versa (Harris, 2000).

As can be seen in this account, the questions are about the development of distinctions and boundaries between separate domains. They are not questions about stages leading in a particular direction. Furthermore, children older than four are characterized as being much

more similar to adults in their basic thought patterns than Piagetian characterizations lead us to believe. Finally, culture, not simply organismic development, explains age changes in what children believe.

What does this mean for the study and understanding of religious and spiritual development? For one thing it means rejecting theologically influenced developmental models in favor of descriptions grounded in cross-cultural field research. For another thing, it means religious development is not a separate cognitive domain but rather a domain that draws on the cognitive achievements designed originally for mundane tasks. Finally, it means religious thinking is neither more primitive nor more mature than other kinds of thinking. It is simply different. And this relativity extends to distinctions between religious traditions themselves so long as individuals in any given tradition develop basic intuitive ontologies (physical, biological, psychological) and so long as the counterintuitive religious agents and worlds serve the usual adaptive functions of fostering moral (communal) commitment and relieving existential anxiety (Atran & Norenzayan, 2005).

This is a composite view of current thinking about religious development from a cognitive-cultural perspective. What are we to make of it? What are its strengths and weaknesses? The main strength in this perspective is providing a better account of how religious beliefs are acquired. The main weakness is the perspective's conflating belief and faith—so much so that, at times, the subject investigated seems to be something other than religious and spiritual development. For example, the perspective fails to distinguish differences between children's questions such as "Why don't angels fall down to earth?" (Harris, 2000), and adults' questions such as "Why do bad things happen to good people?" (Kushner, 1981). The first question lacks moral significance. The second question forces thinking about what kind of universe we live in and how we ought to face injustice and adversity. While there may be disagreement about whether both kinds of questions fall in the domain of religious and spiritual development, it seems clear that the second kind of question has more to do with what has previously been defined as faith.

Developmental Systems Theories

Developmental systems theories shift the focus from individuals to transactions between individuals and their various embedded contexts (Lerner et al., 2003). That is, developmental systems theories are essentially relational in nature. This means that development is located not in the person but in the ongoing transactions between the person and his or her multilayered contexts. Of concern here is the goodness of fit between person and environment. Religiousness and spirituality relate to the extent that they provide ways to foster a better fit. Indeed, one of the main findings coming out of research based on developmental systems theories is that religiousness and spirituality do indeed make it more likely for individuals to thrive because their behavior both improves and is rewarded by their contexts. In sum, thriving is the main interest; religious and spiritual development are of interest only as they lead to thriving.

Among the many types of studies linking religious and spiritual development to thriving are those investigating faith-based communities and their role in helping youth develop positively (Benson et al., 2003; King & Boyatzis, 2004; King & Furrow, 2004; Roehlkepartain, 1995). A study by Regnerus and Elder serves as the main example (Regnerus & Elder, 2003).

This study illustrates the developmental systems approach in several ways, first by its speaking about involvement in a faith based community as a potential "resilient pathway." The term *resilient pathway* reveals the approach's main assumption about plasticity as well as its main interest—what leads to thriving. The results of this study show that in high risk communities, church attendance functions as a protective mechanism "stimulating resilience in the lives of at-risk youth"—as shown by church attendance correlating positively with staying "on track" in school.

However, it is in Regnerus' and Elder's (2003) explanation of the results rather than in the results themselves that we see the main features of the developmental systems approach. Regnerus and Elder explain the results as follows:

> The ritual action of attending worship services or ceremonies, in contrast with theological differences that mark distinct religious affiliations and beliefs, appears to be a process that operates independently of particular belief systems and organizational affiliations. Church attendance may constitute—even if by accident—a form of social integration that has the consequence of reinforcing values conducive to educational achievement and goal setting . . . (In addition) . . . church attendance and doing well in school require commitment, diligence, and routine. The ritual practice of rising and going to church or mass, and so forth—whether compelled by one's own faith or

> one's parents' demands—commits a youth to a practice and routine, a skill that translates into tools needed for academic success. (p. 646)

In other words, for the study's at-risk youth, going to church regularly meant they were exposed to values and good routines that could be transferred to school.

Obviously, studies such as this study are much needed, especially for understanding how to support at-risk youth. But are they studies of religious and spiritual development, or are they simply studies of positive development defined broadly? We think they are the latter because they skirt the task of charting and explaining faith and its development. While these studies often acknowledge that faith is a unique and important variable, they do not explain how faith develops. And in not explaining how faith develops, they leave out the inner workings that define and explain the religious and spiritual development of persons.

In subsequent sections we return to discussing developmental systems theories and their contribution to understanding the positive correlates of religious and spiritual development. However, in the next section, we look more closely at the ongoing debate between stage-structural and cognitive-cultural theories—as we take up the task of explaining concept formation in religious and spiritual development.

CONCEPTUAL DEVELOPMENT IN RELIGIOUS AND SPIRITUAL DEVELOPMENT

Nowhere do we see the contrast between stage-structural and cognitive-cultural approaches more clearly than when characterizing conceptual development in religious and spiritual development. Stage-structural approaches provide the following composite picture:

- With age, children go from having mostly anthropomorphic and concrete conceptions of supernatural agencies to having mostly symbolic and abstract conceptions.
- With age, children go from reliance on magical and egocentric-imaginative reflecting, which includes thinking about supernatural agencies and prayer, to more rational and decentered thinking.

In contrast, cognitive-cultural approaches provide the following composite picture:

- With age, children, adolescents, and adults maintain conceptions of supernatural agencies that are both anthropomorphic and nonanthropomorphic.
- With age, children, adolescents, and adults develop intuitive ontologies having to do with what they can perceive directly, which coexist with counterintuitive ontologies having to do with what they cannot perceive directly. The acquisition of the latter constitutes neither magical-egocentric nor logical-decentered thinking.

What is the evidence supporting each of these approaches? And in looking at the evidence, can we find a way to reconcile the differences? To answer both questions we look next at studies carried out from each of these approaches—beginning first with studies carried out from a stage-structural approach. For the most part, we compare what the two sets of studies have to say about development with respect to concepts of (a) supernatural agencies, (b) religious institutions and prayer, and (c) death/life after death.

However, in discussing studies of religious concepts and their development, we remind readers that concepts can never be sorted neatly into *religious* and *nonreligious*. Certain concepts may not appear to be associated with religious or spiritual development. Nevertheless, by taking into account the context in which these concepts are experienced, they become religious or spiritual concepts. For example, at the surface level, the concepts of "work" and "family" may not appear to have religious or spiritual meaning. However, by placing these concepts in specific contexts their meaning becomes modified such that they take on a religious or spiritual meaning—as when Shakers speak of "consecrated labor" and Mormons speak of "the eternal family." Meaning is tied not only to development but also to culture and faith tradition.

Studies Carried Out from a Stage-Structural Approach

Studies of religious conceptual development carried out from a stage-structural approach have largely followed in the rationalist tradition exemplified in the work of Piaget. In this tradition, children's concepts reflect qualitatively different and less rational (when compared to adults' concepts) ways of thinking. This can be seen when examining a variety of religious concepts, the

most notable being those having to do with supernatural agencies, religious institutions, prayer, and death.

Supernatural Agencies

By far the most studied religious concept has been the concept God. Children's conceptions of God have been assessed in a variety of ways, most frequently by asking children to draw what they picture in their minds when they hear the word *God* . Having children draw pictures of God, write letters to God, and other relatively unstructured and projective methods have shown themselves useful for bringing out children's conceptions of God more readily than closed methods (Klepsch & Logie, 1982, p. 36; Tamminnen, 1991, p. 160).

These unstructured and projective methods are not without their problems. In particular, they encourage anthropomorphizing and, when used with children only, they can create biased comparisons based on children and adults being assessed differently (J. Barrett, 2001).

Methodological issues notwithstanding, numerous studies (Bucher, 1994; Hanisch, 1996; Heller, 1986; Nye & Carlson, 1984; Pitts, 1977; Pnevmatikos, 2002) have confirmed the trend described by Harms (1944). On the basis of more than 4800 drawings and conversations, Harms found that children, aged 3 to 6, produced predominantly fairy-tale figures of God, while older children portrayed God in an anthropomorphous manner. Only adolescents provided abstract-symbolic conceptions.

Since Harm's research, studies have repeatedly demonstrated that young children typically see God as a friendly, smiling old man, often with a beard, and often residing in heaven, with heaven depicted as a place somewhere above the earth (Bucher, 1994; Goldman, 1964; Heller, 1986; Tamminnen, 1991, p. 195). A number of surveys have shown that, with age, fewer and fewer children give anthropomorphous depictions of God, and more and more give symbols or metaphors to represent God—such as God being represented as light, nature, or love (Bucher, 1994; Goldman, 1964; Hanisch, 1996). Strict, or demonic images are rare (Frielingsdorf, 1992).

According to this set of studies, children's conceptions of God move from the anthropomorphic and concrete to the symbolic and abstract, albeit at different speeds in different religions. For example, Pitts (1977) found that Mormon children held on to anthropomorphous conceptions longer than average, while Jewish children did the opposite.

Do children's drawings reflect their *real* conceptions of God? The answer is not clear. Children may reproduce in their drawing schemes what can be canonized, schemes that may persist even though their inner conceptions have changed (Freeman, 1980).

However, anthropomorphizing in childhood cannot be attributed solely to the drawing method because, with respect to conceptions of God, other research methods have revealed a similar developmental trend. For example, in interview studies, a number of investigators have found that anthropomorphous depictions of the Divine dominate, more so than later on (Barnes, 1892; Vogel, 1936). Similarly, Thun (1959), who recorded the classroom conversations of German elementary schoolchildren during religious instruction, and Deconchy (1967), who classified French children's images of God by using a word association technique, found that children up to 11-years-old conceived of God anthropomorphously, while adolescents conceived of God in ways that were both abstract and vague. Hyde (1965), too, investigated adolescents' images of God with methods other than by using drawings and found a steady receding of anthropomorphisms, delayed in the case of children who regularly went to church.

In summary, numerous studies following in the stage-structural tradition have found that with age, children's conceptions of God become less anthropomorphic and less concrete and more symbolic and abstract. Similar results have been found in studies of children's conceptions of religious institutions and prayer.

Conceptions of Religious Institutions, Prayer, and Death

Religiousness and spirituality are not continually being invented anew. Rather, they are handed down by tradition in faith communities. Therefore, ideas possessed by children of religious institutions and practices are of particular interest not only to researchers but also to teachers of religion. The central studies remain those carried out by Elkind and his coworkers (1961, 1962, 1963), in which Jewish, Catholic, and Protestant children were asked how they perceived their denomination and religious community. The results supported the following description of age changes:

- Undifferentiated conceptions, according to which even a domestic cat could be regarded as Catholic (to age 7)

- Concretely differentiated conceptions (to age 9) in which religious affiliation was defined in terms of specific, concrete acts such as going to church or synagogue
- Abstractly differentiated conceptions (from age 10) that made reference to beliefs and ideology

As for prayer, given the diversity and universality of prayer, it is not surprising that the psychology of religion has, from its beginnings, investigated its development (Brown, 1994; Hyde, 1990). Early investigations derive from Pratt (1910), who characterized the development of prayer as leading from primitive and spontaneous supplication to more ritualized forms.

Goldman (1964) distinguished three stages in the development of the prayer concept. At the first stage, normally ending at age 9, children conceive of prayers like magic. Furthermore, younger children believe that God literally hears prayers and is compelled to accede to requests because the praying person has prayed properly and is a good person. Later on, children believe that the effect of prayer is dependent on its content; if prayers contain only material and selfish wishes, they will not likely be granted. In adolescence, development continues when prayer is seen as an expression of faith and as a form of psychic-spiritual self-help.

Rosenberg (1989) investigated age changes in several content areas of prayer: *How* (for instance, the physical position of the praying person), *What* (the content of prayer), *Whom* (the addressee of prayer or conception of God), and the reflective-subjective aspect of praying. Children and adolescents were shown pictures of people praying and asked to associate freely to what they saw. The results showed that, with age, the "how" became less significant. For younger children, externalities such as covering the head during prayer were important, and supplications as well as anthropomorphous conceptions of God dominated. For adolescents, prayer required a more psychological conception, such that they saw prayer's value as having to do with its effect on the praying person him- or herself.

Other studies have confirmed this trend of prayer developing from being a magical speech act to a spiritual dialogue. For example, Long, Elkind, and Spilka (1967) distinguished three stages of prayer. Children younger than nine regarded praying as essentially a way of asking for things. Beginning around age 9, the relevance of asking for things diminished, and prayer became an inner dialogue with God (Godin, 1968a; Thouless & Brown, 1964). Brown (1967) also found that belief in the magical-causative effect of prayer decreased with age.

In a study of prayer and its development in adolescence, Scarlett and Perriello (1991) had subjects provide prayers for hypothetical situations calling for prayer (e.g., praying for a dying friend). Their results showed that with age, adolescents prayed less for God to intervene directly to make dramatic changes, such as curing a sick friend, and more for God to provide support and guidance. Furthermore, with age, adolescents shifted from "talking at" God to "talking with" God such that they engaged more in sharing feelings, questions, and doubts and not just requests.

Together, these studies of age changes in how children and adolescents pray and think about prayer are reminiscent of William James' (1902) words about the development of prayer:

> the belief is, not that particular events are tempered more towardly to us by a superintending providence, as a reward for our reliance, but that by cultivating the continuous sense of our connections with the power that made things as they are, we are tempered more towardly for their reception. The outward face of nature need not alter, but the expressions of meaning in it alter. (p. 474)

Death, or rather the possibility of life after death, is perceived by many as a religious phenomenon, which means that children's and young people's conceptions of death should be taken into account (see reviews by Faulkner, 1993; Ramachers, 1994; Wittkowski, 1990). Early on, Anthony (1940) questioned 128 children about their definitions of death and found that, with age, children only gradually come to realize that death refers to the cessation of life functions and is biologically necessary. Numerous studies since then have demonstrated that children between ages 3 and 5 do not understand death to be universal (mostly old people die, but not one's parents), nor do they consider death to be irreversible. By age 7, children normally develop at least a nascent understanding of the irreversibility and universality of death so that most children, by age 9, possess a developed conception of death (Wittkowski, 1990, p. 58).

Relatively little has been written about how the concept of life after death changes over time (Tamminnen, 1991, p. 262). Barth (1911), in a survey of German children, showed that children conceived of heaven as a specific locality somewhere above the earth. Burgardsmeier (1951) found, in a survey of German children of compulsory school age, that children conceived of heaven as a fantastic, beautiful, and sacred place and

then as air, firmament, and the residence of God, and, finally, as a symbol. Blum (cited in Ratcliff, 1985) found that children's conceptions of life after death became vaguer with increasing age, and that age accounted for more of the variance than did religious background. These results were replicated by Tamminnen (1991, p. 260–278), who found that young schoolchildren depicted eternal life and heaven with above average graphic detail (p. 278). Older children had difficulties locating heaven in the cosmos, or else provided theologically inspired ideas (e.g., "Heaven is within us.").

Once again, studies carried out following a stage-structural approach accentuate differences between children's, adolescents', and adults' religious concepts as well as accentuate the usefulness of using the anthropomorphic to nonanthropomorphic and concrete-literal to abstract-symbolic criteria for describing and evaluating religious and spiritual development. The same is not the case with studies carried out following a cognitive-cultural approach—as the subsequent discussion explains.

Studies Carried Out from a Cognitive-Cultural Approach

The previous section provided an overview of the cognitive-cultural viewpoint or approach. Here, we look more closely at the evidence and arguments supporting this viewpoint and its characterization of conceptual development in religious and spiritual development. We begin with evidence and arguments related to concepts of supernatural agencies.

Two questions have framed studies carried out from the cognitive-cultural approach. The first is, "Are children mostly anthropomorphic in their thinking about supernatural agencies, such as God—as stage-structural theories lead us to believe?" The second is, "Are children's concepts of supernatural agencies essentially different from adults' concepts of supernatural agencies—as stage-structural theories lead us to believe?"

The first question has been addressed by asking children what they know about ordinary agents such as humans. The starting point for discussion is Wimmer and Perner's (1983) study showing that children as young as 5 understand that others' thinking may differ from their own depending on what information others have available to them. For example, a 5-year-old discovering rocks in a cereal box will correctly predict that an adult encountering the box for the first time will think there is only cereal in it, not rocks. Therefore, even young children have a theory of mind.

However, when asked whether God will make the same mistake, children, by age 5, say, "No." Even young children understand that God is no ordinary agent—that God has supernatural, counterintuitive powers. In short, with respect to the concept of God, children are not as anthropomorphic as previously pictured. Rather, children make a clear distinction between persons and God. The same holds true for children raised in cultures and faith traditions with supernatural, religious agents other than God—such as Krishna and ancestors.

The second question, about differences between children's and adults' conceptions of God, has led to studies that show adults, as well as children, conceive of God anthropomorphously. J. Barrett and Keil's (1996) study is the one most cited. Barrett and Keil found that their adult subjects, when asked directly about God's nature, gave theologically correct answers, answers that avoided defining God anthropomorphously. However, when asked to recount stories involving God, the same adults added to or distorted the stories by anthropomorphizing God—such as speaking of God as "not noticing" or as acting sequentially. They spoke of God as acting in very human ways. Barrett and Keil concluded that adults, like children, develop and maintain conceptions of God that combine their counterintuitive understanding of God as a supernatural agent with their intuitive understanding of how normal agents act. This same combining of the intuitive and counterintuitive applies to other religious supernatural agencies as well (spirits and ancestors).

With respect to prayer, Woolley's research provides a similar finding to that of Barrett and Keil (1996). Woolley (2000) asked children, ages 3 to 8, to teach a puppet to pray. She also interviewed the children about their understanding of prayer, its effects, and why prayers sometimes do not get answered. Her results share certain findings with studies carried out from a stage-structural approach. However, there were important differences stemming from her comparing children's understanding of prayer and their intuitive knowledge of causation.

First, Woolley (2000) showed that children as young as age 5 develop a mentalistic conception of prayer—much earlier than that reported by Long et al., 1967. Second, she showed that, by age 5, children begin to give up belief in the causal powers of wishing, even as they begin

to believe in the causal powers of prayer. Therefore, children's belief in the efficacy of prayer cannot be attributed to their holding magical views of the causal powers of thinking in general and wishing in particular. Their believing in prayer's efficacy is, rather, a result of their being taught or socialized. Woolley's participants came from religious families. Furthermore, their belief in the efficacy of prayers but not in the efficacy of wishes seemed to be tied to their understanding that prayer, unlike wishing, involves an intermediary, God, who is a supernatural agent.

With respect to children's conceptions of death and life after death, the same cognitive-cultural framework applies. In the course of direct experience with death, children construct their own, intuitive ontology about death such that they understand death's irreversibility and inevitability at much younger ages than stage-structural theories lead us to believe (Slaughter, Jaakola, & Carey, 1999). However, in the course of experiencing death, children also acquire counterintuitive beliefs about death and life after death—beliefs transmitted by culture and faith tradition through the testimonies of trusted others (Harris, 2000).

Together, these cognitive-cultural accounts of children's religious concepts leave us with a quite different picture of children's capacities and of culture's role in religious and spiritual development. Whereas some researchers see children as having limited capacity and culture being responsible for helping children overcome their natural propensity for magical thinking, others conceive them as having considerable capacity and culture being responsible for teaching or communicating beliefs about what is counterintuitive. Therefore, at the center of the newer picture is the distinction between intuitive and counterintuitive ontology.

However, because there is much that is counterintuitive that is not learned in childhood, for example, the Darwinian concept of evolution, why are religious counterintuitive concepts learned much earlier? Harris (2000) provides a compelling answer. Counterintuitive religious concepts, such as the concepts of gods, spirits, and ancestors as supernatural agencies, do not require children to give up their intuitive, commonsense concepts of ordinary agents. In contrast, scientific concepts, such as the Darwinian concept of evolution, do indeed require children to give up their intuitive, commonsense concepts. One cannot, for example, hold both the intuitive, creationist view that species are immutable and the counterintuitive, Darwinian view that states the opposite. In contrast to counterintuitive scientific concepts, counterintuitive religious concepts operate in parallel to intuitive, nonreligious beliefs—at least for most people, most of the time.

A Synthesis

Where do these contrasting pictures leave us with respect to our present understanding and future research? One possibility is that they force us to reject one in favor of the other. However, this possibility seems a poor choice. On the one hand, the cumulative results of numerous studies suggests that there are indeed important differences in the way children as compared to adolescents and adults give meaning to religious concepts. These differences are not simply the result of faulty research methods and unevenness with respect to socialization. On the other hand, the results of careful and thoughtful studies comparing intuitive and counterintuitive ontologies demonstrate important similarities in the way children, adolescents, and adults provide meaning to religious concepts.

We suggest that these two approaches are not so opposite as they first appear to be, and that a synthesis is possible. Focusing on differences does not exclude focusing on similarities. Furthermore, these two foci complement rather than contradict one another. The strength of the cognitive-cultural approach lies in its providing better explanations for how religious *beliefs* are acquired. The strength of the more normative, stage-structural approach lies in its providing possibilities for explaining how religious beliefs become existentially relevant or, as Johnson and Boyatzis (2005) said, how religious concepts help with the task of connecting the self with a more valued reality. Put another way, the stage-structural approach may be more useful with respect to explaining how beliefs become integrated with feelings and actions to form a pattern of faith that can lead individuals to function at higher religious or spiritual levels. After all, religious and spiritual exemplars are exemplary largely because of their positive and powerful faith and not because of their concepts and beliefs.

RELIGIOUS AND SPIRITUAL DEVELOPMENT IN CONTEXT

Religious and spiritual development always takes place in multiple and layered contexts. Furthermore, each

context has in itself parts operating together to form systems—with the various systems themselves operating together to form larger systems. This observation about contexts makes any attempt at causal explanation complex indeed—for clearly, in any final analysis, cause is to be found in the combination of a seemingly infinite number of causes (Lerner, 2002).

In the following discussion, when we speak of a particular cause, influence, outcome, or dependent variable, we do so with a developmental systems paradigm still in mind. We use these concepts for what they are—still useful concepts for exploring how religiosity and spirituality develop, even if they are not useful for fitting religiousness and spirituality into some procrustean bed. They are useful, too, given the fact that our methodologies lag behind progress in theorizing.

Now, we look at three main contexts for thinking about what influences or supports religious and spiritual development. These three are the family, the religious school, and the congregation. We focus on these three because of their logical connection to religious and spiritual development but also because they have been contexts that have been studied empirically.

The Family Context

As several have noted, the family is the most powerful influence on children's religious and spiritual development (Boyatzis, Dollahite, & Marks, 2005). Its influence is twofold. First, as an institution of socialization, the family directly impacts the developing child. This occurs when practices, beliefs, traditions, and values are transmitted from parent to child. Second, children are indirectly influenced in their religious and spiritual development by the attachments they form in their family. The Divine can function as an object of attachment, and the attachment a child forms with the Divine can occur either as a way to continue having a secure attachment or as a means of compensating for an insecure attachment. In sum, parents and families influence the religious and spiritual development of their children in direct and targeted ways, especially through religious teachings and practices, but also in indirect and untargeted ways, especially through the way they foster attachments.

Socialization and Practice

Empirical research has repeatedly demonstrated that with regard to religious development, mothers and fathers have the most influence (Beit-Hallahmi & Argyle, 1997; Hood et al., 1996). For example, Ozorak (1989) found parents' influence on their children's religious development to be much greater than that of peers, as well as more lasting than parents' influence on their children's political development and ways of structuring leisure time. And, as indicated in Table 17.5, Cavalli-Sforza (1982) found correlations that are consistent with the findings and interpretations of these other studies.

Similar results have come from self-report studies of young adults. For example, the young adult interviewees in B. Hunsberger & Brown's (1984) study reported that the strongest influence on their religious and spiritual development was their mother, followed by the church and their father, with friends and the media playing only a modest role. B. Hunsberger (1995) also found that older subjects considered their religious development to have been most influenced by their mothers, followed by their fathers and the church, and then by the media, friends, and school.

In a number of studies, mothers are credited with having the primary influence on children's religious and spiritual development (Boyatzis et al., 2005). Several reasons seem to apply. First, mothers maintain a higher profile in matters of religious practices such as church attendance and family prayer (Beit-Hallahmi & Argyle, 1997). Also, mothers are more likely than fathers to converse with their children about religion. For example, Strommen and Hardell (2000), in a study of mainline protestant youth, found that mothers had conversations with their children about faith and life issues nearly two-and-a-half times more frequently than did fathers. Finally, mothers are most often the ones who introduce children to religious practices, for example, by leading them in family prayer and taking them to religious services (Hood et al., 1996).

One of the most interesting findings has to do with the extent to which parents influence their children's religious *practices* as compared to their religious *beliefs.* There are stronger correlations between the religious *practices* of parents and those of their children than there are between the religious *beliefs* of parents and those of their children. Gibson (Gibson, 1990) found that parents' church attendance correlated with that of

TABLE 17.5 Parental and Peer Influence Compared

	Parent-Child	Friend-Child
Religious behavior	.57	.20
Political behavior	.32	.16
Entertainment	.16	.10
Sports played	.13	.16

their young adult offspring more powerfully ($r = .60$) than with their attitudes toward Christian beliefs ($r = .50$). Similarly, Ozorak (1989) found that family cohesion influenced children's religious practices but not their beliefs. Beliefs, it seems, become increasingly individual as children grow older. Furthermore, a more powerfully individualized faith is accompanied by higher intellectual aptitude.

In the family, the available research suggests that religious development is furthered by a number of factors, including a climate of support characterized by encouragement to have independent views, encouragement to engage in discussion, and closeness between parents and children. For example, closeness between parents and their children predicts higher positive correlations between the religiousness of parents and the religiousness of their children. This still is the case when children become adolescents (Erickson, 1992).

In two parent families, support also depends on whether parents share the same religious convictions with each other. When parents share the same religious convictions, they influence the religiousness of their children more powerfully than when they hold opposing convictions (Hoge & Petrillo, 1982). Parents holding opposing convictions are associated with their offspring's religious apostasy (Caplovitz & Sherrow, 1977).

The phenomenon of giving up one's religious origins (apostasy) has been the subject of a number of studies (Caplovitz & Sherrow, 1977; Hood et al., 1996). Caplovitz and Sherrow (1977) identified familial strain and dissociation from parents as the main psychological antecedents of apostasy. L. Hunsberger (1980), too, found that the antecedents of apostasy included poor relations with parents. In addition, B. Hunsberger and Brown (1984) found that apostates reported considerably less emphasis on religion in their childhood home as compared to matched controls who remained faithful to their original religion. Thus, apostasy is not so much the result of an excess of religious teaching as it is a result of too little of it. In sum, apostasy can result from not enough religious encouragement—which follows from Niggli's (1988) study that demonstrated that religious encouragement has indeed a significant effect on religious development.

Niggli also developed scales to measure style of religious instruction and their effects on religious development: in particular, the styles of *religious compulsion* and *religious encouragement.* In Niggli's study, young people who reported greater religious encouragement by their parents (e.g., "When I had ideas of my own in matters of religion, my mother/father took me seriously.") were significantly higher on the stage scale of religious judgment (Oser & Gmünder, 1991) than were young people with little or no religious encouragement.

However, influence goes both ways, and children's developmental level is a determining factor in their attitudes toward religion and in the religious climate of the family as a whole. For example, in a random sample of Swiss parents and children, Klaghofer and Oser (1987) found that children evaluated as being at stage 2 on the Oser and Gmünder (1991) scale had a more positive family climate than did children evaluated as being at stage 3. This finding was expected, since persons at stage 3 attribute a lower status to religiousness than do persons at stages 4 and 2.

Similarly, recent research has emphasized the positive role played by conversational dialogues between parents and children on children's religious and spiritual development. In a study of diary entries recording conversations between parents and children, Boyatzis and Janicki (2003) found that children play an active role in initiating, terminating, and driving religious conversations. Furthermore, they found that parents tended to ask questions that were open-ended, and the questions themselves were devoid of suggestions revealing parents' personal views. In another study, of young Jewish adults, Herzbrun (1993) found that the frequency of religious discussion in the family had an enduring influence on young people, especially on girls.

In sum, the collective picture painted of religious socialization in the family supports a constructivist perspective and reveals a reciprocity process such that parents and children are influenced by what the other has to say (Boyatzis, Dollahite, & Marks, 2005). Through conversations with parents, children are afforded the opportunity to puzzle over religious and spiritual matters and to construct their own personal views. Further, the transmission of religious views from parent to child happens not as a result of didactic teaching so much as it happens as a result of parent and child co-constructing their spiritual identities. Therefore, children's participation in their own religious development supports rather than undermines continuity between generations.

There is sufficient evidence to show the deep extent to which the family influences religious development, particularly by the type of religiousness or religious instruction practiced in the family. Most people remain in

the denomination in which they are born and in which they grow up. Even in cases when young people turn to radical forms of religion, there are usually continuities with their parents' religion. An example is the Jesus-people movement, which made such a stir in the 1970s. Most of the followers came from fundamentalist Christian families. Although these young people were rebelling against their parents, they had internalized their parents' religious attitudes and were living them out, albeit in a radicalized form (Richardson, Stewart, & Simmonds, 1979).

Religious development is also influenced by parenting *style*. The available research suggests that parental emphasis on obedience encourages a religious attitude according to which human nature is corrupt, sin is to be punished, and the Bible must be interpreted literally (Ellison & Sherkat, 1993). At the beginning of the 1960s, 66% of the children interviewed by Nunn (1964) reported that their parents threatened that God could punish them, and although this happened much more frequently in socially disadvantaged families, it also took place when parents felt themselves to be powerless and in need of a coalition with a strong and vengeful God. Similarly, Potvin and Sloane (1985) found that adolescents whose parents exercised powerful control and constraint were more likely to perceive God as punishing deviant behavior.

Attachment

Images of God become even more relevant in research about attachment. The influence of parents on the religious and spiritual development of their children is not limited to the direct way in which they teach, encourage, and transmit faith traditions. There is a second, more subtle, type in which parents influence their children's spiritual development indirectly, through the ways they interact with their children and determine the quality of their attachments.

Ana-Maria Rizzuto (1979) made an important contribution in studying this indirect influence. Through the use of her God and family questionnaires, Rizzuto demonstrated how individuals' images of God can be strongly related to their images of their relations to their parents.

Since Rizzuto's work, research on parents' indirect influence has continued outside the framework of psychoanalytic theory. Most of this research has been conducted using the constructs of attachment theory, looking at how early attachment patterns between parent and child affect the relationship between person and God in later life. As noted by Granqvist (1998) and Kirkpatrick (1995), God functions as an attachment figure because many believers imagine God as a safe haven and secure base who maintains proximity and is strong in times of distress—all requirements for being an attachment figure.

Most of the attachment research on religious and spiritual development has made use of the Ainsworth (e.g., Ainsworth, 1978) typology—to test for two possibilities. The first is that persons who, early on, developed a secure attachment pattern with a caregiver tend to image a close and always protective God. This possibility is commonly referred to as the *correspondence thesis*. According to the correspondence thesis, a secure attachment attained during early childhood prepares an individual to adopt a corresponding secure attachment with God later on.

The second possibility is that persons who, in early childhood, developed an insecure attachment pattern (ambivalent or avoidant), tend to image God as a guarantor of protection and security. This possibility is commonly referred to as the *compensation thesis*. According to the compensation thesis, God becomes a surrogate attachment figure who compensates for the absence of an internalized secure attachment from childhood.

In a survey of 213 adults, Kirkpatrick and Shaver (1990) found evidence for the compensation thesis. They classified subjects according to the different attachment types, and compared subjects' images of God, also taking into account subjects' status with regard to extrinsic and intrinsic religiousness. Subjects assigned to the avoidant attachment type were clearly the most religious. They scored highest on the loving God and intrinsic scales, on attendance at service, and on reporting a personal relationship with God. This was especially the case for those reporting only infrequent religious practice in their parents' home (Kirkpatrick & Shaver, 1990, p. 325). Furthermore, half of the avoidant group reported having experienced a sudden conversion, whereas in the two other groups this happened to only one person in nine. The differences between the securely attached and the ambivalently attached were markedly lower.

In a later study, Kirkpatrick (1997) reproduced the results of this first study using longitudinal data. Women were first interviewed to determine their attachment status, then, 4 years later, interviewed again about changes in their religiousness. During the second interviews, 40%

of the women who had previously reported experiencing an avoidant attachment relationship with a parent, reported that, since the first interview, they had found a "new relationship with God." The percentage for those who had reported having a secure attachment relationship was significantly lower.

Grangvist (1998) also tested the compensation thesis. In a study of 203 Swedish students, he collected information about the attachment behavior of mothers *and* fathers and about the remembered religiousness of both parents. Combining ambivalent and avoidant groups into one, insecurely attached group, Grangvist found that the insecurely attached group scored higher on religiousness, on relationship with God, and on theism—but only when parents were reported to be not very religious. However, among subjects remembering their fathers as being highly religious, the securely attached expressed greater religiousness and a closer relationship with God: Under these conditions, the correspondence thesis applied.

The correspondence thesis is further supported by a comparison of deity figures in cultures possessing clear differences in the behavior of parents. For example, Lambert, Triandis, and Wolf (1959) demonstrated that in child-centered societies, where children are surrounded by loving care, God and deity figures tend to be benevolent beings, but in cultures with rejecting parenting styles, God and other deity figures tend to be malevolent.

From these results, it becomes clear that the connections between attachment experiences in early childhood and religiousness later on are complicated and not straightforward. Religiousness can function not only in a compensatory manner but also as an extension of the young child's relationships with his or her parents. However, the patterns are not random. They simply derive from more than one combination of antecedent conditions.

Religious Schools and Religious Education

Most of the research on religious schools has been on Christian, denominational sponsored schools in the United States, Europe, and Australia. The main research questions have been about religious schools' influence on pupils' religious beliefs and practices. Differences between school systems and student populations make comparisons difficult (e.g., Hyde, 1990). However, the composite picture drawn indicates that religious schools do not influence religious development and attitudes in any powerful way (Hood et al., 1996).

Francis (1987a) questioned almost 5,000 young persons attending Catholic private schools in England, and found that these schools had very little influence on students' attitudes toward Christian beliefs. A more decisive factor was the influence of the parental home. When the parental home follows the same religious educational choices as the denominational schools, the school's effect with regard to faith and later church practice is greater. Spencer (1971) concluded that in the absence of reinforcement from the family, there is no reason to expect that the religious school will modify values and value-oriented behavior.

With regard to religious development, it seems that religious schools possess not so much a compensatory or independent function as a supplementary one, to the extent that they have any effect at all. The same conclusion was reached in studies carried out on the effect of religious schools in Australia (Hyde, 1990). Anderson (Andersen, 1988) found that the choice of a Catholic private school depended to a large extent on the religious and philosophical attitudes of parents, especially mothers; the schools themselves changed the attitudes and practices of the pupils only marginally.

As for explicit religious instruction in public schools, practices differ depending on national policies. In France, there is no teaching of religion at all in state schools, but in the United Kingdom, religious education is taught under the auspices of the government; in Germany, religious education is taught by and under the auspices of the Church but financed by the government.

With respect to the content of religious education, opinions are divided about what constitutes religious knowledge and the goals of religious education. The spectrum of expectations ranges from the imparting of general religious knowledge to the considerably more ambitious aim of kindling faith and motivating religious practice and church attendance.

The relatively few studies on the effects of religious education are in agreement that its popularity decreases markedly as children get older, especially in adolescence. On the basis of questioning more than 800 schoolchildren in England, Francis (1987b), showed that religious education is the second most popular subject among children in first grade (junior year 1 in the United Kingdom)—only sports ("games") is more popular, but by the time students are in ninth grade (secondary year 4 in the United Kingdom), it is the least

popular subject. A study of 7,000 schoolchildren carried out in Germany on the popularity and perceived efficacy of religious education yielded similar results. The popularity of religious education is high in elementary school, but in the 2nd year of high school it falls to the lowest third, with only physics and Latin being less popular (Bucher, 2000).

With increasing age there is also a marked diminishing of the effects attributed to religious education; these effects are highest in the area of general knowledge, including knowledge of other religions, but the effects are small in matters of church practice and devotion.

How can we account for such a significant drop in popularity and influence of religious education? A first possible explanation is that religious education loses its popularity because the popularity of the school as a whole decreases with age. However, this explanation does not explain why the acceptance of other school subjects (e.g., mathematics and English) remains constant.

A second possible explanation is provided by Oser and Gmünder's theory (Oser & Gmünder, 1991): Convinced that God is able to intervene in the world and that He can be influenced through prayers—indications of stage 2—schoolchildren are considerably better disposed toward religious education and toward considering religious education to be more relevant than are adolescents, whose religious judgment is apt to be at stage 3 (Bucher, 2000, p. 128). At stage 2, children find it important to conform to God's expectations, more so than later on in adolescence when they have developed to stage 3, the deistic stage, in which self-determination is central.

However, whether religious education continues to influence may depend on the character or methods of that education. For example, in a quasi-experimental intervention study, in which two experimental groups discussed religious dilemmas over a long period of time, Oser and Gmünder (1996) found the average judgment stage rose more significantly than did the average for a control group lacking in opportunities to discuss and problem solve collectively. Moreover, this difference remained constant in a follow-up survey carried out 6 months later. A similar result was produced by Caldwell and Berkowitz (1987) who had high school students aged between 15 and 18 discuss religious dilemmas over a period of 12 lessons. A subsequent test revealed that for more than half of the students discussion sessions lead to significant development with respect to stages of religious judgment.

It is possible to use targeted teaching strategies as a means of significantly modifying religious development in positive ways, however, to do so requires engaging students in religious discussion to encourage them to question and modify their earlier religious interpretative patterns.

Congregations

Outside of the family, few contexts have a greater potential for influencing and supporting religious and spiritual development than do congregations. Congregations play a potentially important role in shaping religious beliefs as they, "provide spiritual environments where young people can transcend their everyday concerns and experience connectedness with the divine and human others. . . . Congregations may provide a distinct context in which a young person can explore (spiritual) issues that are critical to commitment to identity" (King, 2003, p. 200). Furthermore, congregations connect youth to their community because they exist not on their own but rather as a subcommunity in some broader community (Roehlkepartain, 2005).

Given this potential, it is surprising that there is so little empirical research on their influence on religious and spiritual development. Congregations have, as Roehlkepartain notes, slipped through the cracks in the divide between psychology's focus on individuals and sociology's focus on institutions (Roehlkepartain, 2005).

Congregational influence on the individual is bidirectional: The congregation shapes individual members, and individuals in the congregation shape the congregation's goals, climate, and activities.

Roehlkepartain (2005) outlines the conditions and processes that are presumed to play a role in driving spiritual development. First, congregations provide opportunities for the formation of meaningful, positive relationships. Youths are able to forge relationships with adults and peers who are invested in them and those relationships become the forum for the transmission and construction of beliefs and values. Second, congregations establish a climate for supporting spiritual development. Presumably, congregations that are welcoming and warm and that are encouraging of thought and service are more likely to promote spiritual development and faith maturity than those that do not.

However, there seems to be a gap between congregations' actual influence and their potential for influence (e.g., Osmer & Schweitzer, 2003; Prell, 1995;

Roehlkepartain, 2005, Yust, 2003). The National Congregational Life Survey (Woolever & Bruce, 2004) found that 50% or fewer of the surveyed congregations (n = 2,000) had effective caring for children and youth, and that a majority was reported to have fewer than 5 of the 10 strengths researchers examined. Based on these results, it appears that too few young people are spending time in congregations that are vibrant, spiritually enriching, communities of faith (Roehlkepartain, 2005).

However, these results are somewhat offset by the more positive reports from young members of congregations themselves. For example, C. Smith (2003) reported that 62% of teenagers surveyed in one study said congregations helped them think about important matters, 75% said their congregation was both warm and welcoming to teenagers, and 82% said that their congregation regularly provided opportunities for leadership and service.

Therefore, congregations present an interesting paradox. They have tremendous potential for shaping and guiding spiritual and religious development. However, they have not been the focus of a great deal of empirical research, and what research there is suggests that we are a long way from determining any actual influence. Furthermore, the existing body of data on congregations is largely from samples that are both Christian and North American—and there is no scientific reason for assuming that results from these samples can be generalized elsewhere.

POSITIVE CORRELATES OF RELIGIOUS AND SPIRITUAL DEVELOPMENT

What effects do religiousness and spirituality have on individuals' health and sense of well-being? Does religiousness produce neurotic behavior, as Freud (1961) asserted, or does it increase the morality of believers, as is generally assumed (Walker & Pitts, 1998)? Does spirituality, especially at higher stages of development, expand social consciousness and capacity to cope? In this section, we examine how religiousness and spirituality relate to the following:

- Health and well-being
- Moral development and social conscience
- Coping
- Adjusting to old age

Health and Well-Being

A good number of studies have addressed the effects of religiosity and spirituality on health and physical and psychological well-being. Plante and Sherman (2001) refer to at least 350 studies on physical health and 850 studies on mental health that treat religiosity as an independent variable. The majority of these studies show that religious involvement and spirituality are associated with better health outcomes. Even when excluding those studies with serious methodological flaws, the evidence suggests that religiosity and spirituality have significant and positive effects on health and on expanding the life span. Those who regularly frequent religious meetings have a 30% reduced risk on mortality. This effect remains highly significant even after controlling for demographic and socioeconomic variables. Furthermore, persons who regularly attend religious services live longer (Oman, Kurata, Strawbridge, & Cohen, 2002).

Undoubtedly, these positive correlations relate to religion's promoting not simply participation at religious services but also a healthy lifestyle. As measured by participation and attendance at religious services, religious persons practice fewer health risk behaviors such as smoking, drinking, and sexual promiscuity.

Powell, Shababi, and Thoresen (2003) demonstrated this connection between religiosity and healthy lifestyle with specific regard for cardiovascular disease and cancer. Their findings suggest that the social support provided by religious communities can reduce distress and feelings of loneliness, both of which can undermine physical health. A similar finding has been found with respect to religious support and drugs and alcohol—with religion serving to help addicts avoid or turn away from drugs and alcohol (Blakeney, Blakeney, & Reich, 2005).

Meditation has long been a religious and spiritual practice for promoting health and well-being. Most religious traditions have developed meditative practices, in part, for this reason. The effects of meditation are one of the best investigated subjects in the psychology of religion (Andresen, 2002) and the majority of studies report positive effects. Meditative practices, such as Transcendental Meditation and yoga, lower systolic and diastolic blood pressure, increase nonrenal blood flow, and decrease respiratory and heart rate (Andresen, 2002). These physiological effects reduce anxiety, depression, and stress (Austin, 1997). The long-term practice of meditation produces more intense experiences of joy, meaning, love, and awareness (Andresen, 2002).

With regard to mental disorders and religious and spiritual development, probably the single most consistent finding has been that there is a negative correlation between substance-related disorders and religiosity, especially when religiosity is measured by involvement in a faith-based community. Put another way, all other things being equal, religious and spiritual development appears to be a significant protective factor preventing an individual from developing a substance-related disorder (Benson, 1992).

The quality or character of religiousness also affects health, not just whether an individual is involved in a religious community. Intrinsic religiousness has stronger and more positive effects on physical and mental health than extrinsic religiousness (Argyle, 2000). Batson, Schoenrade, and Ventis (1993) analyzed 115 studies and found that most studies reported that intrinsic religiosity correlated positively with health, especially mental health, but extrinsic religiosity correlated more negatively (see also Plante & Bovccaccini, 1997). Furthermore, intrinsic religiosity positively correlated with a sense of coherence, which itself enhances mental and physical well-being. In addition, individuals practicing intrinsic religiosity are, on average, happier, especially if they feel close to God (Pollner, 1989).

In sum, religiosity can positively influence physical and mental health and well-being and happiness. Argyle (1999, p. 366) discussed these findings as, in part, due to the effect of the social support provided by the religious communities.

Moral Development

In the history of social science research, religion has been depicted as serving only a weak influence on morality, or none at all. This view has been supported in several well-known studies. For example, Hartshorne and May (1928) showed that neither religious affiliation nor religiously directed character education had any effects on moral behavior. Darley and Batson (1973) found that almost two-thirds of the undergraduates they observed entering a chapel to hear a sermon on the Good Samaritan, failed to help a man lying on the sidewalk and in need of help. And in the current debate over character education, there often is a determined effort to keep religion out of the discussion (Damon, 2002; Schwartz, 2002). However, by far the most important support for this view of religion's relationship with morality being separate has been the research and legacy of Lawrence Kohlberg.

Moral Judgment

For more than 2 decades, Lawrence Kohlberg (1981) labored to have moral development considered as a separate, autonomous domain—with the main engine of moral development being those mundane conflicts that confront children and adolescents daily. In doing so, Kohlberg argued against divine command theory and all those who believe that morality derives from the prescriptions of religion. For most of Kohlberg's career, moral development was independent of religious and spiritual development. If anything, religion had, for him, a potential stultifying effect because of those times when religion suppresses the individual's taking an active role in distinguishing right from wrong.

However, in his later years, Kohlberg softened his stance toward religion as he confronted the meta-ethical question of "Why be moral in an immoral world?" Doing so led to his adopting a positive view of how religious development (or, more specifically, faith development) can support moral development. He came to believe that the primary function of religious structures is to validate and thereby support being moral. Religious structures do this by grounding morality not in promises of personal gain but in faith in human nature and in a cosmic order (Kohlberg, 1981).

To an extent, Kohlberg saw religious development as the by-product or outcome of moral development. Therefore, just as logical structures are necessary but not sufficient for the development of moral structures, moral structures are necessary but not sufficient for the development of religious (faith) structures (Kohlberg, 1981).

This reverses the usual way of relating moral and religious development. Usually, morality is thought of as the outcome of religious and spiritual development. This is the way that laypersons think, and it was also the way that William James thought. In James's (1902) discourse on saintliness, he began not with morality but with the saint's experience of being connected to an unseen, beneficent power. The by-product or "fruit" of this experience was, for James, a powerful and positive morality.

How should we understand this relationship between moral development and religious and spiritual development—in Kohlberg's terms, in James's terms, or of some alternative? And how do the findings of research help us decide?

The necessary but not sufficient hypothesis (Kohlberg & Power, 1981, p. 227) has been tested by several studies—with mixed results. Caldwell and Berkowitz (1987) found in their interviews with 50 Wisconsin students (mean age = 16.4 years) that students' stages of moral judgment were, as a rule, higher then their stages of religious judgment, as measured by the Oser and Gmünder scales. In contrast, studies by Gut (1984) found that a quarter of her sample scored higher on stages of religious judgment than on stages of moral judgment. Considering inconsistent results such as these, more research is needed to determine the exact relationships between the development of moral and religious judgment.

However, recent research on moral *functioning* as distinguished from moral *judgment,* has shown a more intimate and subtle connection between moral development and religious and spiritual development than that characterized in discussions about stages of moral and religious judgment. For example, in a study of adult moral exemplars, Colby and Damon (1992) found that the majority of their sample acted out of some sense for the transcendent and that morality, spirituality, and identity were fused in such a way as to sustain their lives of caring. In other words, caring was, for them, who they were or who they became. In a similar vein, Walker and his colleagues found general support for William James's thesis that authentic religious experience is evidenced in mature moral functioning (Walker, 2003; Walker & Pitts, 1998; Walker, Pitts, Hennig, & Matsuba, 1995; Walker & Reimer, 2005).

These findings refer to "authentic religious experience" and to "mature moral functioning." But what about religious experience that may not be authentic or true to the core values and beliefs of a faith tradition? The results show negative or ambiguous connections between religion and morality: For example, a number of studies have found a clear and positive correlation between ritual attendance, orthodox beliefs, and racial prejudice (Batson et al., 1993). Other studies (B. Hunsberger, 1995) have found a curvilinear effect such that the most religious and the totally irreligious are the least prejudiced. With regard to prejudice, there are no straightforward influences of religion on morality. Similarly, several studies have found only a weak effect of religion in preventing delinquency (Hood et al., 1996). It seems that positive relationships between moral development and religious and spiritual development are most evident at higher stages or when religious and spiritual experience becomes authentic and in accord with positive faith traditions.

Service

Reference to moral exemplars reminds us that moral development involves much more than judgment and reasoning. It also involves action. One measure of moral development is service to others. How does religious and spiritual development relate to community service in those who have yet to become moral exemplars? Most of the research has been about adolescents and their involvement in religious institutions and community service.

A number of studies have demonstrated a positive relationship between involvement in religious institutions and community service. For example, Youniss et al. (1999) found that high school students who valued religion were vibrantly engaged in their schooling and in the betterment of their communities.

For adolescents, community service in the context of religious institutions seems to have a different and more positive meaning than community service in other contexts. For example, Donnelly and his colleagues (Donnelly et al., 2005) have demonstrated that adolescents doing community service in the context of religious institutions as compared to those doing community service in other contexts are more likely to do community service later on, in their adult lives.

Coping

One of the fundamental and undoubtedly universal functions of religiousness is coping, especially in critical life events such as the death of a loved relative and serious illness. Certainly, long before psychologists studied coping processes, religions have disposed resources for facilitating coping.

In the past decades, *coping* has become a very important concept in the psychology of religion (Pargament & Brant, 1998). Pargament and Brant distinguished the following types of religious coping:

- *Self-directed coping,* as when subjects use God-given resources to individually solve their problems.
- *Deferring coping,* as when individuals, especially in seemingly hopeless situations, give up control to a higher power or God, thereby paradoxically gaining control (Baugh, 1988).
- *Collaborative coping,* as when individuals appraise God as a helping partner.

Out of the hundreds of studies on religious coping, most support the following points:

- One of the most frequently used religious coping strategies is prayer.
- Religious coping is more frequent among females, older individuals, blacks, and those who are less educated.
- If individuals have faith in a loving God, the outcomes of religious coping are more apt to be less stress, less anxiety, a greater sense of well-being, and greater capacity for handling difficulties than if they evaluate negative life events as God's punishment.
- Usually, the outcomes of collaborative religious coping are more promising than are the outcomes of other styles.

But how does a person develop competencies in coping? And why do people prefer different coping styles? The lack of explicitly developmental analyses (coping styles at different stages of religious judgment, etc.) is a limitation in this research—a limitation that makes it difficult to answer these and other important questions having to do with coping and religious and spiritual development.

Positive Correlates in Advanced Age

The considerable benefits of religiousness and spirituality in advanced age warrant special attention. From his studies, Argyle (1987) concluded that for older people, religiousness and well-being are closely tied together. Levin (1997) also demonstrated that for many older people, religiousness has significant and positive effects.

Religiousness obviously has a striking effect on how old age is experienced. For example, in one study, out of 1,011 elderly men surveyed, a distinct majority said religiousness was more important to them than it was in their middle years (Koenig, 1994). This seems to be especially true for older women (Mc Fadden, 1996). The older the subjects are, the more powerful are their beliefs in a personal God, and the more their faith provides help with problems in living (Jörns, 1997).

Yet, religious activities diminish in old age (Blazer & Palmore, 1976). Many seniors, on account of their frailty and illness, are no longer capable of active participation in congregations. However, this lack is compensated for by an increase in unorganized, private religious practice, especially prayer.

The obvious benefits produced by religiousness and spirituality in old age are integration and social support, the creation of meaning and purpose, fostering a greater sense of control and maintaining better health. These points can be summarized as follows:

- Religious communities offer integration and social support. Scales for loneliness are more powerfully correlated in a negative way for the elderly than for younger people, and the benefits of church membership are greater for people in retirement or who have been widowed (Argyle, 1987). Religious communities create a bolstering environment in which burdensome life events, such as bereavements, can more easily be coped with. Religious communities also produce an atmosphere of acceptance, hope, and forgiveness (Koenig, 1992). In her wide ranging Yale Health and Aging Project, Idler (1994) found that being integrated with a religious community predicted less depression and lower suicidal tendencies.
- Religions can additionally create an inner sense of security by offering meaningful rites and symbols (Argyle, 1987). They can provide a sense that life as a whole, with its high-points, its lows, and its finiteness, is meaningful. Religiousness is a protective factor against problems of meaning (Dittmann-Kohli, 1990).
- Through the lens of religion, death, which looms ever more inexorably in old age, can be interpreted as the beginning of a better world, as the transition into eternal life or as something natural and positive. As Meadow and Kahoe (1984) report that immortality seems to be the single item of faith that increases substantially with age.
- Religiousness has always been connected with convictions about control, even though we might believe that the religious person is ceding control to a divine being (control illusion). Well-being presupposes possibilities of control. Baugh (1988) reduced this control paradox to the formula, "Gaining control by giving up control." Ceding control to a higher power unburdens the spirit and makes it easier to cope. For example, in the Duke longitudinal study, 100 elderly participants, when asked how they dealt with stressful experiences (death of relatives, etc.), frequently named having trust and belief in God (Koenig, George, & Siegler, 1988).
- Most religions prescribe a code of behavior, which promotes good physical health, and this correlates

highly with happiness and satisfaction with life (Argyle, 1987, p. 176). The greater extent of well-being enjoyed by religious people in old age is also explained by pointing out that they rarely smoke or drink alcohol and eat with greater moderation.

NEGATIVE CORRELATES AND PATHOLOGY

The preceding section has shown that spirituality and religiousness exert positive influences. The term *religion,* however, also elicits images of September 11th, 2001 and of Jonestown, Guyana. We need to look at the evidence for negative and not just positive correlates. However, before doing so, we begin by discussing the negative biases against religion, which, in the social sciences, have impeded progress in sorting out negative from positive.

With respect to religious and spiritual development, the history of both psychological research and clinical practice has been a history of negative bias and prejudice. Bias and prejudice persist today but has perhaps lessened—both because of a new tolerance for cultural diversity and because of empirical research that has challenged old negative stereotypes. Nevertheless, we begin with a brief discussion of the most obvious negative biases and prejudices because their persistence presents a significant roadblock to understanding negative correlates and pathology associated with religious and spiritual development.

Negative bias is particularly evident in stereotyping—in collapsing meaningful distinctions into one negative category. Stereotyping the religious and a failure to make distinctions has been the hallmark of negative bias among research psychologists and clinicians. An overview of the literature indicates that rarely are distinctions made when discussing central religious concepts such as *belief, faith,* and *revelation.* Yet, there are many meanings for each of these three, and the differences matter.

With regard to the concept of belief, research psychologists and clinicians have customarily equated the meaning of religious belief with the meaning of belief as it is used when speaking of, say, belief in trees and dogs, though the two meanings differ from one another (Blackstone, 1963). With regard to the concept of faith, and, as previously discussed, research psychologists and clinicians have customarily equated faith with belief despite these two concepts having quite different meanings in the history of faith traditions (W. C. Smith, 1998a). With regard to the concept of revelation, they have generally given one single meaning to revelation when there are several, including meanings that acknowledge multiple interpretations of sacred texts and religious experience (Dulles, 1994).

Without making important distinctions between the meanings of these and other central religious concepts, religion easily appears to consist mostly of irrational belief and dogmatic, childish denial that truth is a matter of interpretation and argument. Add a quantitative dimension to the discussion, and such negative views of religion often turn into pathologizing religion whenever religion is taken seriously. One is reminded of Albert Ellis's (1980) remark, "The less religious (people) are, the more emotionally healthy they will tend to be" (p. 637).

Failure to make meaningful distinctions has been one problem. Making false distinctions has been another. Perhaps the most obvious example of making a false distinction is between science and religion, such that one is pitted against the other. This distinction often goes unchallenged, despite the fact that the majority of religious persons who are also scientists find no contradiction in being both, and despite the fact that only a small minority of the religious people believe in unscientific theories such as creationism (Gould, 2003b).

This last reference to creationist theory brings up a third prejudicial practice among researchers and clinicians—the practice of selecting unrepresentative examples to support arguments against religion. An example of this practice occurred on the *DSM III-R*'s glossary of terms for defining mental disorders—where an inordinate number of examples with religious content were given to illustrate what is meant by various mental disorders (Larson et al., 1993).

A fourth prejudicial practice has been to report, as objective fact, findings based on flawed, value-laden measures that are biased against religion. For example, on the Minnesota Multiphasic Personality Inventory (MMPI), answering positively to the statement, "I am orthodoxly religious" lowers one's overall score (Gartner, 1996). Such soft measures express the value system of a select group—often proponents of secular humanism and self-actualizing theory (Maslow, 1971).

Researchers in religious psychology have been particularly harsh on fundamentalist groups. Fundamentalists are routinely lumped together to form a negative stereotype consisting of character traits such as *immature, dogmatic, rigid,* and *prejudiced.* There is evidence to support the claim that religious fundamentalism is indeed associated with higher levels of prejudice, authoritarism, and an

"us versus them" mentality (Altemeyer, 2003), however, at least one study suggests that prejudice is not confined to any one group and that groups of so-called healthy, quest-orientated individuals are also prejudiced, especially toward fundamentalists (Goldfried & Miner, 2002).

The point is not that the religious are problem free or that there is no pathology associated with religious and spiritual development. We need not go to the opposite extreme. However, in the history of religious research and clinical practice, there has been persistent negative bias against religion. Religious and spiritual development is a complex phenomenon that challenges us to make numerous distinctions and be scrupulous about evidence and measures. Pathology is real and does not reside in the eyes of the diagnostician, but pathology, as a concept, needs to be used with care.

Having clarified some misunderstandings that have impeded progress, we can turn now to recent research on psychopathology as it relates to religious and spiritual development. We discuss the subjects of cults, occultist practices, terrorist groups, mental disorders, and pathogenic (toxic) religious practices and beliefs—as they relate to religious and spiritual development.

Cults, Occultist Practices, and Terrorist Groups

With regard to cults, occultist practices, and terrorist groups, the literature suggests two points in particular. The first point is that problems of definition have created biases that impede the progress of research on cults. The second point is that there is no conclusive evidence that members of so-called cults are any more developmentally disturbed or pathological than are individuals who do not join cults or terrorist groups.

Cults and Occultist Practices

Historically, the term *cult* has had a neutral meaning—both in faith traditions and in the sociology of religion. However, since the 1960s and especially since the Jonestown and Waco tragedies (in Jonestown 912 people of the Temple Sect died by an organized mass suicide; in Waco, 74 disciples of David Koresh perished by a massacre), the term has been defined by the media and certain government agencies as referring to a particular kind of group, one with a self-appointed, dogmatic, and charismatic leader who promotes deceptive-coercive recruitment practices to ensnare individuals to join a totalitarian community organized to solicit funds and secure favors that benefit neither the group's members nor society (Barrett, 2001). The media sometimes adds negative terms such as *brain-washing* to characterize the socialization of cult members. This negative definition of cults works well as an ideal type for identifying harmful cults, but the definition has been applied indiscriminately and to religious groups that do not fit the definition. As a result, discussions of cults are often polemical and groups of researchers are divided into "cult critics" and "cult sympathizers."

Cult sympathizers are more likely to use the terms *new religious movements* (NRM) and *alternative religions* instead of cult, though these terms, too, have their problems. Certain groups considered by most to be cults are not new and in some contexts would not be alternatives to the mainstream. The International Society for Krishna Consciousness, otherwise known as the Hare Krishna, is an example (Daner, 1976). Nevertheless, new religious movements or alternative religions have become accepted terms. Cult sympathizers point out, tongue in cheek, that the difference between a cult and a religion is about a million members (D. Barrett, 2001).

There is also misunderstanding about the average age of cult members. Cults are associated with "youth religions," which came into prominence in the 1970s. However, the average age of cult members is estimated to be between 25 and 40 (Schmitz & Friebe, 1992). For those in Bhagwan Shree Rajneesch, living in Oregon, the average age is 34 years (Richardson, 1995).

Concerning the second point about who joins cults, the available evidence suggests that members generally are no more pathological than are nonmembers (Richardson, 1995). In explaining why and how a person comes to join a cult, a more historical, less psychological approach may work best because circumstances play a decisive role. For example, a newly arrived freshman at college may, along with other freshman, feel lonely and disoriented but adjust without joining a cult, however if that freshman happens to meet and talk with a cult member, he or she may well end up joining a cult (D. Barrett, 2001).

These words of caution about rushing to judge cults aside, the extreme example of religion taking the wrong course is still taken to be the norm. A clear majority of Europeans live in a state of alert on account of religious cults (Schmidtchen, 1987), and in the United States, there is a similar negative view as well. Pfeiffer (1992) showed that the overwhelming majority of American students (82%) described cult members purely in negative terms, deeming them to be less happy, less intelligent, and less free.

Of particular relevance to developmental psychology is the question of what leads individuals to join cults. Several clinical studies conducted mostly with persons who had left cults, established that before joining cults, many members had serious family and nonfamily problems (Klosinski, 1996). By some accounts, life before joining a cult was characterized by a history of poor relationships with both parents and peers (Silverstein, 1988). In her sample, Rollett (1996) also found that young people with a high exposure to crises tended more strongly toward joining cults. Others have characterized those who join cults as persons who have suffered from the absence of a father during childhood and who have difficulty dealing with the complexities of life (Ullman, 1982). This is consistent with the finding of one study that showed that new converts to cults held stronger authoritarian values than did nonconverts (Shaver, Leneuaer, & Sadd, 1980).

Popular empirical accounts often deliver the blanket judgment that cults rob their members of freedom, individuality, and wealth. These accounts accuse cults of fostering dislocation from reality, thought paralysis, and regression (Lademann-Priemer, 1998). The doctrines of many cults do seem to operate on lower developmental stages—as when cults divide humanity into small groups of those who are good and saved, from the great majority who are bad and lost (Brickerhoff & MacKie, 1986). As another example, the Krishnas, who consider a doll to be the Divine itself, seem to collapse the distinction between a religious symbol and its referent (Cassirer, 1955; Fowler, 1981).

However, negative characterizations of those joining cults may well be the result of interviewing mostly those who have left cults because they were dissatisfied—the research may be biased toward having a negative view because the sample of former cult members is a biased sample (Richardson, van der Lans, & Derks, 1986).

As for the effects of joining cults, in the worst cases, the results have been fatal, especially authoritarian leaders or closed groups hinder development toward religious maturity and autonomy, respectively if they produce a childish and inflexible dependence. Fatal or otherwise, seriously harmful effects may happen, especially when cult members engage in occultist practices. In the past decade, occult forms of religiousness among adolescents have become, at least in Europe, a popular theme (Helsper, 1992). Headlines have covered tragic deaths of young people after they performed occult practices such as moving glasses and holding séances.

However, some researchers have shown positive effects of cults. Salzman (1953) found that cults sometimes help members to cope. In a survey of 517 members of the Unification Church and of Ananda Marga, Kuner (1981) showed that long-term membership produced "resocializing" and "therapeutic" effects. Schibilsky (1976) found that joining cults helped members cope with developmental tasks such as forming an identity and developing self-discipline. As another example of positive effects, Wicca groups have been described as empowering women and helping them to heal wounds inflicted on them in societies where women, especially lesbians, have been disempowered or hurt by homophobia (Warwick, 1995).

Positive views of the effects of cults are sometimes accompanied by the observation that cults help individuals make a transition. People often belong to cults on a temporary basis and experience them as "havens" (Hood et al., 1996). In his thorough meta-analysis of clinical studies on the psychological effects of joining cults, Richardson (1995) concluded that membership is often therapeutic instead of harmful.

Related findings on occultist practices have shown that what may at first appear to be psychopathology of a religious or spiritual nature can be, on closer inspection, a means for spiritual growth. For example, Streib (1999) described the occultist practices of the groups of European adolescents he observed as "off-road religion," implying that they were age and stage appropriate for those who have yet to achieve an adult identity. Furthermore, and contrary to popular negative views, the overwhelming majority of studies have shown that only a minority of teenagers regularly perform occult practices, and for most in this minority, occult practices are performed out of curiosity and not from existential engagement.

Occult practices, rather than expressing pathology, can express religious affiliation and religious stage. Rollett (1992) demonstrated that catholic youth are more attracted to occultism than are youth without any religious denominations, and Bucher (1994) showed that adolescents at stage 2 of religious judgment according to Oser and Gmünder (1991) consider occult practices as being plausible, more so than do adolescents at stage 3.

Terrorist Groups

Similar to what was has been said about cults, what constitutes a terrorist group depends on one's perspective (Scarlett, 2003). Those identifying with or participating in such groups define the groups very differently than outsiders—as aggrieved victims of violent injustice (Silke, 2003). For them, the group is all about justice and freedom, not what is implied by the term *terrorist group.*

Becoming a member of a terrorist group can be seen and experienced as entirely natural and normal—somewhat akin to joining the army or police in times of war or crisis (Silke, 2003). In sum, terrorists, on average, have no appreciable psychopathology and are average with respect to level of education and socioeconomic status. It seems that terrorism is more a group phenomenon than it is an individual phenomenon—and should be studied as such.

There is a particular need for research on religion's role in stimulating terrorism and for understanding better what leads to religiously sponsored evil. Kimball (2002) provides a framework for explaining—using the following list of symptoms for evaluating when religion is in danger of supporting evil:

- Inhibition of (religious) autonomy and freedom
- Absolute truth claims
- Blind obedience
- Establishing an ideal time
- Claiming the end justifies the means
- Declaring Holy War

What should we conclude from this overview of how the literature discusses cults, occultist practices, and terrorist groups? If there is no more psychopathology, on average, within these cults and terrorist groups than without, are there no problems? Obviously, there are severe problems. There are cults that deceive, abuse, and kill, and terrorist groups inflict immeasurable harm and suffering on thousands of innocents. However, the problems do not fit neatly into the category of psychopathology—unless the category itself is expanded to fit just about everyone. With respect to cults, the main conclusions are the following:

- We need to distinguish harmful cults from those new religious movements that do no harm. In doing so, we can apply criteria such as deception, manipulation, coercion, and developmental stage but not without a careful examination of the evidence.
- We need to develop reliable measures to evaluate cults in short- versus long-term functioning.

With respect to terrorist groups, the main conclusions are the following:

- We need to focus on changing the social and political conditions leading to essentially normal religious individuals joining terrorist groups.
- We need to focus on educating the general public about those social and political conditions to minimize the demonizing that continues the cycle of violence.

Mental Disorders

As used here, the concept of a mental disorder is the same as used in major classification systems such as the *American Psychiatric Association's Diagnostic and Statistical Manual* (*DSM*). These classification systems have a number of conceptual and practical advantages over dimensional approaches (Cantwell & Rutter, 2002). However, they also have disadvantages. Professionals agree that classification systems should be used in conjunction with dimensional approaches to correct for their inherent deficiencies. With this cautionary point made, we can proceed to discuss how the current literature treats religious and spiritual development with respect to mental disorders as defined by classification systems, particularly by the *DSM-IV*.

First, with regard to the *DSM-IV* itself, this revised form includes a V-code for "Other Conditions"—those conditions that occasionally warrant a clinician's help but which do not constitute mental disorders. "Medication-induced movement" disorder is one example, and "Religious or spiritual problem" is another.

Including the V-Code "Religious or spiritual problem" marks a step forward—because it says that problems with a religious or spiritual content should not be automatically pathologized. However, some have argued that the inclusion of religious and spiritual problems as one of several "other conditions" marginalizes these problems when, in certain cases, they should not be marginalized (Scott, Garver, Richards, & Hathaway, 2003).

As for the other categories defining mental disorders, the picture is more complex. Perhaps the best overall characterization of the research is that with these other categories (psychotic disorders, mood disorders, etc.), religiosity and spirituality can define the content of the disorders (e.g., having delusions with religious content), but there is no evidence that religiosity and spirituality cause these disorders. For example, the frequency of religious delusions in groups of psychotic individuals varies considerably depending on the group sampled—as much as between 7% and 45% (Kingdom, Siddle, & Rathod, 2001)—suggesting psychotic individuals use whatever content is available in their culture to construct their delusions.

A further point about complexity is made with regard to individuals with the same diagnosis but who differ from one another in their religiosity. For example, when accompanied by strong religious faith, depression may have a very different and more positive meaning with respect to ability to function than depression without faith (Stone, 2000). Stage dependence should also be considered.

Pathogenic (Toxic) Religious Beliefs, Practices and Attitudes

Perhaps the best researched problem of this sort has been that of *prejudice* and its relationship with religion. One of the most consistent findings has been that moderate and superficial levels of religious involvement predict high levels of prejudice (Allport & Ross, 1967). The distinction here is between *extrinsic* and *intrinsic* religious orientation or those who use religion for self-serving means such as making social connections versus those whose core identity is defined by their faith tradition. It is not that religion fosters prejudice so much as it is how individuals use their religion. Just why intrinsic types are similar on measures of prejudice to nonreligious types is unclear.

However, there are clear instances of religiously sponsored prejudice that should be distinguished from the psychological prejudice manifest in extrinsic religious orientation. For example, certain fundamentalist groups find in the Bible grounds for considering homosexuality a sin. Religiously sponsored prejudice and the psychological prejudice in extrinsic religious orientation are quite different in nature and should be discussed, explained, and treated separately. This distinction between psychological problems of individuals and problems associated with a group's thinking comes up when discussing cults and terrorist groups as well.

Religious attributions (see Spilka & McIntosh, 1995) can foster self-esteem and psychic equilibrium, but they can also weaken them. In particular, a person's ability to cope can be impeded when critical events in life are attributed to the *punishment of God,* which traditional religious instruction used to encourage. Such attributions foster feelings of anger, helplessness, shame, and fear (Pargament, Ensing, & Falgout, 1990), and they undermine self-effectiveness (Di Loreto & Oser, 1996). For example, 13% of the cardiac patients interviewed by Croog and Levine (1972), convinced themselves that their illness was a punishment for earlier sins, and, in so doing, damaged their ability to cope—as measured by their recovery time being longer and their sense of well-being being poorer than for those without negative religious attributions. An avenging God brings about guilt feelings and can drive the self into punishing itself if it perceives itself to be disobedient in the eyes of God (Hood 1992, p. 118). As another example and on the basis of clinical studies, Frielingsdorf (1992) described shocking examples of casuistry, where people lost all self-respect and felt themselves to be "like dirt" on account of demonic images of God. He found that these people were often unwanted and neglected as children.

What can we conclude about the research reported on negative correlates and pathology related to religious and spiritual development? For one thing, we seem to be just at the beginning stage. To build an adequate research base, we need to develop a more nuanced description system for defining problems of a religious and spiritual nature. There are, for example, conceptual reasons for distinguishing between different forms of problematic faith. There is idolatrous faith, structurally immature faith, dysfunctional faith, and structurally developed faith whose content promotes evil (Scarlett, 2003). We need more research to establish whether these and other distinctions can be used scientifically to further define problematic religious and spiritual development. One of the main reasons for our adopting a normative, stage-structural analysis of religious and spiritual development becomes clear when discussing problems relating to religiosity and spirituality. A normative analysis is crucial for evaluating these problems and for developing the right means to solve them.

CONCLUSIONS

One goal for this chapter was to connect disparate voices in developmental science in general and in the study of spiritual and religious development in particular. Obviously, a field is enriched by there being different voices and alternative perspectives. Especially when the topics in the study of religious and spiritual development have been about culture, stages of development, and the relationship between belief and faith development, additional perspectives and more research are needed. Nevertheless, we have argued in this chapter that there are meaningful ways to attend to individual and cultural differences while still attending to what is universal and normative. We need to find ways to attend integratively to both diversity and general principles, and we also need to attend to matters of belief as well as to matters of faith.

Another goal of this chapter was to make our own position clear, and to explain why we believe that a constructivist and normative, stage-structural approach

will always be needed. Stage theory is indispensable for defining religious and spiritual development, and it provides possibilities for guiding interventions designed to support religious and spiritual development. In addition, a stage-structural approach can provide ways to explain universals in religious and spiritual development.

We contend that higher stages of positive religious and spiritual development provide adaptive functions. The current body of evidence seems to bear us out. The main functions provided by mature, positive faith have to do with giving humans hope for a better world, fostering greater tolerance and respect for others, and providing motivation to work for justice, demonstrate care, and experience well-being even in the face of adversity.

However, the main goal of this chapter has been to show the richness and importance of research and thinking in the study of spiritual and religious development. This chapter is the first on religious and spiritual development to appear in the *Handbook of Child Psychology,* although its inclusion was anticipated about a decade ago (Cairns, 1998; see also Cairns, Chapter 3; Lerner, Chapter 1, this *Handbook,* this volume), We hope and trust that it will not be the last—given that the study of religious and spiritual development is so central to our understanding of human development.

Furthermore, this field is expanding rapidly, and the next edition of the *Handbook* will likely be reporting on exciting new research findings in areas not even noted in the present chapter. For example, there are beginning efforts to connect research on brain development to religious and spiritual development, and, while there are currently no good bridge theories (J. A. Feldman, in press) that adequately connect mind to brain to make the brain a truly useful source of explanations for religious and spiritual development, those theories are likely to be in place by the time of the next edition. The same predication may be forwarded about other areas either not discussed at all in this chapter or reported on only slightly. For example, we expect that the research now being conducted on the role of spirituality in youth development will yield a much better account of interactions between organismic and contextual factors central to religious and spiritual development. In sum, the future of theory and research on religious and spiritual development seems, at this writing, to be a bright and scientifically productive one.
