In humans, substrates tend to remain comparable in their ability to detect common ANA but differ in the antibody titer.[50] In dogs, it has been suggested that multiple substrates be used in order to increase the sensitivity of the test.[51] Two canine studies found markedly different ANA results when rat liver and HEp2 cell substrate were compared[51,52]; however, results were well correlated in a third report.[53] Feline ANA test results have been found to have a low coefficient of correlation when identical sera are sent to different laboratories.[54]

In conclusion, the most appropriate substrate, conjugate, and methodology for ANA testing remain undefined and each laboratory's value should be interpreted individually. ANA-negative SLE cases have been described in veterinary patients,[5,26-28] and a positive ANA should be neither required nor sufficient in itself to make a diagnosis of SLE.

Autoantibodies

Suspicion of human SLE leads to testing for specific antibodies that provide diagnostic and prognostic information (E-Table 205-4). Similarly, certain autoantibody studies have been performed in veterinary patients (E-Table 205-5).

E-TABLE 205-4

Autoantibody Associations in Human SLE

EPITOPE	COMMENTS
ds-DNA	Highly specific for the diagnosis of SLE
Sm	Highly specific for the diagnosis of SLE. Associated with membranous nephropathy
RNP	Associated with Raynaud's phenomenon, pulmonary and muscle involvement
SS-A/Ro	Associated with cutaneous manifestations, sicca complex, neonatal lupus
SS-B/La	Associated with neonatal lupus
Phospholipid	Associated with thrombocytopenia, thrombosis, infertility

ds-DNA, Double-stranded DNA; *RNP*, ribonucleoprotein; *Sm*, *Ro*, *La*, extractable nuclear antigens named for the first two letters of the

patient from which the antigen was first described (Sm = Smith, etc.); *SS-A,* Sjogren's syndrome A antigen (or its equivalent, Ro); *SS-B,* Sjogren's syndrome B antigen (or its equivalent, La).

Data from Dall'Era, 2013.[34]

Antibodies to DNA

Anti–double-stranded (native) DNA is highly specific for the diagnosis of human lupus, even though only 60-83% of patients are positive. Anti–double-stranded DNA has been found infrequently in dogs with SLE.

Extractable Nuclear Antigens

Extractable nuclear antigens (ENA) are molecules extracted from the soluble fraction of cell nuclei (DNA and histone proteins are insoluble and therefore excluded). The binding of serum antibodies to commercially available tissue extracts is the basis for serologic testing, and important ENA include Sm, Ro, La and ribonucleoprotein. In veterinary medicine, antibodies against ENA have not yet been shown to offer diagnostic or prognostic significance.

Antihistone Antibodies

Histones are a group of proteins that bind the DNA helical structure into supercoil formation. Histone antibodies are characteristic of drug-induced SLE in humans. Investigators at one university[13,56,57] detected antihistone antibodies in 61-72% of dogs with SLE. Antihistone antibodies have been detected in canine sera by other investigators; however, there was no significant difference in concentration between ANA positive and negative sera[52] and antihistone antibodies were detected in conditions other than canine SLE.[55] The use of antihistone antibodies as an indicator of drug-induced SLE in veterinary patients has not been reported.

Antiphospholipid Antibodies

Antiphospholipid antibodies bind to cell-associated phospholipids, such as the cell membrane. The antibody interferes with the function of procoagulant phospholipids in clotting tests *in vitro.* Patients with the lupus anticoagulant have prolonged activated partial thromboplastin time that fails to correct with a 1 : 1 mixture of the patient's plasma and normal plasma. In humans, their presence is associated with thrombocytopenia, thrombosis, and fetal loss. Antiphospholipid antibodies have been described in one dog with SLE,[35] 2 dogs with hemolytic anemia,[36] and one cat with SLE.[29]

Management

Sunlight should be avoided if photosensitization occurs. Most patients also require immunosuppression (see ch. 165 and 360). Prednisone 1-2 mg/kg PO q 24 h is started initially; lower dosages could be effective in cases that are less severe. These high dosages are administered until the disease is in complete remission, defined as resolution of clinical signs and laboratory changes that were present initially. After remission is attained, the dosage is tapered, generally in half, for ≈4 weeks. Reevaluation is performed, and if signs of disease remain absent on both physical and laboratory evaluations, the dosage is halved again. Rechecking and tapering are repeated monthly until the animal either relapses or stops medication. The recommended minimum duration of therapy is 4 months. If relapse occurs during taper, the dosage should be increased to the most recently effective dosage and held there for a few months. If the maintenance requirement is unacceptable because of corticosteroid-associated side-effects, an additional immunosuppressive agent is added.

Some cats do not respond to prednisone,[37] and an alternate corticosteroid (prednisolone, methylprednisolone, triamcinolone, or dexamethasone) should be substituted instead of, or prior to, adding additional immunosuppressant therapies.

For dogs, combination immunosuppressive therapy with mycophenolate mofetil often is more effective and has fewer adverse effects than corticosteroid therapy alone (see ch. 165). Prednisone (1 mg/kg PO q 12-24 h) and mycophenolate (10 mg/kg PO q 12 h) are administered in combination. The dosage of prednisone is

tapered every 2 weeks while mycophenolate is continued at the same dosage. The goal is to discontinue corticosteroids completely and maintain remission with mycophenolate alone. If remission is maintained on mycophenolate alone for 2 months, the dosage is halved for an additional 2 months, and, barring recurrence, then is discontinued. Animals that relapse after discontinuation of mycophenolate are reinduced with a short course of prednisone; mycophenolate (10 mg/kg PO q 12-24 h) then is continued for life. Side-effects of mycophenolate are generally mild (diarrhea) and dosage related; hematologic side-effects are uncommon.

For cats that require additional immunosuppression, chlorambucil may be administered along with corticosteroids. Chlorambucil is given to cats at 15 mg/m^2 (4 mg dose for most cats) PO q 24 h for 4 days and repeated every 3 weeks. Alternatively, 2 mg chlorambucil (total dose) may be administered every 2-3 days. Potential side effects include anorexia and bone marrow suppression; blood counts should be monitored periodically. In cats, the dosage of chlorambucil should be tapered before the prednisone is tapered.

Lack of response or inability to taper corticosteroids while maintaining remission should prompt consultation with an internal medicine specialist. Alternative immunosuppressants may include azathioprine, cyclosporine, chlorambucil, cyclophosphamide, or leflunomide.

One therapeutic approach in dogs included prednisone (1-2 mg/kg PO q 24 h) combined with levamisole (2-5 mg/kg, max 150 mg PO q 48 h).[13] The prednisone was tapered and discontinued after 2 months, while levamisole was given continuously for 4 months and then stopped. If there was relapse of disease, levamisole was readministered for a further 4-month period. Approximately 75% of dogs treated with such therapy were reported to attain remission. Side-effects included agranulocytosis, excited behavior, and aggression.[42]

In humans, an antimalarial drug such as hydroxychloroquine can provide additional relief. Antimalarial agents have multiple sun-blocking, antiinflammatory, and immunosuppressive effects, although their mechanism of action is not understood completely.[61] Their use has not been reported in dogs or cats with SLE.

Marked proteinuria (urine protein/creatinine ratio >2 with normal serum creatinine, or >0.5 if serum creatinine is elevated) should be treated with a protein-restricted diet supplemented with omega 3 fatty acids, enalapril (0.5 mg/kg PO q 12-24 h), and aspirin (1 mg/kg PO q 24 h; caution if corticosteroids are concurrently administered).[62] Blood pressure should be monitored in proteinuric patients, who can be prone to systemic hypertension (see ch. 99). Corticosteroids promote a transient or persistent increase in proteinuria, and their effect should be considered when monitoring. Localized skin lesions can respond to topical corticosteroids or tacrolimus.

Prognosis

The natural course of SLE in veterinary patients is difficult to predict and is variable. Patients can remain well controlled and medications tapered; however, relapses should be anticipated. Routine evaluation should include complete blood count (CBC), serum biochemistry profile, urinalysis, and possibly a serum ANA titer every 1-3 months. The titer of ANA could correlate with clinical severity and fall with clinical improvement, but the antibody might persist at low titer during clinical remission. It has been suggested that therapy should be more aggressive when the clinical presentation includes renal disease.[42] The outcome for lupus nephritis is highly variable, ranging from asymptomatic proteinuria to rapidly progressive glomerulonephritis. Monitoring for change of renal function is important for SLE patients.

CHAPTER 206

Nonneoplastic Diseases of the Spleen

David John Argyle, Robert T. O'Brien

"Spleen is like the tongue of an ox [or] the sole of the foot; slightly bowed out on the left side, a little concave on the inner side, toward the stomach. It has an uneven surface and is a little rough with some tubercles…."

William Harvey, Lectures on the Whole of Anatomy (1653)

For many years, the ability to laugh was for long considered a sign that the spleen was working well. Regarded as the repository of the most noxious substance of the body—black bile (in Greek: *melanos kholis*), the spleen prevented the onset of melancholia by containing the bodily fluid that produced this mental state. Understanding of the spleen has greatly improved over the last several centuries. However, clinical evaluation of this organ remains mostly morphologic, based on palpation, diagnostic imaging, and especially ultrasound examination, followed by cytology or histopathology. No biochemical tests have been designed to assess splenic function. Consequently, although splenomegaly is common in clinical practice, identifying the cause can often be a clinical challenge.

Prevalence

The prevalence of splenic disorders cannot be easily estimated in dogs and cats. Splenomegaly can be asymptomatic, and in the absence of splenomegaly, it is difficult to determine, on the basis of clinical signs, that the spleen is responsible for the animal's condition. Most prevalence studies in dogs and cats are based on either necropsy or biopsies. Necropsy-based studies overestimate diseases with a poor prognosis or with no clinical relevance. Diseases that are treated by surgery are overestimated in prevalence studies based on biopsies but are underestimated in prevalence studies based on necropsy data. This might explain the absence of hemangiosarcoma and the low hemangiosarcoma/hematoma ratio found in necropsy studies in dogs. Based on biopsies submitted to a regional diagnostic laboratory from 1372 dogs[1] and 455 cats,[2] spleen samples from dogs represented 1.3% of all submissions to the laboratory, whereas spleen samples from cats represented 0.3%. However, these percentages do not represent true prevalence because biopsies from all species were included in the total submission number.[1]

In two necropsy surveys, nonneoplastic diseases represented approximately 50% of feline splenic disorders.[2,3] Congestion, lymphoid hyperplasia, capsulitis, extramedullary hematopoiesis, and hyperplastic nodules accounted for more than 50% of the cats with nonneoplastic splenic disease. Unfortunately, those were pathologic descriptions, with the underlying disease not apparent in many cases. In two retrospective studies that looked at prevalence of arrhythmias in dogs with splenic masses,[4,5] hematomas were found in 17%[5] to 44%[4] of the cases. In a prospective study that looked at prevalence of arrhythmias in dogs undergoing splenectomy, 38% of the dogs had neoplasia and 32% had hematomas.[6] Nodular hyperplasia, immune-mediated disease unresponsive to medical therapy, and splenic torsion each accounted for 10% of the cases. Nodular hyperplasia, hematoma, extramedullary hematopoiesis, congestion, and lymphoid hyperplasia were the most common nonneoplastic lesions found in the spleens of dogs at necropsy or on biopsies.[1,7-9] In a lifetime study of Beagles chronically exposed to radioactive radium and strontium, splenic abnormalities were present in 105 of the 865 dogs. Hyperplastic nodules with or without hematoma and diffuse lymphoreticular hyperplasia accounted for 66% of the splenomegalies found in these dogs.

Thus, the ratio of nonneoplastic to neoplastic splenic disease in dogs varies among studies. Populations that included all cases of splenomegaly or masses[1,8] show a higher than 50% prevalence of nonneoplastic diseases. A higher prevalence of tumors is found in populations subjected to splenectomy[6,9] and in dogs with splenic masses and arrhythmias.[4,5] Nonneoplastic masses, therefore, are as common as neoplastic masses in the spleen of dogs.

Clinical Manifestations

Owner complaints for dogs and cats with splenic disorders are usually vague, and these signs may arise from the underlying disease. Common complaints include vomiting, anorexia, weakness, collapse, abdominal enlargement, and weight loss (Box 206-1). Polyuria and polydipsia may occur; the mechanism is unclear, but it resolves after splenectomy. Clinical signs are usually related to abdominal distention from a mass, uniform splenomegaly or intraabdominal bleeding. Lethargy and collapse may occur due to hypovolemia, arrhythmias, or anemia.

Box 206-1

Clinical Signs of Splenic Disease in Dogs and Cats

Abdominal distension
Palpation indicating:
- Splenomegaly
- Splenic mass*

Intraabdominal bleeding*
Arrhythmias
Nonspecific signs and signs of the underlying disorder
- Lethargy
- Weakness
- Collapse
- Anorexia
- PU-PD
- Diarrhea
- Pale mucous membranes
- Jaundice

PD, Polydipsia; *PU,* polyuria.

*Signs suggestive of a splenic tumor.

Signs related to the underlying disorder may also be present (Box 206-1). Ventricular tachyarrhythmias appear to be highly prevalent in dogs with splenic masses (hematoma, hemangiosarcoma or leiomyosarcoma),[4-6] particularly if the mass has ruptured.[6] Dogs subjected to splenectomy, regardless of the reason, are also prone to arrhythmias during and after surgery (see ch. 248).[6]

The most reliable clinical sign of splenic disease is palpable splenomegaly. However, not all splenomegalies are abnormal. Breed variations in spleen size exist, particularly in dogs. German Shepherds have large spleens and some other breeds (e.g., Miniature Schnauzer, Cocker Spaniel, Greyhounds) may have their spleens located more caudally in the abdomen artificially making them feel enlarged.[10] It is important to remember that not all enlarged spleens are palpable.

The major laboratory abnormalities accompanying splenic disease are related to the underlying systemic illness. Changes in blood cell counts may be due to the primary disease or caused by the abnormal spleen. Erythrocyte counts are usually normal or decreased, but can be increased in patients with splenomegaly associated with polycythemia vera.[11] Schistocytosis, which is highly indicative of a neoplastic splenic disorder, was observed in 23% of patients with splenic tumors but only in 3% of dogs with nonneoplastic disease.[9] Granulocyte and platelet counts also can be decreased, normal, or increased (see ch. 58 and 59).

Extramedullary hematopoiesis can occur in the spleen. Because the spleen maintains the ability for hematopoiesis but does not retain the normal inhibitory mechanisms present in the bone marrow, it releases young blood cells into the circulation.[12] Increases in nucleated red blood cells and immature white blood cells (leukoerythroblastic effect) may appear in the peripheral blood in patients with splenic disorders.

Diagnostic Approach

Splenomegaly can be detected by physical examination, abdominal radiographs, ultrasound or by advanced

imaging techniques such as computed tomography (CT) or magnetic resonance imaging (MRI). Although splenomegaly can be identified during palpation, the severity of the enlargement cannot be reliably assessed in dogs with this technique alone. Differentiating between a splenic mass (localized splenomegaly with at least one large mass) and diffuse splenomegaly (uniform enlargement of the spleen) helps to narrow the number of potential diagnoses (Box 206-2). Fine-needle aspiration of the spleen may provide the final diagnosis or characterize the type of inflammation present. However, this should never be performed without appropriate imaging to ensure there is little or no risk of major bleeding from a blood-filled tumor. A sequential approach to diagnose the origin of splenomegaly is shown in Figure 206-1.

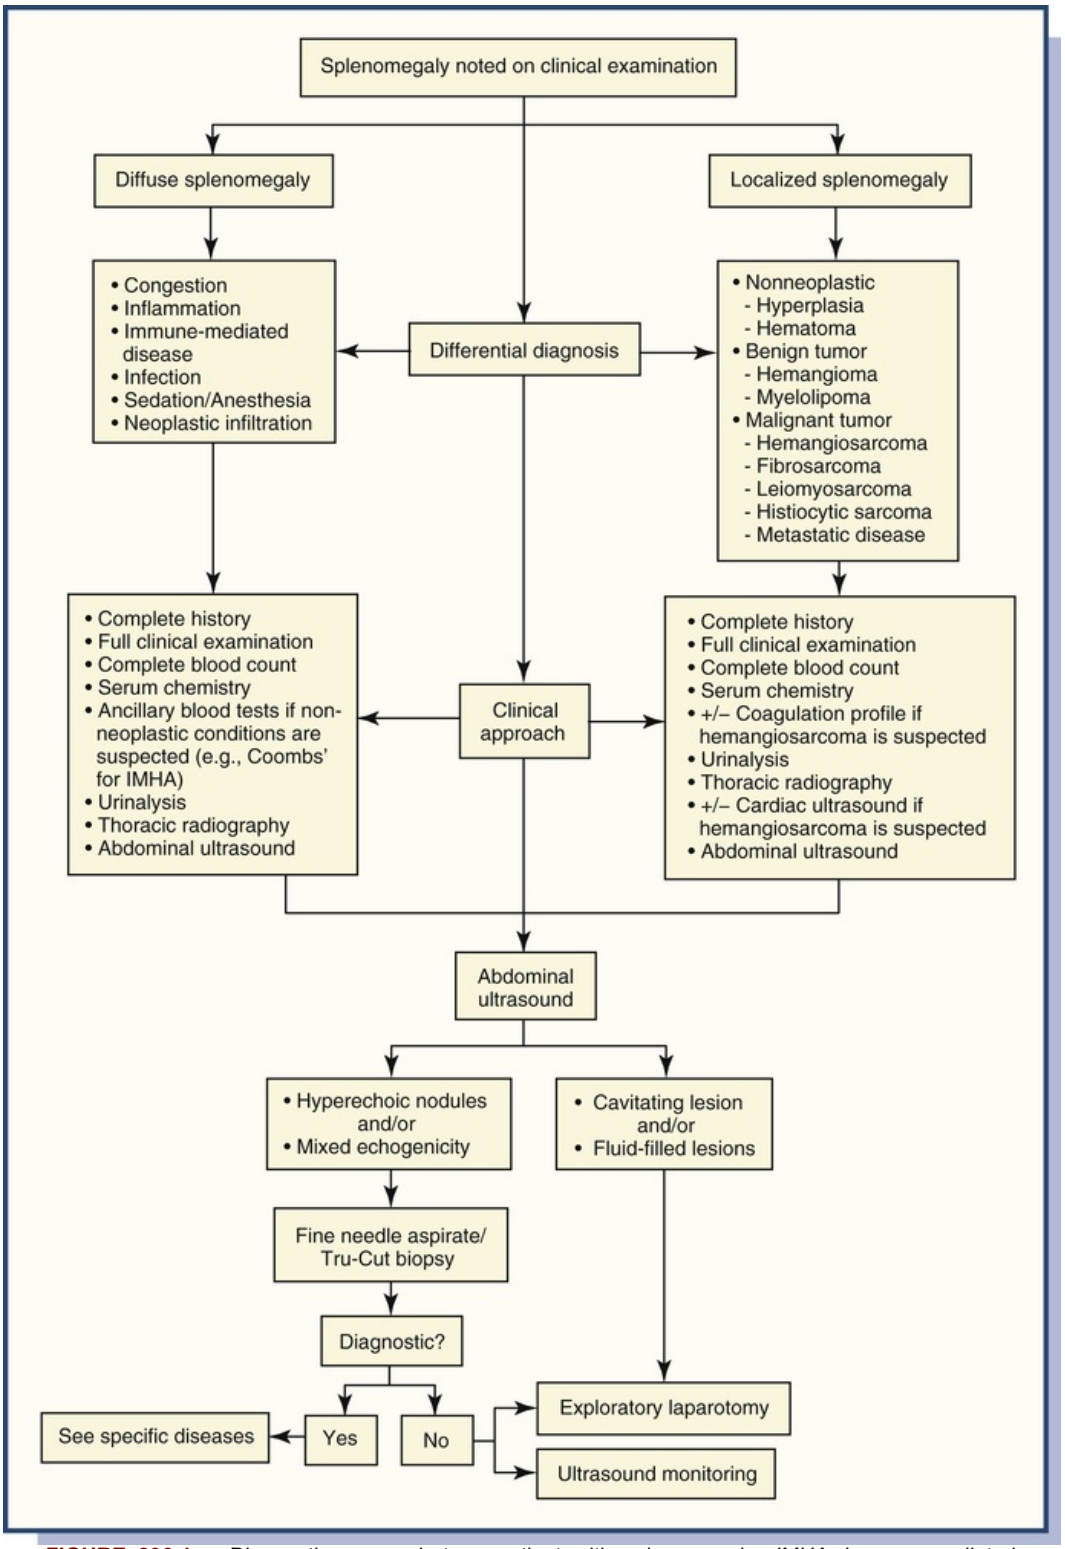

FIGURE 206-1 Diagnostic approach to a patient with splenomegaly. *IMHA,* Immune-mediated hemolytic anemia.

Abdominal Radiography

Radiographically, the spleen is apparent in both the dog and cat. The dorsal extremity (head) is commonly seen on ventrodorsal projections in the cranial left abdomen caudal to the gastric fundus and cranial to the left kidney, along the left body wall. On this projection, the splenic head is triangularly shaped. The body of the

spleen may be directed transversely across the abdomen immediately caudal to the stomach, along the left body wall, or anywhere in between. In dogs, the ventral aspect (tail) is often seen along the ventral body wall immediately caudal to the liver in the lateral projection. Distension of the stomach may caudally displace the tail. The tail of the spleen is uncommonly seen in cats.

Generalized splenomegaly may increase splenic length. The spleen may also fold up from the ventral wall, extending to varying lengths up the right body wall or expand more caudally towards the urinary bladder. In the cat, visualization of the splenic tail along the ventral body wall supports a diagnosis of splenomegaly. Alternatively, with generalized enlargement or focal masses, the spleen produces a mass effect, displacing the intestines caudally. The spleen is a very common origin for masses in the midcranial and left cranial abdomen. Atypical splenic location, with changes in shape, may occur in dogs with splenic torsion. Concurrent peritoneal effusion is common. Lesions rarely cause changes in splenic radiopacity.

Abdominal Ultrasonography

Ultrasonography is a very effective tool for evaluation of the size, shape, and vascular supply of the spleen (see ch. 88). There are no objective criteria for normal splenic size. As a rule, cats have much smaller spleens than do dogs of similar size. Normal variations in dogs include capsular invagination (hyperechoic foci adjacent to splenic veins), a bent spleen, or a portion folded back upon itself. Generalized isoechoic enlargement may be a normal variation in German Shepherds and other dog breeds and in some cats. Overall spleen length and evidence of intestinal displacement are the criteria used to assess for splenomegaly. A true decrease in splenic size (microsplenia) may occur with acute anemia due to contraction of the spleen. Ultrasonography is more sensitive than radiography for detecting alterations in the shape and outer margination of the spleen. Irregularities in shape and focal changes in echogenicity are the major criteria for characterization of splenic disease in dogs and cats.

Nodular disease is easily detected in the middle and tail regions of the spleen. Often the head of the spleen is within the rib cage, and masses in the dorsal extremity may require a rigorous examination with an intercostal approach. Benign masses may be hypoechoic, hyperechoic, or of mixed echogenicity. Benign masses cannot be differentiated from malignant masses solely based on gray-scale ultrasonography. Extramedullary hematopoiesis and nodular hyperplasia (Figure 206-2), which are common regenerative lesions, are usually hypoechoic and are seen in the spleen of older dogs. These lesions are much less common in cats.

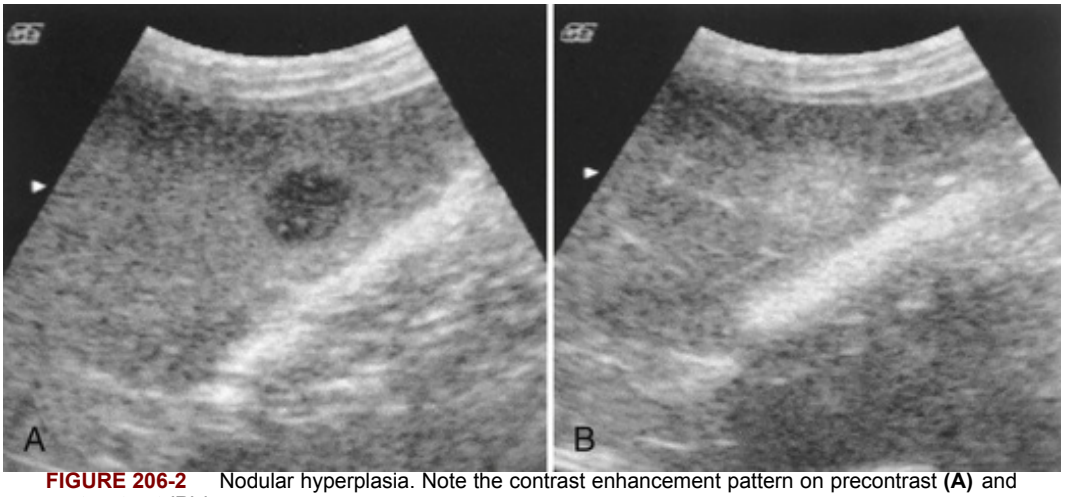

FIGURE 206-2 Nodular hyperplasia. Note the contrast enhancement pattern on precontrast **(A)** and postcontrast **(B)** images.

Certain lesions have a more characteristic sonographic appearance. Myelolipoma, a benign tumor seen in older dogs, is both very echogenic and attenuating. The result is a classic hyperechoic and indistinctly shadowing lesion (Figure 206-3). Unlike with mineralization, the attenuation is not complete, and the internal architecture of the lesion can be seen to varying depths.

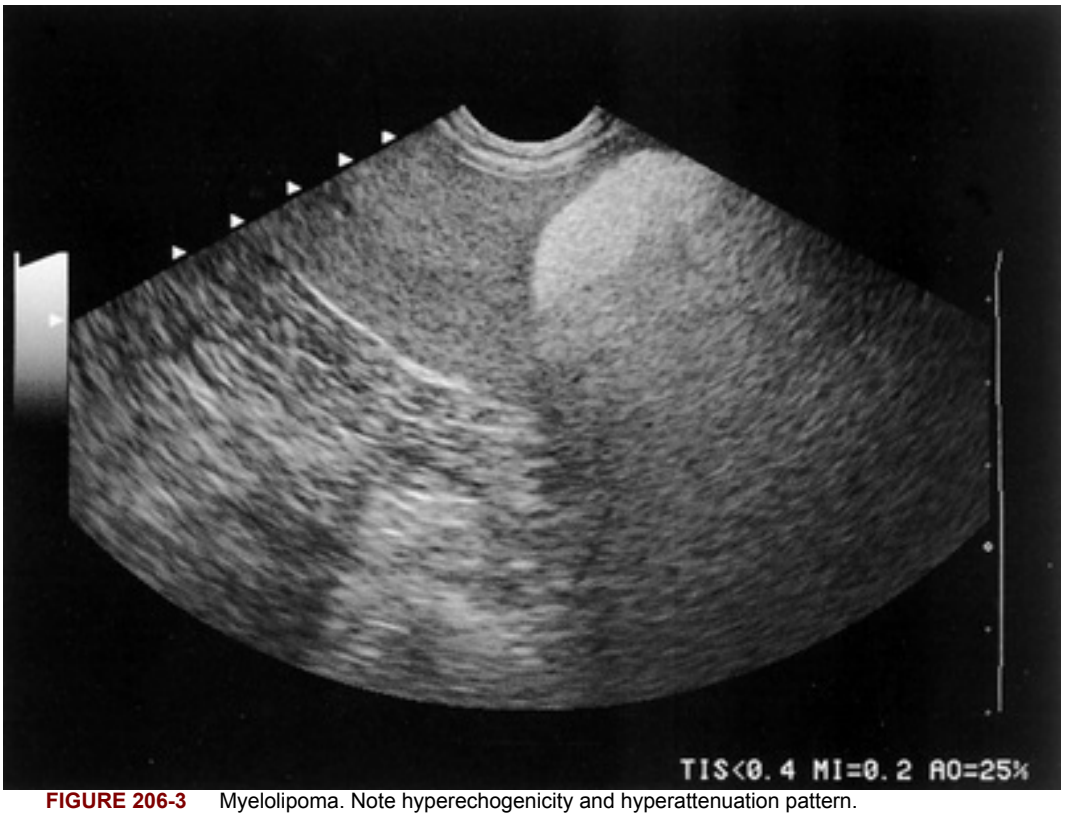

FIGURE 206-3 Myelolipoma. Note hyperechogenicity and hyperattenuation pattern.

The spleen has a predisposition for vascular disease because it is attached at only one pole and is prone to harbor diffuse neoplasia. Splenic torsion and diffuse tumor invasion may result in uniform diffuse hypoechogenicity or a more mixed "Swiss cheese" appearance (Figure 206-4). Doppler examination of the splenic veins is an important step to identify lack of venous return. As with portal vein flow, splenic venous flow is low-velocity and essentially nonpulsatile. Power Doppler is especially valuable, as this modality is more sensitive to very low-velocity flow. Thrombosis may occur after mechanical torsion, tumor vascular invasion, or thromboembolic diseases. Regional infarcts are commonly seen in dogs with disseminated intravascular coagulation (DIC; see ch. 197) and autoimmune conditions, such as immune-mediated hemolytic anemia (see ch. 198) and immune-mediated thrombocytopenia (see ch. 201). Infarcted regions are usually peripheral, hypoechoic, and swollen (Figure 206-5). Necrosis may be seen with chronic severe vascular disease and result in formation of free gas in the spleen and free fluid in the peritoneum.

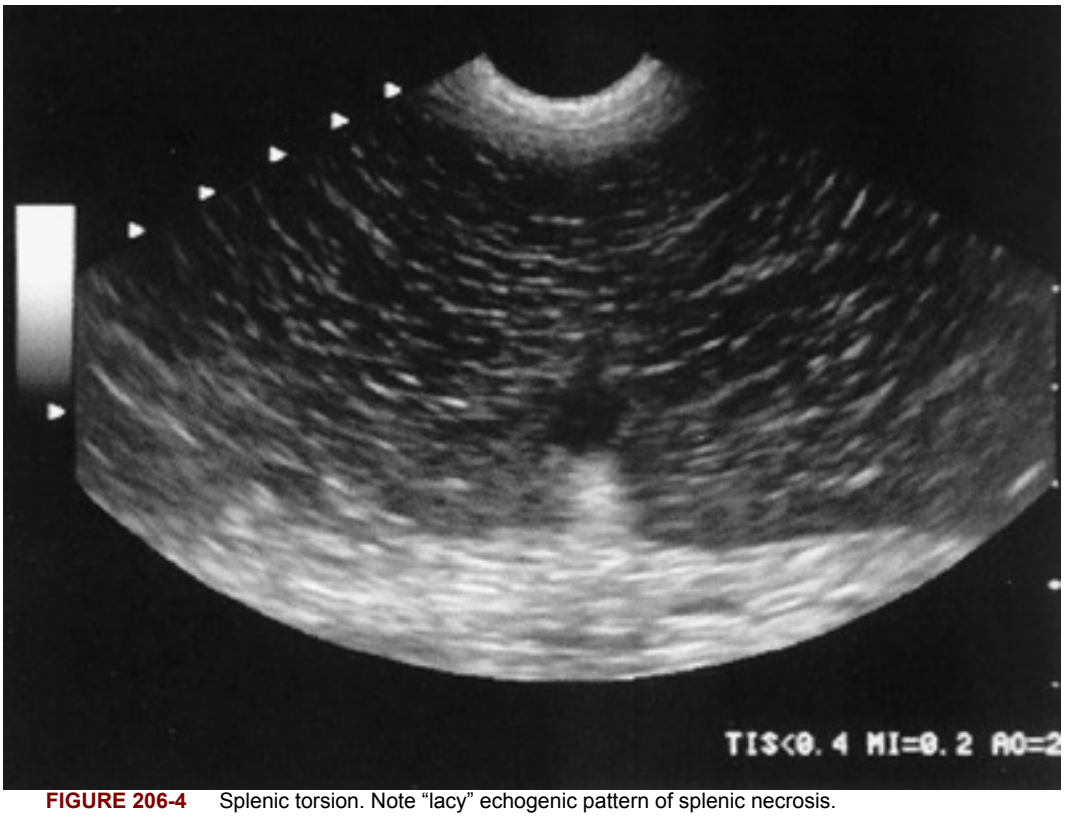

FIGURE 206-4 Splenic torsion. Note "lacy" echogenic pattern of splenic necrosis.

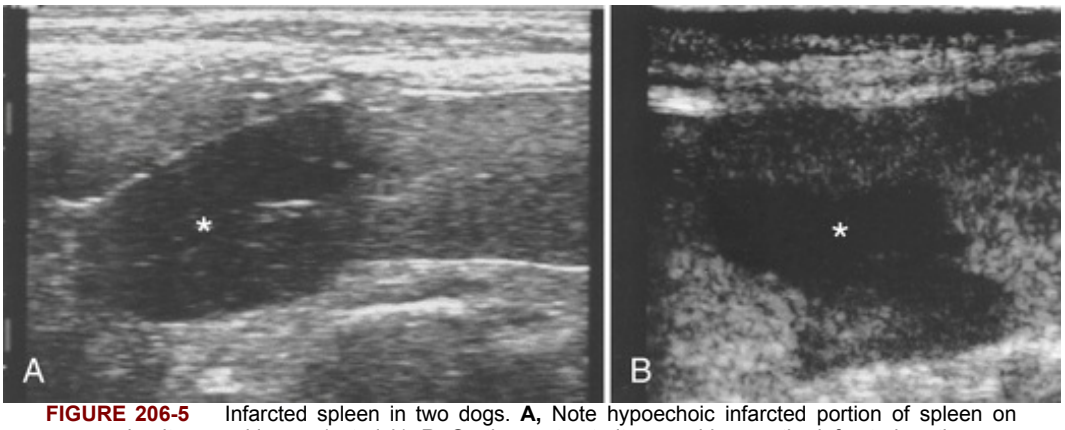

FIGURE 206-5 Infarcted spleen in two dogs. **A,** Note hypoechoic infarcted portion of spleen on gray-scale ultrasound image (asterisk). **B,** On the contrast ultrasound image, the infarcted portion was not seen on gray-scale ultrasound but was hypoechoic compared to surrounding well-perfused, contrast-enhanced spleen (asterisk).

An additional ultrasound modality for evaluation of focal nodular and vascular diseases of the spleen is contrast harmonic ultrasound. Second-generation ultrasound contrast agents are liposome-encapsulated inert gas spheres that are injected intravenously and small enough (3 to 5 microns) to pass through the pulmonary circulation without embolization. Harmonic ultrasound software technology allows detection of sound waves that are multiples of the transmitted frequency. Ultrasound contrast bubbles are very powerful generators of harmonic frequencies, and, combined with tissue signal suppression, they create a novel method to image perfusion of organs. These contrast media, which can be used as blood pool agents, will cause infarcted regions to appear hypoechoic compared to the surrounding normally perfused spleen. Preliminary studies indicate that ultrasound contrast agents may help discriminate between malignant and benign masses by exploiting differences in blood supply. Hemangiosarcomas and hematomas have a very poor overall perfusion pattern, but hemangiosarcomas have distinct tortuous feeder vessels.[13] This perfusion pattern has

been noted in hemangiosarcoma masses in the liver, lung, peritoneum, and the spleen. In the liver, metastatic nodules have a more rapid wash-in and wash-out compared to normal liver or benign liver nodules. Benign hyperplastic nodules in the spleen have good overall perfusion.

Abdominal Computed Tomography

Computed tomography can add greatly to the overall assessment of splenic disease. With the exception of contrast ultrasound, which is not widely available in the United States, contrast CT is the only modality capable of detecting perfusion deficits.[14] In addition, CT provides a more global assessment of the abdomen and can be performed on critical patients without general anesthesia in an emergency situation.[15]

The normal splenic vascular supply is through the splenic arteries, which, very soon after entering the spleen, uniquely lose any distinct vascular identity and enter the red pulp. The perfusion of the spleen is often bimodal, with the presumed red pulp enhancing regionally before the white pulp.[16,17] Timing for CT studies needs to account for this bimodal pattern, and clinicians should plan to use a protocol that will not lead to false lesions due to perfusion deficits.

Reports of the CT findings of nonneoplastic splenic lesions are sparse in the veterinary literature. Splenic infarcts are seen with any preexisting disease that causes hypercoagulability, including autoimmune disease. Infarction results in a persistent regional perfusion deficit in the splenic parenchyma (Figure 206-6). As previously noted, this needs to be verified by use of a protocol that includes a late-venous phase. Splenic torsion, based on a single case report, has a more complex combination of imaging features, including pan-splenic perfusion deficit and poor splenic arterial enhancement. Presumably, CT angiography would add significantly to the overall CT features of this disease. Abscesses of the spleen are very uncommon but can result in regional perfusion deficits and parenchymal gas. Depending on the severity and chronicity of the abscess, concurrent fat stranding, peritoneal free fluid, regional lymphadenopathy and free peritoneal gas can be seen[14] (Figure 206-7). Fat stranding is a nonspecific CT finding of a streaky appearance of the peritoneal fat that has increased water content as a result of cellular infiltration (e.g., white blood cells) or edema of the peritoneal fat. Fat stranding on CT images corresponds to regions of hyperechoic peritoneal fat on ultrasound images (Figure 206-8). The CT appearance of benign and malignant nodules has not been studied.

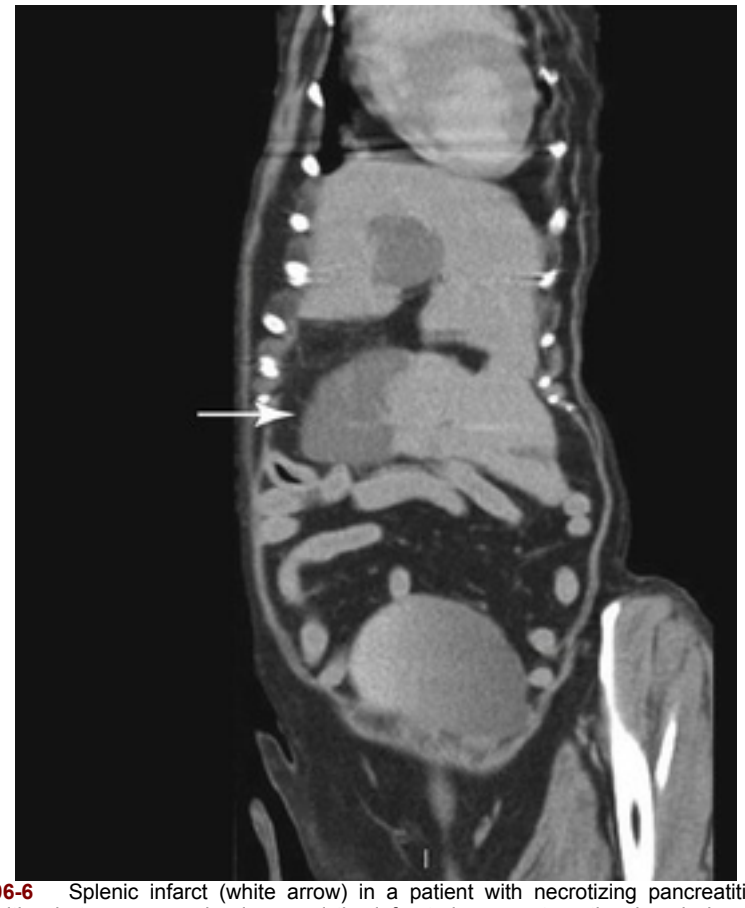

FIGURE 206-6 Splenic infarct (white arrow) in a patient with necrotizing pancreatitis. Note the abrupt transition between normal spleen and the infarcted segment on the dorsal plane multiplanar reconstruction (MPR) postcontrast CT image.

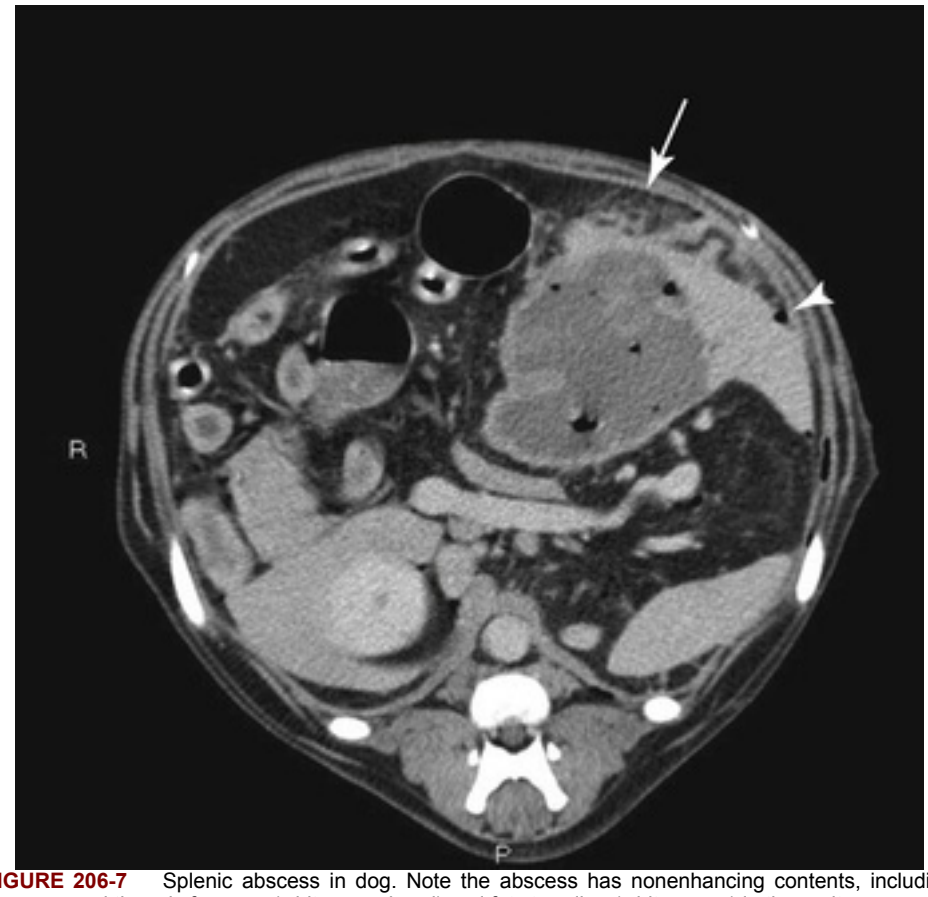

FIGURE 206-7 Splenic abscess in dog. Note the abscess has nonenhancing contents, including free gas, and there is free gas (white arrowhead) and fat stranding (white arrow) in the peritoneum.

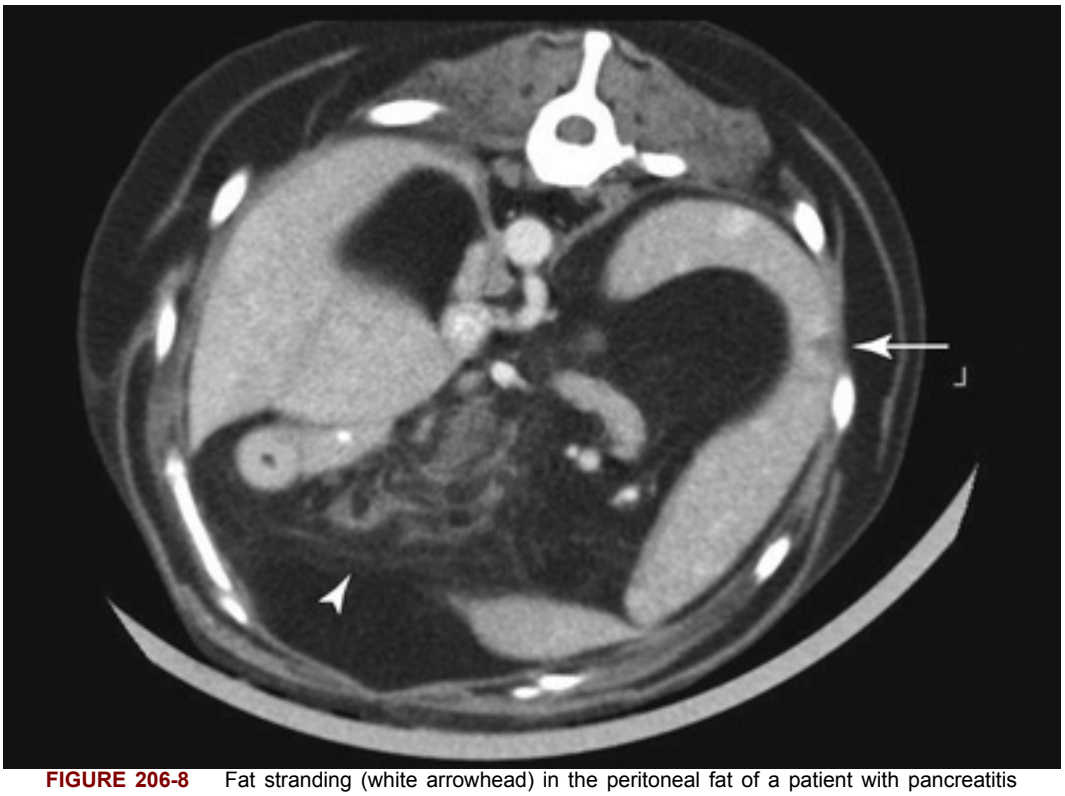

FIGURE 206-8 Fat stranding (white arrowhead) in the peritoneal fat of a patient with pancreatitis

and a small splenic infarct (white arrow).

The comparison of hemangiosarcoma and hematoma based on CT findings has been reported.[18] The most important imaging distinction across all imaging modalities, including contrast-enhanced ultrasound and contrast CT, is aberrant tortuous feeder vessels (Figure 206-9). Additionally, there was a significantly lower attenuation (Hounsfield units, HU) on both pre- and postcontrast images within the mass and greater prevalence of concurrent free peritoneal fluid in patients with malignant masses. The largest masses, relative to the overall size of the remaining normal spleen, were hematomas.

FIGURE 206-9 Tortuous feeder vessels in a patient with hemangiosarcoma of the spleen. Note curvilinear contrast enhancing vessels (white arrow) on postcontrast dorsal plane multiplane reconstruction (MPR) CT image.

Fine-Needle Aspiration

Although imaging of the spleen only rarely results in a diagnosis, an aspirate may provide a cytologic sample and the possibility of a diagnosis (see ch. 89). Core biopsy is possible but is not usually necessary. Most diseases of the spleen exfoliate well and are suitably sampled with fine-needle techniques. Splenic aspirates correctly identified the underlying problem in over 60% of cases in one study. Incorrect diagnosis occurred in 15% of the cases, and histopathology was required to distinguish between neoplastic and reactive conditions in 22% of the cases.[19] Of the fine-needle techniques, the variation that seems to provide the most cells without undue hemodilution involves no negative pressure with the attached syringe and multiple thrusting motions with the needle. With the plunger already pulled back in the barrel of the syringe prior to insertion of the needle, it thereafter is easy to expel the content of the needle by depressing the plunger. This technique works well for nodular hyperplasia and extramedullary hematopoiesis–benign nodules, metastatic carcinomas, and hematopoietic tumors. Solid sarcomas may not exfoliate well with aspiration techniques, and a core sample may provide a better result. Cavitated lesions are rarely sampled, based on the risk to the patient.

Fine-needle aspiration appears to be safe even in presence of coagulopathies or thrombocytopenia.[20] As a

general rule, all abnormal spleens that do not have cavitated lesions should be aspirated. Aspiration is not necessary in patients with splenic torsion whenever lack of adequate blood flow can be determined by Doppler ultrasonography, nor in patients with myelolipoma if only lesions with the classic acoustic properties are present. Aspiration also may not be required for patients with diffuse homogeneous splenomegaly and no clinical signs attributable to splenic disorders and in patients with a known cause of congestion (e.g., tranquilizers, portal hypertension, right-sided heart failure) or for "classic" infarct lesions in asymptomatic patients.

Fine-needle aspiration can provide the final diagnosis in neoplastic disorders or, when the organism can be identified, in infectious disease. Aspirates of normal spleen reveal small lymphocytes with occasional medium and large lymphocytes and rare neutrophils (see ch. 93). A few macrophages and plasma cells may be present.[21] Precursors of all three cell lines may be seen in patients with extramedullary hematopoiesis, but erythroid cells are more common. In hyperplasia resulting from antigenic reaction, there is an increase in medium and large lymphocytes and in macrophages and plasma cells.[21] Patients with splenitis have an increase in inflammatory cells. Identification of the predominant cell type narrows the number of potential diagnoses. Inflammation can be further characterized based on the predominant cell type as suppurative, granulomatous, pyogranulomatous, eosinophilic, or lymphoplasmacytic. The most common causes for each type of inflammation are shown in Box 206-2.

Splenic Biopsies/Splenectomy

Spleen biopsies can be obtained in patients where the primary diagnosis of a mass is not obtained by fine-needle aspiration. Care should be taken with impression smears made from spleen biopsies. Inadvertently making impressions of the capsular surface instead of parenchyma will reveal uniform sheets of loosely attached mesothelium that will be nondiagnostic.[15] Splenectomy should be considered in animals with cavitated masses without metastasis or necrosis.

Other Diagnostic Tests

In addition to imaging techniques and fine-needle aspiration, urinalysis, complete blood count, and biochemical profile are necessary in all patients with splenomegaly. Cats should be tested for infection with feline leukemia virus (FeLV; see ch. 223) and feline immunodeficiency virus (FIV; see ch. 222). Thoracic radiographs should be obtained in patients with splenic masses to rule out metastasis, and bone marrow examination may be indicated in patients with unexplained cytopathies (see ch. 92).

Common Causes of Splenomegaly in Dogs and Cats: Neoplastic Diseases

In both the dog and the cat, the spleen can be the site for both malignant and benign tumors as well as nonneoplastic disease. In dogs, around two thirds of splenic masses are diagnosed pathologically as neoplastic. Of these lesions, around one half to two thirds are diagnosed as hemangiosarcoma. In cats, around one half of splenic lesions submitted for pathologic examination are diagnosed as neoplastic. Tumors of the spleen usually present either as localized or diffuse splenomegaly and can be confused with nonneoplastic conditions. The actual clinical features of primary splenic tumors can be very vague, except in cases of splenic rupture and bleeding.

Malignant Tumors of the Canine Spleen

Hemangiosarcoma

Hemangiosarcoma (see ch. 347) is a highly malignant tumor arising from the vascular endothelium. It is most common in the larger breeds of dog (especially German Shepherd), with the median age of affected dogs being 10 years. The most common primary site of hemangiosarcoma in the dog is the spleen, but it can also affect cutaneous sites. Around 25% of dogs with splenic hemangiosarcoma also have concurrent hemangiosarcoma affecting the right atrium.[22,23]

The classical presentation of hemangiosarcoma in dogs is that of a solitary cavitated lesion that bleeds, causing hemoperitoneum and sudden-onset hypovolemic collapse (see ch. 143). Dogs often present with sudden-onset collapse, pallor, tachycardia and tachypnea, and distended abdomen. Abdominocentesis (see ch. 90) reveals frank hemorrhage. If possible, a platelet count and clotting profile should be performed.

Approximately 50% of dogs that present with abdominal bleeding are in DIC (see ch. 197). Anemia and thrombocytopenia are common. Reticulocytosis and polychromasia may occur depending on when the bleed took place. A peripheral blood smear may reveal schistocytosis as red cells shear as they course through the tortuous lesion in the spleen (microangiopathic hemolytic anemia).[24-27]

Diagnosis and Clinical Staging

Dogs with hemoperitoneum and concurrent hematologic changes such as schistocytosis and thrombocytopenia with concurrent anemia should carry a high suspicion for hemangiosarcoma. Clinical staging to determine the nature and extent of disease should include three-view thoracic radiography (right and left lateral views and dorsoventral), complete blood count and serum chemistry, coagulation profile, cardiac and abdominal ultrasound, and potentially exploratory laparotomy (see ch. 347). The World Health Organization staging system for canine hemangiosarcoma is given in Box 206-3.[28] The only way to definitively diagnose hemangiosarcoma is by histopathology following splenectomy. Even at surgery, distinguishing between hemangiosarcoma or hemangioma is impossible morphologically. Cytology is often unrewarding, and the gross appearance of the spleen is often a poor indicator of the underlying disease. Large hematomas or benign hemangiomas can have an identical "appearance" to hemangiosarcoma at surgery, and no decision should be taken on euthanasia during surgery unless there is evidence of gross metastatic disease. To achieve a good pathologic diagnosis, it is also important to submit the most appropriate samples to the pathologists. If the pathologist is not on site, then it will be difficult to submit a spleen in its entirety, as it will not properly fix in formalin. In addition, multiple sites need to be sampled and fixed because the spleen will also contain multiple areas of hemorrhage and fibrosis that grossly may look like tumor. Large samples can be sliced like a loaf of bread to ensure even penetration of formalin.

Box 206-3

The World Health Organization Staging System for Canine Hemangiosarcoma

Primary Tumor (T)

T0	No evidence of tumor
T1	Tumor confined to spleen
T2	Tumor confined to spleen but ruptured
T3	Tumor that is invading adjacent structures

Regional Lymph Node (N)

N0	No regional lymph node involvement
N1	Regional lymph node involvement
N2	Distant lymph node involvement

Distant Metastasis (M)

M0	No evidence of distant metastasis
M1	Distant metastasis

Stages

I	T0 or T1, N0, M0
II	T1 or T2, N0 or N1, M0
III	T2 or T3, N0, N1 or N2, M1

From Wood CA, Moore AS, Gliatto JM, et al.[28]

Treatment

The treatment of choice for primary splenic hemangiosarcoma is splenectomy (see ch. 347). Dogs that present in acute hypovolemic shock are not surgical candidates and should be stabilized before surgery is contemplated (see ch. 127). Often dogs present following one major bleed, but if bleeding does not continue, these patients will auto-transfuse and become better surgical candidates over the subsequent 24-hour period. It is noteworthy that around 20% of dogs can develop ventricular arrhythmias associated with splenic tumors. Dogs should be monitored electrocardiographically before and during surgery and in the immediate postoperative period (see ch. 103). In some of these dogs, arrhythmias can be difficult to control until the spleen has been surgically removed.[29,30]

Splenectomy will relieve abdominal distension caused by the tumor and prevent any further bleeding. However, the role of surgery alone in improving survival is difficult to determine because of the rapid onset of metastasis. The most common cause of death in dogs is metastasis, and many chemotherapy protocols have been described as adjunctive therapies to improve survival. Survival time following surgery with or without chemotherapy is shown in Table 206-1.[31-41] Overall, the prognosis should be considered poor even with adjunctive chemotherapy. Although stage is considered a negative prognostic factor for survival, a recent study exploring the use of VAC protocol for stage III hemangiosarcoma demonstrated no significant differences between dogs with stage I/II and III disease.

TABLE 206-1

Survival Times for Dogs Treated for Splenic Hemangiosarcoma

TREATMENT	MEDIAN SURVIVAL TIMES
Splenectomy alone (stage 1 or 2)	86 days
Splenectomy plus VAC*	164 days
Splenectomy plus AC*	179 days
Splenectomy plus doxorubicin	60 days if evidence of gross disease after splenectomy
	172 days if no evidence of further disease

*Stage unknown.

AC, Doxorubicin, cyclophosphamide; *VAC*, vincristine, doxorubicin, cyclophosphamide (plus chlorambucil and methotrexate).

Adapted from Murphy and Brearley.[42]

The most promising improvements in survival came from a study that combined both chemotherapy (doxorubicin and cyclophosphamide) and liposome-encapsulated muramyl tripeptides (LMTP) as an immunotherapy. LMTP is a nonspecific biologic that enhances macrophage activation. In this study, the median survival time improved from 179 days (chemotherapy alone) to 273 days.[43] At the time of writing, LMTP is no longer available for veterinary use. However, recently a European license was granted for Mifamurtide (Mepact), an LMTP developed for use in children and adolescents with osteosarcoma. The use in veterinary patients with this product is limited by cost and availability at the current time.

Nonangiomatous, Nonlymphoid Sarcomas of the Spleen

Fibrosarcoma, leiomyosarcoma, myxosarcoma, osteosarcoma, liposarcoma, and undifferentiated sarcoma have all been described as primary splenic malignant tumors (see ch. 346). Unlike hemangiosarcoma, the clinical signs associated with these tumors are usually vague and typically involve progressive anorexia and lethargy. In rare cases where the tumor has become large, it may result in splenic torsion.

The treatment of choice is surgery, with no large-scale clinical trials describing the benefits of adjunctive chemotherapy. As a group, a median survival time following splenectomy is reported to be around 4 months, but there is a large variation depending on tumor type. The mitotic index at histopathologic examination has prognostic implications. Tumors with a mitotic index less than 9 have a better prognosis that those with an

index greater than 9.

Histiocytic Sarcoma

Canine histiocytic disorders represent a range of diseases that are a diagnostic and therapeutic challenge (see ch. 350). This disease is most common in the Bernese Mountain Dog and Retriever breeds but has been reported in a number of other breeds. The spleen can be a site for primary histiocytic sarcoma or a site of dissemination from malignant histiocytosis. Primary splenic histiocytic sarcoma has been associated with a hemophagocytic syndrome characterized by a Coombs'-negative anemia due to erythrophagia by malignant histiocytes. Whether primary or part of a secondary disease complex, histiocytic disease associated with the spleen carries a poor prognosis. Dogs will often die from disseminated disease even after splenectomy. Lomustine (CCNU) or liposome-encapsulated doxorubicin have been suggested as adjunctive therapies, but large-scale clinical studies are still lacking.[44-47]

Benign Tumors of the Canine Spleen

A number of benign tumors have been reported in the canine spleen. In general, these carry a good prognosis with long survival times following splenectomy. Myelolipomas are tumors containing a mixture of adipose tissue and hematopoietic tissue (see Figure 206-3). Lipomas are benign fat tumors that may affect the spleen. Hemangiomas are benign tumors arising from the vasculature. They can be distinguished from hemangiosarcoma only on histopathology. Splenectomy is considered curative.[48,49]

Metastatic Tumors of the Canine Spleen

As well as being a site for primary neoplasia, the spleen is also a site for secondary tumor deposits or infiltrates. Notable among these are lymphoma, leukemias, multiple myeloma, primary erythrocytosis (polycythemia vera), high-grade metastatic mast cell tumors, and carcinomas. The management of secondary splenic tumors revolves around management of the underlying primary malignancy and usually involves systemic chemotherapy.

Malignant Tumors of the Feline Spleen

Mast Cell Tumor (See Ch. 349)

In cats, the spleen is a common site for primary mast cell tumor and mast cell tumor represents the most common differential for splenic disease in the cat. There is no sex predilection, but it tends to occur in cats in the older age range (>10 years). Although the spleen appears to be the primary site of the tumor, other organ systems are often affected, including liver, lungs, bone marrow, lymph nodes and intestine. Some cats will have pleural or peritoneal effusions that are rich in mast cells. Mastocytosis is common. Typically, these patients present with a history of dullness and lethargy, progressive anorexia, occasional vomiting (histamine release), and diffuse splenomegaly on clinical examination.[50,51]

Diagnosis is usually made by ultrasound-directed fine-needle aspirate of the spleen. The treatment of choice is splenectomy, with a mean survival time of around 12 to 18 months following surgery. However, this is a high-risk surgery because excessive handling of the spleen could lead to massive histamine and heparin release leading to shock and ultimately death. Presurgical therapy with antihistamines, careful surgical technique, and proper anesthetic monitoring are essential for success. Following surgery, the mastocytosis usually clears without any chemical therapy. Adjunctive use of chemotherapy is controversial, with no large-scale clinical studies proving their benefit.[50]

Feline Splenic Hemangiosarcoma

Compared to the canine disease, feline splenic hemangiosarcoma is rare (see ch. 347). Cats with this condition will normally present with nonspecific clinical signs such as anorexia, weight loss, and vomiting. Very rarely will cats have hypovolemic shock and collapse. There is a paucity of feline cases reported in the literature, although those that have been described have been associated with metastatic disease. A median survival of 20 weeks following surgery has been reported. There are no large-scale clinical studies showing the benefit of chemotherapy following surgery.[52]

Other Malignant Tumors

As with dogs, other primary sarcomas (e.g., fibrosarcoma) have been reported but are very rare. Treatment of choice is surgery, and there is no information on the use of adjuvant therapies. Histiocytic sarcoma of macrophage origin has been reported in the cat but is very rare and, like the dog, carries a poor prognosis.[53]

Benign Tumors of the Feline Spleen

A number of benign tumors have been reported in the feline spleen. In general these carry a good prognosis with long survival times following splenectomy. These include hemangiomas, which are benign tumors arising from the vasculature. Splenectomy is considered curative.

Metastatic Tumors of the Feline Spleen

The feline spleen can be a site for both primary neoplasia and for secondary tumor deposits or infiltrates. Notable amongst these are lymphoma, leukemias, multiple myeloma (rare in cats), and carcinomatosis. The management of secondary splenic tumors revolves around management of the underlying primary malignancy and usually involves systemic chemotherapy.

Common Causes of Splenomegaly in Dogs and Cats: Nonneoplastic Diseases

Generalized splenomegaly occurs not only with tumor infiltration but also may be caused by congestion, splenic hyperplasia/extramedullary hematopoiesis, inflammation, or cellular infiltration. Splenic masses are usually due to neoplasia, hematoma, abscess, or nodular hyperplasia.

Congestion

Congestion is commonly seen as a consequence of sedation or anesthesia, portal hypertension, or splenic vein thrombosis. Administration of phenothiazine sedatives (e.g., acepromazine) or ultrashort-acting barbiturates (e.g., thiopental) produces substantial splenomegaly. Splenomegaly can be severe because up to 30% of the blood volume can be pooled in the spleen. Administration of propofol to dogs, however, did not produce statistically significant splenomegaly.[54]

Congestion can also be secondary to portal hypertension with hepatic disease and systemic venous hypertension in right-sided heart failure or intrathoracic caudal vena cava compression. Chronic congestion of the spleen may lead to splenic hyperplasia. No changes in echogenicity were subjectively noted in congested spleens, although significant increased attenuation and a trend towards increased backscatter (echogenicity) were noted.[54] Diffuse changes in splenic echogenicity in patients with a known cause of congestion, therefore, are likely due to another underlying condition.

Splenic pedicle torsion is a special cause of congestion in dogs. It usually develops in large, deep-chested dogs, especially the German Shepherd and Great Dane.[55] Males represented 79% of the cases in one study.[55] Acute torsion causes profound systemic signs with shock and abdominal discomfort, whereas chronic torsion is associated with vague signs including vomiting, anorexia, lethargy, and icterus. Radiographically, a decrease in abdominal detail, displacement of other abdominal organs, and loss of visualization of the body of the spleen in the left cranial quadrant of the abdomen are seen in the ventrodorsal view. In the lateral view, the spleen is enlarged, is abnormally positioned or shaped, and may have intrasplenic gas.[56] Ultrasonographically, the spleen is diffusely enlarged and abnormally located. It is usually hypoechoic, with decreased flow through splenic veins. In one study, intravascular thrombi could be identified in 50% of the cases (see Figure 206-4).[55] CT imaging of the spleen during torsion is described above.[57] Supportive therapy should be instituted immediately in these patients and the spleen removed surgically. If appropriately treated, splenic torsion carries a favorable prognosis.[55]

Splenic Infarction

Infarcts can be observed in patients in hypercoagulable states associated with liver disease, renal disease, or hyperadrenocorticism.[58] The most common cause is immune-mediated disease such as autoimmune hemolytic anemia and thrombocytopenia. It also can occur with preexisting uniform splenomegaly[20] or splenic torsion.[56] Splenic infarction is a sign of abnormal coagulation or blood flow, and the clinical signs are

related to the underlying cause. Ultrasonographically, infarct regions are usually peripheral and are visible as hypoechoic, swollen areas (see Figure 206-5). After contrast injection, they appear hypoechoic when compared to the surrounding, normally-perfused spleen. Infarcted regions may resolve with appropriate therapy of the underlying disease.

Splenic Hyperplasia/Extramedullary Hematopoiesis

The splenomegaly seen with splenic hyperplasia and extramedullary hematopoiesis reflects "work hypertrophy" resulting from removal of abnormal blood cells from circulation, increased activity of mononuclear phagocytic and lymphoid cells, and increased blood cell production. In immune-mediated hemolytic anemia and thrombocytopenia, the spleen serves as a site of antibody production and also as an important site of removal of antibody-sensitized cells. Chronic increased destruction of red blood cells in some non–immune-mediated hemolytic diseases also appears to cause hyperplastic splenomegaly in dogs and cats.[59] Chronic antigen stimulation by infectious agents (e.g., bacterial endocarditis), blood parasites, or immune-mediated disease can stimulate hyperplasia of mononuclear phagocytic and lymphoid cells.

In work hypertrophy, the spleen is uniformly enlarged and may be hypoechoic on ultrasonographic examination. Cytologically, small lymphocytes still predominate, but there is an increase in medium- and large-sized lymphocytes, and plasma cells are commonly observed.[59]

Extramedullary hematopoiesis (EMH) may accompany splenic hyperplasia in patients with concomitant anemia, thrombocytopenia, or leukopenia. It is a very common cytologic diagnosis in dogs with uniform splenomegaly[14] and may also occur with a variety of splenic neoplasms. EMH is also common in cats; it was diagnosed in 21% of cats in one study.[60] A nodular pattern is more common in cats with EMH. The presence of nucleated red blood cells in peripheral blood suggests EMH. Cytologically, precursors of all three cell lines may be observed in this condition.[59] A finding of hematopoietic precursors with large numbers of vacuoles in the background suggests the presence of a myelolipoma rather than EMH.[59]

Nodular Hyperplasia/Hematoma

Nodular hyperplasia is a nonneoplastic regional proliferation of component cells normally found in the parenchyma of the canine spleen.[61] Nodular hyperplastic lymphoid proliferation is the most common form in dogs, but it is not common in cats.[1,2] A high percentage of splenic lesions in dogs have features of hematomas and nodular hyperplasia, which suggests that these disorders may be different stages of the same process. Lymphoid elements are usually observed with superimposed hematomas.[1] It has been suggested that marginal zoning distortion caused by nodular hyperplasia disrupts regional splenic blood flow in and around the hyperplastic nodule, eventually leading to hematoma formation.[1] Cats have a "nonsinusal" type of spleen and a different architecture and blood flow pattern of the intermediate circulation bordering the white pulp.[2] Those differences could render the feline spleen less vulnerable to disrupted blood flow and hematoma formation.

Nodular hyperplastic lesions are usually hypoechoic on ultrasonographic examination (see Figure 206-2). Splenic hematomas in dogs are associated with large splenic masses. A history of trauma is rare.[62] Most dogs with splenic hematoma are relatively healthy and do not have acute splenic rupture,[59] although they may develop hemoabdomen.[63] Large hyperplastic nodules and splenic hematoma cannot be differentiated from hemangiosarcoma grossly. Splenectomy is the treatment of choice for hematomas and hyperplastic nodules large enough to cause splenomegaly.[62]

A particular variation of hyperplastic nodule in dogs is the fibrohistiocytic nodule.[61] Nodular fibrohistiocytic proliferation is characterized by a mixed population of histiocytoid or spindle cells intertwined with hematopoietic elements, plasma cells, and lymphocytes. These nodules appear to form a continuum between lymphoid nodular hyperplasia and malignant splenic fibrous histiocytoma.[61] Histologically, the lymphoid: fibrohistiocytic ratio is the most important predictor of survival in these dogs. A higher proportion of lymphoid to fibrohistiocytic-type cells was associated with increased long-term survival.[61]

Inflammatory Splenomegaly

Inflammatory splenomegaly (splenitis) is a uniform splenomegaly usually secondary to infection. In addition

to the inflammatory response associated with hyperplasia, patients with splenitis also have increases in other inflammatory cells. It is important to classify the splenitis according to the predominant cell type because different etiologic agents are associated with different types of inflammation. Some overlap exists, and the same organism can cause a different inflammatory response in a different patient. For example, lymphoplasmacytic splenitis has been observed in patients with feline infectious peritonitis, histoplasmosis, and blastomycosis. Care must be taken in diagnosing suppurative splenitis in patients with peripheral neutrophilia or eosinophilic splenitis in patients with peripheral eosinophilia. The most common causes of splenitis according to the predominant inflammatory response are listed in Box 206-2. Infectious agents that can cause splenitis or lead to splenomegaly by chronic antigen stimulation, disturbances of blood flow, or by causing chronic anemia are listed in Box 206-4.

Box 206-4

Infectious Causes of Splenomegaly/Splenitis*

Viral

Feline immunodeficiency virus (C)
Feline infectious peritonitis (C)
Feline leukemia virus (C)
Infectious canine hepatitis (D)
Systemic calicivirosis (C)

Rickettsial and Mycoplasmal

Ehrlichiosis and anaplasmosis (C, D)
Hemotropic mycoplasmosis
Q fever *(Coxiella burnetii)*
Rocky Mountain spotted fever *(Rickettsia rickettsii)*

Bacterial

Bacteremia
Bartonellosis
Brucellosis (D)
Endotoxemia
Florida borreliosis
Lyme borreliosis
Melioidosis
Salmonellosis
Tularemia

Mycobacterial

Nocardiosis
Plague

Fungal

Blastomycosis
Cryptococcosis
Histoplasmosis
Sporotrichosis
Opportunistic infections
  Paecilomycosis
  Monocillium indicum (D)
  Systemic candidiasis

Protozoal

Babesiosis
Cytauxzoonosis (C)
Hepatozoonosis (*Hepatozoon canis*, D)

Leishmaniasis
Toxoplasmosis
Trypanosomiasis
C, Cats; *D*, dogs.

*Infectious disease may affect the spleen directly or cause splenomegaly by causing chronic anemia, chronic antigen stimulation or disturbances in blood flow (e.g., endotoxemia).

The Patient With A Splenic Nodule

Splenic nodules without associated splenomegaly are a relatively common finding in older dogs undergoing abdominal ultrasound for unrelated reasons. Most splenic nodules in this age group are benign and might require no further action. Myelolipomas can be easily identified, whereas lymphoid hyperplasia, EMH, and splenic infarcts may be more difficult to differentiate from an early neoplastic lesion. Further diagnostics should be attempted in breeds with high risk for hemangiosarcoma, patients with systemic tumors likely to involve the spleen (e.g., lymphoma, hemangiosarcoma), hematologic abnormalities, fever, or other signs of systemic infectious disease.[63] Fine-needle aspiration should be attempted in all splenic nodules (see ch. 89). The main risk associated with the procedure is contamination of abdominal cavity with tumor cells in case of hemangiosarcoma. Hemangiosarcoma is not likely to manifest itself as one or a few small nodules, but it may be a risk in predisposed breeds. A more conservative approach involving repeating the ultrasonographic examination in 4 weeks has been suggested.[27] Any increase in size in the nodule over this period should then be pursued aggressively. It should be remembered that a change in diameter from 1.0 to 1.2 cm is associated with a doubling in volume for a spherical mass.[63]

General Management of A Patient With Splenic Disease

Diffuse splenomegaly is usually managed medically. Most diseases that cause diffuse splenomegaly are systemic, and treatment should be directed at the underlying cause. Splenic torsion in dogs is the exception to the rule. A few tumors and myeloproliferative disease can also benefit from removal of the spleen. Splenectomy can also be considered in patients with immune-mediated anemia or thrombocytopenia refractory to therapy. It is important to demonstrate bone marrow hyperplasia in the cell line with decreased peripheral numbers before splenectomy is performed. Spleen removal is the treatment of choice for patients with splenic masses.

Removal of the spleen may predispose the patient to infections. Splenectomized humans are more likely to die of sepsis, but this predisposition has not yet been confirmed in dogs and cats. A few organisms that infect blood cells (e.g., babesiosis, hemotropic mycoplasmosis, and ehrlichiosis) are known to occur more in splenectomized patients. Ideally, dogs and cats should be tested before splenectomy and treated accordingly if infected.

CHAPTER 207

Laboratory Diagnosis of Infectious Disease

Michael R. Lappin

There are two primary methods for diagnosing infectious diseases: detection of the organism or detection of antibodies against the organism. Infectious agents are detected in biological specimens most frequently by culture, cytology, fecal examination, histopathology, immunologic techniques, and nucleic acid amplification techniques. Polymerase chain reaction (PCR) assay and reverse transcriptase PCR (RT-PCR) assay are the most commonly used nucleic acid amplification techniques. Detection of the organism gives the most information supporting a clinical diagnosis of an infectious disease, but these assays are neither available nor optimal for all agents. Thus, antibody detection is still commonly used to aid in the diagnosis of some infectious diseases. In some clinical situations, the combination of organism detection and antibody detection assays is indicated.

When evaluating the results of infectious disease diagnostic tests, the *analytical sensitivity* defines the minimum detectable amount of the substance in question that can accurately be measured; the *analytical specificity* defines whether the substance detected cross-reacts with other substances. The *diagnostic sensitivity* is the proportion of positive test results from known infected animals; the *diagnostic specificity* is the proportion of negative test results from known uninfected animals. The *predictive value of a positive test* (PPV) is the probability that a test-positive animal is diseased; the *predictive value of a negative test* (NPV) is the probability that a test-negative animal is normal. The lower the prevalence of disease, the lower the PPV. Disease prevalence has little effect on negative predictive values.

Sensitivity, specificity, PPV, and NPV vary with each assay. Many of the infectious disease agents encountered in small animal practice colonize normal animals, as well as induce disease in some individuals. For example, the DNA of "*Candidatus* M. haemominutum" can be amplified from the blood of approximately 20% of healthy cats and rarely is associated with illness.[1] Thus, when DNA of "*Candidatus* M. haemominutum" is amplified from the blood of a cat with anemia of fever, the test result alone does not prove the agent is the cause of the clinical signs (PPV <100%). Thus, veterinarians generally need to use a combination of findings to aid in the clinical diagnosis of an infectious disease:

- Appropriate signalment and history for the infectious agent suspected
- Clinical signs referable to the agent
- Detection of the agent (cytology, culture, antigen assay, PCR assay) or antibodies against the agent
- Exclusion of other causes of the clinical syndrome
- Response to an appropriate treatment[2]

When these criteria are met, the suspected infectious agent might have been the cause of the clinical disease. However, it is always possible that the disease process resolved in spite of the therapy prescribed.

The following is a discussion of some of the most common infectious disease organism detection and antibody detection techniques used in small animal practice. Also see the individual chapters of the textbook for each infectious agent for more detailed information.

Organism Detection

Culture

Culture can be used to document the presence of some bacteria, rickettsia, fungi, viruses, and protozoans in biologic specimens. However, some bacteria (e.g., hemoplasmas) have never been cultured, and many rickettsia, viruses, and protozoans are difficult to culture. Thus, PCR assays are now being used frequently to document these infections (see Nucleic Acid Amplification section). However, for many bacteria and fungi, culture is still the optimal way to document infection. For example, for most aerobic bacterial diseases, culture

is superior to PCR assay because antimicrobial susceptibility testing can be used to determine optimal drug therapy.

In small animal practice, aerobic bacterial culture is used most frequently. To minimize organism death or overgrowth of normal flora, the material to be cultured should be collected without contamination, the material should be transported to the laboratory as quickly as possible in the most appropriate medium, and the most appropriate culture materials should be used. For routine aerobic bacterial culture, swabs containing transport medium should be used if a delay of greater than 3 hours is expected. If cultures are not to be started within 4 hours, the swabs should be refrigerated (or transported with cold packs) to inhibit bacterial growth; some bacteria will grow more rapidly than others, potentially masking fastidious organisms. Most aerobes will survive at 4° C (routine refrigeration temperature) in tissue or on media-containing swabs for 48 hours. Routine aerobic culture is generally successful on fluid samples (e.g., urine, airway washings) stored at 20° C for 1 to 2 hours, 4° C for 24 hours, or 4° C for 72 hours if placed in transport medium. See the bacterial endocarditis (ch. 251) and *Bartonella* spp. (ch. 215 and 216) chapters of the textbook for a discussion of optimal blood culture techniques.

If feces are to be cultured for *Salmonella* spp. or *Campylobacter* spp., the laboratory should be provided approximately 2 to 3 g of fresh feces for optimal results. A transport medium should be used if a delay is expected. The laboratory should be notified of the suspected pathogen so that appropriate culture media can be used. *Tritrichomonas foetus* and *Giardia* spp. can also be cultured from feces but these techniques are rarely performed because antigen assays (*Giardia* spp.) or PCR assays (both organisms) are now widely available (see ch. 276).[3-5] In addition, it has now been shown that culture is not specific for *T. foetus* and that PCR should be considered to speciate prior to treatment.[3]

In certain situations, anaerobic, *Mycoplasma* spp., *Mycobacterium* spp., or fungal culture may also be indicated. Solid-phase transport media that will support the growth of most aerobes, anaerobes, *Mycoplasma* spp., *Mycobacterium* spp, and fungi for several days if refrigerated are available. Amies medium or modified Stuart bacterial transport medium are also often used to transport materials for *Mycoplasma* spp. culture. *Mycoplasma* and *Ureaplasma* cultures are most commonly performed on airway washings, synovial fluid, and exudates from chronic draining tracts in cats, urine from animals with chronic urinary tract disease, and the vagina of animals with genital tract disease. *Mycobacterium* spp., *Mycoplasma* spp., *Bartonella* spp., and fungal culture may be indicated if pyogranulomatous inflammation is present. Most commercial laboratories do not provide *Mycoplasma* spp., *Mycobacterium* spp., anaerobic bacterial, or fungal antimicrobial susceptibility testing, so positive samples should be saved for transport to specialized laboratories as indicated.

In-house culture systems are available for cutaneous fungal agents. Materials from dogs or cats with suspected systemic fungal infection can be transported to the laboratory as described for bacteria, and the laboratory can be told specifically that fungal culture is needed. The mycelial phase of some systemic fungi like *Blastomyces dermatitidis* and *Histoplasma capsulatum* occurs in culture and can infect humans, so in-house culture for these agents is not recommended.

Viral agents can be isolated from tissues or secretions at some laboratories. However, for most routine viral infections of dogs and cats, PCR or RT-PCR assays to amplify RNA viruses are now available (see Nucleic Acid Amplification section).

Cytology and Histopathology

Cytologic evaluation of exudates (see ch. 74), bone marrow aspirates (see ch. 92), blood smears, synovial fluid (see ch. 74 and 94), gastric brushings (see ch. 113 and 275), duodenal secretions (see ch. 113 and 275), urine (see ch. 72), prostatic washings (see ch. 111), airway washings (see ch. 101), fecal smears (see ch. 81), tissue imprints (see ch. 93), and aspiration biopsies (see ch. 89) is an inexpensive and extremely valuable tool for the documentation of current infections. For demonstration of most blood-borne infectious agents, thin smears are preferred. Cells in airway washings, prostatic washings, urine, aqueous humor, and cerebrospinal fluid (CSF) should be pelleted by centrifugation at 2000 × g for 5 minutes before staining. Multiple slides should always be made. After being placed on the microscope slide, the material is air-dried at room temperature, fixed if indicated by the procedure used, and stained. Slides that are not stained immediately should be fixed by dipping in 100% methanol and air-dried. Cytologic specimens can be stained with routine stains; immunocytochemical techniques for certain pathogens are available (see Immunologic Techniques). Stains routinely used for the diagnosis of infectious diseases in small animal practice include Wright-Giemsa stain, Diff-Quik, Gram stain, and acid-fast stain.

One slide for cytologic evaluation is generally stained initially with Wright-Giemsa or Diff-Quik stains. If bacteria are seen (Table 207-1), Gram stain is applied to another slide to differentiate Gram-positive and

Gram-negative agents that can be used to aid in the empiric selection of antibiotics.

TABLE 207-1

Characteristic Cytologic Morphology of Common Small Animal Bacteria

AGENT	MORPHOLOGIC CHARACTERISTICS
Actinomyces spp.	Gram-positive, acid-fast–negative filamentous rod within sulfur granules
Anaerobes	Usually occur in mixed morphologic groups
Bacteroides fragilis	Thin, filamentous, Gram-negative rods
Campylobacter spp.	Seagull-shaped spirochete in feces
Chlamydia felis	Large, cytoplasmic inclusions in conjunctival cells or neutrophils
Clostridium spp.	Large, Gram-positive rods
Clostridium perfringens	Large, spore-forming rods in feces
Hemoplasmas*	Rod- or ring-shaped on the surface of red blood cells
Helicobacter spp.	Tightly coiled spirochetes in gastric or duodenal brushings
Mycobacterium spp.	Intracytoplasmic acid-fast rods in macrophages or neutrophils
Nocardia spp.	Gram-positive, acid-fast–positive filamentous rod within sulfur granules
Leptospira spp.	Spirochetes in urine; dark-field microscopy required (see ch. 217)
Yersinia pestis	Bipolar rods in cervical lymph nodes or airway fluids

*_Mycoplasma haemofelis_, "_Candidatus_ M. haemominutum," and "_Candidatus_ M. turicensis" infect cats, and _M. haemocanis_ and "_Candidatus_ M. haematoparvum" infect dogs.

Actinomyces (nonacid-fast) and *Nocardia* (generally acid-fast) can be differentiated by acid-fast staining characteristics. If pyogranulomatous inflammation is present, acid-fast staining is indicated to assess for *Mycobacterium* spp. within the cytoplasm of macrophages.

The hemoplasmas (see Table 207-1 and ch. 219), some rickettsial agents (Table 207-2; *Anaplasma* spp., *Ehrlichia* spp.), and some protozoans (*Babesia* spp., *Cytauxzoon felis*) can be noted on cytologic examination of thin blood smears. However, organism numbers can fluctuate and so cytology can be falsely negative. Wright-Giemsa stain is the best stain to use in practice for these organisms. Hemoplasmas can leave the surface of the red blood cell when the blood is placed into EDTA. Thus, making thin blood smears immediately with blood that has not been placed into anticoagulant may give optimal results (Figure 207-1). Collection of blood from an ear margin vessel for blood smear cytology may improve the likelihood of detecting *Ehrlichia* spp. (Figure 207-2) or *Anaplasma* spp. morulae (Figure 207-3) within white blood cells.

TABLE 207-2

Characteristic Cytologic Morphology of Common Small Animal Rickettsial Agents

AGENT	MORPHOLOGIC CHARACTERISTICS
Anaplasma phagocytophilum	Clusters of Gram-negative bacteria (morulae) in neutrophils and eosinophils
Anaplasma platys	Clusters of Gram-negative bacteria (morulae) in platelets
Ehrlichia canis	Clusters of Gram-negative bacteria (morulae) in mononuclear cells
Ehrlichia chaffeensis	Clusters of Gram-negative bacteria (morulae) in mononuclear cells
Ehrlichia ewingii	Clusters of Gram-negative bacteria (morulae) in neutrophils
Neorickettsia risticii	Clusters of Gram-negative bacteria (morulae) in mononuclear cells

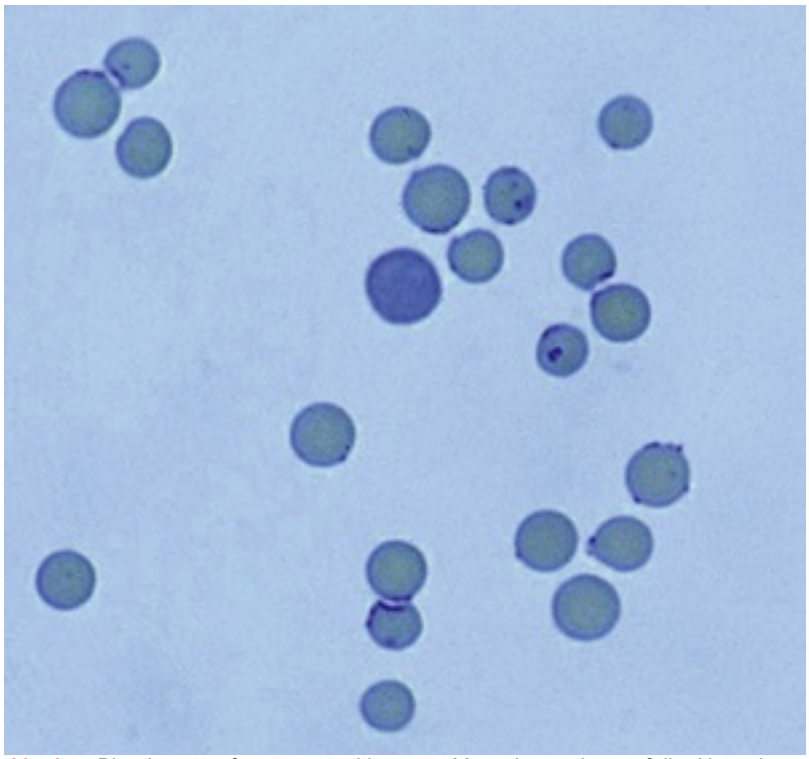

FIGURE 207-1 Blood smear from a cat with acute *Mycoplasma haemofelis.* Note the epicellular location of the organisms (1000×).

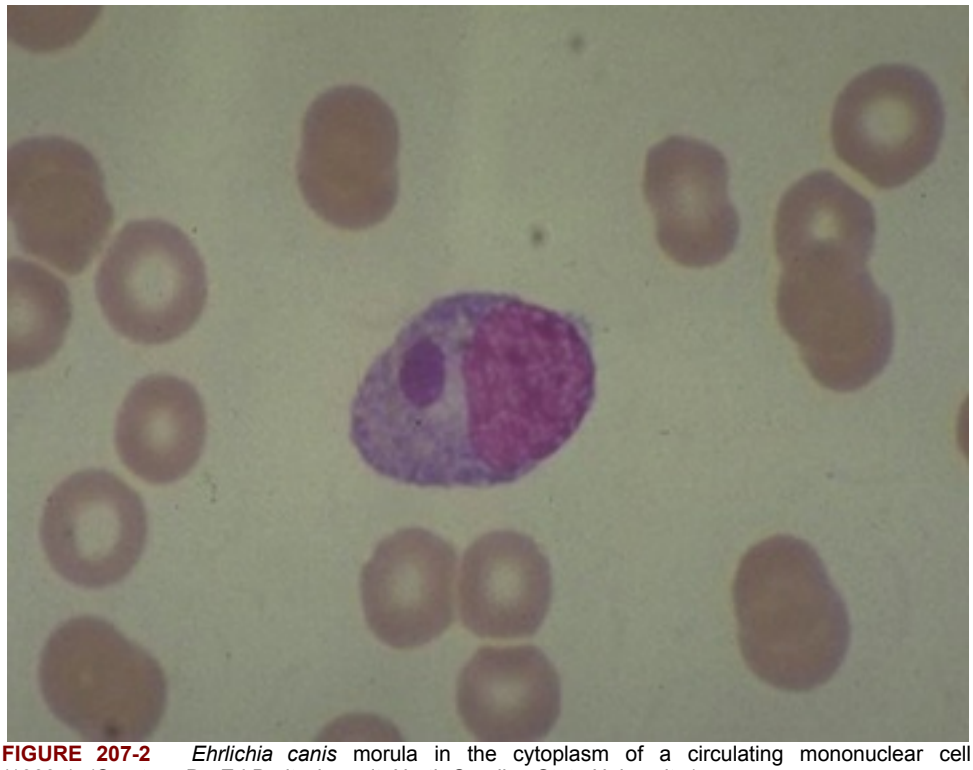

FIGURE 207-2 *Ehrlichia canis* morula in the cytoplasm of a circulating mononuclear cell (1000×). (Courtesy Dr. Ed Breitschwerdt, North Carolina State University.)

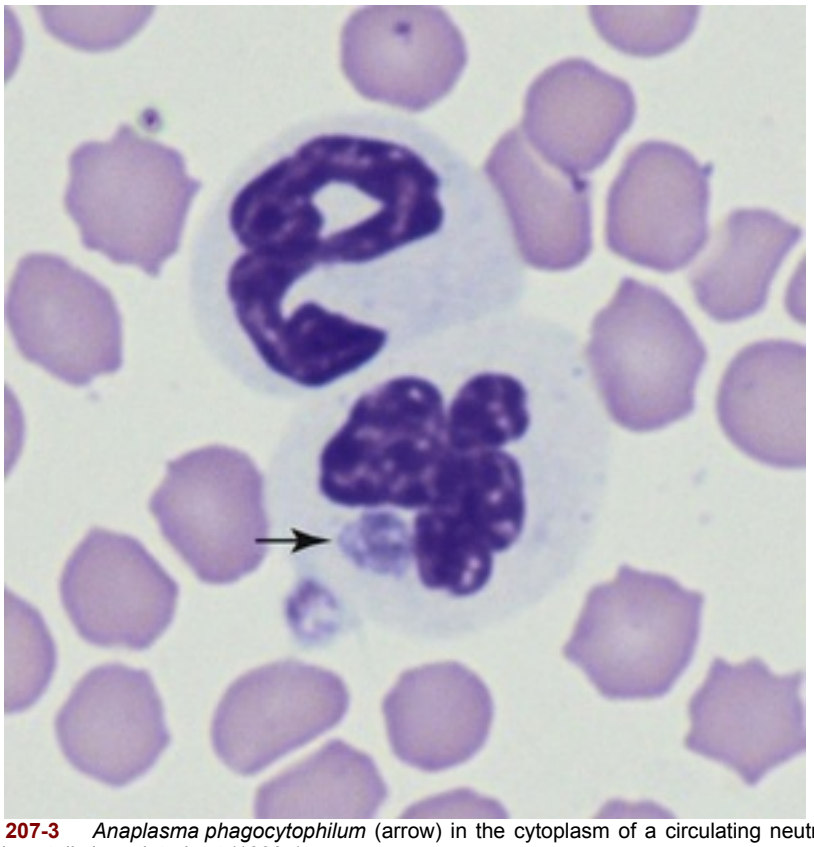

FIGURE 207-3 *Anaplasma phagocytophilum* (arrow) in the cytoplasm of a circulating neutrophil of an experimentally inoculated cat (1000×).

While a definitive diagnosis may not be made with the following techniques, fecal or rectal cytology can be considered for all dogs and cats with diarrhea to help guide the diagnostic or therapeutic plan. A small amount of fecal material should be collected from the surface of the feces or the wall of the rectum by cotton swab, which is rolled on a microscope slide multiple times to give areas with varying smear thickness. After air-drying, the slide is generally stained with Diff-Quik stain and examined for white blood cells and bacteria morphologically consistent with *Campylobacter* spp. (spirochetes; Figure 207-4) or *Clostridium perfringens* (spore-forming rods; Figure 207-5). It is also possible that *H. capsulatum* or *Prototheca* may be observed in the cytoplasm of mononuclear cells. Other stains can be applied to aid in identification of the enteric protozoans (see ch. 221).

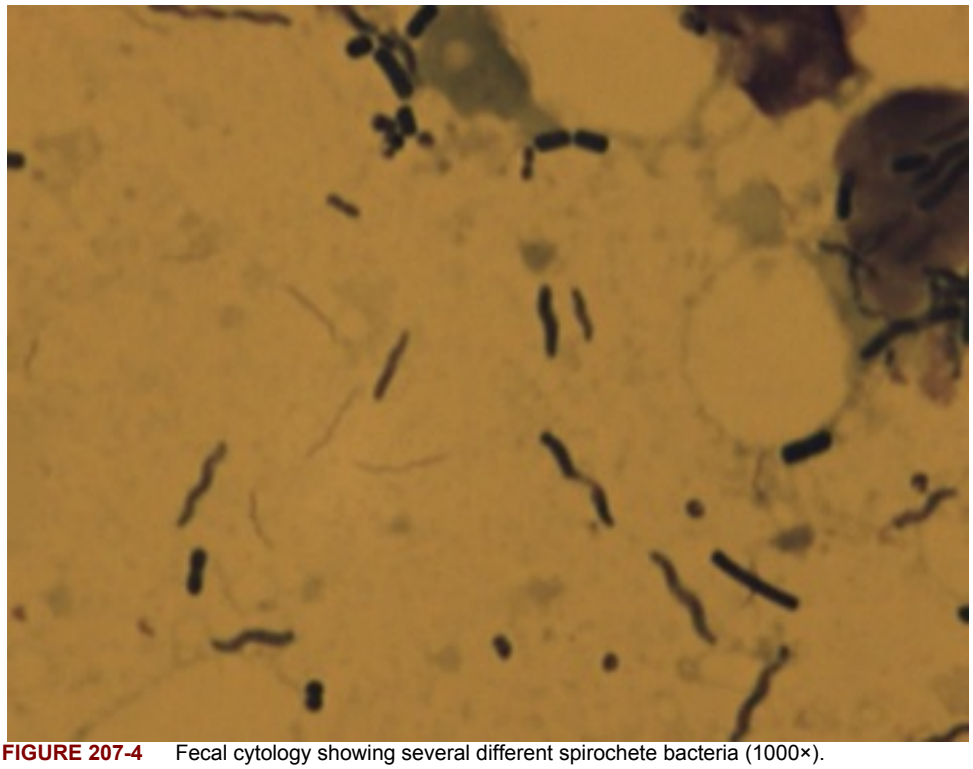

FIGURE 207-4 Fecal cytology showing several different spirochete bacteria (1000×).

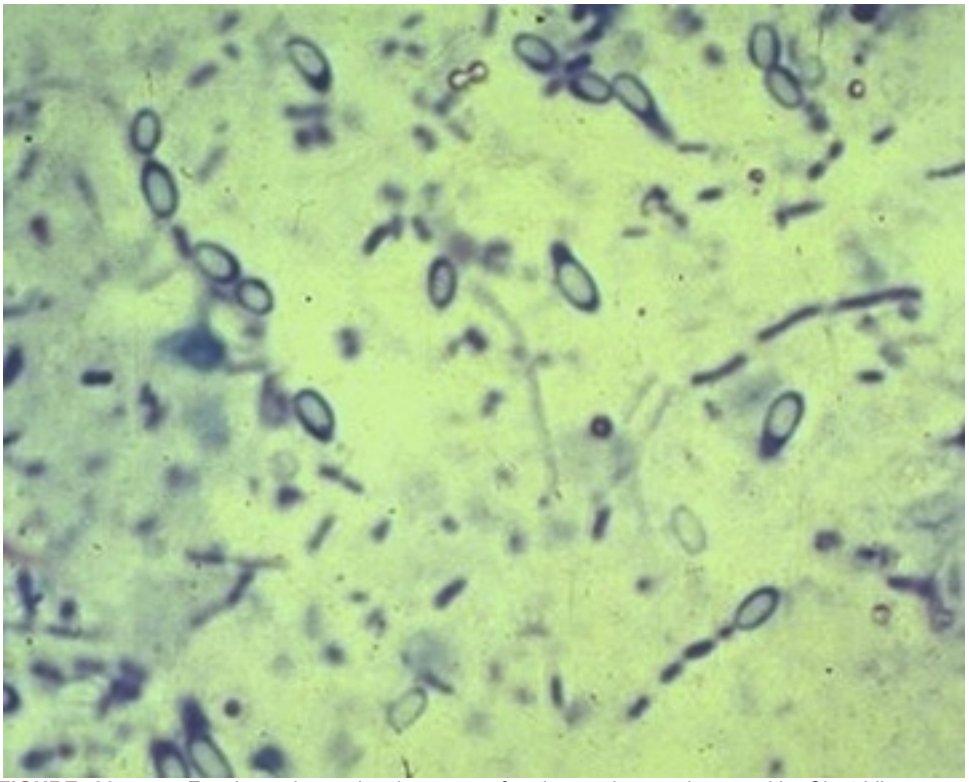

FIGURE 207-5 Fecal cytology showing spore-forming rods consistent with *Clostridium* spp. (1000×).

Arthrospores and conidia of dermatophytes can be identified cytologically. Hairs plucked from the periphery of a lesion are covered with 10% to 20% potassium hydroxide on a microscope slide to clear debris.

The slide is then heated but not boiled, and it is examined for dermatophytes. All dogs or cats with chronic, draining skin lesions should have imprints of the lesions made and evaluated cytologically for the presence of fungal organisms (Table 207-3). This is very important if *Sporothrix schenckii* is on the differential list, as this organism is capable of zoonotic transmission to people (Figure 207-6 and ch. 236).[6]

TABLE 207-3

Characteristic Cytologic Morphology of Small Animal Systemic Fungal Agents

AGENT	MORPHOLOGIC CHARACTERISTICS
Blastomyces dermatitidis	Extracellular yeast, 5 to 20 microns in diameter, thick, refractile double-contoured wall, broad-based bud; routine stains are adequate
Cryptococcus neoformans	Extracellular yeast, 3.5 to 7 microns in diameter, thick unstained capsule, thin-based bud, violet color with light red capsule with Gram stain, unstained capsule with India ink
Coccidioides immitis	Extracellular spherules (20 to 200 microns in diameter) containing endospores, deep red to purple double outer wall with bright red endospores with periodic acid–Schiff stain
Histoplasma capsulatum	Intracellular yeast in mononuclear phagocytes, 2 to 4 microns in diameter, basophilic center with lighter body with Wright's stain
Sporothrix schenckii	Intracellular yeast in mononuclear phagocytes, 2 to 3 microns × 3 to 6 microns in diameter; round, oval, or cigar-shaped

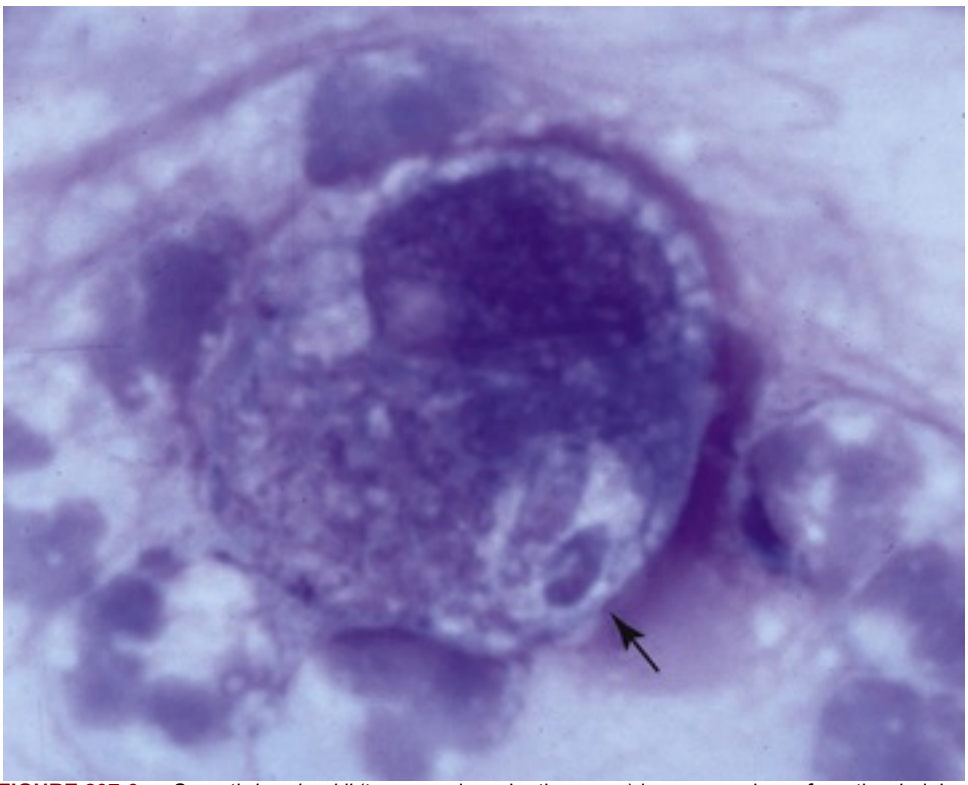

FIGURE 207-6 *Sporothrix schenkii* (two organisms by the arrow) in a macrophage from the draining tract of a cat (1000×).

Canine distemper virus infection causes inclusions in circulating lymphocytes, neutrophils, and erythrocytes of some dogs (see ch. 228). Rarely, feline infectious peritonitis-associated coronavirus results in intracytoplasmic inclusions in circulating neutrophils (see ch. 224). Feline herpesvirus 1 (FHV-1) transiently results in intranuclear inclusion bodies in epithelial cells (see ch. 229). However, cytology is commonly falsely negative for canine and feline viral diseases. Immunocytochemical or nucleic acid amplification techniques

are generally more sensitive and specific than cytology for these agents.

Tissues collected from animals with suspected infectious diseases can be evaluated by several different techniques. Specimens for culture should be collected from the fresh samples and then tissues can be frozen, placed into 10% buffered formalin solution, or placed into glutaraldehyde-containing solutions. Routine histopathologic evaluation is performed on formalin-fixed tissues. Special stains can be used to maximize the identification of some infectious agents, and the clinician should alert the histopathology laboratory to the infectious agents suspected. Frozen specimens can be superior to formalin-fixed tissues for immunohistochemical staining and nucleic acid amplification techniques. Glutaraldehyde-containing fixatives are superior to other fixatives for electron microscopic examination of tissues.

Fecal Examination

Infectious agents are commonly associated with gastrointestinal disease. A number of fecal examination techniques, including direct saline smear, fecal or rectal cytology, fecal flotation, Baermann funnel technique, immunologic techniques, and nucleic acid amplification techniques, are used to evaluate dogs and cats with vomiting or diarrhea (see ch. 276-278). In addition, some fecal examination techniques can aid in the diagnosis of respiratory parasites as these agents are often swallowed and passed in feces (see ch. 81).

Fecal flotation is indicated in dogs or cats with gastrointestinal signs of disease. Cysts, oocysts, and eggs in feces can be concentrated to increase the sensitivity of detection. Most eggs, oocysts, and cysts are easily identified after centrifugation in zinc sulfate solution or Sheather's sugar solution.[7,8] These procedures are superior to passive flotation techniques for identification of most parasites, in particular *Giardia* spp. If diarrhea is present, the fecal flotation is often combined with microscopic examination of fresh, liquid feces or a wet-mount examination for the presence of protozoal trophozoites (*Giardia* spp. [small bowel diarrhea], *T. foetus* [large bowel diarrhea], and *Pentatrichomonas hominis* [large bowel diarrhea]). A 2 mm × 2 mm × 2 mm quantity of fresh feces or mucus is mixed thoroughly with one drop of 0.9% NaCl or water, a coverslip is applied, and the slide is evaluated immediately for motile organisms by examining it under 100× magnification (Video 207-1).

Immunologic Techniques

Several immunologic techniques are used to identify infectious agents or their antigens in body fluids, feces, cells, or tissues. In general, polyclonal or monoclonal antibodies against the agent in question are used in a variety of different test methodologies, including direct fluorescent antibody assay with cells, tissue, or feces, immunohistochemistry with tissues, and agglutination assays and enzyme-linked immunosorbent assays (ELISAs) for antigen detection in serum, plasma, blood, or feces. Sensitivity, specificity, NPV, and PPV vary among assays but are generally high for most assays. Some assays require specialized equipment like fluorescent microscopes and so are only available at diagnostic laboratories. Other assays are available as point-of-care tests.

Currently available antigen assays for use with serum or plasma from dogs or cats include *Dirofilaria immitis, Cryptococcus neoformans, B. dermatitidis, H. capsulatum,* and feline leukemia virus. Parvovirus, *Cryptosporidium parvum,* and *Giardia* spp. antigen detection procedures are available for use with feces. The *Blastomyces* antigen assay has also been shown to have clinical utility using urine.[9]

Immunocytochemistry and immunohistochemistry techniques are available for the documentation of a variety of infectious diseases. These procedures are particularly valuable for the detection of viral diseases, detection of agents present in small numbers, and for differentiating among agents with similar morphologic features. In general, these techniques are more sensitive and specific than histopathologic techniques and are comparable to culture. See individual chapters for further discussion of these assays.

Nucleic Acid Amplification Techniques

The PCR reaction amplifies DNA.[10] Very low DNA copy numbers can be amplified to detectable levels with this technique (Figure 207-7). By use of a reverse transcriptase step, RNA is converted to DNA; therefore, the technique can also be used to detect RNA (RT-PCR). Depending on the infectious agent in question, the techniques can be more sensitive than other available assays. In addition, PCR assay results can often be returned within 24 hours of sample submission, which is generally quicker than culture. However, the assays must always be shipped to a diagnostic laboratory as special equipment is required. If the organism in question is difficult to culture (e.g., *Ehrlichia* spp.) or cannot be cultured (e.g., hemoplasmas), PCR assays are

of particular benefit for documenting infection.

FIGURE 207-7 Conventional polymerase chain reaction assay example. *S,* Standards; *1,* positive amplicon; *2,* positive amplicon; *3,* negative sample.

Specificity of PCR assays can be very high, depending on the primers used in the reaction. For example, primers can be designed to detect one bacterial genus but not others. Primers can also be designed to identify only one species. For example, a PCR assay can be developed to detect all *Anaplasma* spp. or just one species such as *A. phagocytophilum.*

PCR assays are prone to false-positive results if sample contamination occurs during collection or at the laboratory performing the procedure. False-negative results can occur if the sample is handled inappropriately while being collected or transported. Some PCR assay results may also be affected by administration of antimicrobial drugs prior to sample collection. For example, hemoplasma or *Bartonella* spp. PCR results can be transiently negative during antibiotic treatment even though infection persists. Acute infections generally have higher DNA (or RNA) copies in samples than do chronic infections because in chronic infections, the immune response has attenuated the organism. Thus, the optimal sample for assessment by PCR assay is usually one collected during the acute phase of illness prior to antimicrobial treatment.

While many commercial laboratories are offering nucleic acid amplification assays, there is minimal to no standardization of assays. In addition, there may be little external quality control at some laboratories. For example, samples from cats with and without feline immunodeficiency virus (FIV) infection were sent to four different laboratories offering FIV PCR assay.[11] The laboratory with the best performance obtained the correct result on 90% of the samples; two of the laboratories obtained the correct result on <60% of the samples.

While PCR assays are very sensitive, the PPV of many assays can be very low. For example, because the technique detects DNA or RNA of both live and dead organisms, positive test results may be achieved even if the infection has been controlled. When the organism being tested for commonly infects the background population of healthy pets, interpretation of results for a single animal can be difficult. For example, feline calicivirus (FCV) is an important pathogen of cats. However, the organism is also commonly carried by healthy cats and modified live vaccine strains colonize cats.[12] Thus, although FCV RT-PCR is a sensitive way to document infection by FCV, the PPV of a FCV RT-PCR result is actually very low. In one study of cats with and without stomatitis, the PPV of FCV RT-PCR assays results from oral swabs was 0%.[13] Similar problems exist for FHV-1 PCR assay results.[14,15] In one study of cats with and without conjunctivitis, more FHV-1

positive tests were detected in the healthy control group than the group with conjunctivitis.[14]

Real-time PCR or fluorogenic PCR is a type of PCR assay that can be used to determine the amount of microbial DNA in a sample (Figure 207-8).[12-15] This technique can be used to monitor response to drug treatment.[16-19] It is possible that the DNA or RNA load in a sample will correlate to the presence of disease for some agents. However, that does not appear to be true for chronic FHV-1 conjunctivitis, *Mycoplasma haemofelis*, or "*Candidatus* M. haemominutum" infections.[16-18]

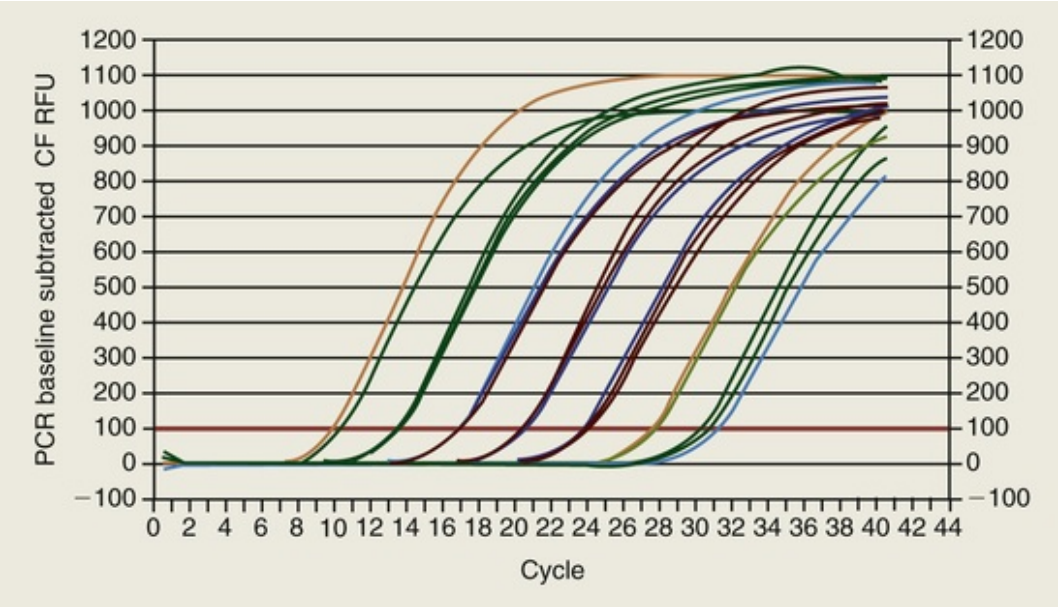

FIGURE 207-8 Example tracing from a fluorogenic real-time polymerase chain reaction *(PCR)* assay. *CF RFU*, Curve-fit relative fluorescence units.

Based on these observations, it is very important that small animal practitioners carefully assess the predictive values of currently available PCR and the expertise and reliability of the laboratory that will be performing the assays. New PCR assays are being developed almost daily. See specific chapters for a discussion of the use of PCR for the detection of individual agents.

Antibody Detection

Serum Antibodies

Once exposed to foreign antigens, the immune system generates serum antibodies (humoral immune response). Complement fixation, hemagglutination inhibition, serum neutralization, agglutination assays, agar gel immunodiffusion, indirect fluorescent antibody assay (IFA), ELISA, and Western blot immunoassay are commonly used to detect serum antibodies against infectious agents. Complement fixation, hemagglutination inhibition, serum neutralization, and agglutination assays generally detect all antibody classes in a serum sample. Specific antibodies most commonly assayed for include immunoglobulin M (IgM), immunoglobulin G (IgG), immunoglobulin A (IgA), and immunoglobulin E (IgE). ELISA, Western blot immunoassay, and IFA are the assay types that are usually adapted to detect specific IgM, IgG, or IgA responses. Western blot immunoassays have the potential advantage of allowing the determination of the different antigens recognized by the humoral immune responses (Figure 207-9).

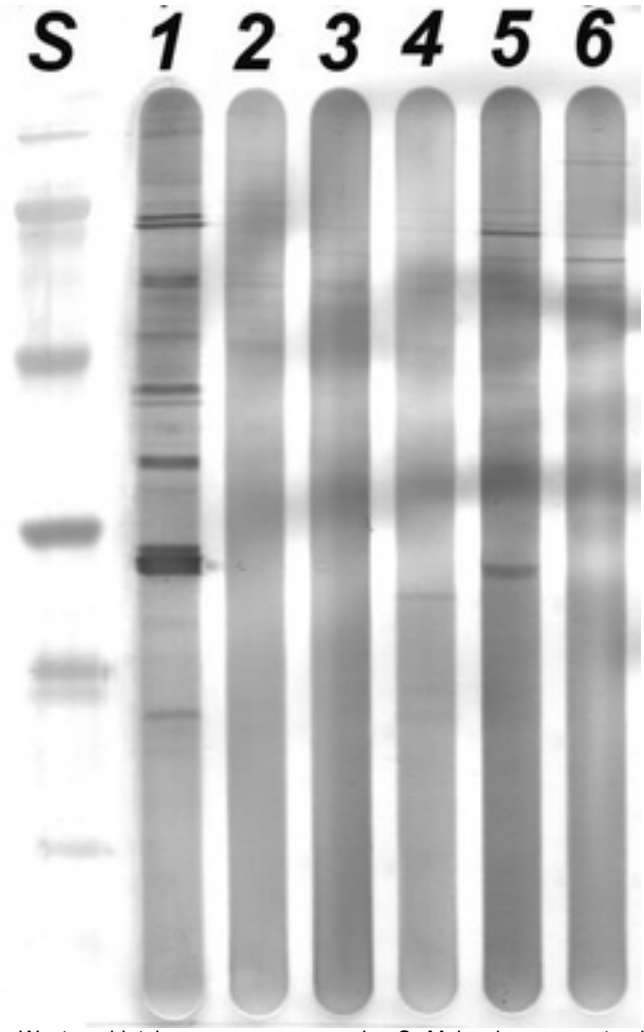

FIGURE 207-9 Western blot immunoassay example. *S,* Molecular mass standards; *1,* positive control; *2,* negative control; *3,* negative sample; *4,* positive sample; *5,* positive sample; *6,* negative sample.

Comparison of IgM, IgA, and IgG antibody responses against an infectious agent can be used to attempt to prove recent or active infection. In general, IgM is the first antibody produced after antigenic exposure.[20] Antibody class shift to IgG occurs in days to weeks. Serum IgA responses often mirror those of IgG (Figure 207-10).

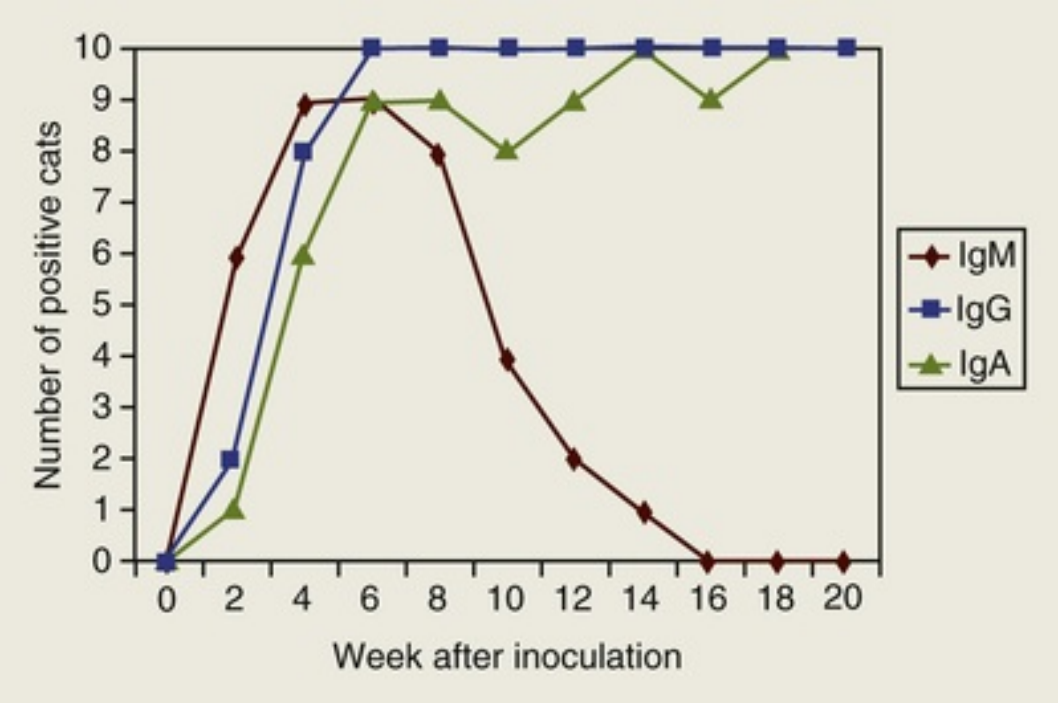

FIGURE 207-10 Hypothetical example of the serum IgM, IgG, IgA responses to an antigen over time.

Timing of antibody testing is important. In general, serum antibody tests in puppies and kittens cannot be interpreted as specific responses until at least 8 to 12 weeks of age due to presence of antibodies from the dam passed to the puppy or kitten in colostrum (see ch. 208). Most infectious agents can induce disease within 3 to 10 days after initial exposure; using many assays, serum IgG antibodies are usually not detected until at least 2 to 3 weeks after initial exposure. Based on these facts, false-negative serum antibody tests during acute disease are probably common in small animal practice. If specific serum antibody testing is negative initially in an animal with acute disease, repeat antibody testing should be performed in 2 to 3 weeks to assess for seroconversion. Documentation of increasing antibody titers is consistent with recent or active infection. Because of a slight potential for interassay variation, it is preferable to assess both the acute and convalescent sera using the same assay on the same day.

Many of the infectious agents encountered in small animal practice infect a large percentage of the population, resulting in serum antibody production, but only induce disease in a small number of animals in the infected group. Notable examples include coronaviruses, *Bartonella henselae, Toxoplasma gondii,* and *Borrelia burgdorferi.*[20-22] For these examples, even though assays with good sensitivity and specificity for the detection of serum antibodies are available, the PPV for presence of disease is extremely low, since antibodies are commonly detected in nondiseased animals. Diagnostic utility of some serologic tests is also limited due to the presence of antibodies induced by vaccination. Examples include feline coronaviruses, some *Borrelia burgdorferi* assays, FHV-1, FIV, parvoviruses, calicivirus, and canine distemper virus (see ch. 208).

Positive results in serum antibody tests should always be interpreted only as evidence of present or prior infection by the agent in question. Recent or active infection is suggested by the presence of IgM, an increasing antibody titer over 2 to 3 weeks, or seroconversion (negative antibody result on the first test, positive antibody result on convalescent testing). If detected, documentation of increasing antibody titers can suggest recent exposure to an antigen. However, the time period from the first positive result and maximal antibody titers can be very short. For example, some cats experimentally inoculated with *T. gondii* will go from the first detectable titer to the maximal titer within 1 to 2 weeks.[20]

Detection of recent infection based on antibody testing does not always prove disease due to the agent in question, especially if most infected animals are subclinical. *Borrelia burgdorferi, T. gondii,* and *B. henselae* are common examples. Conversely, failure to document recent or active infection based on serologic testing does not exclude a diagnosis of clinical disease. For example, many dogs with ehrlichiosis and dogs or cats with systemic fungal infections develop clinical signs of disease after serum antibody titers have reached their plateau.

Individual animals vary in their humoral responses against specific antigens. Some animals are high

responders and produce large concentrations of specific antibody, whereas others do not. Thus, the magnitude of an antibody titer does not definitely document that an antigenic exposure was recent, active, or associated with clinical disease. This is particularly true for the IgG class of antibody and for agents resulting in persistent infections. For example, many healthy cats experimentally inoculated with *T. gondii* have IgG antibody titers >10,000 6 years after the last inoculation.[20] Since there are no antibody test results that alone prove the presence of disease, they must be combined with other clinical parameters.

Antibodies in Body Fluids

Some infectious agents induce disease of the eyes and central nervous system (CNS). Documentation of agent-specific antibodies in aqueous humor, vitreous humor, or CSF can be used to document the involvement of these tissues. Quantification of ocular and CSF antibodies is difficult to interpret if serum antibodies and inflammatory disease are present because serum antibodies leak into ocular fluids and CSF in the face of inflammation. Detection of local production of antibodies within the eye or CNS has been used to aid in the diagnosis of canine distemper virus infection (see ch. 228), FHV-1 (see ch. 229), feline bartonellosis (see ch. 216) and feline toxoplasmosis (see ch. 221). The following is a method to prove local antibody production by the eye or CNS.

$$\frac{\text{Aqueous humor or CSF specific antibody}}{\text{Serum specific antibody}} \times \frac{\text{Serum total antibody}}{\text{Aqueous humor or CSF total antibody}}$$

If this ratio is greater than 1, it suggests that the antibody in the aqueous humor or CSF was produced locally. This formula has been used extensively in the evaluation of cats with uveitis. Approximately 60% of cats with uveitis in the United States have *T. gondii*–specific IgM, IgA, or IgG C values >1.[23] The technique was also used to help prove that FHV-1[24] and *B. henselae*[23] are causes of uveitis in cats.

CHAPTER 208

Companion Animal Vaccinations

Michael J. Day

Client Information Sheets:
Vaccination of Your Dog
Vaccination of Your Cat

History of Vaccines and Vaccination

Edward Jenner's demonstration of the cross-protection between cowpox (vaccinia) virus and human smallpox in 1796 paved the way for more than two centuries of research and development in human and veterinary vaccinology. The power of vaccination in the control of infectious disease is readily demonstrated by the eradication of human smallpox in 1979 and the subsequent eradication of rinderpest in ruminants in 2011. With the exception of the work of Louis Pasteur on rabies vaccines, small companion animal vaccination has a shorter history, with the introduction of feline parvovirus vaccines as early as the 1940s and canine distemper vaccines in the following decade. Companion animal vaccines are now a major global industry with remarkable advances in technology paralleling, or in the case of cancer vaccines, preceding, the introduction of equivalent new products into human medicine.

The Immunology of Vaccination

Active immunization (as opposed to the delivery of preformed antibodies in passive immunization) involves the administration of an antigen by a means that generates an active immune response and persistent immunological memory in the host. The majority of current vaccines are designed to induce protective effector immune responses to infectious agents, but some vaccines trigger immune responses to cancer antigens (e.g., the canine melanoma vaccine) or induce suppressive immune responses to allergens (e.g., allergen-specific immunotherapy). The focus of this chapter will be on the former class of vaccine.

Delivery of a vaccine aims to replicate the natural protective host immune response to the specific pathogen, and it is now clear that the nature of protective immunity differs for different organisms. Knowing the optimal type of immune response to the target organism enables the development of efficacious vaccines, but being able to detect and measure the immune response after vaccination also provides a "correlate of protection" that indicates that the vaccinated animal now has immunity. For companion animal vaccines, the correlates of protection depend on the organism, its route of entry into the body, the pathogenesis of the disease caused by the infection, and the optimum host immune response. For some vaccines there is a very strong correlation between the induction of circulating organism-specific antibody and protective immunity. For example, in the case of canine distemper virus (CDV), canine adenovirus-2 (CAV2), canine parvovirus-2 (CPV2) and feline parvovirus (FPV), there is a strong association between protection and the presence of serum virus-neutralizing or hemagglutination-inhibiting antibody. In the case of feline herpesvirus-1 (FHV1) the stronger correlate of protection is the presence of a cell-mediated immune response, and in the case of pathogens infecting the upper respiratory tract (e.g., *Bordetella bronchiseptica*) the best correlate of protection is the presence of a local, mucosal immune response. The detection of cell-mediated or mucosal immune responses is technically challenging, but it is now straightforward to measure serum antibody responses in vaccinated animals to indicate that they have been protected by particular vaccines (see below).

The science of immunology has made rapid advances in the past decades, and this new knowledge informs our understanding of how vaccines work and how we might design more effective vaccines. Vaccinal immune responses follow the pattern for induction of active immunity to any foreign antigen.[1] Vaccine antigens must first be detected by antigen-presenting cells (APCs) such as dendritic cells or macrophages, at

the site of vaccine administration or at distant sites reached by vaccine infectious agent. The interaction between vaccine antigen and APC likely involves the detection of "microbe-associated molecular patterns" on or within the vaccine organism with "pattern recognition receptors" on or within the APC. The APC has a series of key roles in the induction of activity immunity: (1) internally processing and presenting small peptide fragments from vaccine antigens associated with class I or class II molecules of the major histocompatibility complex (MHC) on the surface of the cell, (2) carrying the vaccine antigen from the site of delivery to the closest organized lymphoid tissue, (3) engaging with antigen-specific T lymphocytes that carry a T-cell receptor that can recognize the peptide-MHC combination on the APC surface, and (4) activating that T cell by delivery of costimulatory signals including specific soluble messenger proteins (cytokines) that act on cytokine receptors on the target T cell.

The nature of the antigen, the context of its entry into the body, and the signals received from the APC, in turn, instruct the further development of the naïve antigen-specific $CD4^+$ T cell. The naïve T cell starts to divide (clonal proliferation) but also takes on a specific functional phenotype as either a $CD4^+$ T helper (Th) 1, Th2, Th17 or T regulatory (Treg) cell. Th1 cells are characterized by the production of the cytokine interferon (IFN)-gamma and stimulation of cell-mediated immunity involving the activation of $CD8^+$ cytotoxic T cells (Tc) and natural killer (NK) cells. Th17 cells produce cytokines including interleukin (IL)-17 and are important in, amongst others, the immune response to fungal infections mediated by granulocytes and macrophages. Th2 cells produce cytokines including IL-4, IL-5, IL-9 and IL-13 and are key to the generation of humoral immunity via coactivation and clonal proliferation of antigen-specific B lymphocytes, their transformation into plasma cells and secretion of antigen-specific antibody (in the context of vaccines, generally of the immunoglobulin [Ig] G or IgA class). With each of these activation events, long-lived memory T and B lymphocytes will be produced and it is these that mediate the sometimes lifelong vaccinal protective immune response. Treg cells are the population that suppress active immune responses, and it is likely that the delivery of allergen-specific immunotherapy works at least in part by stimulating this population.

Whilst it is likely that many vaccines containing infectious agents stimulate elements of both cellular (Th1) and humoral (Th2) immunity, vaccinal immune responses with strong circulating or mucosal antibody as a correlate of protection might be expected to be dominated by Th2-driven immunity, while those requiring a cellular response might involve Th1-dominated immune responses.

The Epidemiology of Vaccination

In small companion animal practice vaccination is now part of "individualized medicine," and vaccination requirements should be tailored for the needs of the individual pet (see below). However, vaccination is not solely about protecting the individual; it should also be about protecting the population through conferring "herd immunity." The concept of herd immunity simply suggests that the more vaccinated individuals there are in a community, the more difficult it is for many infections to spread through that community when the infections are introduced.

Herd immunity is best demonstrated with the case of canine rabies virus infection, where, because of the relatively low R_0 value, vaccination coverage of 70% of the population will achieve protection of the human and animal population against the disease. R_0 is defined as the number of secondary cases caused by an infected individual in an entirely susceptible population, and for rabies this is around 1.2 (meaning that each rabid dog infects on average 1.2 others). Our aim should always be to maximize the number of vaccinated animals in our herd, but we are far from achieving even 50% vaccine coverage for companion animals in most areas (even in the developed world). A reduction in existing herd immunity can also lead to the recurrence of infectious disease. An excellent example of this was the outbreak of CDV infection in Finland in the mid-1990s. Over 5,000 dogs died during this outbreak, which reflected a reduction in vaccination uptake in the canine herd.[2]

Types of Vaccine

The range of companion animal vaccines has expanded considerably in recent years. It is helpful to consider vaccines as either "infectious" or "noninfectious" in nature. An infectious vaccine contains a live, but attenuated, whole organism that is capable of circulating in the body, infecting cells and replicating within them, establishing a low-level and transient infection that engenders a strong immune response without the need for additional nonspecific immune stimulation (i.e., via incorporation of an adjuvant). For example, an infectious CPV vaccine leads to transient viremia and fecal shedding of vaccine virus post-vaccination.[3]

Infectious vaccines are also known as "live," "live attenuated" or "modified live" vaccines.

A noninfectious vaccine contains a whole organism that is killed and inert, usually after treatment with one of a range of chemical agents. Other types of noninfectious vaccine include selected immunodominant antigens extracted from the organism or produced using molecular biological techniques as recombinant antigens. These are referred to as "subunit vaccines." Noninfectious vaccines cannot therefore produce active infection and often require incorporation of adjuvant. Noninfectious vaccines generally require multiple doses to generate immunity and more frequent readministration (i.e., boosting) to maintain immunological protection and memory. For these reasons, with some exceptions (see below), an infectious version of a vaccine will generally be preferred when there is a choice between an infectious or noninfectious product.

The newest forms of noninfectious vaccine are produced using molecular techniques. "Recombinant vectored" vaccines involve inserting genetic material encoding an immunodominant protein from the target organism (e.g., feline leukemia virus [FeLV], CDV or canine rabies virus) into the genetic material of a benign "carrier" virus that is incapable of causing disease in the target species (e.g., the use of canary pox virus in the dog or cat). "Naked DNA" vaccines remove the need for a carrier organism entirely and rely on administration of a bacterial plasmid containing the gene of interest. These plasmids are taken up by host cells (including APCs) by the process of "transfection," resulting in expression of the immunodominant antigen from the target organism by host cells. The canine melanoma vaccine utilizes this technology.[4]

The means of delivery of vaccines to companion animals is also expanding in range. Most traditional vaccines are given by subcutaneous needle injection, but increasingly certain vaccine organisms are delivered by the intranasal route and one product is now given orally. Administration of vaccine direct to the anatomical site of natural infection will confer the most relevant and potent protective immune response. Recombinant vectored or naked DNA vaccines have also been delivered via a "needle-free" percutaneous route involving use of a high-pressure transdermal system. This route of delivery has the advantage of using a lower amount of vaccine whilst more specifically targeting the key APC populations within the epidermis and dermis of the skin.

Vaccine Licensing

As with any pharmaceutical product, veterinary vaccines must go through a rigorous regulatory procedure before they come to market. Essentially, vaccines must be shown to be safe for use in the target species, must be produced to high-quality standards, and must have demonstrated efficacy in being able to protect from infectious disease. Efficacy testing generally involves experimental challenge studies, in which vaccinated and unvaccinated animals are challenged with virulent infectious agent at a defined time point after vaccination. The vaccine must be able to provide acceptable protection against infection or clinical disease.

These regulatory studies form the basis for the "claim" for the vaccine, which will be detailed (together with other information) on the vaccine datasheet or "summary of product characteristics." Practitioners should be aware that the claim for vaccines may differ and that no vaccine, human or animal, can be guaranteed to provide 100% protection. Some vaccines will claim to prevent infection with the organism, but others will claim only to ameliorate the severity of clinical signs after infection and not to prevent infection or even shedding of the infectious agent.

Adverse Events Following Vaccination

The 60-year history of companion animal vaccination has had profound effects on the health and well-being of the pet population with many infectious diseases no longer as prevalent as they once were in numerous geographical areas. Additionally, in the case of canine rabies vaccination, and more recently canine *Leishmania* vaccination, vaccination of dogs has had a major impact on human health. There is no question that vaccination is a key element of preventive health care for companion animals and must be promoted by the veterinary profession.

With many millions of animals vaccinated throughout the world each year, it is inevitable that on rare occasions some animals may show adverse events post-vaccination. There is a wide spectrum of such vaccine-associated adverse events recognized in companion animals and for most of them the precise pathogenesis (i.e., how a vaccine might mechanistically lead to the reaction) is unknown.[5] At one end of the spectrum is the frequent occurrence of mild and transient pyrexia, lethargy and anorexia for 2-3 days post-vaccination, particularly in young animals. This "adverse event" simply indicates that the vaccine is stimulating immunity with release of proinflammatory cytokines as part of that response. At the other end of the spectrum are lethal reactions such as acute anaphylaxis (see ch. 137), induction of life-threatening autoimmune disease (see ch.

10), or induction of the feline injection-site sarcoma (FISS; see ch. 346). Some studies have attempted to quantify the frequency of such reactions, and the largest epidemiological investigations suggest that these might arise in something like 30 to 50 animals for every 10,000 animals that are vaccinated.[6,7] Veterinarians should be encouraged to report all postvaccinal adverse events to the manufacturer, or in countries where there is such a scheme, to national reporting databases.

There is much Internet discussion about the safety of veterinary vaccines from well-meaning pressure groups, and this continues to cause concern amongst pet owners. It is beholden on the veterinary profession to advise that the very slight risk of adverse event following vaccination is far outweighed by the benefits to the animal of protection against life-threatening infectious disease.

Changes in Vaccination Practice

Driven by professional and public concerns over companion animal vaccine safety, the veterinary profession has established a number of scientific expert panels to consider vaccination and how it might best be delivered in the context of modern veterinary practice. To that end, a number of panels have produced guidelines for the vaccination of dogs and cats. The first of these groups was the American Academy of Feline Practitioners, which produced guidelines as early as 1998 with the most recent iteration published in 2013.[8] The American Animal Hospital Association has produced guidelines for canine vaccination, last updated in 2011,[9] and the Advisory Board on Cat Diseases also published guidelines for feline vaccination most recently in 2013.[10] The most overarching guidelines come from the World Small Animal Veterinary Association (WSAVA) Vaccination Guidelines Group (VGG), which has produced advice for the vaccination of both dogs and cats for practitioners in the 80 WSAVA member countries[11] and, more recently, specifically for practitioners on the Asian continent.[12] The VGG is currently working on a 2015 revision of the world guidelines. In reality, there is now great consistency in the recommendations given in these various guidelines documents and over time, the recommendations given in vaccine datasheets is also moving towards those given in guidelines.

Practitioners should be aware that guidelines are a distillation of the latest scientific thinking on vaccines and vaccine delivery and are designed to provide information to veterinarians such that they may formulate their own practice policies on vaccination. Guidelines recommendations may well differ from those given on vaccine datasheets as guidelines groups consider recent published and unpublished scientific studies that may postdate the production of a datasheet. Vaccine datasheets (or SPCs) are the legal document describing how vaccines should be used, but any veterinarian can use a vaccine "off label" in accordance with guidelines recommendations and with informed client consent. No veterinarian has ever been prosecuted for failing to adhere to manufacturer's recommendations for vaccine delivery.

Core Versus Noncore Vaccines

The vaccination guidelines groups have adopted the concept of classifying vaccines into one of three categories. A "core" vaccine is one which every dog or cat, no matter where or how it lives, should receive because it protects that animal against infectious disease which may be lethal or cause high morbidity. The concept of core vaccination also incorporates rabies vaccination, which should be given to all dogs and cats in any country in which the disease is endemic, even if legislation does not mandate this. In contrast, a "noncore" vaccine is one which every dog or cat does not need to receive. The choice of giving a noncore vaccine should be based on consideration of the geographical prevalence of infection, the lifestyle of the individual pet and the risk for that animal coming in contact with the infection. A third category of "not recommended" is used for vaccines that do not have sufficient scientific evidence base to justify their use in the field.

Core Vaccination for Dogs

The core vaccines for dogs are those that protect against CDV (see ch. 228), CAV (see ch. 228) and CPV (see ch. 225), and for any dog in a rabies-endemic country, rabies vaccine (Table 208-1; see ch. 226). The choice of core vaccines for the dog is therefore simple and uncontroversial. The most efficacious and convenient formulation of the canine core vaccines is a trivalent infectious (modified live virus) product, which should be selected above similar noninfectious products if they are available. In some countries, a recombinant virus-vectored CDV vaccine is available. Although use of core vaccines therefore sounds simple, the complication arises in many countries that the three core antigens are often formulated with additional noncore

components in anything up to an "eight-in-one" combination. This makes it very difficult for practitioners in those countries to vaccinate in accordance with current guidelines, and it is hoped that, in time, industry will provide to these countries the same vaccine range that is available elsewhere.

TABLE 208-1

Recommended Canine Core Vaccination

VACCINE	POSSIBLE PUPPY PROTOCOL	POSSIBLE ADULT DOG PROTOCOL
CDV, CAV and CPV (infectious MLV vaccine; CDV viral vectored recombinant; injectable)	8, 12 and 16 weeks or older with a 12-month booster	Revaccination no more frequently than every 3 years; serology may be used to determine protection
Rabies (noninfectious killed adjuvanted vaccine; injectable)	12 weeks and a 12-month booster	Revaccination every 3 years depending on local law and licensed DOI of products

For full details refer to WSAVA[11] or AAHA[9] Vaccination Guidelines.

CAV, Canine adenovirus; *CDV*, canine distemper virus; *CPV*, canine parvovirus; *DOI*, duration of immunity; *MLV*, modified live virus.

Core vaccination must be started in puppy- or kittenhood. It is well known by practitioners that puppies and kittens acquire passive maternal immunity in the form of antibody by taking in colostrum during approximately the first 24 hours of life. This maternally derived antibody (MDA) circulates in the neonate and provides passive protection from infection over the first weeks of life. Canine MDA has a half-life of around 11 days, meaning that every 11 days there is one half of the amount of circulating MDA remaining than was present 11 days previously. The presence of MDA interferes with the ability of the neonate to mount its own protective immune response to the majority of currently available core vaccines. At some point after birth, the amount of remaining MDA is insufficient to provide complete immunological protection, but still enough to block the endogenous immune response. This short period of time is referred to as the "window of susceptibility." It is not possible to predict accurately when this "window" occurs for any one neonate as the amount of MDA transferred will vary between litters and within litters for individuals. Until recently, it was believed that in the majority of pups the "window" lay between 8-10 weeks of age, and so a core vaccination schedule of 8 and 12 weeks would induce a primary immune response either at 8 or at 12 weeks in all puppies. We now know that this is not the case, and so blocking levels of MDA are likely to persist in 10% of pups at 12 weeks of age (RD Schultz, unpublished study). For that reason, all canine vaccination guidelines now recommend a series of three primary vaccines in the pup: starting at 8-9 weeks of age, with a second vaccine 3-4 weeks later and a third vaccine given between 14-16 weeks (and preferably at the 16-week-or-older end of that spectrum). Crucially, a "boosting" vaccine must be given to pups within the first year of life, and this is often delivered at 12 months of age or 12 months after the final primary vaccine. Where MDA is suspected to be low, in many countries there are products containing CDV and CPV antigens that may be given from 6 weeks of age, but infectious vaccines should not be given to puppies at younger age (particularly before 4 weeks of age).

In endemic areas, pups must also be vaccinated against canine rabies. All canine rabies vaccines are killed and adjuvanted products. The global recommendation is for one of these vaccines to be delivered at 12 weeks of age with a second vaccine given within the first year of life. The WSAVA guidelines also suggest that in highly endemic areas (e.g., in Africa or Asia) a second rabies vaccine may be delivered at 16 weeks of age.

For adult dogs, the delivery of core vaccination is now also relatively straightforward. The core canine vaccines (i.e., CDV, CAV2 and CPV2) are highly efficacious, and there is an extremely strong correlation between the presence of serum antibody against the antigen and protection from disease. One of the biggest global changes in canine vaccination practice has been with respect to the frequency of core revaccination of adult dogs. Core trivalent infectious vaccines were originally licensed with a 1-year "duration of immunity" (DOI), meaning simply that an experimental challenge study had determined that vaccinated dogs were protected 1 year after vaccination from infectious challenge. However, this was always a minimum DOI and it was well recognized that dogs appropriately vaccinated as puppies (and never again) usually had lifelong protective serum antibody concentrations. There are now data that show that the minimum DOI for canine core infectious vaccines is actually 9 years (by experimental challenge)[13] and that protective antibody titers can persist for at least 15 years after puppyhood vaccination. In response to vaccination guidelines, vaccine manufacturers performed new challenge studies that provided evidence for a minimum DOI of either 3 or 4

years. Consequently, over the past decade, most vaccine datasheets have now been changed to reflect this fact and advise revaccination of adult dogs with core infectious vaccines only every 3 or 4 years.

Knowing that triennial revaccination still reflects only the minimum DOI, and that there is an exceptionally strong correlation between protection and serum antibody to CDV, CAV and CPV, many practitioners now elect to perform serological testing every 3 years rather than automatically revaccinate an adult dog. Serological testing has now become more accessible with the availability of in-clinic test kits that can rapidly determine whether a dog has serum antibody to these three viral antigens.[14,15] Serology rather than revaccination is currently a more expensive option but reduces the risk of adverse events post vaccination and has proven very popular with clients in many countries.

Vaccination of adult dogs against rabies may now also be performed triennially as in many countries the internationally produced noninfectious adjuvanted rabies vaccines carry a 3-year licensed DOI. This can become problematic in countries in which there is still a legal requirement to deliver annual revaccination, even where a 3-year product is available. In that situation, the veterinary profession should lead in lobbying to allow the law to keep pace with the science. It is also worth noting that in some countries there are nationally produced vaccines with a 1-year DOI and that there is no evidence that these products can protect for longer periods. Finally, rabies vaccination for individual, owned pet dogs visiting the veterinarian is distinct from mass vaccination campaigns in endemic countries. In the latter context, it is important to maintain annual revaccination, simply because of the high population turnover in communities of "free-roaming" dogs.

Noncore Vaccination for Dogs

The most widely used noncore vaccines for dogs are those that confer protection against pathogens within the group responsible for the canine infectious respiratory disease (CIRD) complex ("kennel cough"; i.e., *Bordetella bronchiseptica,* CAV2 and canine parainfluenza virus [CPiV]; see ch. 227) and against leptospirosis (Table 208-2; see ch. 217). Other noncore vaccines with more restricted geographical availability include those against *Borrelia* (see ch. 211), canine influenza virus (CIV; see ch. 227), canine herpesvirus (see ch. 228), *Leishmania* (see ch. 221) and *Babesia* (see ch. 221).

TABLE 208-2

Recommended Canine Noncore Vaccination

VACCINE	POSSIBLE PUPPY PROTOCOL	POSSIBLE ADULT DOG PROTOCOL
Bordetella bronchiseptica alone or with CPiV and/or CAV2 (infectious intranasal or oral vaccine)	1 dose from 3-4 weeks of age	Annual booster
Leptospira (noninfectious multivalent vaccine most relevant to location; injectable)	2 doses 3-4 weeks apart starting after core viral components, 12-month booster	Annual booster
Borrelia (noninfectious whole organism or subunit injectable vaccine)	2 doses 3-4 weeks apart starting after core viral components, 12-month booster	Annual booster

For full details refer to WSAVA[11] or AAHA[9] Vaccination Guidelines; use of noncore vaccines is selected based on risk assessment.
CAV2, Canine adenovirus type 2; *CPiV*, canine parainfluenza virus.

Where the lifestyle of an individual dog justifies use of a CIRD vaccine, it must be remembered that there are numerous pathogens in this complex that are not represented in current vaccines and that this disease has other (e.g., environmental) aspects. A CIRD vaccine will not prevent clinical disease but may ameliorate its severity. These vaccines are available in different combinations of the three antigens listed above and either as injectable (noninfectious killed *Bordetella bronchiseptica*), intranasal (infectious attenuated *Bordetella bronchiseptica* with or without CPiV and CAV2) and now, oral (infectious attenuated *Bordetella bronchiseptica*) formulations. Intranasal and oral vaccines may be given as a single dose to puppies (intranasal vaccines can be used as early as 3-4 weeks of age and the oral vaccine from 8 weeks of age), whereas injectable vaccines are given by two injections 2-4 weeks apart. All of these vaccines must be given annually to adult dogs to maintain protective immunity.

Canine leptospirosis is currently a disease receiving much research interest (see ch. 217). Numerous studies

are now starting to measure the geographical prevalence of this infection and the serogroups of the bacterium involved in field cases. This new knowledge has led to the introduction of new multivalent noninfectious (killed) canine leptospirosis vaccines.[16] The traditional canine *Leptospira* vaccine contained the serogroups *L. canicola* and *L. icterohaemorrhagiae,* but now trivalent or quadrivalent vaccines (e.g., in the United States *L. canicola, L. icterohaemorrhagiae, L. grippotyphosa* and *L. pomona*) carry a wider range of serogroups. A dog vaccinated against leptospirosis might still be susceptible to disease as there are numerous serogroups (not included in vaccines) that can cause this infection. In many parts of the world, canine *Leptospira* vaccine is regarded as "core" rather than "noncore" because of the belief that this is a highly prevalent and severe disease that also has potential zoonotic implications. However, in other areas the disease is not recognized, and so global guidelines reflect this by classifying the vaccine as noncore.

Advice on vaccinating puppies against leptospirosis differs between vaccine datasheets and guidelines recommendations, although in all cases it is recognized that two doses of vaccine, 2-4 weeks apart, are required. Experimental studies performed by manufacturers have proven that the vaccine can induce immunity when integrated with the timing of the canine core vaccines given to puppies; however, guidelines suggest delaying administration of the vaccine until after completion of the core viral series (i.e., at 16 weeks or older). This recommendation is largely based on traditional concerns that adjuvanted bacterins may be more likely to trigger allergic reactions in young dogs. Whichever *Leptospira* vaccine is used, adult dogs must be revaccinated annually to maintain protective immunity and the WSAVA guidelines also suggest that for dogs at high risk of exposure, 6-monthly revaccination might be considered.

Noninfectious CIV (killed virus) or *Borrelia* (killed bacterium or recombinant subunit vaccines) is given to puppies by injection (twice, 2-4 weeks apart) and then by annual booster to adult dogs.

Not Recommended Vaccines for Dogs

Vaccination guidelines groups do not generally recommend the use of vaccines against canine enteric coronavirus (CCoV) or *Giardia.* CCoV induces only mild gastrointestinal disease in dogs, unless there is concurrent CPV infection, and it has not been possible to induce experimental CCoV disease in dogs over 6 weeks of age, making it impossible to assess the efficacy of any vaccine. Field studies have not shown clear evidence that CCoV is a primary gastrointestinal pathogen in this species. Canine *Giardia* vaccines have now been removed from most global markets but persist in some countries. Canine *Giardia* infection is of low prevalence, is non–life threatening, responds to therapy and is rarely zoonotic. There is no evidence that the strain of *Giardia* included in the vaccine confers cross-protection against the multiple strains that might infect dogs.

Core Vaccination for Cats

The core vaccines for cats are universally considered to be those that protect against FPV (see ch. 225), FHV1 (see ch. 229) and feline calicivirus (FCV; see ch. 229), and in any country where rabies is an endemic disease (see ch. 226), cats should also receive rabies vaccination even if not mandated by law (Table 208-3). Core vaccines for cats are often available as a trivalent combination of infectious (modified live viral) antigens or noninfectious (killed adjuvanted or nonadjuvanted) antigens, and in some countries an intranasal infectious (modified live viral) combination is available. The two respiratory tract components (FHV1 and FCV) are also sometimes formulated as a bivalent vaccine to be used in conjunction with monovalent FPV vaccine. One noninfectious (killed and nonadjuvanted) FCV product contains two strains of the virus. In general, the preference should be for infectious injectable vaccine as inducing the most efficacious protective response to all three components; however, noninfectious vaccines should be selected for use in retrovirus-infected cats or for the rare occasion on which cats might be vaccinated during pregnancy or for use in multicat households where there is no preexisting upper respiratory tract disease. The same noninfectious (killed and adjuvanted) rabies vaccines are used in cats as in dogs, but for the cat there is additionally a noninfectious viral-vectored recombinant vaccine against rabies.

TABLE 208-3

Recommended Feline Core Vaccination

VACCINE	POSSIBLE KITTEN PROTOCOL	POSSIBLE ADULT CAT PROTOCOL

FPV, FHV1, FCV (infectious MLV vaccine; injectable)	8, 12 and 16 weeks or older with a 12-month booster	For FPV, revaccination no more frequently than every 3 years; for FHV1 and FCV revaccination every 3 years for low-risk cat and annually for high-risk cat
Rabies (noninfectious killed adjuvanted or viral-vectored recombinant vaccine; injectable)	12 weeks and a 12-month booster	Revaccination every 3 years depending on local law and licensed DOI of products

For full details refer to WSAVA,[11] AAFP[8] or ABCD[10] Vaccination Guidelines.

DOI, Duration of immunity; *FCV*, feline calicivirus; *FHV1*, feline herpesvirus-1; *FPV*, feline panleukopenia virus.

The same considerations related to MDA apply to kittens as to puppies; however, recent studies suggest that persistence of MDA in kittens may be for even longer than in pups, with some kittens having blocking levels of MDA up to 20 weeks of age.[17,18] Advice for core vaccination of kittens is similar to that for puppies. Vaccination should start at 8-9 weeks of age, with a second dose given 3-4 weeks later and third dose given at 16 weeks or older (moving from some current recommendations for 14-16 weeks). Again, revaccination within the first year of life, often at 12 months of age or 12 months after the final primary vaccination, is crucial. Rabies vaccination of kittens is by a single injection at 12 weeks of age with a second injection at 12 months.

Core vaccination of adult cats is subject to greater debate than that for the dog. A number of FPV vaccines (either monovalent products or where FPV is incorporated into a trivalent vaccine) now have a licensed minimum DOI of 3 years. FPV vaccines, like the core canine vaccines, show strong correlation between the presence of serum antibody and protection, but this is not the case for the FHV1 and FCV components. FPV vaccines also lead to long-lived protection with a demonstrated minimum DOI of 7.5 years for noninfectious vaccine in one study.[19] Therefore, when available product range allows, current recommendations are for triennial revaccination of adult cats against FPV. Given the strong correlation between seropositivity and protection for FPV, some practices now choose to use the in-clinic rapid serological test kit to determine protection and decide on revaccination frequency.[20,21] Note that such serological testing should not form the basis of decision-making for the upper respiratory tract core components.

In contrast, all current feline FHV1 and FCV vaccines carry a licensed minimum DOI of 1 year, although in the same study cited above, a noninfectious trivalent vaccine provided equally good protection against infectious challenge in cats last vaccinated 7.5 years previously compared with cats receiving regular adult core booster vaccines. The recommendations for revaccination of adult cats against FHV1 and FCV are therefore more variable and determined by the risk of exposure of the individual cat. A low-risk cat (i.e., a solitary indoor animal that does not visit catteries) might safely be vaccinated triennially (as for FPV), but a high-risk cat (i.e., an indoor-outdoor cat or a cat within a multicat household or regularly visiting catteries) may better receive an annual or biennial vaccine against the upper respiratory virus components.

Adult cats may be revaccinated against rabies triennially (depending on legal requirements) when using either noninfectious (killed adjuvanted) vaccine or the recombinant virus-vectored vaccine that carries a 3-year licensed DOI.

Noncore Vaccination for Cats

Noncore vaccines for cats include those that protect against FeLV (see ch. 223), *Chlamydia felis* (formerly *Chlamydophila felis*; see ch. 229) and *Bordetella bronchiseptica* (see ch. 227 and 229). The vaccine against feline immunodeficiency virus (FIV; see ch. 222) is variably classified as noncore or not recommended (Table 208-4).

TABLE 208-4

Recommended Feline Noncore Vaccination

VACCINE	POSSIBLE KITTEN PROTOCOL	POSSIBLE ADULT CAT PROTOCOL
Bordetella bronchiseptica (infectious intranasal vaccine)	1 dose from 8 weeks of age	Annual booster if sustained risk of infection
FeLV (noninfectious adjuvanted whole virus or subunit; recombinant viral vectored; injectable)	2 doses 3-4 weeks apart starting at 8 weeks; booster at 12 months	Not more often than every 3 years if sustained risk of infection

Chlamydia felis (noninfectious adjuvanted or infectious; injectable)	2 doses 3-4 weeks apart starting at 9 weeks; booster at 12 months	Annual booster if sustained risk of infection
FIV (noninfectious adjuvanted; injectable)	3 doses 2-3 weeks apart starting at 8 weeks; booster at 12 months	Annual booster if sustained risk of infection

For full details refer to WSAVA,[11] AAFP[8] or ABCD[10] Vaccination Guidelines; use of noncore vaccines is selected based on risk assessment.

FeLV, Feline leukemia virus; *FIV,* feline immunodeficiency virus.

The prevalence of FeLV infection varies geographically and has reduced over recent years, but in many countries it is regarded as important to provide protection for kittens against this virus, and in some countries the vaccine is considered more core than noncore. A range of FeLV vaccines is available, including noninfectious (killed whole virus) and subunit vaccines, both of which are adjuvanted, and a recombinant virus-vectored and nonadjuvanted product. In general, these vaccines may be administered to kittens from 8 weeks of age with a second vaccine given 3-4 weeks later. WSAVA guidelines then recommend a 12-month booster vaccine and subsequent revaccination of adult cats only every 3 years thereafter, which is longer than the 1-year licensed DOI carried by these products.

Chlamydia felis vaccines may be used in multicat groups in which there is a background of infections associated with clinical disease. There are infectious (attenuated live) and noninfectious (killed adjuvanted) injectable vaccines available. These may be used in kittens from 9 weeks of age with a second vaccine 3-4 weeks later and with an annual booster for adult cats at sustained risk of exposure.

The *Bordetella bronchiseptica* vaccine might be considered for cats in similar high-risk situations. The vaccine is an infectious (attenuated) intranasal product that may be used as a single dose in kittens over 8 weeks of age, with an annual booster for adult animals at sustained risk of exposure.

The FIV vaccine has been contentious for a number of reasons: (1) there has been debate as to whether the two clades of virus contained within the vaccine (A and D) effectively cross-protect against other clades dominating in different geographical areas, (2) the vaccine leads to seropositivity that will interfere with diagnosis using serological (but not molecular) methods, (3) the vaccine is adjuvanted and must be given repeatedly (see below). The vaccine is a noninfectious (killed and adjuvanted) product that may be given to kittens from 8 weeks of age with two further injections each 2-3 weeks apart, a 12-month injection and then an annual booster for adult cats deemed at being of sustained risk.

As discussed above, one of the risk factors for FISS (see ch. 346) is regarded as being administration of adjuvanted vaccines. There is varying guidelines advice on how to best minimize the risk of FISS. Clearly, choosing nonadjuvanted over adjuvanted feline vaccines is one possibility and minimizing use of noncore vaccines is another. The site of administration of vaccines, particularly adjuvanted products, should be considered carefully in the cat. Recommendations range from the skin of the lateral abdomen,[11] to the distal hindlimbs,[8] to a new study considering vaccination into the tail.[22] Whichever protocol is adopted, it would be sensible to rotate the sites of injection (of vaccines or any other product) in the skin of a cat and not to inject repeatedly into the scruff of the neck.

Delivery of Vaccination

Vaccination guidelines provide current best-practice scientific advice for canine and feline vaccination; however, they also emphasize that we should change the way in which vaccination is "sold" to clients. The concept of the annual veterinary visit being for a "vaccine booster" should be replaced with the new concept of the "annual health check," which considers the overall health and well-being of the animal, with discussion of which vaccine might be given in any one year being just one part of that discussion. In this way, emphasis should be placed on the professional consultation and expertise, rather than the contents of the needle and syringe.

CHAPTER 209

Antimicrobial Resistance, Surveillance and Nosocomial Infections

J. Scott Weese

Introduction

Antimicrobial resistance (AMR) has been a clinical concern since shortly after the introduction of antimicrobials, and it now represents a significant problem in both veterinary and human medicine. While the main concerns about AMR have been accentuated in the past 50 years, AMR is not a new phenomenon. Bacteria have developed means of resisting the effects of antimicrobial substances for millennia as a way to counteract the ongoing biological warfare between microbes in the environment. Humans have harnessed this ability for tremendous gain, through development of therapeutic antimicrobials from these naturally occurring substances. However, we also have suffered profound consequences of the ability of bacteria to evade antimicrobials. As antimicrobials become more important for maintaining the health of patients, the implications of AMR become greater. Further, as the ability of bacteria to develop new resistance methods outpaces the ability (or rather, the efforts) to develop new antimicrobials, AMR will undoubtedly continue to have a major impact on companion animal medicine.

Antimicrobial Resistance in Small Animals

Pathogens of Concern

Antimicrobial resistance can be a concern with virtually any pathogen, but issues are greater among certain bacteria because of their tendency to acquire resistance and their role in disease. A list of concerning multidrug resistant (MDR) bacteria might vary between regions, between clinics in the same region, or even between clinical services (e.g., dermatology versus critical care) in the same facility. The list is also continually evolving, as issues of concern now could have been of limited concern, or even unknown, only a few years ago.

Methicillin-resistant (MR) staphylococci are among the most important opportunistic pathogens in animals (and humans). This includes methicillin-resistant *S. pseudintermedius* (MRSP), an increasingly common cause of skin and soft tissue infections in dogs (and, to a lesser degree, cats); methicillin-resistant *S. aureus* (MRSA), a predominantly human-associated cause of opportunistic infections in dogs and cats; and a variety of other methicillin-resistant staphylococcal species of varying pathogenic potential. Beyond their inherent resistance to virtually all beta-lactam antimicrobials, MR-staphylococci, particularly MRSP, often are resistant to a wide range of other antimicrobials, severely limiting treatment options. Zoonotic concerns also exist, particularly for MRSA.

Extended spectrum beta-lactamase (ESBL)-producing Enterobacteriaceae are Gram-negative bacteria possessing genes that render them resistant to extended-spectrum (third generation) cephalosporins and monobactams. They are increasingly prevalent in veterinary patients and are a cause for concern because of their inherent resistance, the potential for establishment of long-term reservoirs in the gut microbiota, and the potential for zoonotic transmission.[1-3]

Carbapenemase-producing Enterobacteriaceae (CPE) are Gram-negative bacteria that are resistant to carbapenems (e.g., meropenem).[4-6] While carbapenems are used uncommonly in veterinary medicine, CPE typically also are resistant to many other antimicrobials, and the loss of efficacy of last-line drugs such as meropenem is of tremendous concern. Currently, CPE appear to be rare in animals but if (or as) the prevalence of these organisms increases in people in the community, transmission to animals is probably inevitable. Of even greater concern is the emergence of New Delhi metalloproteinase 1 (NDM-1)-producing Enterobacteriaceae, with some isolates approaching pan-resistance.[7] While currently this appears to pose

limited risk to veterinary patients because of its rarity, it could be an emerging issue and, curiously, it appears that one of the first identified NDM-1-containing isolates in North America was from a cat with a urinary tract infection.[8] This highlights a realistic potential for an "untreatable infection," one caused by a bacterium that is resistant to all available options.

Enterococci tend to be of limited virulence compared to other opportunists, but resistance is not uncommon and some infections can be difficult to treat. Because of their inherent resistance to many antimicrobials, acquired resistance to more antimicrobials can hamper treatment through reduction of the already limited number of viable antimicrobial options. Vancomycin-resistant enterococci (VRE) are the subjects of the most attention in humans.[9] While VRE are rare in dogs and cats,[10,11] enterococci that are susceptible to vancomycin but resistant to most other options are relatively common and can be a challenge to treat.

This is far from an exhaustive list and pathogens resistant to only one antimicrobial can be of significant clinical relevance if that antimicrobial is chosen empirically to treat a patient.

Prevalence and Incidence

Most resistant pathogens are opportunists that can be found in healthy individuals.[12-15] Carriage rates vary greatly between different bacteria, different species and different regions, but it is reasonable to assume that a small but appreciable percentage of clinically normal animals is shedding one or more resistant pathogens at any time. These carriers can be sources of infection for themselves, other animals, or people, and shedding of MDR pathogens by healthy animals poses one of the greatest challenges for MDR infection control.

The incidence of infections caused by resistant pathogens is poorly understood. While carriage rates have been well defined for some pathogens such as MRSP, disease incidence data are less well described. In particular, the incidence of disease in primary care (non-referral) facilities is unclear and likely variable between regions. Understanding local and facility-specific infection rates is important for identification of problems, determination of optimal diagnosis and treatment approaches, for implementation of relevant infection control measures and for proper client counseling.

Impact of Antimicrobial Resistance

In humans, infections caused by various resistant pathogens have been shown to be associated with significantly higher morbidity, mortality, and treatment costs.[16-18] Equivalent data largely are lacking in veterinary medicine, mainly because of limited evaluation or study limitations. For example, no difference in mortality was reported for MRSP versus methicillin-susceptible *S. pseudintermedius* in one study[19]; however, most cases involved skin infections, which would not be expected to be associated with mortality, even if ineffectively treated. It is reasonable to assume that infections caused by MDR pathogens are of greater impact to the patient than those caused by susceptible pathogens, but this is the result of failure of empirical antimicrobial therapy. Resistant pathogens are not inherently more virulent than susceptible pathogens because resistance genes just confer antimicrobial resistance. This highlights the need for prompt diagnostic testing to identify resistance, because the outcome of infections caused by resistant versus susceptible infection should be identical if appropriate treatment is started, something that is dependent on diagnostic testing.

Risk Factors

Various risk factors have been identified for shedding different MDR pathogens. These relate largely to antimicrobial and veterinary hospital exposure, but also include factors such as source (e.g., shelter versus household) and contact with human healthcare facilities.[1,20-22] Despite these studies, broad understanding of the epidemiology of MDR pathogens, particularly in the general population, is poorly understood.

Zoonotic Risks

Many AMR pathogens that affect animals can also infect people. Indistinguishable strains of MRSA, MDR enterococci, and ESBL-producing bacteria can be found in humans and animals, supporting concerns that infected or colonized animals could be a source of infection of human contacts. Yet the actual role of animals in human infection and the incidence of zoonotic infection are largely unknown. Reducing the incidence of these infections in animals and use of basic infection control practices to reduce animal-animal, animal-human and human-animal transmission probably are the most important measures to reduce zoonotic

disease risks.

Controlling Antimicrobial Resistance

Antimicrobial resistance cannot be eliminated. Even complete withdrawal of antimicrobials would not result in reversion of all bacteria to a pan-susceptible state. The goals of antimicrobial stewardship are to reduce the incidence of AMR and reduce the clinical impact of AMR (in both animals and humans). While straightforward in concept, this can be difficult in application because of limitations in knowledge about the impact of antimicrobial use and antimicrobial restriction on AMR.

Diagnostic Testing

When pathogen and resistance trends are predictable, diagnostic testing is less important. However, with the widespread emergence of AMR in both veterinary hospitals and the community, it is more difficult to predict pathogen and susceptibility results accurately, complicating empirical antimicrobial choices and increasing the likelihood of empirical treatment failure. This highlights the importance of diagnostic testing. While MDR pathogens are not inherently more virulent than their susceptible counterparts, successful treatment is dependent on prompt and effective diagnostic information so that proper treatment can be started. Additionally, the proliferation of AMR in the commensal microbiota, including in bacteria that can be isolated commonly from clinical specimens as contaminants, indicates the need for proper sample collection and consideration of the clinical relevance of culture results to prevent unnecessary treatment of MDR but clinically irrelevant bacteria. Unnecessary treatment can be reduced by avoiding contamination during sample collection, ensuring that laboratories follow standard testing and reporting practices, and considering the clinical relevance of results (not blindly treating every bacterium that is reported on a culture result).

Treatment Guidelines

In human medicine, extensive efforts have been put towards development of clinical guidelines to optimize diagnosis and management of a wide range of diseases.[23-25] These guidelines are based on thorough review of scientific evidence, which typically includes numerous large and well-designed clinical trials. Clinical guideline development is a relatively recent occurrence in veterinary medicine, but a few clinical guidelines have been released in recent years (Table 209-1), including guidelines directed specifically at antimicrobial therapy as well as broader, disease-based consensus statements that include treatment recommendations. A weakness of most (if not all) veterinary guidelines is the lack of high quality supporting data. In contrast to the numerous large well-designed studies that are often available in humans, veterinary guidelines typically are based on a combination of human data, small veterinary studies, basic information about the disease, principles of antimicrobial therapy, pharmacokinetic studies, and expert opinion. These can still be very useful documents; however, the lack of evidence highlights an important weakness in veterinary infectious disease research that probably hampers optimal diagnosis and treatment.

Antimicrobial Stewardship Programs

Concerns about AMR have resulted in development of comprehensive programs to improve antimicrobial use in human medicine. While mainly focused on hospitals, efforts to improve community-level (e.g., general physician) antimicrobial prescription have also been implemented.[26-28] The overall goals are to limit inappropriate and excessive antimicrobial use, while optimizing patient outcomes. These programs can take many forms, but core elements are outlined in Table 209-2.

TABLE 209-2

Core Elements of Antimicrobial Stewardship Programs[36]

ELEMENT	EXAMPLES
Leadership commitment	Providing necessary personnel, financial and information technology resources Supporting activities
Accountability	Designating a leader, preferably a clinician
Antimicrobial expertise	Appointing a pharmacist leader to help work to improve prescribing
Action	Implementing an action in response to other program experiences or facility-specific observations (e.g., automatic stop orders if prolonged antimicrobial use in hospital is linked to failure of anyone to bother to say to stop, restriction certain drugs, changes in susceptibility reporting)
Tracking	Monitoring prescription and AMR patterns
Reporting	Providing feedback about antimicrobial use and AMR to caregivers and other relevant personnel
Education	Educating prescribers about resistance and optimal prescribing practices

AMR, Antimicrobial resistance.

Antimicrobial Restriction

Restricting access to antimicrobials is a controversial area but one that veterinary medicine needs to address. Some countries (e.g., the Netherlands) have banned the use of certain antimicrobial classes (e.g., carbapenems) while others have restricted when and how drugs such as fluoroquinolones and later (3rd or 4th) generation cephalosporins can be used in animals. It has been recommended that veterinary medicine consider voluntary restriction practices to both optimize use of important antimicrobial classes and to demonstrate a proactive approach (and therefore perhaps reduce the pressure for broad regulatory restrictions). An example of this would be vancomycin restriction guidelines that are used for some facilities, which allow the drug to be used but only in specifically designated situations where there is a clear need. All veterinary facilities would benefit from consideration of their antimicrobial use practices and whether (or which) restriction practices could be implemented to both optimize patient care and limit use of "last resort" drugs.

Prevention of Disease

Perhaps the greatest potential positive impact on antimicrobial use and AMR is reducing infections. If infections are prevented, the need for antimicrobials and the corresponding pressure for AMR are eliminated. While complete elimination of infections is impossible, better use of preventive medicine programs (e.g., vaccination), managing comorbidities that might predispose to infection (e.g., atopic dermatitis, hyperadrenocorticism; see ch. 360) and reducing transmission of pathogens in veterinary hospitals and community sites (e.g., kennels, puppy classes) could have a profound impact.

CHAPTER 210

Zoonoses

Michael R. Lappin

Introduction

There are many infectious agents that are "common to, shared by, or naturally transmitted between humans and other vertebrates," which is one of the classic definitions for a zoonotic disease. While the majority of concern with zoonoses is directed towards humans acquiring infections from pets or other animals, the predominant pathway of infection from animals to humans or from humans to other animals (anthroponosis) varies by agent. For practicing small animal veterinarians, the major issues concerning zoonotic disease relate to protecting staff and owners and providing accurate information to owners to aid in their decisions about pet ownership as it relates to zoonotic disease risks.

Most of the infectious agents discussed in this chapter can infect and cause disease in immunocompetent people, but disease is generally more prevalent or more severe in people that are immune-suppressed. There are many forms of immunosuppression in people that may influence pet ownership decisions; people with acquired immunodeficiency syndrome (AIDS) are discussed frequently. However, there are many other individuals that could be at greater risk for developing clinical illness if exposed to a zoonotic agent, including the very old, the very young, and those receiving chemotherapy for immune-mediated diseases, organ transplantation, or neoplasia. Immunosuppressed people are sometimes advised to give up their pets. However, if the pet is healthy and appropriate precautions are taken, the health benefits associated with pet ownership may outweigh the potential risk of pet ownership. Work continues around the world to attempt to determine the true risks and benefits associated with pet ownership.[1,2] All human and other animal health care providers should provide accurate information to pet owners concerning the risks and benefits of pet ownership so that an informed decision about acquiring and keeping pets can be made. There are now many online resources that can help owners, veterinarians, and physicians work together to make logical family decisions concerning pet ownership. The Center for Disease Control and Prevention (CDC) website "Healthy Pets Healthy People" is an excellent resource (http://www.cdc.gov/healthypets/index.html). For individuals with conditions associated with immune suppression, the CDC "Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents" is also an excellent resource (http://www.cdc.gov/mmwr/preview/mmwrhtml/rr58e324a1.htm).[3]

Many infectious agents can infect humans by direct contact with pets, their exudates, or their excrement. These agents are the most important to veterinary health care providers and to dog and cat owners and are discussed in this chapter by likely route of exposure. Some agents are "shared vector zoonoses," which includes *Anaplasma* spp., *Bartonella* spp., *Borrelia burgdorferi, Ehrlichia* spp., *Rickettsia* spp., and others. For a number of these agents, the pet brings the vector into the home environment, potentially resulting in exposure of the person. With other zoonotic agents, including *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis,* and *Cryptococcus neoformans,* the owner and pet are infected by shared environmental exposure to the agent.

The purpose of this chapter is to provide an overview of common canine and feline zoonoses encountered in small animal practice. General guidelines for the avoidance of zoonotic transfer of disease for veterinarians and pet owners are listed in Boxes 210-1 and 210-2. For some of these agents, the reader is directed to other sections of this textbook for further information concerning diagnosis and treatment.

Box 210-1

General Guidelines for Veterinary Staff Members to Lessen Risk of Zoonotic Transfer of Disease

- Veterinary staff members should familiarize themselves with zoonotic issues and take an active role in discussing the health risks and benefits of pet ownership with clients so that logical decisions concerning ownership and management of individual animals can be made.
- Veterinary staff members should teach all owners techniques to avoid being bitten or scratched.
- Veterinary staff members should make it clear to owners that they understand conditions associated with immune deficiency, are discreet, and are willing to help; signs or posters can be effective for this purpose.
- Veterinary staff members should provide pet owners information concerning veterinary or public health aspects of zoonoses, but should not diagnose diseases in humans or discuss specific treatments.
- Veterinary staff members should always refer clinically ill pet owners to a physician for additional information and treatment.
- Veterinarians should volunteer to speak to the pet owner's physician to clarify zoonotic issues when indicated.
- When veterinary staff members offer public health–related advice, it should be documented in the medical record.
- When reportable zoonotic diseases are diagnosed, appropriate public health officials should be contacted.
- Diagnostic plans to assess for presence of organisms with zoonotic potential should be offered, particularly to owners with clinically ill pets.
- Rabies vaccination should be recommended for all dogs and cats.
- Drugs that control hookworms and roundworms should be recommended for all dogs and cats.
- Flea and tick control products should be recommended for all dogs and cats.
- Veterinary clinic staff members should avoid needle sticks contaminated with blood or effusions.

Box 210-2

General Guidelines for Pet Owners to Lessen Risk for Zoonotic Transfer of Disease

- Veterinary care should be sought for all clinically ill pets.
- Physical examination and fecal examination should be performed at least once or twice yearly.
- Fecal material produced in the home environment should be removed daily, preferably by someone other than an immunocompromised individual.
- Use litterbox liners and periodically clean the litterbox with scalding water and detergent.
- Do not allow dogs or cats to drink from the toilet.
- Wear gloves when gardening and wash hands thoroughly when finished.
- Filter or boil water from sources in the environment.
- Wash your hands after handling animals.
- Do not handle animals that you are unfamiliar with.
- Immunocompromised people should not handle clinically ill animals, if possible.
- Pets should be maintained within the home environment to lessen exposure to other animals that may carry zoonotic agents, exposure to excrement of other animals, and exposure to fleas and ticks.
- Pets should only be fed commercially processed food.
- Do not share food utensils with pets.
- Avoid being licked by animals.
- Claws of cats should be clipped frequently to lessen the risk of skin penetration.
- To lessen the risk of bites and scratches, do not tease or physically restrain dogs and cats.
- If bitten or scratched by a dog or cat, seek medical attention.
- Control potential transport hosts, such as flies and cockroaches that can bring zoonotic agents into the home.
- Cook meat for human consumption to 80°C for 15 minutes minimum (medium to well-done).

- Wear gloves when handling meat and wash hands thoroughly with soap and water when finished.
- If a new pet is to be adopted into a household with an immunocompromized family member, the dog or cat least likely to be a zoonotic risk is a clinically normal, arthropod-free, adult animal from a private family.
- Once the animal to be adopted is identified, it should be quarantined from any immunocompromised person until a thorough physical examination and zoonoses risk assessment is performed by a veterinarian.

Enteric Zoonoses

Multiple infectious agents of the gastrointestinal tract can be shared between animals and humans (Table 210-1). Some enteric agents are infectious immediately when passed in feces (e.g., *Campylobacter* spp., *Cryptosporidium* spp., *Giardia*) while others require time out of the body to become infectious (e.g., *Ancylostoma* spp., *Toxocara* spp., *Toxoplasma gondii*). Since there are many enteric zoonotic agents that can be associated with diarrhea, diagnostic workups for enteric infections in dogs or cats with gastrointestinal signs of disease are indicated not just to aid the animal but also because of potential human health risks. Resolving the diarrhea is paramount to lessening zoonotic risk because formed feces is easier to control in the environment and while it can be difficult to eliminate the carrier phase of some agents (e.g., *Giardia*), it is generally believed that dogs or cats with normal stools are passing lower organism numbers than pets with diarrhea. The reader is directed to other individual chapters for more detail concerning diagnostic procedures and treatment for dogs or cats with vomiting or diarrhea.

TABLE 210-1

Common Enteric Zoonotic Infections of Dogs and Cats

AGENT	PRINCIPAL CLINICAL SYNDROMES
Ancylostoma caninum (D) and *A. tubaeforme* (C)* (hookworms)	Dogs and cats: Blood loss anemia, diarrhea, unthrifty Humans: Cutaneous larva migrans; eosinophilic pain
Baylisascaris procyonis (roundworm)	Dogs: Failure to thrive Humans: Visceral larva migrans; CNS disease
Campylobacter jejuni and *C. coli* (bacteria)	Dogs and cats: Diarrhea and vomiting Humans: Diarrhea and vomiting
Cryptosporidium spp.† (coccidia)	Dogs and cats: Diarrhea and vomiting Humans: Diarrhea and vomiting
Escherichia coli (bacterium)	Dogs and cats: Diarrhea and vomiting Humans: Diarrhea and vomiting
Echinococcus multilocularis (cestode)	Dogs and cats: Subclinical infection Humans: Polysystemic disease
Echinococcus granulosus (cestode)	Dogs: Subclinical infection Humans: Diarrhea and vomiting
Entamoeba histolytica‡ (amoeba)	Dogs: Diarrhea and vomiting Humans: Diarrhea and vomiting
Giardia spp.§ (flagellate)	Dogs and cats: Diarrhea and vomiting Humans: Diarrhea and vomiting
Helicobacter spp.‖ (bacteria)	Dogs and cats: Vomiting Humans: Reflux disease and vomiting
Salmonella spp. (bacteria)	Dogs and cats: Diarrhea and vomiting Humans: Diarrhea and vomiting
Strongyloides stercoralis (hookworm)	Dogs and cats: Blood loss anemia, failure to thrive Humans: Cutaneous larva migrans
Toxocara canis and *T. cati** (roundworms)	Dogs and cats: Vomiting, failure to thrive

	Humans: Ocular and visceral larva migrans
Toxoplasma gondii¶ (coccidian)	Cats: Rarely diarrhea, polysystemic disease Humans: Ocular, CNS, polysystemic disease
*Uncinaria stenocephala** (hookworm)	Dogs and cats: Blood loss anemia, diarrhea, unthrifty Humans: Cutaneous larva migrans
Yersinia enterocolitica (bacterium)	Dogs and cats: Subclinical infection Humans: Diarrhea and vomiting

*Larvation of eggs occurs after passage into the environment, so direct transmission is less likely than exposure through environmental contamination.

†Most dogs and cats are infected by *C. canis* or *C. felis*, respectively, and these host-adapted species are rarely found in humans.

‡Infection of dogs in the United States is thought to be rare.

§Host-adapted and zoonotic assemblages exist. Dogs and cats can harbor zoonotic assemblages but whether levels of infection result in re-infection of humans is not established.

||Most *Helicobacter* spp. found in dogs and cats are host-adapted species. When *H. pylori* is detected in a dog or cat, it is likely from reverse zoonotic transmission.

¶Sporulation of oocysts occurs after passage into the environment, so direct transmission is less likely than exposure through environmental contamination.

CNS, Central nervous system.

Visceral larva migrans can be induced by infection of humans with *Toxocara cati*, *Toxocara canis*, or *Baylisascaris procyonis*.[4-6] Antibodies against *Toxocara* spp. are common in humans and a recent review concluded the burden of disease is significant.[5,6] These roundworms are passed as eggs in feces which larvate and become infectious after 1 to 3 weeks. The infectious eggs can survive in the environment for months and are the primary source of human infection. Roundworms are commonly passed by young and adult dogs and cats.[7-9] Embryonated *Toxocara* spp. eggs have been transmitted by earthworms, filth flies and cockroaches, and have been found on the fur of pets.[10,11] Illness in dogs and cats is mild. In humans, larvae are released from larvated eggs, are ingested, penetrate the intestinal wall and migrate through the tissues. Eosinophilic granulomatous reactions involving the skin, lungs, central nervous system (CNS), or eyes then occur, potentially leading to clinical signs of disease.

Ancylostoma caninum, *Ancylostoma braziliense*, *Ancylostoma tubaeformis*, *Uncinaria stenocephala*, and *Strongyloides stercoralis* have been associated with cutaneous larva migrans.[12,13] In one large study of over one million dogs examined at 547 private veterinary hospitals in 44 states of the United States, 4.5% of samples contained eggs of *Ancyclostoma* spp.[8] *Ancylostoma tubaeforme* and *A. braziliense* were found in feces of 75% and 33%, respectively, of cats tested in one study in Florida.[7] After the passage of hookworm eggs into the environment in feces, infectious larvae are released after incubating for 1 to 3 days; humans are infected by skin penetration. In addition, eosinophilic enteritis in humans can occur after ingestion of larvated *A. caninum* eggs.[12] *Trichuris vulpis*, the dog whipworm, has been detected in feces in some people and has rarely been associated with gastrointestinal signs of disease in humans.[14]

Due to the risk of human infection associated with these dog and cat nematodes, it is recommended that animal excrement be controlled in human environments. All puppies and kittens should be routinely treated with an anthelmintic that has efficacy against nematodes. The Companion Animal Parasite Council (http://www.capcvet.org) and the European Council (http://www.esccap.org/) are excellent resources for current information concerning strategic deworming of pets.

Dipylidium caninum, *Echinococcus granulosus*, and *Echinococcus multilocularis* are cestodes of dogs and cats that can infect humans.[15-17] Wild carnivores are more common definitive hosts of *Echinococcus* spp. and shed infective eggs into the environment. *Echinococcus granulosus* eggs can be transmitted in feces of dogs after ingestion of infected sheep or rabbit tissues; *E. multilocularis* can be transmitted in feces of dogs or cats after ingestion of an infected rodent. Transmission to humans occurs after ingestion of the intermediate host (flea, *Dipylidium*) or eggs (*Echinococcus* spp.). Infection of dogs and cats with cestodes is generally subclinical; infection of humans with either *Echinococcus* spp. can result in significant illness.[16] Prevention or control of cestodes is based on sanitation procedures and use of taeniacides. Restricting hunting behavior of dogs and cats and feeding only processed or cooked foods should lessen potential exposure to *Echinococcus* spp. Monthly administration of drugs with activity against cestodes should be considered in dogs and cats allowed to hunt in endemic areas. Flea control should be maintained to lessen risk of *D. caninum* infection.

Cryptosporidium spp. and *Toxoplasma gondii* are the enteric coccidians that people are most likely to come in contact with via fecal contamination (see ch. 221).[18,19] *Cryptosporidium canis* is most common in dogs and *C. felis* is most common in cats; these agents are not considered to be significant zoonotic agents in humans.[18,20,21] Humans are more likely to develop infection with *C. parvum* or *C. hominis,* which are generally associated with ingestion of oocysts in large animal feces or human feces, respectively.[22,23] *Cryptosporidium* spp. have an enteric life cycle that culminates in the production of thin-walled, autoinfective oocysts and thick-walled, environmentally resistant oocysts that are passed in feces already sporulated and so, infectious. The oocysts (approximately 5 microns in diameter) are small, which makes them hard to diagnose but easy to acquire in water or food contaminated with feces. The strains that infect both pets and people cannot be differentiated by light microscopy from those that infect only pets, so all *Cryptosporidium* spp. should be considered potentially zoonotic. Polymerase chain reaction can be used to genotype *Cryptosporidium* spp. in dog or cat feces if owners are concerned about carriage of zoonotic species (www.dlab.colostate.edu). However, dogs or cats are almost never positive for *C. parvum* or *C. hominis.* Routine use of PCR assays as a screening diagnostic tool can have the unintended consequence of detecting the carrier stage of *Cryptosporidium* spp.[24] No treatment is known to eliminate the *Cryptosporidium* spp. carrier state (see ch. 221), but if feces of dogs and cats are normal, the risk of infection of a human should be minimal. Avoiding exposure is the most effective way to prevent acquiring a *Cryptosporidium* spp. infection. Routine disinfectants require extremely long contact with the organism to be effective. Drying, freeze-thawing, and steam cleaning can inactivate the organism. Surface water collected in the field for drinking should be boiled or filtered.

Cats are the only known definitive host of *Toxoplasma gondii* and the risks to humans, cats, and dogs have been recognized for years (see ch. 221).[19] After being passed by a cat, *T. gondii* oocysts sporulate in 1 to 5 days, are then infectious to most warm-blooded vertebrates, and survive in the environment for months. After *T. gondii* infection of cats or intermediate hosts including dogs and humans, an extraintestinal phase with formation of tissue cysts containing the organism develops. Infection of tissue cysts in undercooked meat is a major route of infection of humans.[25] The organism is also transmitted transplacentally in dogs, cats, and humans if the dam is infected for the first time during gestation. Recent evidence based on detection of anti-sporozoite antibodies in serum of humans suggests that ingestion of sporulated oocysts in the environment is a common way for humans to become infected.[26] Infected immunocompetent humans are generally asymptomatic; self-limiting fever, lymphadenopathy, and malaise occur occasionally. Transplacental infection of humans results in clinical manifestations, including stillbirth, hydrocephalus, hepatosplenomegaly, and retinochoroiditis. In addition to all the previous clinical findings associated with *T. gondii* infection, there is a weak to moderate association with *T. gondii* and several behavioral abnormalities in humans.[27,28] Thus, it is clear that avoiding *T. gondii* infection is a good strategy for people. In short, prevention is accomplished by avoiding the ingestion of feline feces that have been passed for >24 hours and avoid ingestion of undercooked meat. However, as discussed in ch. 221, acquiring *T. gondii* infection from an individual cat is unlikely because the oocyst shedding period is so short, oocysts are passed unsporulated, most cats do not leave feces on their body for extended periods of time, and repeat oocyst shedding, even in the face of cyclosporine administration, is unlikely (see Table 210-1).[19,29]

Giardia spp. (flagellate), *Entamoeba histolytica* (amoeba), and *Balantidium coli* (ciliate) are enteric protozoans of dogs and cats that can be transmitted to humans by contact with feces; the cysts of these agents do not require an incubation period to become infectious (see ch. 221). It is unknown how often humans are exposed to *E. histolytica* or *Balantidium coli.* However, *Entamoeba* spp. cysts were identified in 94 of 600 dog fecal samples in Pakistan[30] and *E. histolytica* cysts are found in public parks in Spain.[31] While zoonotic assemblages of *Giardia* (A and B) are occasionally amplified from dog or cat feces, most are positive for the dog or cat adapted assemblages C, D, or F.[32-36] However, determining zoonotic strains of *Giardia* spp. by microscopic examination or antigen testing is not possible, so feces from all dogs and cats infected with *Giardia* spp. are considered a potential human health risk. If infection cannot be eliminated, genotyping is available to prove whether a dog or cat is carrying a zoonotic genotype (www.dlab.colostate.edu). Prevention of zoonotic giardiasis includes boiling or filtering surface water for drinking and washing hands that have handled materials that could be contaminated with feces, even if gloves were worn. In dogs and cats treated for giardiasis, infection can be documented again several weeks later in approximately 75% of animals. Whether these cases are a treatment failure or a reinfection is unknown. Thus, the primary goal for the treatment of giardiasis is elimination of diarrhea. Whether to treat healthy dogs or cats carrying *Giardia* is still controversial (www.capcvet.org).[37]

Salmonella spp., *Campylobacter* spp., *Escherichia coli, Yersinia enterocolitica,* and *Helicobacter* spp. each infect

dogs and cats, are directly infectious, and can cause disease in humans.[38-42] Transmission between animals and humans is by fecal-oral contact. Gastroenteritis can occur in dogs or cats after infection by *Salmonella* spp., *Campylobacter* spp., or *E. coli. Helicobacter* infections cause gastritis, which is commonly manifested as vomiting, belching, and pica. Although *Helicobacter pylori* was isolated from a colony of cats, most dogs and cats are infected with non-zoonotic *Helicobacter* spp. *Yersinia enterocolitica* is probably a commensal agent in most dogs and cats but causes fever, abdominal pain, polyarthritis, and bacteremia in humans and was associated with diarrhea in one puppy.[42]

Diagnosis of *Salmonella* spp., *Campylobacter jejuni, E. coli,* and *Y. enterocolitica* in clinically affected animals is based on culture of feces or PCR (see ch. 220). Culture is preferred so that antimicrobial susceptibility can be provided to use in developing a treatment plan. In general, treatment of bacterial enteric agents is only used to manage clinical illness when indicated. Treatment of subclinical carriers likely just leads to drug resistant strains. Prevention of enteric bacterial zoonoses is based on sanitation and control of exposure to feces. Veterinary clinicians should strive to resolve diarrhea in affected dogs and cats, as normal animals are less likely to be shedding large numbers of enteric pathogens. Immunodeficient people should avoid young animals and animals from crowded or unsanitary housing, particularly if clinical signs of gastrointestinal tract disease are occurring. Feeding raw foods is a risk factor for dogs or cats with bacterial enteric zoonoses and should be avoided (https://www.avma.org/KB/Policies/Pages/Raw-or-Undercooked-Animal-Source-Protein-in-Cat-and-Dog-Diets.aspx), particularly if there is an immune-suppressed family member (see ch. 192).[39-41]

Exudate Exposure Zoonoses

There are several bacterial and fungal agents associated with draining tracts or other skin diseases in dogs or cats that could be directly infectious to the owner or veterinary staff members (Table 210-2). Methicillin-resistant *Staphylococcus aureus* (MRSA) and *Staphylococcus pseudintermedius* (MRSP) are associated with skin infections, wound infections, and can be carried by normal dogs and cats.[43-49] These agents can be spread amongst veterinary or human patients and doctors and are a significant problem in hospitals.[43,49] A recent study of nasal and perianal samples completed in an open-admission shelter showed MRSA in 0.5% of cat samples, MRSA in 0.5% of dog samples, and MRSP in 3% of dog samples.[50] These prevalence rates are generally lower than those from dogs or cats from veterinary hospitals. Healthy dogs or cats carrying MRSA or MRSP are generally not a risk for immunocompetent and otherwise healthy people but care should be taken to avoid contamination of open wounds if an infected animal is being cared for.

TABLE 210-2

Common Scratch-, Bite-, or Exudate-Associated Zoonotic Infections of Dogs and Cats

AGENT	PRINCIPAL CLINICAL SIGNS
Bartonella spp.* (bacterium)	Cats and dogs: Subclinical, fever, hyperglobulinemia, uveitis, lymphadenopathy, others Humans: Fever, malaise, lymphadenopathy, bacillary angiomatosis, bacillary peliosis, others
Capnocytophaga canimorsus (bacterium)	Dogs and cats: Subclinical oral carriage Humans: Bacteremia
Dermatophytes (fungi)	Cats and dogs: Superficial dermatologic disease Humans: Superficial dermatologic disease
Francisella tularensis† (bacterium)	Dogs and cats: Fever, lymphadenopathy, septicemia, pneumonia Humans: Ulceroglandular, oculoglandular, glandular, pneumonic, or typhoidal (depending on route of inoculation)
Rabies (virus)	Cats and dogs: Progressive central nervous system disease Humans: Progressive central nervous system disease
Sporothrix schenkii† (fungus)	Cats: Draining cutaneous tracts Humans: Draining cutaneous tracts
Yersinia pestis† (bacterium)	Cats: Bubonic, bacteremic, or pneumonic (depending on route of inoculation) Humans: Bubonic, bacteremic, or pneumonic (depending on route of inoculation)

Bartonella henselae, B. koehlerae, and *B. clarridgeiae* are transmitted amongst cats and dogs by *C. felis* and so are also listed under flea-borne disease. There are other *Bartonella* spp. with zoonotic implications. Cats generally develop a higher level of bacteremia than do dogs, and so are epidemiologically linked more frequently to human disease. The vectors are unknown for some *Bartonella* spp.

†Dogs rarely shed enough organism to be a public health risk.

Sporothrix schenckii (see ch. 236) and the dermatophytes are the fungi that are most likely to infect owners or veterinary staff members by direct contact.[51-55] *Histoplasma* (see ch. 233), *Blastomyces* (see ch. 233), *Coccidioides* (see ch. 232), *Aspergillus* (see ch. 234 and 235), and *Cryptococcus* (see ch. 231) infections of humans and animals can occur in the same household but generally result from a common environmental exposure (see a following section). Management of zoonotic dermatophytes has been reviewed.[51,52] *Sporothrix schenckii* is a species complex containing *S. schenckii sensu stricto, S. brasiliensis, S. globosa, S. mexicana,* and *S. luriei.* Brazil is one of the most common countries with endemic infections and most are *S. brasiliensis*.[54,55] The organisms are found in the soil around the world. Most cases of zoonotic transfer have been from cats that seem to have higher concentrations of the organism in exudates when compared to dogs. Cats are believed to be infected by scratches from contaminated claws of other cats and sporotrichosis is most common in outdoor males. Cats can develop cutaneolymphatic, cutaneous, or disseminated sporotrichosis and chronic draining cutaneous tracts are common. Humans can be infected by contamination of cutaneous wounds with exudates from infected cats; thus veterinary care personnel are at high risk when treating infected cats. The organism can be demonstrated by cytologic examination of exudates or culture. See ch. 236 for a discussion of the treatment of this syndrome. Gloves should be worn when attending to dogs or cats with infected wounds or draining tracts, and hands should be cleansed thoroughly afterwards.

Bite or Scratch Zoonoses

The number of animal bite injuries has been estimated to be 300,000 to 4.7 million per year in the United States.[56,57] In one study, 70% of bites were from dogs and 13% were from cats.[56] Dogs and cats are subclinical carriers of multiple bacteria in the oral cavity. Most of the aerobic and anaerobic bacteria associated with bite or scratch wounds cause only local infection in immunocompetent individuals. However, cat bites were six times more likely than dog bites to become infected in a recent study.[58] After a person is bitten or scratched, local cellulitis is noted initially, potentially followed by evidence of deeper tissue infection. Severe sequelae, including meningitis, endocarditis, septic arthritis, osteoarthritis, and septic shock, can occur. Immunodeficient humans or those exposed to *Pasteurella* spp., *Capnocytophaga canimorsus* (DF-2), or *Capnocytophaga cynodegmi* more consistently develop systemic clinical illness (see Table 210-2).[59-61] Splenectomized humans are at increased risk for developing bacteremia. Other less common animal bite bacterial infections include *Mycoplasma* spp., L-form bacteria, *Francisella tularensis,* and *Yersinia pestis.*[62] Tularemia and plague are also vector-borne diseases and also can be acquired by inhalation. See those sections of this chapter for further discussion of these two syndromes. Diagnosis of bacterial infections is confirmed by culture. Treatment of clinically affected humans includes local wound management and parenteral antibiotic therapy. Penicillin derivatives are highly effective against most *Pasteurella* infections; penicillins and cephalosporins are effective against *Capnocytophaga* spp. *in vitro*. Treatment of dogs and cats that carry *Capnocytophaga* spp. is not needed.

The most recognized scratch- or bite-associated zoonosis is cat scratch disease (fever) associated with *Bartonella henselae.*[63,64] Dogs, cats and humans can be infected with multiple other *Bartonella* spp., including *B. clarridgeiae, B. koehlerae, B. vinsonii* subspecies *berkhoffi* (dogs and humans), and *B. quintana;* see ch. 215 and 216 for a discussion of the clinical syndromes in small animals. Shortly after the *Bartonella* genus was discovered, *B. henselae* was associated with bacillary angiomatosis and bacillary peliosis, common disorders in humans with AIDS. In the last several years, *Bartonella* spp. have been associated with endocarditis and a multitude of chronic inflammatory diseases in people.[63-67] Neurobartonellosis appears to be a common manifestation and veterinary health care providers are at increased risk.[65,67]

Contact with cats or dogs is a known risk factor for development of bartonellosis. These infectious agents are amongst the most common in the world. *Bartonella henselae, B. clarridgeiae,* and *B. koehlerae* are common in cats and their fleas.[68] *Bartonella vinsonii* subspecies *berkhoffi* DNA has been amplified from fleas and a number of *Bartonella* spp. has been detected in ticks.[69] Thus, *Bartonella* spp. infections should also be considered a shared vector zoonosis. Cats with *B. henselae* infection housed together with naïve cats without *Ctenocephalides felis* do not share the infection.[70,71] However, transmission occurs quickly when fleas are added. *Bartonella henselae* survives in flea frass for days and it appears likely that cat's claws and teeth are contaminated with *B.*

henselae during grooming and then inoculated into humans during bites or scratches. It is also possible that *Bartonella* spp. infections occur after flea frass contaminates broken dermal barriers like hangnails. These findings emphasize the maintenance of flea control on dogs and cats, year round. Use of imidacloprid-containing products has blocked transmission of *B. henselae* amongst research cats.[71,72] *Bartonella* spp. infection has also been associated with needle sticks, so blood from dogs or cats should be handled carefully.

Blood culture, blood PCR, and serologic testing can be used to determine the *Bartonella* spp. infection status of individual cats, dogs, or people. The use of BAPGM culture media with PCR assay has been shown to be one of the most sensitive ways to prove *Bartonella* spp. bacteremia in dogs and people; these assays are available at one commercial laboratory (www.galaxydx.com). In dogs and cats, although serologic testing can be used to determine whether an individual has been exposed, both seropositive and seronegative cats and dogs can be bacteremic, limiting the diagnostic utility of serologic testing. Thus, testing healthy cats or dogs for *Bartonella* spp. infection is not currently recommended by the Centers for Disease Control and Prevention or the American Association of Feline Practitioners.[3,64]

In experimental studies, administration of doxycycline, tetracycline, erythromycin, amoxicillin-clavulanate, or enrofloxacin can limit bacteremia but does not cure infection in all cats and antibiotic treatment of healthy cats has not been shown to lessen the risk of cat scratch disease. Azithromycin was commonly administered to cats with suspected clinical bartonellosis, but is now considered contraindicated for feline bartonellosis due to rapid induction of antimicrobial resistance.[73] Thus, antibiotic treatment of healthy bacteremic cats is controversial and not currently recommended by the Centers for Disease Control and Prevention or the American Association of Feline Practitioners.[3,64] Flea and tick control should be maintained on all dogs and cats. Immunodeficient people should avoid kittens with fleas. Cat claws should be kept clipped or claw covers used and cats should never be teased. Cat-induced wounds should immediately be cleansed, and medical advice sought.

Rabies is still the only relevant direct small animal viral zoonosis in the United States. See ch. 226 for a discussion of this agent as well as the Compendium on Rabies Control 2016.[74] Pseudorabies is a herpesvirus that infects pigs; dogs and humans can develop clinical illness after exposure.[75] To date, there is no evidence that retroviruses of cats infect people.[76] However, because both feline leukemia virus and feline immunodeficiency virus can induce immune deficiency, infected cats should be considered more likely than retrovirus-naïve cats to be carrying other potential zoonotic agents, particularly if clinical signs of disease are present.

A major goal in the prevention of zoonosis is for veterinarians to train pet owners and new veterinary staff members how to avoid bites or scratches.[77,78]

Respiratory Tract and Ocular Zoonoses

There are only a few respiratory pathogens of dogs or cats that are associated with clinical disease in people (Table 210-3). *Bordetella bronchiseptica* is the most common primary bacterial pathogen associated with the canine infectious respiratory disease complex in dogs (see ch. 227) and can be a pathogen in some cats (see ch. 212, 229, and 241). Humans rarely develop clinical disease caused by *B. bronchiseptica* unless they are immunologically compromised.[79-81] Fewer than 100 cases of *B. bronchiseptica* infection in humans have been reported; most of the patients were immune-suppressed. *Bordetella bronchiseptica* infection in humans has been associated with cats as well as dogs. Diagnosis is best confirmed by culture so that antimicrobial susceptibility testing can be performed. Dogs or cats with clinical signs generally respond to the administration of amoxicillin-clavulanate or doxycycline. Immune-suppressed people should avoid handling cats or dogs with suspected infectious upper or lower respiratory tract inflammatory disease until the animals are clinically normal. However, treated animals can still shed *Bordetella bronchiseptica* in low numbers.

TABLE 210-3

Common Ocular or Respiratory Zoonotic Infections of Dogs and Cats

AGENT	PRINCIPAL CLINICAL SYNDROMES
Bordetella bronchiseptica (bacterium)	Dogs and cats: Sneeze and cough Humans: Pneumonia in immunosuppressed
Chlamydia felis (bacterium)	Cats: Conjunctivitis, sneezing

	Humans: Conjunctivitis
*Francisella tularensis** (bacterium)	Cats: Fever, lymphadenopathy, septicemia, pneumonia Humans: Ulceroglandular, oculoglandular, glandular, pneumonic, or typhoidal (depending on route of infection)
Streptococcus group A (bacterium)	Dogs and cats: Subclinical, transient carrier Humans: "Strep throat," septicemia
*Yersinia pestis** (bacterium)	Cats: Bubonic, bacteremic, or pneumonic Humans: Bubonic, bacteremic, or pneumonic

*Also can be vector-borne.

Chlamydia felis (formerly *Chlamydia psittaci*) causes conjunctivitis and mild rhinitis in cats.[82] In Japan, the prevalence rates of antibodies against an isolate of *C. felis* were 51% in stray cats, 15% in pet cats, 3% in the general human population, and 5% in small animal clinic veterinarians, suggesting that transfer between cats and humans may occur.[83] Conjunctivitis in humans after direct contact with ocular discharges from cats has been described.[84] A human isolate of *Chlamydia* spp. was inoculated into cats, resulting in conjunctivitis and persistent infection, suggesting that the isolate was a feline strain. Occasionally the organism is associated with systemic disease including atypical pneumonia, endocarditis and glomerulonephritis. However, DNA of *C. felis* has also been amplified from healthy people.[85] Diagnosis is based on organism demonstration by culture, cytologic documentation of characteristic inclusion bodies, fluorescent antibody staining of conjunctival scrapings, or amplification of specific DNA by polymerase chain reaction. Tetracycline or chloramphenicol-containing eye ointments generally are effective in the treatment of infection. Oral administration of doxycycline is still considered the optimal way to clear the carrier state in catteries. Care should be taken to avoid direct conjunctival contact with discharges from the respiratory or ocular secretions of cats, especially by immunosuppressed persons. Employees should be directed to wear gloves or wash hands carefully when attending to cats with conjunctivitis.

Humans are the principal natural hosts for *Streptococcus* group A bacteria, *Streptococcus pyogenes,* and *Streptococcus pneumoniae,* which cause "strep throat" in humans. Dogs and cats in close contact with infected humans can develop transient, subclinical colonization of pharyngeal tissues and can transmit the infection to other humans. However, this is poorly documented and believed to be unusual. The organism can be cultured from the tonsillar crypts. Culture-positive animals should be treated with penicillin derivatives. If animals are to be treated in a household with chronic, recurrent "strep throat" in children, all humans should also be treated because they also could be chronic subclinical carriers.

Francisella tularensis is the Gram-negative bacillus found throughout the continental United States that causes tularemia. Of the 4 subspecies, *F. tularensis* subsp *tularensis* (type A) and *F. tularensis* subsp *holarctica* (type B) occur commonly in the Northern Hemisphere including all of the United States (except Hawaii), and are most commonly associated with illness in humans and other animals.[86-89] Humans are exposed to the organism most commonly by direct animal contact (primarily rabbits or cats), ingestion, inhalation from aerosolization, or by tick or deer fly bites. Infection of people after inhaling the organism after mowing over infected rabbits or rodents may be common. Cats and dogs are most likely infected by tick bites or ingestion of infected rabbits or rodents. Dogs may be less likely to become ill than cats and are not usually considered a source of infection, but may facilitate human exposure by bringing infected ticks into the environment. Whether clinical signs develop is dependent on the inoculation dose, the strain of *F. tularensis,* and the immune status of the exposed individual. Clinically affected cats or dogs usually develop fever or lymphadenopathy. Ulceroglandular, oculoglandular, glandular, oropharyngeal, pneumonic, and typhoidal forms have been described in humans and develop depending on the route of exposure. Human cases were greatly increased in Colorado, Nebraska, South Dakota, and Wyoming in 2015 (n = 100) compared to 2004-2014.[86] In this report, the pneumonic form of disease (n = 26), ulceroglandular form of disease (n = 26), or fever (n = 25) were the most common presenting complaints. The organism may not be visible cytologically, so infection is confirmed by culture, fluorescent antibody stain, PCR assay, or demonstration of a rising serological titer. Infected humans usually respond to antimicrobial therapy; one death was reported in the 2015 western United States outbreak.[86] Optimal treatment for infected cats and dogs is unknown. Aminoglycosides, doxycycline, chloramphenicol, or quinolones are used in people.[90] The disease is prevented by avoiding exposure to lagomorphs, ticks, and clinically ill infected cats. All cats with fever or lymphadenopathy or with clinical evidence of bacteremia should be handled carefully and a workup performed for tularemia and plague if in endemic areas and/or with appropriate exposure history. Local

authorities should be alerted when a diagnosis of tularemia is made. Animals that are hospitalized should be housed in isolation, handled by as few individuals as possible, and those handling the animals should wear a gown, gloves, eye shield, and respirator if available.

Feline plague is caused by *Yersinia pestis*, a Gram-negative coccobacillus found most commonly in Midwestern and far Western states, particularly Arizona, New Mexico, and Colorado.[91,92] Rodents are the natural hosts for this bacterium; cats are thought to be most commonly infected by ingestion of bacteremic rodents or lagomorphs or by being bitten by *Yersinia*-infected rodent fleas.[91-95] Non-domestic cats in endemic areas are also exposed.[93] Humans are most commonly infected by rodent flea bites, but many cases of transmission by exposure to wild animals and infected domestic cats have been documented. One infected dog was thought to be associated with pneumonic plague in people and a human to human case was also suspected.[94] Animal contact can be associated with *Y. pestis* infection of humans by inhalation of respiratory secretions, through bite wounds, or by contamination of mucous membranes or abraded skin with secretions or exudates.

Bubonic, septicemic, and pneumonic plague can develop in cats and humans; each form has accompanying fever, headache, weakness, and malaise. Untreated pneumonic plague is commonly fatal.[95] Because cats are most commonly infected by ingestion of bacteremic rodents, suppurative lymphadenitis (buboes) of the cervical and submandibular lymph nodes is the most common clinical manifestation. Exudates from cats with lymphadenopathy should be examined cytologically for the presence of large numbers of the characteristic bipolar rods. Fluorescent antibody staining, culture or PCR of exudates, the tonsillar area, or saliva or documentation of increasing antibody titers confirms the diagnosis. People who are exposed to infected cats should be urgently referred to physicians for antimicrobial therapy, and public health officials should be alerted. Doxycycline, fluoroquinolones, chloramphenicol, or aminoglycosides can be used successfully for the treatment of plague.[96] Parenteral antibiotics should be used during the bacteremic phase. Cats with suppurative lymphadenitis should be considered plague suspects, and extreme caution should be exercised when handling exudates or treating draining wounds. Suspect animals should be treated for fleas, housed in isolation, handled by as few individuals as possible, and those handling the animals should wear a gown, gloves, eye shield, and respirator if available. Cats are generally not considered infectious to humans after 4 days of antibiotic treatment but veterinarians should consult with local public health officials for guidance.

Currently, there are no respiratory viruses of dogs or cats in the United States that have been associated with human infection. However, multiple occurrences of inter-species transmission of influenza A viruses have occurred and potential for increased zoonotic risk with these, and other viruses, may occur over time.[97-99]

Genital and Urinary Tract Zoonoses

The most common infectious agents associated with zoonotic transmission via exposure to urine or genital tract materials are *Brucella canis*, *Coxiella burnetii*, and *Leptospira* spp. (Table 210-4).

TABLE 210-4

Common Urogenital Zoonotic Infections of Dogs and Cats

AGENT	PRINCIPAL CLINICAL SYNDROMES
Brucella canis (bacterium)	Dogs: Orchitis, epididymitis, abortion, stillbirth, vaginal discharge, uveitis, fever Humans: Fever, malaise
Coxiella burnetiii (rickettsia)	Cats: Subclinical, abortion, or stillbirth Humans: Fever, pneumonitis, lymphadenopathy, myalgia, arthritis
Leptospira spp. (spirochetes)	Dogs: Fever, malaise, inflammatory urinary tract or hepatic disease, uveitis, central nervous system disease Humans: Fever, malaise

Brucella canis is a bacterium that preferentially infects the testicles, prostate, uterus, and vagina of dogs (see ch. 213). The infection is maintained in dogs primarily by venereal transmission but direct transmission from oral or nasal exposure can occur in puppies. Humans can be infected by direct contact with vaginal and preputial discharges from dogs. Clinical syndromes in dogs are diverse but commonly include abortion,

stillbirth, failure to conceive, orchitis, epididymitis, vaginal discharge, uveitis, discospondylitis, and bacteremia. Intermittent fever, depression, and malaise are common in infected people.[100,101] Diagnosis is based on serologic testing or demonstration of the organism by culture or PCR assay. Seronegative dogs are unlikely to harbor *B. canis* unless the exposure was peracute. Seropositive dogs should have results confirmed by tube agglutination or agar gel immunodiffusion and should be cultured or assessed by PCR assay. Long-term antibiotic treatment (tetracyclines, aminoglycosides, quinolones) does not always clear the infection, so some recommend euthanasia of infected dogs. Ovariohysterectomy or castration will lessen contamination of the environment. Veterinary staff members should avoid direct contact with genital tract secretions while managing cases with suspected brucellosis. Owners should seek advice from their physician concerning ownership of a proven *B. canis*-positive dog.

Coxiella burnetii is a rickettsial agent found throughout the world, including North America. Many ticks, including *Rhipicephalus sanguineus,* are naturally infected with *C. burnetii* but the importance of ticks in the transmission of this agent has been recently questioned.[102] Most humans are infected by inhalation of the organism and so pneumonia is common. Other clinical findings of Q fever include fever, malaise, headache, pneumonitis, myalgia, and arthralgia.[103] Cattle, sheep, and goats are commonly subclinically infected and they pass the organism into the environment in urine, feces, milk, and parturient discharges. Some cats and dogs are also seropositive or PCR-positive for *C. burnetii* and cats have been implicated in human cases of Q fever a number of times.[104-106] Fever, anorexia, and lethargy developed in some experimentally infected cats and abortion has been documented in cats. Tetracyclines, chloramphenicol, and quinolones are usually effective therapeutic agents in humans. Gloves and masks should be worn when attending to parturient or aborting cats or dogs. People who develop fever or respiratory tract disease after exposure to parturient or aborting cats or dogs should seek medical attention and inform the attending physician about the potential for zoonotic Q fever.

Leptospira spp. can be transmitted in urine from infected dogs and cats to humans, resulting in clinical disease.[107-109] Host-adapted species cause subclinical infection; infection by non–host-adapted species commonly results in clinical illness. See ch. 217 for a detailed discussion of the clinical manifestations of this disease and its treatment in dogs and cats. Human clinical syndromes vary with the serovar but are similar to those that occur in the dog. Control of *Leptospira* spp. in hospitalized animals is detailed in the ACVIM Consensus Statement.[109] *Leptospira* spp. vaccine side-effects are minimal and so vaccines containing 4 leptospire serovars should be considered in at-risk dogs[109,110] (https://www.aaha.org/public_documents/professional/guidelines/caninevaccineguidelines.pdf); see ch. 208.

Shared Vector Zoonoses

Some zoonotic agents are transmitted between animals and humans by shared vectors such as fleas, ticks, mosquitoes, sand flies, or kissing bugs (Table 210-5).[111] *Rickettsia rickettsii* (ticks), *R. felis* (fleas), *Ehrlichia* spp. (ticks), *Anaplasma phagocytophilum* (ticks), *Borrelia burgdorferi* (ticks), *Bartonella* spp. (fleas and ticks), *Dipylidium caninum* (fleas), *Dirofilaria immitis* (mosquitoes), West Nile virus (mosquitoes), *Trypanosoma cruzi* (triatomines—kissing bugs) are examples of vector-borne zoonoses common in the United States. In other countries, sandfly-borne *Leishmania* spp. infection is also important. For the flea- and tick-borne zoonoses, the pet brings the vector of the organism into the environment, resulting in exposure of the human being. Veterinary health care providers could have a slightly increased risk of exposure because they handle many animals infested with fleas and ticks. However, the vector, not direct contact with the infested animal, generally results in infection of the person. Flea and tick control should always be maintained in animals (www.capcvet.org), and infested animals that are seen in the clinic should be treated immediately. See other sections of this text for detailed discussions of these agents.

TABLE 210-5

Common Vector-Borne Zoonotic Infections of Dogs and Cats

AGENT	PRINCIPAL CLINICAL SYNDROMES
Fleas	
Bartonella spp.* (bacteria)	Cats and dogs: Subclinical, fever, hyperglobulinemia, uveitis, lymphadenopathy, others Humans: Fever, malaise, lymphadenopathy, bacillary angiomatosis, bacillary peliosis, CNS,

	polyarthritis, endocarditis, others
Rickettsia felis (rickettsia)	Dogs: Subclinical Humans: Fever, CNS
Yersinia pestis (bacterium)	Cats: Bubonic, bacteremic, or pneumonic (depending on the route of inoculation) Humans: Bubonic, bacteremic, or pneumonic (depending on the route of inoculation)
Ticks*	
Anaplasma phagocytophilum (rickettsia)	Dogs and cats: Fever, polyarthritis Humans: Fever, polysystemic
Borrelia burgdorferi (spirochete)	Dogs: Subclinical infection, fever, polyarthritis, nephropathy Humans: Polyarthropathy, cardiac and CNS disease
Ehrlichia spp. (rickettsia)	Dogs: Subclinical infection, fever, polysystemic Humans: Fever, polysystemic
Francisella tularensis (bacterium)	Cats: Fever, lymphadenopathy, septicemia, pneumonia Humans: Ulceroglandular, oculoglandular, glandular, pneumonic, or typhoidal (depending on route of infection)
Rickettsia rickettsia (rickettsia)	Dogs: Subclinical infection, fever, polysystemic Humans: Fever, polysystemic

*_Bartonella_ spp. DNA has been amplified from some ticks but the extent of the role ticks play in the transmission of these agents has not been fully ascertained.

CNS, Central nervous system.

Shared Environment Zoonoses

Some agents that infect both animals and man are not commonly transmitted between the pet and the owner by direct contact but are acquired from the same environmental source. Notable examples include *Histoplasma capsulatum* (see ch. 233), *Coccidioides immitis* (see ch. 232), *Blastomyces dermatitidis* (see ch. 233), *Cryptococcus neoformans* (see ch. 231), and *Aspergillus* spp. (see ch. 234 and 235). See the relevant chapters of this text for detailed discussions of these agents.

Lyme Disease

Meryl P. Littman

Client Information Sheet: Lyme Disease

Introduction

Lyme disease (borreliosis) is the most common tick-borne disease in people in North America. Many dogs and cats are exposed, become chronic carriers, and have persistently high antibody titers, yet only a small fraction becomes ill. Comprehensive reviews[1-7] and opinion papers[8-10] show that controversy still exists regarding diagnosis, treatment, and prevention of canine Lyme disease.

The Agent, the Tick, and the Birds, Mice, and Deer

There are at least 36 *Borrelia* spp. (16 pathogenic) including at least 20 species of *Borrelia burgdorferi* sensu lato, the agent of Lyme borreliosis. The main causes of Lyme disease are *B. burgdorferi* sensu stricto *(Bb)* in North America and *Bb*, *B. afzelii* and *B. garinii* in Eurasia. *Borrelia* spp. DNA was found in ticks embedded in 20 million year-old amber[11] and DNA of *Bb* was found in the 5000-year-old alpine "Tyrolean Iceman" mummy,[12] so the disease is not new, but it was named after a large cluster of children in Lyme, CT (U.S.) that were misdiagnosed with juvenile rheumatoid arthritis in 1976.[13] Maternal activism led to investigations by the Centers for Disease Control and Prevention and Dr. Allen Steere. The organism is named after Willy Burgdorfer, who studied ticks from Shelter Island, NY, for *Rickettsia rickettsii,* and found many *Ixodes scapularis* ticks carried spirochetes.[14] Serologic testing became available, proving exposure to these spirochetes in affected people, and the association was made that the illness was caused by them. Experimental models in laboratory animals and dogs confirmed this association, and the organisms and the disease have been studied extensively, including genomic sequencing. At least 30 strains of *Bb* exist, based on OspC antigen genotypes, and different strains predominate in sick people versus dogs.[15-17]

There is transstadial, but not transovarial, transmission of *Bb* in ticks. In the typical 2-year life cycle of *Ixodes,* eggs hatch outdoors, with larvae being active in the summer, attaching to and feeding on birds, mice, and small mammals that recently acquired *Bb* from infected nymphs which fed on them recently that previous spring. Transmission of *Bb* occurs in the mouse at 53 hours[18] (or less[19]) after tick attachment, which is the time it takes for OspA (the outer surface protein A that acts as a hook onto the tick's midgut) to be downregulated enough to allow the agent to come away and enter the host. By this time, OspC and many other antigens are expressed more than are OspA and antigens expressed by *Bb* within the tick or when cultivated *in vitro*. Tick larvae pick up *Bb* in summer from their first host, overwinter, and emerge as nymphs, with *Bb* intact (transstadial transmission), infecting the next generation of birds, mice, small mammals, as well as dogs, deer, people, and other animal species the next spring. The nymphs feed, moult, and emerge the following autumn, transmitting *Bb* to their third hosts, often large mammals, as adult ticks quest on higher brush.

The geographical range of ticks infected with *Bb* will expand as ticks hitch a ride on migratory birds. As of 2013, 95% of Lyme disease in people occurs in just 14 New England, mid-Atlantic, and Upper Midwestern states: PA, MA, NY, NJ, CT, WI, MN, NH, ME, VA, MD, VT, RI, DE.[20] Results for Lyme-seropositive dogs are similar.[21] In some areas, 70-90% of healthy dogs are Lyme-seropositive.[22-24]

Besides *Bb, Ixodes* ticks can transmit other spirochetes (*B. mayonii,* which is another cause of Lyme disease, tick-borne relapsing fever [TBRF] group agents *B. miyamotoi [Bm]* and *B. davisii*),[25] rickettsia *(Anaplasma phagocytophilum* and *Ehrlichia muris),* a protozoan *(Babesia microti),* a bacterium (*Bartonella* spp.), a virus

(Powassan or tick-borne encephalitis virus), and possibly more agents. Coinfections can occur but could be missed, e.g., with *Bm*, only recently identified. In CT, 35% of *Ixodes* ticks were positive for *Bb* and 6% for *Bm* in one study.[25] In people, *Bm* can cause neurologic and flu-like signs.[26,27] In New England, *Bm*-seropositivity was found in 1% of healthy people, 3.2% of people diagnosed with Lyme disease, and 21% of patients with a flu-like illness in late spring/summer in southern NY State.[27]

Lyme *Borrelia* spp. are spiral-shaped, motile, Gram-negative spirochetes, transmitted by *Ixodes* ticks which infect host mammals and birds, and migrate from the tick bite site interstitially, hiding out extracellularly with collagen and fibroblasts. There may be an L-form, spheroplast, or cystic dormant form of *Bb* in a hostile environment.[28-37] Evasion of the host's immune system also occurs by recombination of DNA cassettes, producing antigenic variation and possibly recurrent signs.[2] In contrast to TBRF *Borrelia* spp., such as *Bm* from *Ixodes* ticks and *B. hermsii (Bh)* and *B. turicatae (Bt)* (from *Ornithodorus* soft argasid ticks that only feed for 15-90 minutes), *Bb* does not generally circulate in blood or body fluids. The TBRF organisms can be seen in peripheral blood smears with dark-field microscopy, or Wright-Giemsa, acridine orange, or silver stains. Blood for TBRF culture (Barbour Stoenner Kelly medium) or PCR analysis (sequencing the 16S rRNA gene, flaB or intergenic spacer domains to identify the specific agent) is best taken before initiating antibiotics. Cross-reactive TBRF antibodies can be seen on the old whole cell IFA or ELISA testing for *Bb* antibodies. *Bh* has been found in a sick dog in Washington state and *Bt* in sick dogs in Texas and Florida.[38,39]

Comparing Human and Canine Lyme Disease: the Canine Experimental Model

In Europe, for many years, it was known that a post-tick bite illness in people (rash and neurologic signs) responded to penicillin. In the US, the expanding rash at the site of the tick bite is more often accompanied by flu-like signs (headache, fever, myalgia/arthralgia) and, later, swollen painful oligoarthritis in a joint near the tick bite site, but subsequent neuroborreliosis, cardiac, and chronic skin manifestations also can be seen.[40,41] An experimental canine model of Lyme disease via tick bite has been studied extensively.[42-56] When infected ticks from New England were placed on 6- to 12-week-old puppies, they showed no acute illness but after 2-5 months showed a self-limiting illness (i.e., 4 days of fever, decreased appetite, and lameness with a hot/swollen joint in the leg closest to where the ticks attached), possibly with a few recurrent episodes in the same or different limb every 2 weeks.[42,45-51] Affected joints showed nonseptic neutrophilic inflammatory changes. When infected ticks were placed on 13- to 26-week-old puppies, only 2 days of this self-limiting illness occurred, with fewer recurrences.[52,53] When ticks were placed on older puppies and adult dogs, no signs of illness occurred even when the dogs were followed for more than a year, yet all the experimental dogs showed carrier status and persistently high antibody titers.[42-44] Subclinical mild synovial histological changes were seen,[42,54] although sometimes such changes also are seen in seronegative and vaccinated dogs.[55,56] Other histologic changes included suppurative and nonsuppurative dermatitis, and lymphoplasmacytic periarteritis and perineuritis.[55]

Interestingly, many experimental dogs have had coinfections from the tick exposure, mostly (35-45%) with *Anaplasma phagocytophilum*[46,53] or sometimes *Babesia microti*[42]; these dogs have not been tested for *Bartonella*, however. Carrier status for *Bb* for more than a year after tick exposure was documented by positive cultures or polymerase chain reaction (PCR) test results on skin biopsies of the tick bite sites. Antibiotics usually have cleared the carrier status; however, 10-15% of dogs have remained carriers despite treatment with 1 month of high-dosage doxycycline (10 mg/kg PO q 12 h), amoxicillin (20 mg/kg PO q 8 h), azithromycin (25 mg/kg PO q 24 h), or ceftriaxone (25 mg/kg IV q 24 h).[45,47-49] Carriers in the experimental model remained nonclinical, persistently seropositive (the magnitude of titers was not correlated with illness), and none developed Lyme nephritis. Some dogs showed lameness after abrupt withdrawal from steroids, but coinfections or trauma could have played a role.[48]

Cats appear more resistant to illness from spirochetal infections; seropositive cats are not more likely to show illness.[57] Screening for coinfections (bartonellosis, anaplasmosis, feline leukemia virus, feline immunodeficiency virus) is recommended. Experimentally, cats exposed to organisms from ticks have shown multiple-limb lameness and joint, pulmonary, lymphoid and CNS inflammation at necropsy.[6]

Signs of Canine Lyme Disease in the Field

Lyme Arthritis

As in the experimental model, a Lyme-positive status in the field, no matter how high the titer, does not predict illness in dogs.[58] Cutaneous rash,[55] neurologic,[59] and cardiac[60] signs of Lyme disease rarely or never occur. Original reports from New England showed that <5% of seropositive dogs had a history of lameness, even when followed for 20 months, and the same percentage of seronegative dogs had similar signs.[61] Even fewer seropositive cats show signs. One study showed that Lyme arthritis is overdiagnosed 40% of the time.[62] Thus perhaps <3% of seropositive dogs have signs due to Lyme arthritis. Clinical signs attributed to Lyme disease include oligo- or polyarthritis with painful, hot, swollen joint(s), joint effusion, local lymphadenopathy, fever, and hyporexia. Differential diagnoses include tick-borne arthritis, immune-mediated polyarthritis, systemic lupus erythematosus, rheumatoid arthritis, bacterial endocarditis, septic arthritis, degenerative joint disease, cranial cruciate ligament rupture, intervertebral disc disease, trauma, panosteitis, osteomyelitis, polymyositis, neoplasia, or immobility due to cardiopulmonary, metabolic, or neurologic disease.[1] Many dogs in Lyme-endemic areas have coinfections with *Anaplasma,* and coinfected dogs could be more likely to show clinical signs.[63] Cytopenia suggests coinfection. Synovial fluid cytology from arthrocentesis shows neutrophilic inflammation, and sometimes *A. phagocytophilum* morulae (see ch. 74 and 94). Radiographs show only soft tissue swelling (a nonerosive arthritis; see ch. 203). Signs typically are self-limiting or respond quickly to antimicrobial treatment (1-2 days); treatment for 1 month is recommended.[1] Doxycycline or minocycline usually is chosen because of possible sensitive coinfection (*Anaplasma, Ehrlichia, Rickettsia, Bartonella, Mycoplasma* spp.) and for anti-inflammatory and anti-arthritic properties (see Treatment, below). *Bb* also is sensitive to amoxicillin, erythromycin, azithromycin, cefovecin, and ceftriaxone.[64,65]

Lyme Nephritis

A smaller percentage (<2%) of seropositive dogs can develop Lyme nephritis, a protein-losing nephropathy (PLN) associated with immune-mediated glomerulonephritis and Lyme-specific antigen-antibody complex deposition in renal glomeruli.[7] Labradors and Golden Retrievers appear at higher risk, although proteinuria was not found to be associated with Lyme-seropositive status in retrievers in one study.[66] It is unknown why so many dogs with high titers and presumably high concentrations of circulating immune complexes do not develop Lyme nephritis. There could be host genetic or immune factors, or infective strain differences. In people, certain genetic haplotypes are predisposed to developing immune-mediated disease triggered by Lyme antigens (HLA-DR4).[1,67] Without an experimental model of Lyme nephritis in dogs, it is difficult to study this aspect of the disease. Perhaps some retrievers are genetically predisposed to having glomerulopathy (e.g., Bernese Mountain Dogs with coincidental seropositivity),[7] possibly due to a podocytopathy or immunodysregulation. It is unknown if Lyme-specific immune complexes are primary (causative of illness) or if they are passively caught in already-abnormal glomeruli. Elution studies on kidneys taken after death showed a variety of Lyme antigen-antibody complexes, but such studies are not available for clinical cases. There are no validated stains to use on renal biopsies for immunohistochemical documentation that immune complexes found in glomeruli are Lyme-specific, so Lyme nephritis is diagnosed presumptively in seropositive dogs with PLN. Clinical signs can be occult (proteinuria), or dramatic, e.g., thromboembolic events causing neurologic deficits, hind limb paresis/paralysis, or respiratory distress (see ch. 243 and 256); hypertensive damage causing blindness or cerebrovascular accidents (see ch. 11 and 157); or the nephrotic syndrome, with edema or effusions, even before signs of uremia (anorexia, vomiting) are seen (see ch. 325). Polyuria/polydipsia is a late sign, signaling secondary tubular damage. Dogs with primary glomerular disease can present with azotemia without isosthenuria, e.g., with urine specific gravity of 1.020-1.030. The differential diagnosis includes leptospirosis and causes of PLN (infectious, immune-mediated, genetic, toxic, vascular, neoplastic, and amyloidosis).[1,7,68-71]

In the original description of Lyme nephritis, only 30% of affected dogs had a history of lameness.[72] Clinical manifestations of PLN can include systemic hypertension, thromboembolic events, edema, effusions, and eventually signs of uremia such as anorexia, weight loss, vomiting, and/or polyuria/polydipsia. Laboratory changes are those seen with PLN, such as proteinuria, cylindriuria, hypoalbuminemia, hypercholesterolemia, possibly anemia, and thrombocytopenia (consumptive or due to coinfection). Some dogs have an active urinary sediment, glucosuria, and isosthenuria due to tubular changes secondary to severe glomerular disease. Tubular changes, hypoalbuminemia, and/or azotemia can be seen due to

leptospirosis and Lyme seropositivity may be coincidental.[71]

Original reports of histopathologic changes in severely affected dogs showed a triad of immune-mediated glomerulonephritis (IMGN), tubular necrosis/regeneration, and interstitial nephritis,[72] but perhaps early or milder forms exist without tubular changes. Original reports included 30% of dogs with prior Lyme vaccine history, but it is unknown if vaccine was given after exposure or was non-protective, or whether Lyme vaccine antigens could cause sensitization or aggravation of immune-complex deposition. Only 30% had a history of lameness.

Diagnostic Tests for Lyme Exposure

The site of the tick bite rarely is known, and *Bb* migrates interstitially, does not circulate in blood, and is rarely found in joint tap or bodily fluids. Therefore, diagnostic tests to document exposure do not rely on cultures or PCR testing but rather on serologic testing for antibodies directed against *Bb* antigens. Older tests, such as whole-cell IFA or ELISA, showed cross-reactions with other spirochetes as well as vaccinal antigens. Western immunoblotting helps to show banding patterns that change over time due to antigenic variation shown by *Bb* in the host during the carrier state. Again, there may be cross-reactions. IgM and IgG titers are not helpful in dogs because of the long incubation time before illness (2-5 months), so that dogs are unlikely to present ill during IgM+/IgG− status. Antigenic variation can induce new IgM peaks during the carrier phase, so IgM+/IgG+ status does not necessarily prove recent exposure.

The SNAP-4DxPlus (IDEXX) cage-side test gives a qualitative result for heartworm antigen, and antibodies against *Ehrlichia canis, E. chaffeensis, E. ewingii, Anaplasma phagocytophilum, A. platys,* and against the Lyme C6 peptide antigen. This antigen is a recombinant replica of the constant region of an antigen (VlsE) that is only expressed by *Bb* when it is in the host, and is not found in the tick, in *Bb* cultivation *in vitro,* nor in any Lyme vaccines. Thus, C6 peptide antibodies are specific for natural exposure. Since the SNAP-4DxPlus test uses no species-specific reagents, the test can be used off-label on cats for identification of exposure antibodies to *Bb* as well as *Anaplasma* spp.

The Lyme C6Quant test (IDEXX) gives a quantitative result. The magnitude of any Lyme titer does not predict illness and is not cause for initiation of treatment in nonclinical, nonproteinuric dogs. In treated dogs, the qualitative SNAP-4DxPlus test is very sensitive and is likely to remain positive for years, even with a low C6Quant level. The C6Quant level has been shown to wane after treatment[73] so that a post-treatment baseline test (3-6 months after treatment) can be useful for future comparisons. If signs of illness suggest Lyme disease recurrence or reinfection, but the C6Quant level is not much higher than the post-treatment baseline, the signs are probably not attributable to Lyme disease and retreatment is not indicated.

The AccuPlex4 (Antech) test gives a qualitative result for heartworm antigen, antibodies to *Ehrlichia canis, Anaplasma phagocytophilum* and 5 Lyme antigens. An algorithm is used for interpreting the magnitude and relationship of antibodies to (1) OspA (p31, the antigen found in all Lyme vaccines but sometimes also expressed in the host and found in non-vaccinated people with chronic non-antibiotic-responsive Lyme disease which could be an immune-mediated disease[74-76]); (2) OspC (which rise 2-3 weeks after natural exposure and decline 3-5 months later if the dog is not reexposed; new bacterin vaccines might induce OspC antibodies); (3) OspF (which rise 6-8 weeks after exposure and persist long-term, possibly despite treatment); (4) p39 (antibodies seen in 88% of naturally exposed animals vs. 47% of vaccinates[77]); and (5) SLP (proprietary). According to Antech Laboratories and studies done at Colorado State University, the AccuPlex4 test may detect antibodies 1 week earlier for Lyme and *Anaplasma* when compared to the SNAP-4Dx test.[78] However, a recent study comparing the tests found the AccuPlex4 was not as repeatable and was less specific and less sensitive than the SNAP-4DxPlus test for Lyme and *Anaplasma* antibody testing.[79] Other tests include the Multiplex (Cornell University Animal Health Diagnostic Center) test, which gives quantitative results for titers against OspA, OspC, and OspF; and the VetScan Canine Lyme Rapid qualitative bedside test (Abaxis) which tests for antibodies against VlsE, OspC, and flagellin (which might cross-react with other bacterial flagellins).

Differentiation of vaccinal from natural-exposure antibodies and early from late infection might not be as straightforward as previously thought. OspA antibodies (seen mostly in vaccinates, protective titer unknown) and OspC antibodies (seen mostly in non-vaccinates) can appear in either vaccinates or non-vaccinates. OspC and OspF antibodies might give a clue regarding when a dog was *last* exposed to these Lyme antigens, but not when it was *first* exposed. Whether an infection (exposure) is early or late might not be clinically useful information in the dog.

Whenever a dog shows evidence of natural exposure, whether it is healthy or sick, at least three important

repercussions are apparent: (1) the dog should be screened for renal proteinuria, so that early intervention for possible early Lyme nephritis can be initiated if indicated; (2) the dog has been exposed to ticks and wildlife, so further testing for exposure or signs of coinfections (anaplasmosis, babesiosis, bartonellosis, ehrlichiosis, Rocky Mountain spotted fever, leptospirosis, other *Borrelia* spp., etc.) might be indicated; and (3) the dog needs better tick control. Seropositive dogs are sentinels, indicating that the owners live in an area where ticks are carrying Lyme disease. Owners are grateful when their veterinarians educate them about tick-borne diseases, tick control, landscaping, and public health issues. For instance, veterinarians can warn people not to wait for the rash or illness before calling their physician when they find an engorged tick on themselves, because for people living in a Lyme endemic area, taking 1 day's dose of doxycycline within 72 hours of removal of an engorged *Ixodes* tick has been helpful in preventing Lyme disease.[80]

Treatment of Lyme Arthritis and Lyme Nephritis (Table 211-1)

Treatment of Nonclinical, Nonproteinuric Dogs

There is debate about whether to treat nonclinical nonproteinuric dogs that have positive Lyme titers.[8,9] The magnitude of Lyme titers is neither predictive of, nor even associated with, illness, and this author does not advocate treatment for all of these dogs. All seropositive dogs should be screened and monitored several times a year for proteinuria (the necessary frequency and duration are unknown). Treatment has not been shown to prevent future illness.

TABLE 211-1

Recommendations for Dogs with Natural-Exposure Lyme Antibodies

	NONCLINICAL	PROTEINURIC	OLIGO- OR POLYARTHRITIS, FEVER
Diagnostic Testing	Screen for proteinuria*	Localize proteinuria (renal?); IRIS staging Rule out other causes of PLN (CBC; serum biochemistry profile; BPM; urinalysis; urine culture; UPC; C6Q; chest radiographs; abdominal ultrasound; possible renal biopsy) (see text)	Screen for proteinuria* Joint tap for cytology and cultures CBC, serum biochemistry profile, radiographs C6Q Consider other causes of lameness/fever (see text)
Consider Coinfections: Lyme+ status may be coincidental and just a marker for tick and wildlife exposure	Consider screening for stealth pathogens: • Anaplasmosis/ehrlichiosis • Babesiosis • Bartonellosis • Heartworm	Screening for infectious diseases: • Anaplasmosis/ehrlichiosis† • Babesiosis • Bartonellosis • Heartworm • RMSF† • Leptospirosis† • Consider possible fungal diseases, brucellosis, hepatozoonosis, leishmaniasis, other infections	Consider screening for infectious diseases: • Anaplasmosis/ehrlichiosis† • Babesiosis • Bartonellosis • Heartworm • RMSF† • Leptospirosis (myositis)† • Brucellosis, fungal, other infections
Treatment and Monitoring	Tick control (see text) Antimicrobial treatment has not been shown to prevent future illness and is controversial. Lyme titer magnitude has not been associated with future illness. If antimicrobials are used, do C6Q at 0 and 3-6 months later for a new baseline for	Tick control (see text). Treat with antibiotics (unknown protocol, possibly 3-6 months) and standard PLN treatments: renal diet, ACEi/RAASi, omega 3-fatty acids, antithrombotics, antihypertensives, phosphate binders, antiemetics/protectants, consider using immunosuppressives, colloids, etc. Check C6Q at 0 and 3-6 months later for a new baseline for future comparisons.	Tick control (see text). Treat with antibiotics (1 month). If non-responsive after 1-2 days, consider another cause for the clinical signs. Avoid NSAIDs in case steroids are needed to be added for suspected IMPA. Check C6Q at 0 and 3-6 months later for a new

	future comparisons.		baseline for future comparisons.

*Check for proteinuria 3-4 times the first year and twice yearly thereafter.

†May need acute and convalescent testing.

ACEi, Angiotensin converting enzyme inhibitor; *BPM*, blood pressure measurement; *CBC*, complete blood count; *C6Q*, Lyme C6Quant test (IDEXX); *FA*, fatty acids; *ICGN*, immune-complex glomerulonephritis; *IMPA*, immune-mediated polyarthropathy; *IRIS*, International Renal Interest Society (www.iris-kidney.com); *NSAIDS*, nonsteroidal anti-inflammatory drugs; *PLN*, protein-losing nephropathy; *RAASi*, renin-angiotensin-aldosterone system inhibitors; *RMSF*, Rocky Mountain spotted fever; *UPC*, urine protein/creatinine ratio.

Treatment of Canine Lyme Arthritis

The experimental model showed Lyme arthritis to be self-limiting; therefore, the necessity for treatment is questionable. In the field, however, dogs with suspected Lyme arthritis usually are treated with doxycycline or minocycline because of common coinfections (e.g., anaplasmosis), typically for 4 weeks at 5-10 mg/kg PO q 12 h, although the best protocol is unknown. Clinical signs generally improve dramatically within 1-2 days of starting therapy, and if not, other diagnoses should be entertained, such as immune-mediated polyarthropathy, which responds to corticosteroids. Most Lyme disease cases will be cleared of the carrier state with 1 month of antibiotics. Lyme C6 Quant (IDEXX) levels are helpful for comparisons (0 and 3 to 6-month post-treatment) since a ≥50% decline commonly is seen if the level was >100 originally and if proper tick control is used for preventing reexposure. The 6-month post-treatment level may then be used as a new baseline, and it is helpful for comparisons should the dog show new signs of possible Lyme disease in the future, to indicate whether reinfection/relapse warrants retreatment or not. Qualitative Lyme tests are likely to remain positive for years, even after treatment, and therefore, they are not an indication of carrier status or need for retreatment. It is unknown whether OspF antibodies wane after treatment, but whole cell IFA or ELISA antibodies do not wane as markedly as C6 peptide antibodies do after treatment.[48,73] The antibodies could be due to immune memory and not necessarily due to ongoing carrier status.

Treatment of Canine Lyme Nephritis

Without an experimental model for Lyme nephritis, the best protocol for treatment is speculative. The duration of antimicrobial treatment usually is prolonged (for 3-6 months or until the Lyme C6Quant [IDEXX] level has waned) because in 10-15% of dogs, the organism might not be cleared with only 1 month's treatment. Standard treatment for PLN[81] (see ch. 325) is indicated, e.g., angiotensin-converting enzyme inhibitors, other inhibitors of the renin-angiotensin-aldosterone system (RAAS) if necessary, modified low protein diet, omega-3 fatty acid supplementation, antithrombotics, antihypertensives, and treatment for chronic kidney disease as needed (see ch. 324) (e.g., phosphate binders, antiemetics, gastric protectants, appetite stimulants, crystalloids/colloids, etc.). Monitoring of proteinuria is recommended every 1-2 weeks when dogs are showing moderate clinical signs, or less frequently in stable patients. Monitoring is based on averaged urine protein/creatinine ratio (UPC) results on a mixture of equal aliquots of 3 daily samples; hematocrit; serum albumin, globulin, creatinine, BUN, phosphorus, calcium, Na, and K; and blood pressure measurement. These results are used for adapting the management protocol as needed. The prognosis is guarded for dogs that are already azotemic, vomiting, and anorexic. Dogs identified earlier, before they present with signs of uremia, can respond to standard treatments for PLN.

Since Lyme nephritis is associated with immune-mediated glomerulonephritis (IMGN), immunosuppressive therapy could be warranted.[70,82,83] Ruling out differential diagnoses and documentation of IMGN by renal biopsy are recommended before immunosuppressive treatment is initiated, if possible.[69] Renal biopsies should be sent to the International Veterinary Renal Pathology Service for examination by thin section light microscopy, special stains, immunofluorescence, and transmission electron microscopy; however, there are no validated stains to prove if any immune complexes are Lyme-specific. If clinical signs of disease are rapidly progressive, immunosuppressive therapy could be warranted even without biopsy confirmation of IMGN.[70] The best protocol is unknown. Mycophenolate is chosen often, but it can cause gastrointestinal side-effects. Other protocols include pulse corticosteroids (2 days), cyclophosphamide every 2 weeks, chlorambucil, azathioprine, or cyclosporine (see ch. 165).

Prevention of Lyme Disease in Dogs

Tick Control

Since there are many tick-borne diseases besides Lyme disease in Lyme-endemic areas, tick control is warranted whether or not Lyme vaccines are used. Tick control/prevention entails landscaping, avoiding tick habitats, tick removal (Video 211-1) and the use of tick control products. Although Lyme transmission does not generally occur until 2-4 days of tick attachment, products which only kill ticks after 24 hours of attachment (e.g., fipronil) are not preferred because other tick-borne agents can be transmitted faster. Therefore, products that prevent tick attachment or that kill ticks soon after attachment are advocated. Examples are topical products that contain permethrin (e.g., K9 Advantix II [Bayer], monthly), pyrethroid collars (e.g., Seresto [Bayer], works for 8 months), amitraz collars (e.g., Preventic [Virbac], works for 3 months), or the new oral (chewable) isoxazoline compounds that inhibit the arthropod-specific GABA-gated chloride channels and kill ticks early after feeding is started, e.g., NexGard (Merial, monthly), Bravecto (Merck, works for 3 months against *Ixodes, Rhipicephalus* and *Dermacentor* ticks and 2 months against *Amblyomma* ticks), or Simparica (sarolaner, Zoetis).

Lyme Vaccines

Several bacterins, a recombinant non-adjuvanted OspA subunit vaccine, and a new chimeric recombinant vaccine (crLyme, Zoetis, which includes OspC material from 7 strains of *Bb*) are available.[10] All of these vaccines induce production of OspA antibodies, to reduce the number of live *Bb* within the tick as it feeds. Currently, all available bacterins also claim induction of OspC antibodies as well as other antibodies that can kill any *Bb* organisms that are transmitted to the host. Lyme vaccines are still controversial because (1) excellent tick control products are available and are needed anyway to prevent other tick-borne diseases in Lyme-endemic areas; (2) Lyme arthritis only occurs in <5% of dogs exposed to *Bb;* (3) Lyme arthritis is self-limiting or easily treatable with antibiotics; (4) Lyme vaccines are less effective, with shorter duration of immunity and more post-vaccinal events, than vaccines for other diseases[1,56,84-88a]; (5) vaccination can give a false sense of security; (6) Lyme vaccines have not been shown to prevent Lyme nephritis; (7) Lyme vaccines can interfere with the interpretation of some diagnostic test results; and (8) the most serious forms of Lyme disease are rare but probably immune-mediated, and it is unknown if Lyme vaccinal antigens could sensitize or aggravate illness in genetically predisposed individuals.[10] In animal models and genetically predisposed people, OspA is inflammatory, sensitizing, and induces a marked T_H1 response; high anti-OspA antibody levels are associated with chronic non-responsive post-Lyme immune-mediated disease; and Lyme antigens including OspA were found in immune-complex deposits in dogs with suspected Lyme nephritis.[7,22,67,89-96]

Future vaccination development could take advantage of other paradigms, e.g., the tick salivary protein, Salp-15, which binds to *Bb* and facilitates early infection in the host.[97-99]

CHAPTER 212

Mycobacterial Infections, Actinomycosis and Nocardiosis

Joanna Whitney, Carolyn R. O'Brien

Client Information Sheet: Mycobacterial Infections in Dogs and Cats

Mycobacterial Infections

The genus *Mycobacterium* is a member of the order Actinomycetales. Mycobacteria are mostly intracellular, aerobic, acid-fast, non-spore-forming, environmentally resistant bacilli. They are usually saprophytic and non-pathogenic; however, several species are considered primary or opportunistic pathogens. Mycobacterial infections are being more commonly diagnosed in companion animals due to improved diagnostic techniques, use of immunosuppressive medications, and their zoonotic potential. It is likely that the prevalence of mycobacteriosis in dogs and cats is underestimated since there is a low index of suspicion, it causes non-specific signs, and it can be difficult to confirm an antemortem diagnosis.[1]

Mycobacteria are classified on their clinical presentation in human patients (tuberculoid, non-tuberculoid, leproid) or their physical and biochemical properties. In companion animals, mycobacteriosis is generally divided into tuberculous, saprophytic (rapid- and slow-growing) and lepromatous disease. However, there is much overlap within small animal patients. Many different organisms produce similar clinical signs and categorization of such organisms is not consistent.

Tuberculous Mycobacteriosis

Overview

Tuberculosis is an infection caused by members of the *Mycobacterium tuberculosis* (MTB) complex, which are obligate pathogens. Feline tuberculosis has been reported to be caused by infection with *M. bovis, M. microti* and rarely *M. tuberculosis.*[1-12] Canine tuberculosis is less common and associated with *M. tuberculosis* or *M. bovis.*[2,13-29] A dog with *M. microti* tuberculosis has been reported.[12]

Epidemiology and Pathogenesis

Reservoirs

The primary reservoir of *M. bovis* is domestic cattle; however, rats, feral pigs, wild deer, badgers and brush-tailed possums are proposed vectors of infection.[3,30,31] Both cats and dogs are considered to be "spill-over" hosts in the epidemiology of *M. bovis.* Cats appear more susceptible than dogs to infection.[2,32] Humans are the reservoir host of *M. tuberculosis* and infection of cats and dogs is considered a result of close contact with affected humans.[19,29,33-35] High levels of transmission to dogs living in high-risk environments have been demonstrated, although the incidence was low.[25] High levels of subclinical infection have been demonstrated in dogs experimentally infected with *M tuberculosis.*[36] The field vole has been identified as the maintenance host of *M. microti* in Great Britain. Infection with this organism has been reported in people, alpacas, llamas, badgers, pigs, cattle, horses, ferrets and, most commonly, cats.[10,37,38]

Cats and Dogs

Feline tuberculosis, in mutually exclusive clusters based on mycobacterial species, is usually identified in

endemic areas.[2,3,5] Canine tuberculosis is considered rare, particularly in areas in which rates of human and cattle infection are low.[15] Adult non-pedigree cats with outdoor access are most commonly infected with members of the *Mycobacterium tuberculosis* complex, although Siamese cats may be overrepresented in *M. microti* infections. Cats with *M. microti* infection are commonly older males, in contrast to those from which *M. bovis* is isolated.[5] Hunting and catching rodents has been shown to be a risk factor for *M. microti* infection in cats, and immunosuppression may result in reactivation of latent infections.[5,9,29,39] Feline immunodeficiency virus (FIV) infection was proposed as a cause of rapid disease progression (see ch. 222). However, only 2/339 cats with mycobacteriosis were FIV-positive.[5,6] The host immune response and duration of infection are believed responsible for lesion morphology, rather than the specific agent.[40] Tuberculoid lesions develop due to the aggregation of macrophages at sites of infection. This response may determine whether the infection becomes dormant or remains active. Pro-inflammatory mediators released by the macrophages may result in systemic signs of infection.[41]

Route of Infection

Route of infection appears responsible for the initial manifestations of disease and for location of the primary lesion(s). Thus, the disease tends to begin in the skin, gastrointestinal (GI) or respiratory tracts. However, due to the chronicity of infection and the potential for hematogenous dissemination, the primary site may not be identifiable at time of diagnosis. The presence of peripheral lesions and a history of bites from wildlife in cats (and on occasion, dogs) suggest that most infections develop following inoculation of organisms via bite wounds.[7,20,42] A recent case series has highlighted the risk of nosocomial spread of *M. bovis* in cats.[43]

History and Clinical Signs

The most common manifestation of tuberculosis in cats is development of subcutaneous (SC) masses, often with draining tracts and regional lymphadenopathy.[5-7,9,13,42] Cats may have non-specific systemic signs of lethargy, anorexia, weight loss or respiratory distress, in addition to cutaneous lesions.[5-7] The clinical signs of tuberculosis in dogs are nonspecific or reflect the site of infection. Common historical findings include lethargy, anorexia, weight loss, coughing, dyspnea, vomiting and diarrhea.[12,14,15,20,22,28,29,44-46] Less common signs include neurological dysfunction, cutaneous lesions, epistaxis and lameness.[12,14,20,28,29,47] Dogs are frequently pyrexic and in poor body condition at the time of presentation.[12,15,22,28,44]

Diagnosis

Clinical pathology and diagnostic imaging findings are generally non-specific in cases of tuberculosis, although they may reflect the location of infection or severity of disease.[48] Differentiation between individual agents of tuberculosis or differentiating between tuberculous and other mycobacterial infections cannot be based on clinical findings alone.[5] Initial diagnosis of tuberculosis is based on clinical suspicion, geographical location and identification of acid-fast bacilli (AFB) within tissue samples evaluated histologically. Traditionally, confirmation required culture of the organism. Culture may take 4-6 weeks and requires specialized media.[49] A subset of cats has been identified that are negative for AFB on initial laboratory evaluation but from which mycobacteria, particularly *M. bovis* and *M. microti,* can be cultured.[5,50]

Intradermal (ID) tuberculin and *M. bovis* antibody testing in cats and ID testing in dogs are not helpful.[51] Several immunodiagnostic assays for the antemortem diagnosis of *M. bovis* have been evaluated and shown excellent potential.[49,52-54] DNA amplification has been demonstrated to be a rapid and accurate means of identifying members of the *M. tuberculosis* complex.[11,36] Molecular methods are being reported to help identify causative agents in tuberculosis, particularly in dogs.[9,12,15,22,28,47,55]

Treatment and Prognosis

The zoonotic potential of tuberculosis must be explained to owners before treatment begins. Not only are there zoonotic risks, but cats with tuberculosis have a guarded prognosis. Although many respond well to a variety of antimicrobials, inappropriate drug selection and duration of treatment often results in disease recurrence and systemic spread.[50] Successful treatment involves surgical excision or debridement of cutaneous lesions and long-term antimicrobial therapy. Cats should initially be treated for two months with a

combination of rifampicin, a fluoroquinolone (preferably pradofloxacin or moxifloxacin) and clarithromycin or azithromycin, followed by an additional 4-6 months of rifampicin and either the fluoroquinolone or macrolide (E-Table 212-1).[56] Dogs with systemic disease have a grave prognosis. Most have been euthanized due to progression of infection and/or adverse effects of therapy.[12,15,44,45,55] Successful treatment using triple antibiotic therapy has been reported in a dog with acute peritonitis.[22]

E-TABLE 212-1

Antimicrobial Therapy in Dogs and Cats

		CANINE	FELINE	POTENTIAL SIDE EFFECTS
Tuberculous *Mycobacteria*		**Rifampicin** (10-15 mg/kg, max 600 mg/day, PO q 24 h)	**Rifampicin** (10-15 mg/kg PO q 24 h)	**Hepatotoxicosis,** GIT upset, pruritus (cats)
		Enrofloxacin (5 mg/kg IV/IM/SC/PO q 24 h)	**Fluroquinolone** • Marbofloxacin (2.75-5.5 mg/kg PO q 24 h) • Moxifloxacin (10 mg/kg PO q 24 h) • Pradofloxacin (3 mg/kg PO q 24 h)	GIT upset, cartilage abnormalities (young animals)
		Macrolide • Clarithromycin (5-15 mg/kg PO q 12 h) • Azithromycin (5-15 mg/kg PO q 24 h)	**Macrolide/Lincosamide** • Clindamycin (125 mg/cat PO q 12 h) • Azithromycin (5-15 mg/kg PO q 24 h)	GIT upset, esophagitis (cats) GIT upset
		Pyrazinamide (15-40 mg/kg PO q 24 h)	*Pyrazinamide (15-40 mg/kg PO q 24 h)* *Isoniazid (10-20 mg/kg PO q 24 h)*	**Hepatotoxicosis,** GIT upset **Hepatotoxicosis, neurotoxicosis,** thrombocytopenia
Saprophytic *Mycobacteria*	**Rapid growing***	**Enrofloxacin** (5 mg/kg IV/IM/SC/PO q 24 h)	**Fluroquinolone** • Pradofloxacin (3 mg/kg PO q 24 h) • Moxifloxacin (10 mg/kg PO q 24 h) • Marbofloxacin (2.75-5.5 mg/kg PO q 24 h)	GIT upset, cartilage abnormalities (young animals)
		Rifampicin (10-15 mg/kg, max 600 mg/day, PO q 24 h)		**Hepatotoxicosis,** GIT upset GIT upset, erythema (cats) GIT upset, hepatopathy (dogs), esophagitis (cats) Nephrotoxicosis, ototoxicosis, neuromuscular blockade Nephrotoxicosis, ototoxicosis, neuromuscular blockade

Nocardia **spp.**	**Sulphonamides** • Trimethoprim-sulphonamide (30 mg/kg PO q 12 h)	**Sulphonamides** • Trimethoprim-sulphonamide (30 mg/kg PO q 12 h)	**Bone marrow suppression, acute hepatitis** (dogs), KCS (dogs), GIT upset Nephrotoxicosis, ototoxicosis, neuromuscular blockade GIT upset, neurotoxicosis, infusion reactions
	Amikacin (10-15 mg/kg IV/IM/SC q 24 h)	Amikacin (10-15 mg/kg IV/IM/SC q 24 h)	
	Imipenem-cilastatin (2-5 mg/kg slow IV q 8 h)	Imipenem-cilastatin (2-5 mg/kg slow IV q 8 h)	
	Cefotaxime (25-50 mg/kg IV/IM/SC q 6 h)	Cefotaxime (22 mg/kg IV/IM/SC q 6 h)	

*Treatment should be based on susceptibility testing.

†Not effective against *M. smegmatis.*

Medications in **bold** are recommended as first-line therapy.
Side effects in **bold** are major or severe.
Medications in *italics* should only be used as a last resort.
GIT, Gastrointestinal tract.

Public Health Considerations

There are, uncommonly, reports of tuberculosis transmission from pets to owners. The zoonotic potential of infected animals is of increasing concern, particularly for immunocompromised owners.[57] Tuberculosis is a notifiable disease in many countries. Public health authorities should be informed of any positive diagnosis in dogs or cats where required. Care should be taken in patient and specimen handling in veterinary hospitals when tuberculosis is a differential diagnosis. Infection of veterinary personnel with *M. tuberculosis* was reported following aerosolization of the organism during necropsy of an infected dog.[29]

Saprophytic Mycobacteriosis

Etiology

Saprophytic mycobacterioses are bacteria found in terrestrial and aquatic environments. Infections caused by these *Mycobacteria* spp. are divided conceptually into rapid-growing mycobacteria (RGM) and slow-growing mycobacteria (SGM; Table 212-2). The *Mycobacterium avium* complex (MAC) are SGM comprised of *M. avium* and *M. intracellulare*. *M. avium* is divided into 4 subspecies. *M. avium* subsp. *paratuberculosis* is the only known obligate pathogen in this group of organisms. Saprophytic mycobacteria are reported as agents of disease more commonly in cats than in dogs.[58-132]

Epidemiology and Pathogenesis

Slow Growing

The slow growing saprophytic mycobacteria, particularly *M. avium*, cause local and systemic granulomatous disease resulting in syndromes indistinguishable from tuberculosis.[60-62,64,66,68-70,73,74,76,78,80,83,85,86,94-96,98,104,105,107-109,112-114,117,120,123,125-129,132] Unlike other SGM, *M. ulcerans* produces mycolactone, a macrolide toxin believed to be the cause of the distinct lesions associated with infection with this species.[133] *M. avium* is the most common SGM implicated in dog and cat systemic infections (see Table 212-2) although the pathogenicity of the individual subspecies is yet to be fully elucidated. *M. avium* subsp. *paratuberculosis* has been identified in humans with Crohn's disease and from the GI tract of dogs with chronic enteropathies, but its significance is unclear.[134,135] The SGM cause opportunistic infections usually in young and immunosuppressed animals.[61,66,67,71,72,74,75,78,83,85,87,91,94,96,105,107,109,114,118,124,127,129] Breed predispositions have been reported in cats and dogs, suggesting hereditary immune dysfunction in some. Siamese, Somali and Abyssinian cats, Miniature Schnauzers and Basset Hounds are overrepresented in reports of MAC infections.[61,80,98,104,105,107,109,112,123,129,130]

Rapid Growing

The rapidly growing mycobacteria (RGM), in cats, cause diffuse, rather than nodular, SC, or cutaneous infections. Infection is less common in dogs, presumably following inoculation during fighting or trauma.[60,63,77,79,89,90,97,106,122,136] Affected animals are often obese and apparently immunocompetent.[77,89] Female cats are over-represented.[77,89] Sporadic cases of pulmonary and systemic infections with *M. fortuitum*, *M. thermoresistibile* and *M. smegmatis* have been reported.[65,72,115,119,131]

History and Clinical Signs

Pulmonary, GI or disseminated disease associated with SGM infection is indistinguishable from tuberculosis. Typical presenting signs include chronic weight loss, inappetence, vomiting, diarrhea and/or dyspnea.[61,66,83,91,94,96,105,109,114,117] Physical examination often reveals peripheral lymphadenopathy and pyrexia.[61,86,94,105,107,114,117,118,129] The RGM have a predilection for adipose tissue and most commonly cause panniculitis of the ventral abdomen and inguinal areas of cats. The tissue is often firm due to thickening and ulceration of the overlying skin. One or more draining tracts may be seen. Although respiratory infection and systemic spread are rare, infected cats may be pyrexic, inappetent and lethargic.

Diagnosis

Diagnosis of saprophytic mycobacteriosis is usually based on clinical presentation, cytological or histopathological findings and mycobacterial culture or molecular testing. As with tuberculous infections, systemic SGM infections produce non-specific results on routine hematology, serum biochemistry and diagnostic imaging, consistent with disseminated infiltrative disease of the organs affected. Acid-fast staining of tissue obtained from animals infected with *M. avium* and other SGM often reveal greater numbers of organisms than tuberculous infections. However, these are quite slow-growing in culture and molecular methods are often recommended for further characterization. Cytological examination of lesions from RGM infections often reveals granulomatous inflammation in which organisms may not be visible. RGM can often be grown readily on routine culture medium, although different species have specific culture requirements and molecular diagnostics may be required for definitive diagnosis.

Treatment and Prognosis

The SGM, particularly *M. avium,* have greater innate resistance and variable antimicrobial susceptibilities. Sensitivity testing should be performed where possible. Long-term combination therapy has been recommended but appears to be more successful in cats than dogs.[60,61] The prognosis of disseminated MAC in cats is guarded because even some cats who respond to initial therapy have recurrences. Dogs with systemic disease have a grave prognosis with many euthanized soon after diagnosis.

Treatment of granulomatous panniculitis is most successful with preoperative and perioperative antimicrobials (gentamicin), radical surgical debulking and long-term, single or combination, postoperative antimicrobial therapy based on susceptibility testing (see E-Table 212-1).[88,122] Prognosis is geographically variable with some organisms having high reported rates of disease recurrence.[77]

Public Health Considerations

As saprophytic organisms, these mycobacteria may infect immunocompromised humans in the same environmental manner as animal infections. Saprophytic mycobacteriosis has been rarely reported in humans associated with dog bites or cat-scratch wounds.[137-140]

Leproid Syndromes

Background

Leproid syndromes have been described in both cats and dogs.[141-172] These are characterized by discrete cutaneous lesions. Their causative agents cannot be cultured readily on standard mycobacterial media. Molecular diagnostic techniques have allowed further elucidation of the identity of these organisms.

Etiology

Cats

Feline leprosy results from one of a number of mycobacterial species considered saprophytic organisms that cause opportunistic infections. Gene sequencing of tissue samples has implicated *M. lepraemurium* in about half of cases.[142,148,151] *M. intracellulare, M. mucogenicum* and unclassified mycobacterial species have also been isolated from similar lesions.[144,148,173]

Dogs

It has not been determined whether "canine leproid granuloma syndrome" results from infection with a single or multiple agents. To date, genetically identical organisms have been isolated from canine leproid granulomas. However, the species remains mostly uncharacterized due to laboratory culture failures.[161,164,165] This novel species is possibly an opportunist saprophyte that naturally exists in environment.[166]

Epidemiology and Pathogenesis

Cats

Cases of feline leprosy have been reported in Australia, the Pacific coast of Canada, the United Kingdom, the Netherlands, France, Italy, USA, Japan, Greece and New Zealand.[8,141,142,144-152,154-156,158,174] *M. lepraemurium* infection is believed to be transmitted by contact with or bites from rodents. This is supported by evidence of at least some affected animals hunting and eating rats.[145,150] While insect vector transmission has been suggested, there is limited evidence. A higher incidence of feline leprosy has been reported during the colder months in some countries. While this may indicate preference by at least one of the causative organisms for cooler temperatures, other factors (animals spending more time inside allowing for closer observation) cannot be excluded.[152,158] A biphasic age distribution has been described in cats with feline leprosy. The first group comprises young, apparently immune-competent male cats infected with *M. lepraemurium.* The second group comprises older cats with the lepromatous form of disease. It has been suggested that cats in this second group have impaired immune function secondary to chronic FIV infection or concurrent disease.[151] Immunity to *M. lepraemurium* following recovery from infection has been demonstrated experimentally in cats.[157]

Dogs

Canine leproid granuloma was originally reported in dogs from Zimbabwe.[169,170] It is now considered to be a relatively common mycobacterial dermatopathy in Australia and Brazil.[161,163,165-168,171,175] The condition is far less frequent in the United States and New Zealand, and a single case has been reported in Italy.[162,164,171,172] Similarities in the climates of Brazil, Australia and the west coast of the United States support the hypothesis that climate may play an epidemiological role. Canine leproid granulomas are most commonly diagnosed during warmer months in Brazil.[161,164]

Transmission by insect vectors has been implied by the anatomical location of lesions, the conformation of commonly affected breeds, and their common living environments.[166] Although flies and mosquitoes have been reported to be present in the environment of most affected dogs, some contradictory evidence also exists.[161,169,171] Canine leproid granuloma syndrome has been repeatedly shown to have a predilection for large-breed short-haired dogs, with Boxer dogs, in particular, being overrepresented.[161,164,166,167,169-171]

In one case series, affected dogs ranged from 1-11 years of age, with a median of 7 years.[161] It has been suggested that commonly affected types of dogs may have a genetic predisposition and similar coat characteristics or outdoor housing that facilitates insect bites. Case clusters of disease have been identified in related Foxhounds housed together in New Zealand. It has been proposed that this phenomenon may be due to environmental factors associated with hunting, a genetic predisposition, or an immune deficiency in Foxhounds. An insect vector was considered less likely. Similar clusters have been less well described in Australia and the United States.[171]

History and Clinical Signs

Cats

Leproid granulomas in cats may be single or multiple cutaneous or SC nodules with or without ulceration, anywhere on the body, but are most common on the head and limbs.[142,145,151,152,173] Two forms of the disease have been described in conjunction with the biphasic age distribution. Younger cats often develop rapidly progressive and ulcerated lesions on the limbs whereas older cats are more commonly affected by diffuse, non-ulcerated slowly progressive lesions.[151] Ocular lesions have occasionally been reported.[145,149]

Dogs

Canine leproid granulomas most commonly appear as firm, nonpainful well-circumscribed dermal-to-SC nodules on haired skin. The head and dorsolateral pinnae are most commonly affected.[161,164,166,167,171] However, papules, plaques and masses have also been described with lesions on the face and limbs.[161] Multiple lesions usually occur and may range in size from a few millimeters to several centimeters. Nodules are occasionally ulcerated with exudation usually more extensive over larger or protuberant lesions.[160]

Diagnosis

Suspicion of leproid infection may be based on physical and clinical findings. Impression smears of ulcerated lesions stained using a Kinyuon-modified Ziehl-Neelson method often reveal numerous acid-fast bacilli.[142,160] Confirmation usually requires PCR, as the organisms are fastidious and rarely able to be cultured. 16S rRNA gene,16-23S rRNA gene internal transcribed spacer region (ITS) and *hsp*65 gene sequencing have been demonstrated to facilitate rapid and accurate diagnosis of the pathogen without the need for culture.[145,147-149,151,161,162,164,165,171,172,176-178]

Treatment and Prognosis

Treatment of the leproid syndromes may not always be required, as spontaneous remission has been reported in both cats and, more commonly, dogs.[157,164,166,167] Refractory lesions should be treated with surgical resection and prolonged, dual, antimicrobial therapy.[142,151,167] Dogs usually have an excellent prognosis, although persistent lesions may become disfiguring.[171] Cats should be treated with antimicrobial therapy immediately after diagnosis, as feline leproid disease is generally progressive and may recur after surgical excision if appropriate medical therapy is not administered.[179]

Public Health Considerations

There are no reports of or suspected zoonotic potential associated with the organisms implicated in canine and feline leproid infections.

Actinomycosis

Etiology

Actinomyces spp. are facultatively anaerobic or microaerophilic, Gram-positive, irregularly staining, branching filamentous bacteria that are non-acid-fast, non-sporing and non-motile. These opportunistic pathogens are mucous membrane commensals, particularly in the oral cavity, although they may also inhabit the GI and genitourinary tracts.[180-184] *A. weissii* and *A. canis* have been implicated in canine periodontal disease, while *A. viscosus, A. hordeovulneris, A. bowdenii, A. canis, A. catuli, A. turicensis* have been isolated from lesions at other sites in dogs.[182,185-192] *A viscosus, A. meyeri* and *A. bowdenii* have been isolated from infections in cats.[191,193,194] A number of cases attributed to infection with *A. pyogenes* have been reported; however, this and a number of other *Actinomyces* spp. have been reclassified based on 16S rRNA gene sequencing and are now included in the genus *Arcanobacterium.*[195] These opportunistic pathogens produce disease following inoculation and result in actinomycosis-like manifestations.[196]

Epidemiology and Pathogenesis

The characteristic pyogranulomatous lesions of actinomycosis comprise microcolonies of bacteria and host cells surrounded by macrophages, neutrophils and plasma cells. Subacute and chronic infections result in the formation of granulation tissue, extensive fibrosis and draining tracts.[181] Exudates and effusions are often malodorous and may contain "sulfur granules," macroscopic clumps of bacteria and hyaline.[197,198] Pathogenicity of *Actinomyces* spp. is believed to be enhanced in polymicrobial infections. Synergistic infections have been recognized with facultative and anaerobic bacteria, particularly in association with dental disease. This phenomenon is likely involved in colonization at other sites.[199,200] No specific bacterial toxins that contribute to pathogenesis have been identified in *Actinomyces* spp.; however, adhesions may facilitate oral colonization.[181,201]

Actinomycosis results from introduction of the organism into body tissues. The portals of entry in dogs and cats include loss of the GI mucosal barrier integrity due to chronic gingivitis and periodontal disease, foreign body migration, inoculation via bite wounds or plant material, and aspiration of oropharyngeal material.[194,202-208] Infection typically develops in immune-competent dogs and cats, although it has been reported with concomitant immunosuppressive disease and neoplasia.[209-211]

Young male large-breed dogs kept outside are over-represented in reports of actinomycosis. Hunting and working animals are often affected, particularly with soft tissue abscesses or pyothorax.[205,212,213] There is variability in the signalment of infected cats. Young males are more likely to be infected as a result of aggressive interactions and bite wounds.[214]

History and Clinical Signs

In dogs, *Actinomyces* infections are most commonly seen as periodontal disease, and less commonly as SC or soft tissue abscesses, or pleuritis/pneumonia secondary to penetration or inhalation of contaminated plant material.[205,209,212,215-222] Central nervous system, ocular, peritoneal, cardiac and orthopedic implant infections have been reported.[190,204,216,223-228] Immune-mediated polyarthropathy has been reported in a dog secondary to actinomycosis.[190] Most infected cats develop pyothorax, probably after aspirating oral flora.[202] Other signs include nasal and facial infections, abdominal granulomas, intracranial/spinal empyema and cholecystitis.[203,207,208,210,229-233]

Diagnosis

A provisional diagnosis of actinomycosis may be based on identification of non-acid-fast filamentous organisms on cytological examination of fluid or tissue samples stained using a modified Ziehl-Neelsen (Kinyoun) method. Definitive diagnosis and differentiation from nocardiosis require isolation and

identification of the causative agent. While culture has traditionally been used, it may be time-consuming and phenotypic identification inaccurate due to the large number of novel species. Bacterial genome identification, particularly of the 16S rRNA gene, from clinical specimens is preferred.

Treatment and Prognosis

The combination of surgery and antimicrobial treatment appears to be superior to antimicrobial treatment alone in resolving most actinomycotic infections in dogs and cats.[213] However, while thoracotomy and debridement is recommended in dogs, cats are believed to require only thoracic drainage and medical therapy.[202,212] *Actinomyces* spp. are typically responsive to long-term therapy with high dosages of penicillins as well as a range of other antimicrobials (see E-Table 212-1). The prognosis for pets with SC or soft-tissue infections, and for cats with pyothorax, is good.[202,205] However, survival in dogs with thoracic disease is variable and all reported cases of CNS actinomycosis have been fatal.[203,204,232]

Public Health Considerations

Actinomyces spp. infections may develop in humans following dog and cat bites, but disease transmission from clinically infected animals to humans has not been reported.

Nocardiosis

Etiology

The genus *Nocardia* consists of Gram-positive, variably acid-fast, catalase-positive, non-motile aerobic bacteria that form filaments which may break into bacillus and coccal forms. They are saprophytic soil organisms, ubiquitous in the environment and are involved in the decomposition of plant material. Pathogenic species have been isolated from house dust, garden soil, beach sand, swimming pools and tap water in different regions.[234]

Many reports of nocardiosis in cats and dogs do not include complete or valid identification of the etiological agents and many were reported before reclassification of the actinomycetes.[235] *Nocardia* species reported to be pathogenic in dogs include *N. asteroides, N. abscessus, N. otitidiscaviarum, N. nova* and *N. brasiliensis.*[236-240] Nocardiosis has been reported in cats resulting from infection with *N. tenerifensis, N. africana, N. nova, N. cyriacigeorgica, N. farcinica, N. otitidiscaviarum* and *N. elegans.*[239,241-247]

Epidemiology and Pathogenesis

Infection in dogs and cats is believed to occur following inhalation of aerosolized organisms or inoculation via puncture wounds. The T-cell response is essential in limiting dissemination of nocardial infection following inoculation; however, this is also responsible for the development of the characteristic granulomatous-to-suppurative lesions recognized in nocardiosis.[248] In cats and dogs, nocardiosis commonly causes cutaneous lesions in immunocompetent animals, particularly cats.[213,239,241,247,249,250] Disseminated disease, often involving the central nervous system and thorax, has been reported more commonly in young and immunosuppressed dogs.[237-240,251-254] *Nocardia* spp. have also been isolated from cases of osteomyelitis, cystitis and hepatitis.[236,242,244,255-257]

History and Clinical Signs

Cutaneous and SC lesions may develop as superficial abscesses or more indurated masses (mycetomas) with or without local spread and lymph node involvement.[213,239-243,250] Skin and superficial lesions are often associated with the development of draining tracts and sinuses.[213,214,242,247] Thoracic disease may present as pneumonia or pyothorax resulting in signs of dyspnea, tachypnea, lethargy, weight loss and fever.[212,254,258-260] These signs are non-specific, with similar signs in peritoneal and disseminated disease.[237,240,245,261]

Diagnosis

A presumptive diagnosis of nocardiosis may be made based upon macroscopic and microscopic examination

of clinical specimens. Organisms on Gram-stained slides will appear as Gram-positive, thin, and filamentous within a background of lymphocytes and macrophages. Acid-fast stain may be used to demonstrate "acid fastness" after filamentous organisms are noted with Gram-staining. However, this reaction is unreliable in direct clinical samples and may be dependent on the growth media used and age in culture samples.[262] *Nocardia* spp. can be grown on most culture media over 2-14 days, with marked variation in the appearance of different species. Species identification has traditionally been performed based on biochemical methods, chemotaxonomy and serology. Molecular methods, most commonly 16S rRNA gene sequencing, have become the method of choice in bacterial identification as these provide an accurate and rapid result.[263,264]

Treatment and Prognosis

Like actinomycosis, treatment of nocardiosis relies upon debridement and drainage of the lesion in addition to appropriate antimicrobial therapy. Most *Nocardia* spp. are susceptible to sulphonamide antibiotics and these have historically formed the basis of medical therapy. However, sulfonamides may be poorly tolerated and some species of *Nocardia* are resistant to these drugs.[265,266] A range of other drugs has also been shown to be efficacious with multi-agent protocols advocated for treatment of persistent or disseminated infections (see E-Table 212-1).[238,239] Prolonged therapy of 6-12 months is required in most pets to gain optimal results.[238,247]

Patients with disseminated disease, particularly with CNS involvement, generally carry a grave prognosis, with the majority euthanized or succumbing to their disease.[237,239,253] While cases of superficial disease may initially respond to treatment, many are euthanized due to deterioration despite treatment or recurrence of disease.[239,242,244]

Public Health Considerations

Nocardia spp. infections have been reported in humans associated with cat scratches but disease transmission from infected animals to humans has not been reported.[267-269]

CHAPTER 213

Brucellosis

David P. Beehan

Client Information Sheet: Brucellosis

Etiology

Canine brucellosis is most commonly caused by the Gram-negative coccobacillus bacterium *Brucella canis*, and less commonly by *Brucella melitensis*, *Brucella suis* or *Brucella abortus*. It is predominantly a venereal and orally transmitted bacterium associated with abortion and infertility in dogs. Canine brucellosis can be a reportable disease in certain states or countries, requiring that appropriate local authorities be informed of a positive diagnosis.

Pathogenesis

Brucellosis is most commonly shed in urine, vaginal discharges, aborted tissues, semen and, to a lesser extent, in milk, saliva and nasal secretions.[1] The *Brucella* organism attaches to and crosses mucous membranes (genital, oronasal and conjunctival) and is then phagocytized by macrophages and moved to lymph nodes. Bacteremia begins about 7-30 days after infection and may persist as long as 6 months. Intermittent recurrences can then take place for 66 months or longer.[2] These bacteria have a preference for steroid-dependent reproductive organs (i.e., prostate, epididymides, testes, vagina, uterus and placenta) (Figure 213-1).

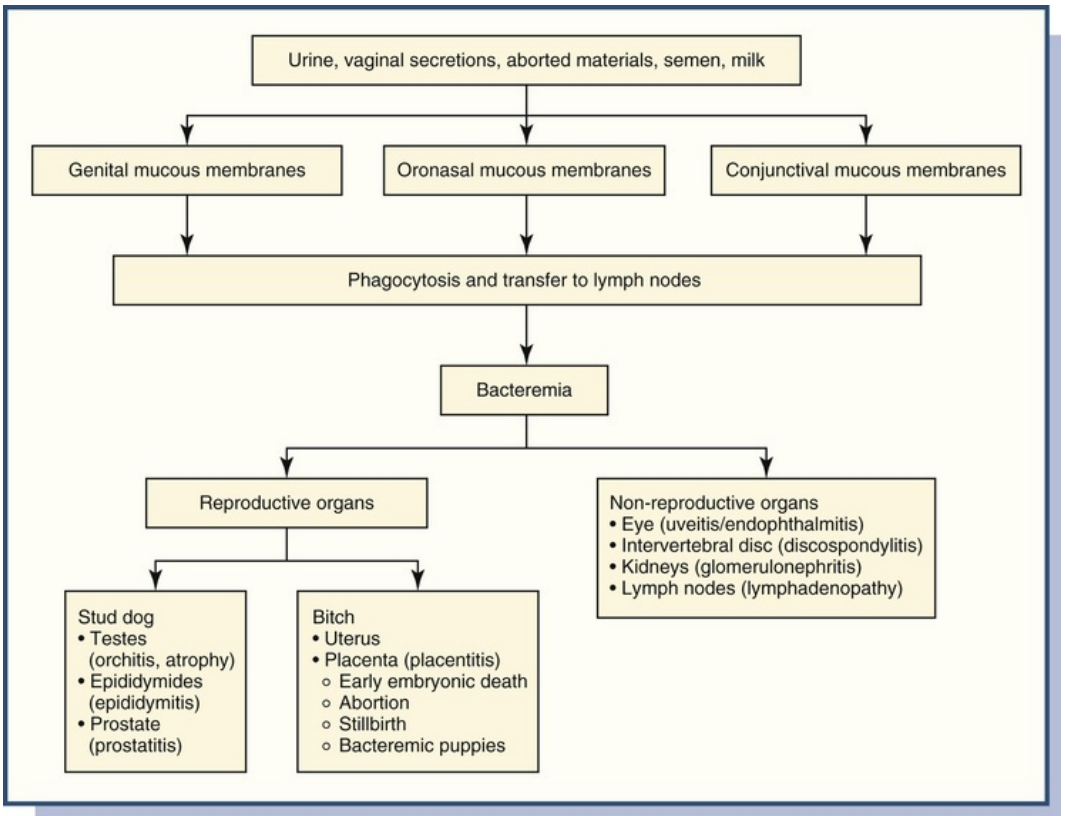

FIGURE 213-1 Pathogenesis of canine brucellosis.

Clinical Signs

Overview

Signs vary by organ and system affected. The most common clinical signs are abortion and infertility. However, other reported clinical signs include poor hair coat, listlessness, fatigue, lethargy, exercise intolerance, weight loss, lameness, back pain, lymphadenopathy, poor vision and behavioral changes.

The Male

Clinical findings in the male may begin as acute epididymitis and orchitis that causes scrotal pain, swelling, and dermatitis. Inflammation and irritation can cause persistent scrotal licking and secondary scrotal dermatitis. Pain on palpation of the testes at semen collection might be noted (see ch. 111). Semen evaluation may reveal asthenospermia, teratospermia, sperm head to head agglutination and white blood cells.[3,4] Finally, testicular atrophy results in the loss of functional seminiferous tubules and azoospermia. Enlarged or firm epididymides and unilateral or bilateral testicular atrophy may be noted. In neutered males, *Brucella* organisms can persist in the prostate and can be shed in the urine.

The Female

In the pregnant bitch, *Brucella* replication occurs inside placental tissues, resulting in abortion usually after 45-59 days of gestation.[3,5] A viscous, serosanguineous vulvar discharge may be observed for a number of weeks post-abortion, containing up to 10^{10} bacteria/mL.[6,7] Infection in females may also result in early embryonic death, stillborn fetuses, or repeated abortions. Some infected bitches have what appears to be a normal litter. However, puppies will begin to die within days or remain bacteremic. Other non-reproductive diseases secondary to *Brucella* infection include endophthalmitis, discospondylitis, lymphadenopathy, and granulomatous responses in skin, testes and organs (see Figure 213-1).[3,8-12]

Diagnosis

Overview

There is no commonly available test that reliably confirms a diagnosis of brucellosis. Reliance on any single test is not recommended. Diagnosis based solely on history or clinical signs is unwise, since canine infertility and abortion have many differential diagnoses (see ch. 315). In addition, many household pets are now adopted from shelters, already neutered. However, they can be infected and asymptomatic. A complete blood count, biochemistry profile and urinalysis can be performed to help rule out other potential differential diagnoses. Results in dogs with brucellosis are usually unremarkable.

Diagnostic Tests

Choices

Serological testing can begin 4 weeks after infection. Available choices include the rapid slide-agglutination (RSAT and ME-RSAT), tube-agglutination (TAT), indirect fluorescent antibody (IFA) and agar gel immunodiffusion (AGID-cell wall antigen or AGID-cytoplasmic protein antigen) tests. The smooth-walled *B. suis* and *B. abortus,* which may also infect dogs, do not cross-react with the serologic tests used to diagnose *B. canis*.

RSAT, AGID, TAT

The RSAT is a highly sensitive, commercially available, relatively inexpensive card test that can rapidly screen dogs for brucellosis. Results, precipitation of antibody-antigen complexes, are available within two minutes, with a low incidence of false negatives. Test sensitivity is >95%.[13,14] False positives, up to 40-60%, occur because antibodies in the assay cross-react with other Gram-negative bacteria.[4] When a positive result occurs, the test should be repeated with the addition of 2-mercaptoethanol (2ME), which inhibits IgM cross-reaction, increasing test specificity.[14] If the RSAT is negative, the dog can be considered *Brucella*-free unless infection occurred in the previous 4-12 weeks. Seroconversion occurs as early as 4 weeks after infection and is delayed in some animals for as long as 12 weeks. Repeating any RSAT is recommended. If positive after the addition of 2ME, it is recommended that AGID or TAT be performed to confirm the diagnosis. These tests can be performed 12 weeks after infection and have a higher sensitivity and specificity than RSAT, but false positives are still possible.

Blood Culture or Polymerase Chain Reaction (PCR)

Blood culture or PCR of *Brucella* organisms provides a definitive diagnosis. However, a negative result still cannot be presumed to indicate a true negative. PCR screening for canine brucellosis is now available and *Brucella*-positive dogs have been identified from serum, blood, lymph nodes, semen, vaginal swabs, urine and uterine tissue.[15-19] PCR is considered more sensitive than blood culture and allows earlier diagnosis than serologic testing.[19,20] Using PCR, vaginal swabs showed good sensitivity. PCR is a useful screening test for dogs being added to a kennel.[18,19] Bitches presenting for abortion should have vaginal discharges, placentas and aborted fetuses submitted for culture or PCR.

Treatment

Brucellosis is an intracellular bacterium, making it difficult to eradicate. No antibiotic, either alone or in combination, has been shown to be 100% effective. Enrofloxacin has shown some promise, potentially preserving fertility in a kennel outbreak situation with no adverse effects on pregnancies.[21] If born infected, puppies facilitate persistence of the infection in any exposed dogs. Antibiotics will decrease circulating bacteria numbers, which can alter serological test results and their interpretation if dogs are treated for as long as 4-6 weeks or treated multiple times. Bacterial re-emergence may happen during periods of animal stress and periods of increased reproductive hormone concentrations, as in estrus. *Brucella* organisms persist in lymph nodes, spleen, uterus and prostate.[21,22] The major disadvantages of antibiotic treatment include cost, drug availability, drug administration routes, periods of treatment, owner compliance, and need for retesting 6-12 months later. There is always the potential for future infection of other dogs and humans. Euthanasia is the treatment of choice for many owners, breeders and veterinarians.

Prevention

There is no commercially available canine *Brucella* vaccine to prevent infection of healthy animals. New animals should be kept isolated and screened, e.g., RSAT monthly, until 2 negative tests results are returned.[3] Similarly, any animals showing clinical signs should be immediately isolated and kept isolated until similar results are available.

Kennels should be designed to be easily cleaned, with run-off into drains and not adjacent kennels. Good kenneling must prevent animal-to-animal contact. There should be no shared equipment between dogs, e.g., bowls and bedding. Preferably, gloves should be worn by workers when handling animals. *Brucella* organisms will not survive free in the environment for very long. Presence of organic material, e.g., wood, paper, feces, or moist warm conditions will prolong its survival. *Brucella* sensitive disinfectants include quaternary ammonium, 1% sodium hypochlorite (bleach), iodophor solutions, 70% ethanol, and formaldehyde. For breeders, artificial insemination (AI) is strongly recommended to help reduce exposure to brucellosis. Canine AI will only prevent infection of males by female dogs and not vice versa. Female dogs can become infected through insemination. No commercially available semen extender effectively inhibits the transmission of *B. canis*.[4]

Zoonosis

Despite having strong host preferences, *B. canis* can cause disease in humans. Infection is most commonly reported in people occupationally exposed to intact breeding animals, i.e., blood, semen and placentas. The prevalence in these workers is higher than expected. All persons in contact with dogs are susceptible.[23] Incubation in humans can be between 5 days and 5 months before the onset of any clinical signs.[24] Acute signs of infection are similar to those of influenza, i.e., fever, sweats, headaches, back pain, malaise and weakness. Chronic infection may recur years later, with symptoms including recurrent fever, joint pain and fatigue. Human brucellosis is a federally reportable disease in the U.S.

CHAPTER 214

Tetanus and Botulism

Simon R. Platt

Clostridial organisms are Gram-positive, anaerobic, spore-forming bacteria found ubiquitously in the environment. Neurotoxins produced by the bacteria are responsible for both tetanus (manifested as spastic paralysis) and botulism (manifested as flaccid paralysis) in humans and domestic animals. The basic underlying mechanism of action of these zinc metalloprotease toxins is inhibition of neurotransmitter release in both diseases, despite the dramatically different clinical signs observed.[1]

Tetanus

The prevalence of tetanus in cats and dogs is relatively low because they are considered to be reasonably resistant to the infection, especially when compared with horses and humans. Cats are approximately 10 times more resistant to infection than are dogs and dogs are 600 times more resistant to tetanus than are horses.[2] The resistance in these species is due in part to the inability of the toxin to penetrate and bind to nervous tissue.

Etiology

Tetanus is caused by the actions of neurotoxins formed in the body by *Clostridium tetani*, a motile, Gram-positive, non-encapsulated, anaerobic, spore-forming, rod-shaped bacterium. The toxin is produced during vegetative growth of the organism in a suitable environment.[3,4] The DNA for this toxin is contained in a plasmid and is antigenically homogenous. The organism's resistant spores are ubiquitous, with a natural habitat in moist, fertile soil; however, they can survive indefinitely in dusty indoor environments. The spores are resistant to boiling water and an autoclave temperature of 120° C for up to 20 minutes.[2] However, the vegetative phase of this bacterium is susceptible to chemical and physical inactivation. Organisms can be isolated from the feces of dogs, cats, and humans, but presence of the organism does not indicate infection because not all strains possess the plasmid.[3]

Pathogenesis

Tetanus develops when spores are introduced into wounds or via penetrating injuries. Most cases develop after skin wounds, but infection can follow teething, dental fractures, nailbed infections, parturition, or surgeries such as ovariohysterectomy.[5-7] Occasionally, no obvious wound can be found.[8] Under anaerobic conditions found in necrotic or infected tissue, the tetanus bacillus secretes two exotoxins: tetanospasmin and tetanolysin. Tetanolysin is capable of locally damaging otherwise viable tissue surrounding the infected area and optimizing the conditions for bacterial multiplication.[3]

Tetanospasmin leads to the clinical syndrome of tetanus. This toxin can constitute >5% of the weight of the organism.[3] It is a two-chain, 150,000 dalton polypeptide that initially is inactive, and is made up of a light and a heavy chain. The heavy chain has a high affinity for ganglioside surface receptors on neuromuscular endplates and is responsible for internalization, cytosolic translocation, and fast retrograde axonal transport of the light chain.[9,10] The light chain is the actual neurotoxin and it acts pre-synaptically to prevent neurotransmitter release from affected neurons. Tetanospasmin binds to the membranes of the local motor nerve terminals. If toxin load is high, some can enter the bloodstream, from where it diffuses to bind to nerve terminals throughout the body and even can enter the central nervous system (CNS) through an intact blood-brain barrier. The toxin then is internalized and transported intraaxonally and in a retrograde fashion to the cell body at a speed of 75 to 250 mm per day.[2,3] Transport occurs first in motor and later in sensory and

autonomic nerves. Further retrograde intraneural transport occurs with toxin spreading to the brainstem in a bilateral fashion, up the spinal cord. This passage includes retrograde transfer across synaptic clefts by a mechanism that is unclear.

The tetanospasmin light chain becomes activated after internalization into inhibitory neurons; at this stage, the toxin is no longer accessible for neutralization by antitoxin.[10] It prevents neurotransmitter release by cleaving and inactivating synaptobrevin, a membrane or "docking" protein necessary for the export of intracellular vesicles containing the neurotransmitter.[11] Synaptobrevin is a member of the SNARE (soluble N-ethylmaleimide-sensitive-factor attachment receptor) protein family, a highly conserved group of proteins essential for docking and fusion of neurotransmitter vesicles with the presynaptic membrane (Figure 214-1).[1,9-12] In addition to disrupting docking proteins, the toxin can lead to cross-linking of synaptic vesicles to the cytoskeleton, further preventing neurotransmitter release.[13]

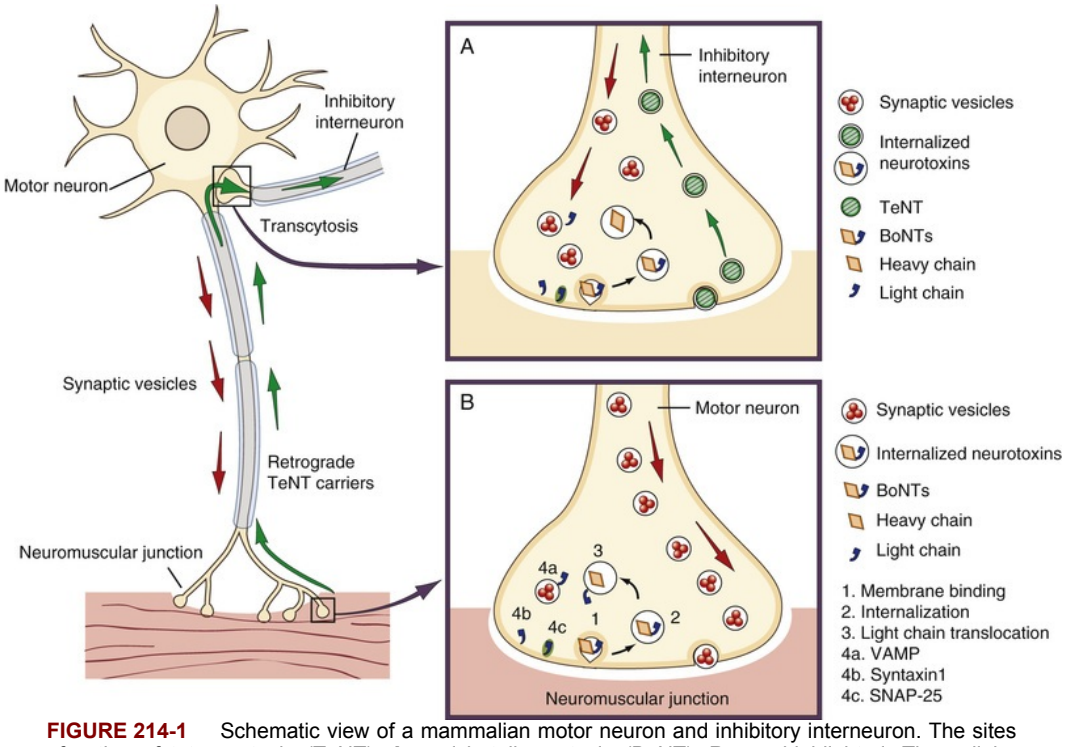

FIGURE 214-1 Schematic view of a mammalian motor neuron and inhibitory interneuron. The sites of action of tetanus toxin (TeNT), **A,** and botulinum toxin (BoNT), **B,** are highlighted. The cellular mechanisms of the clostridial neurotoxins are illustrated; both TeNT and BoNT follow a four-step mechanism to enter and inhibit neurons: membrane binding (1), internalization (2), translocation (3) and intracellular action (4). *SNAP-25*, Soluble NSF attachment protein-25; *VAMP*, vesicle-associated membrane protein.

The toxin predominantly affects inhibitory interneurons, inhibiting release of glycine and gamma-aminobutyric acid (GABA).[3] Interneurons inhibiting alpha-motor neurons are affected first, and the motor neurons lose inhibitory control. The disinhibitory effect on the motor neuron can cause diminution of function at the neuromuscular junction; therefore, the clinical effect is dissimilar to that of the related botulinum toxin. Medullary and hypothalamic centers also can be affected. Disinhibited autonomic discharge leads to disturbances in autonomic control, with sympathetic over-activity and excessive plasma catecholamine levels.

Neuronal binding of toxin is thought to be irreversible. Recovery requires the growth of new nerve terminals, which explains the long duration of clinical tetanus.[14]

Clinical Presentation

Tetanus most commonly affects young, large-breed dogs and is rare in cats.[7] Clinical signs can take up to 3 weeks to become apparent from the onset of infection, although most cases exhibit signs within 5 to 12 days.[5,7,8] The clinical signs initially can be localized or generalized, with the former more common in cats. Only a few cats with tetanus have been documented in the literature; most had predominantly localized

clinical signs.[15-19] A study of 38 dogs with tetanus revealed that ocular and facial changes were the most common initial signs.[5] Localized signs begin proximal to the site of introduction of the infection and can include single muscle rigidity, entire limb rigidity, and facial muscle spasms; cats might be more likely to experience carpal flexion, whereas dogs exhibit extension.[15,16] Clinical signs can progress with more extensive muscle involvement.[20] Generalized signs include a stiff gait affecting all limbs, increased muscle tone, dyspnea, an elevated tail and a "sawhorse stance," although the animal can become uncomfortable standing with such excessive muscle activity. At least 50% of dogs progress within a median of 4 days (range 0 to 14 days) to recumbency with severe muscle spasms.[5,7,8]

Involvement of the head can lead to spasm of the masticatory and pharyngeal muscles, causing trismus (lockjaw) and dysphagia. Trismus is not pathognomic for tetanus on its own and must be differentiated from other causes, which include temporomandibular joint disease or subluxation, masticatory myositis, and retrobulbar abscess.[21] Trismus can be exacerbated functionally by increased salivation, increased bronchial secretions, and increased respiratory rate resulting from involvement of the parasympathetic and somatic cranial nerve nuclei. Regurgitation and gastroesophageal reflux can result rarely from esophageal hiatal hernia and megaesophagus, which could lead to aspiration pneumonia when combined with the problems described earlier.[22] Excessive contraction of the facial muscles causes erect ears and a wrinkled forehead (E-Figure 214-2) and gives the animal a characteristic sneering of the lips known as *risus sardonicus* (sardonic grin) (Figure 214-3 and Video 214-1). In addition, the patient can exhibit protrusion of the third eyelid and enophthalmos resulting from retraction of the globe due to hypertonus of the extraocular muscles.[2] Severe progression of signs can cause recumbency, opisthotonus, seizure-like activity, respiratory paralysis, and central respiratory arrest, potentially causing death if not rapidly recognized and managed. The mortality rate ranged between 8% and 50% of dogs in three recent retrospective studies, and many of the dogs that died demonstrated concurrent autonomic signs.[5,7,8]

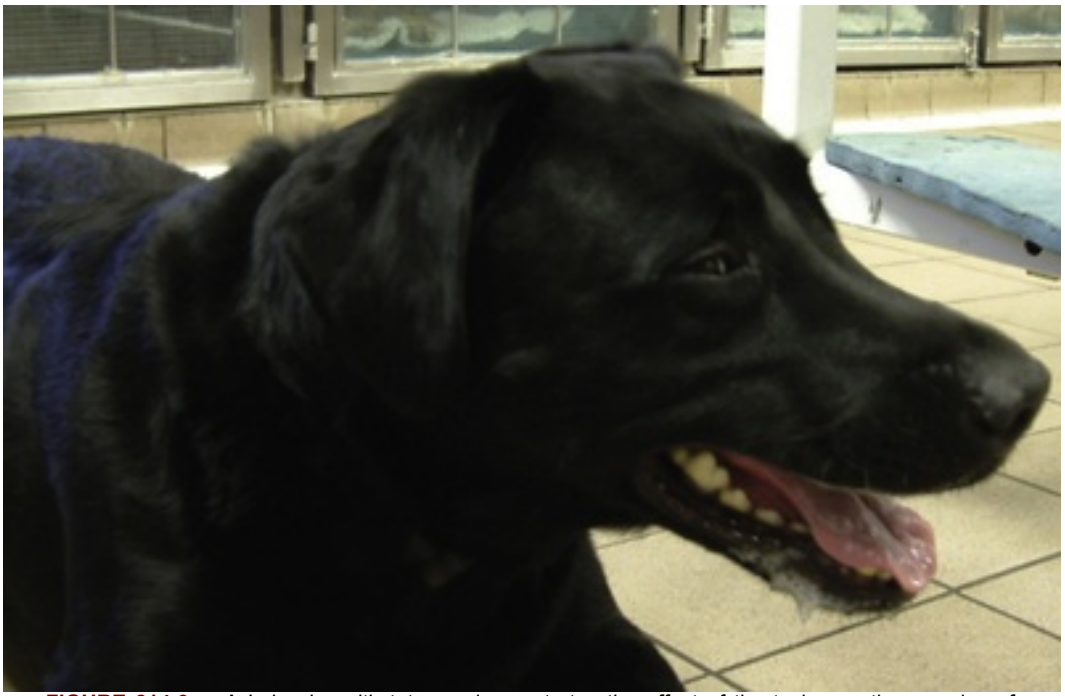

FIGURE 214-3 A Labrador with tetanus demonstrates the effect of the toxins on the muscles of facial expression creating the classical *risus sardonicus* appearance.

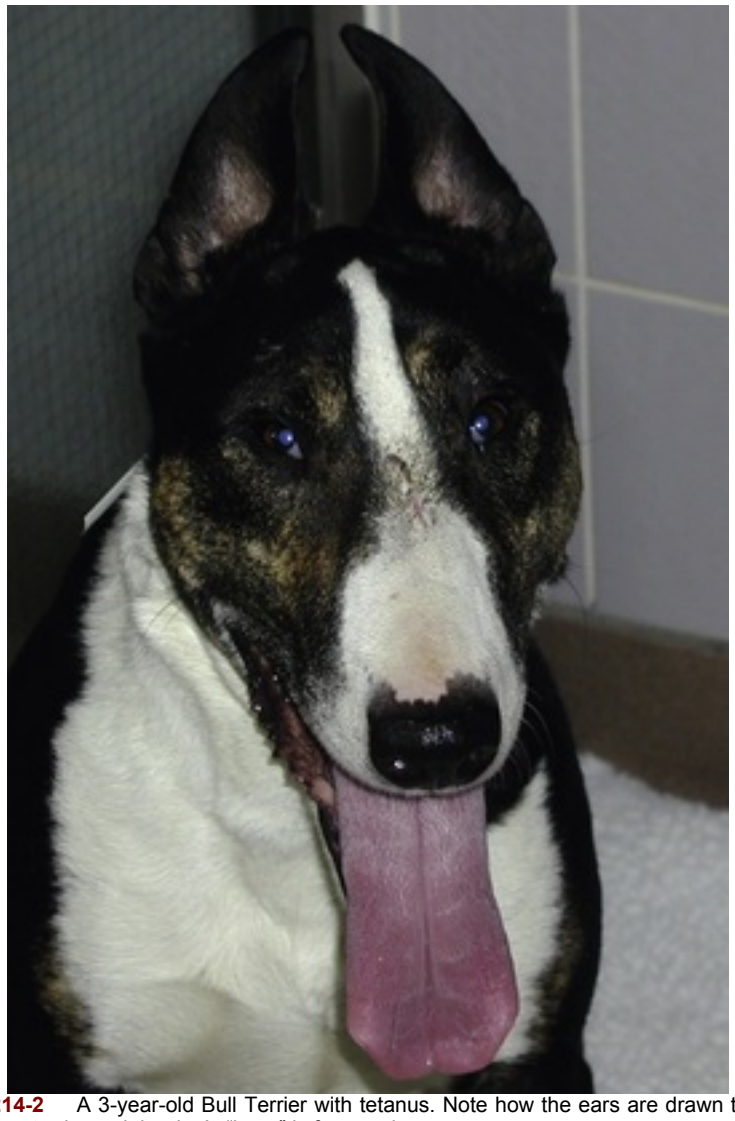

E-FIGURE 214-2 A 3-year-old Bull Terrier with tetanus. Note how the ears are drawn together, the third eyelids protrude, and the dog's "brow" is furrowed.

It is possible to see an effect on the autonomic system, evidenced by episodes of bradycardia and tachycardia, systemic hypertension, marked vasoconstriction, and hyperthermia.[7] A study of 38 dogs with tetanus revealed that 37% demonstrated abnormalities of blood pressure or rectal temperature, or both, consistent with autonomic disturbance.[5] In mild generalized cases, autonomic involvement can be manifested by dysuria and urinary retention, constipation, and gaseous distention of the gastrointestinal (GI) tract. In affected humans, "autonomic storms" occur, causing marked cardiovascular instability, severe hypertension alternating with profound hypotension, and even recurrent cardiac arrest.[3] During these "storms," plasma catecholamine levels are increased tenfold, similar to levels seen in animals with pheochromocytoma.[3]

A tetanus severity classification system has been proposed in dogs[5]: class I dogs have only facial signs of tetanus; class II dogs have generalized rigidity or dysphagia, with or without class I signs; class III dogs have class I or II signs and are recumbent or have seizures; and class IV dogs have class I, II, or III signs as well as abnormal heart rate, respiratory rate, or blood pressure measurements.[5] Survival rate decreases with increasing severity class.

Diagnosis

The patient's history and clinical signs usually are sufficient to make a presumptive diagnosis of tetanus. Differential diagnoses considered in patients with tetanus should include immune-mediated polymyositis, strychnine intoxication, spinal trauma, hypocalcemia, or meningoencephalitis.

If general anesthesia is used for diagnostic tests such as cerebrospinal fluid acquisition, the muscle spasms can be reduced but rarely are abolished. Intubation can be difficult in patients with trismus, and a stylet-assisted intubation should be anticipated in severely affected animals.

A complete blood count (CBC) can suggest an infectious process from a wound, whereas serum biochemistry profile (with the exception of muscle enzymes) and cerebrospinal fluid analysis findings are normal.[2] Because of the persistent muscle spasticity, high activities of creatine kinase (1599-18405 U/L [reference range 61 to 394 U/L]) have been documented in >50% of affected dogs.[8] Radiographs can be helpful to identify involvement of the esophagus, diaphragm, and secondary changes in the lungs resulting from aspiration pneumonia.

Electrodiagnostic abnormalities in patients with tetanus are nonspecific and consist of prolonged electric discharges after needle insertion on electromyography (see ch. 117).[19] There is a subsequent persistence of motor unit discharges occurring as "doublets," which are double discharges of the same motor unit at short intervals and often simultaneous activity of agonist and antagonist muscles.[19] Nerve conduction velocities are normal.[23] F waves have been reported to be abnormal in cats with localized tetanus.[19]

Measurement of serum antibodies to tetanospasmin can be performed by some laboratories and used for a definitive diagnosis. Values have to be compared with those of control animals. Polymerase chain reaction (PCR) testing has been used for detecting the tetanus toxin gene in wounds but it is not commercially available at this time in veterinary medicine.[24]

Attempts to isolate *C. tetani* from wounds often fail because of the low concentration of organisms and the requirement for strict anaerobic culture conditions at 37° C for at least 2 weeks.[2] A Gram stain of a smear from an open wound can identify Gram-positive rods and dark-staining spheric endospores, but the morphology of the bacterium is nonspecific and similar to that of many other bacteria.[2]

Treatment

There are three treatment strategies for dogs and cats with tetanus: (1) toxins present in the body outside the CNS should be neutralized; (2) organisms present in the body should be destroyed to prevent further toxin release; and (3) the effects of the toxin already in the CNS should be minimized. Intensive care management of affected animals is essential.

Neutralization of Unbound Toxin

Antitoxin neutralizes any toxin that is unbound to the CNS. Therefore, the timing of administration in relation to the onset of the disease is essential to its effectiveness. The antitoxin can be either anti-tetanus equine serum or human tetanus immune globulin. The latter could be more likely to produce reactions if given intravenously.[25] Early intervention has been recommended as a matter of routine, but there are no prospective studies objectively evaluating antitoxin use in dogs or cats, and its efficacy in cases with no evidence of a recent wound is unknown. There has been no significant benefit in survival, severity of clinical signs, or duration of clinical signs shown for dogs treated with antitoxin.[7] Additionally, a benefit of earlier administration of antitoxin on progression of clinical signs (i.e., worsening tetanus severity classification) or mortality rate has not been demonstrated.[5]

The recommended dosage of equine antitoxin for dogs and cats is 100 to 1000 U/kg (maximum 20,000 U/kg) IV, SC, or IM.[2] Intravenous administration is preferred to IM or SC administration. However, IV use of antitoxin is associated with a high incidence of anaphylaxis (see ch. 137).[2] To reduce this risk, a test dose (0.1 to 0.2 mL of 1 : 10,000 solution) should be administered intradermally 15 to 30 minutes before the intravenous dose.[2] A wheal at the site of injection can indicate that an anaphylactic reaction will develop. Epinephrine (0.1 mL/kg IV of the 0.1 mg/mL dilution), glucocorticoids, and an antihistamine (e.g., diphenhydramine) should be readily available in case of an adverse reaction, or the latter two even are sometimes given on a prophylactic basis. Repeated doses of antitoxin are more likely to cause adverse reactions and are not recommended or necessary because therapeutic levels persist for approximately 14 days.

Intramuscular injection at and proximal to the wound site (1000 U) could be helpful in localized forms of tetanus.[2] Although intrathecal administration of antitoxin has not been proven effective, experimental studies have suggested that it may be of use in dogs, reducing the morbidity and mortality in affected patients.[2]

Removal of Source of Infection

Any obvious wounds should be radically debrided after the administration of antitoxin. Flushing the wound with 3% hydrogen peroxide increases oxygen tension, which inhibits anaerobic organisms, although wound healing also could be impaired.[2]

Antimicrobials are essential to kill vegetative *C. tetani* organisms and thereby reduce the amount of circulating toxin. Although local administration of antimicrobials at the wound site has been advised, parenteral administration is recommended more routinely.[2] Classically, penicillin G has been the drug of choice, either IV as an aqueous potassium or sodium salt or IM as the procaine salt (20,000 to 100,000 U/kg q 6-12 h for 10 days in cats and dogs). However, metronidazole (7 to 10 mg/kg PO or IV q 8-12 h for 10 days) has been shown superior to penicillin G in clinical tetanus because it achieves bactericidal therapeutic concentrations in anaerobic tissues.[2] Other options include clindamycin (10 mg/kg PO, IV, or IM q 8-12 h) and tetracycline (22 mg/kg PO or IV q 8 h) or doxycycline (5 to 10 mg/kg PO or IV q 12 h).[2]

Control of Rigidity and Spasms

Prevention of unnecessary sensory stimulation is mandatory, but the mainstay of treatment is sedation with a benzodiazepine. Benzodiazepines augment GABA agonism at the $GABA_A$ receptor. Diazepam (0.5 to 1 mg/kg PO q 8 h in dogs [maximum 10 mg], 0.25 to 0.5 mg/kg in cats [maximum 5 mg, caution with oral diazepam in cats because of hepatotoxicosis], or a continuous IV infusion of 0.1 to 1 mg/kg/h in dogs and cats) or clorazepate (0.5 to 1 mg/kg PO q 8 h in dogs; 0.2 to 0.5 mg/kg PO q 12-24 h in cats) can be used in this regard, although both may cause over-sedation in some patients. As an alternative, midazolam can be used as a continuous IV infusion (0.2-0.5 mg/kg/h).

Additional sedation can be provided with anticonvulsant therapy, particularly phenobarbital (1 to 4 mg/kg PO or IV q 12 h or IM q 6 h), which further enhances GABAergic activity. Phenothiazines can be highly effective in controlling the hyperexcitable state; chlorpromazine (0.1 to 0.5 mg/kg IM, IV, or PO q 6-12 h) is the drug of choice, although acepromazine (0.005 to 0.05 mg/kg IV q 2 h as needed [maximum 3 mg in any dog]) is a useful substitute.

With severe signs such as generalized tonic-clonic seizure activity, generalized body stiffness, and opisthotonus, a propofol IV infusion may be necessary, but cardiorespiratory parameters should be monitored closely and careful consideration should be given to whether the patient should be intubated and placed on positive-pressure ventilation. Sedation with propofol has been shown to assist with muscle spasm and rigidity control in humans, without the use of neuromuscular-blocking drugs.[26] Neuromuscular blocking agents can be an option for the most severely affected veterinary patients, but assisted ventilation is imperative. Recently, the use of magnesium sulfate ($MgSO_4$) infusions or supraphysiologic magnesium therapy has been documented as a potential adjunct therapy in the management of spastic paralysis in dogs with tetanus.[27] However, a recent human meta-analysis of tetanus patients treated with magnesium could not detect a difference in mortality.[28] A dose of 70 mg/kg over 30 minutes followed by an initial IV CRI of 100 mg/kg/day has been recommended for dogs, based on human literature. The goal of this treatment is to increase total serum magnesium to 2 to 4 mmol/L (4.86 to 9.73 mg/dL) based on a target therapeutic range derived from the human literature.[27]

The use of botulinum toxin for tetanus-induced rigidity in humans recently has been suggested.[29] The effects of botulinum toxins remain fairly confined to the nerve terminals of lower motor neurons, inhibiting release of acetylcholine and activation of voluntary muscles. For this reason they could have a role in reducing the muscular hyperactivity in tetanus patients.

Supportive Intensive Care

Intensive nursing care is essential for successful treatment of patients with tetanus. The dog or cat should be isolated in a dark and quiet environment, with cotton wool balls placed in the external ear canals to reduce the effect of even mild auditory stimuli (Figure 214-4). Minimal handling is optimal, and all treatments therefore should be coordinated to occur together at set times through the day. A study of 13 dogs with tetanus documented the complications that occurred in these dogs during treatment; these included aspiration pneumonia, upper respiratory tract obstruction requiring tracheostomy, hiatal hernia, hyperthermia, and coxofemoral luxation.[8]

FIGURE 214-4 Tetanus in a dog. Note how the ears are drawn together and the lips are drawn caudally. Intensive care treatment of tetanus patients often requires respiratory support; in this patient intranasal oxygen and a tracheostomy were necessary. Supportive therapy includes reducing the environmental stimulation which can be accomplished by placing cotton wool balls in the external ear canals as can be seen in this dog, and even using sleep masks.

Percutaneous gastrostomy tube placement (see ch. 82) can prevent the complications associated with nasogastric tube feeding, particularly the stress that could be associated with an indwelling intranasal tube. Gastrostomy- or gastrojejunostomy-assisted tube feeding also can reduce the risk of aspiration pneumonia, a potential complication in dogs with severe forms of tetanus and those that are recumbent for a prolonged period. If airway obstruction develops because of laryngeal spasm or an accumulation of saliva or tracheal secretions, intubation and mechanical ventilation could be necessary. A tracheostomy often is performed in these patients to decrease the need for continuous anesthesia. Urinary and fecal retention occur in some patients with hypertonic anal and urinary sphincters. An indwelling urinary catheter (see ch. 106) might be beneficial in these patients, although the urine should be analyzed regularly for evidence of nosocomial infection. Pressure sores or decubital ulcers should be prevented with appropriate soft or padded bedding and frequent turning.

Prognosis

Recovery in dogs with tetanus depends on successful support of the animal while new axonal terminals form. Most dogs that recover (58% to 77%) show some improvement within 5 to 12 days, although the presence of autonomic abnormalities is a poor prognostic indicator.[5,7] Median length of hospitalization for dogs has been reported to be 13 days (range: 6 to 42 days). One study estimated the mortality rate to be ≈18% in affected dogs, but it also has been reported to be as high as 50%.[27] Mortality likely is related to the severity of clinical signs; one study revealed that all dogs with class I or II clinical signs survived and only 58% of dogs with class III or IV signs survived.[5] However, actual mortality might be difficult to estimate given the financial burden of long-term intensive care on a patient's owners; therefore, many animals are euthanized humanely instead of treated long-term. A full recovery might not be possible in at least 15% of dogs that survive, but

continued improvement can be seen for 3 to 5 months.[5,7,8] Cats are reported to recover well from localized tetanus, with some residual deficits remaining several months later[15-18]; there are no large studies assessing the prognosis in cats with generalized tetanus.

Botulism

Botulism is relatively uncommon in veterinary patients and the majority of cases can be linked to eating food that has spoiled, or carrion, allowing the growth of botulinum-toxin–producing bacteria.

Etiology

Botulinum toxin usually is produced by *C. botulinum,* which are a heterogeneous group of Gram-positive, anaerobic, spore-forming, rod bacteria distributed in the soil worldwide. Seven antigenically distinct types of toxin are described (A, B, C1, D, E, F and G).[30] All reported canine and feline cases to date have been caused by type C toxin, with the exception of two dogs reported from Senegal (type D toxin) and one dog in France (type B toxin).[30,31] This could be at least in part because *C. botulinum* type C appears to be an obligate parasite of animals and birds and can be found in carrion.[32] The spores formed by these bacteria, which are highly resistant to severe environmental conditions, will germinate in anaerobic conditions such as those provided by rotten carcasses of dead animals. Lysis of the spore is necessary for the release of the inactive, progenitor toxin complex, which becomes active following consumption, within the alkaline environment of the intestinal tract.[33] The activated toxin consists of a heavy and light chain.

Pathogenesis

Botulism occurs following ingestion of preformed toxin in rancid food or carrion, particularly dead birds, but in occasional cases, botulism can occur following colonization of anaerobic tissues by *C. botulinum,* with local toxin production.[30,31,34-36] There also is some anecdotal evidence of ingestion of botulism toxin through coprophagia in kenneled dogs. The only known natural outbreak of botulism in cats was associated with ingestion of a pelican carcass.[37] The toxico-infectious form of botulism described in humans, in which the toxin is produced by the bacteria multiplying within a wound or the GI tract has not been described in dogs or cats.[30]

Following cell or spore lysis, the toxin is released and it binds with other protein complexes to form progenitor toxins. These progenitor toxins are extremely stable, particularly at low pH, and they pass through the stomach into the small intestine where the toxin is released and absorbed. The toxin is absorbed from the small intestine by endocytosis; it enters the lymphatic system and from there, the bloodstream. The botulism toxin heavy chain then binds rapidly and with extremely high affinity to presynaptic peripheral nerve terminals, affecting the limb, trunk and head muscles. The process of neuronal binding comprises: (1) binding with neuronal cell surface receptors, (2) endosomal internalization of the toxin, (3) membrane translocation, and finally (4) modification of target SNARE proteins required for exocytosis of acetylcholine at the neuromuscular junction (see Figure 214-1).[9,10,30] Targeting of the SNARE proteins by the botulism toxin light chain prevents presynaptic release of acetylcholine at the neuromuscular junction, resulting in flaccid (lower motor neuron) paralysis and evidence of autonomic nervous system dysfunction.[10,38,39] Action of the toxin is prolonged, and functional recovery depends on sprouting of new axon terminals and reformation of the functional neuromuscular endplates.[40]

Clinical Presentation

Botulism is characterized by an afebrile, acute-onset, progressive, flaccid paresis, with additional involvement of the autonomic nervous system[30,34,35] (Videos 214-2, 214-3, 214-4, 214-5, and 214-6). Clinical signs typically develop rapidly within 12 hours (but the latent period can be up to six days) following ingestion of the toxin.[30,41] The onset and severity of clinical signs are dependent on the total dose of toxin ingested and the individual susceptibility of the animal. Some animals can quickly progress to tetraplegia while others will only show a mild ascending weakness predominantly affecting the pelvic limbs. Consistent with a lower motor neuron lesion, reflexes and muscle tone are decreased to absent. Cranial nerve deficits (e.g., facial nerve paralysis, depressed gag reflex, decreased jaw tone, reduced vocalization, and megaesophagus) are common

in severely affected animals, but sensory function, including pain perception and level of consciousness, are unaffected. Cholinergic signs can be seen, including alterations of heart rate (increased or decreased), pupil changes (mydriasis with depressed pupillary light reflexes), keratoconjunctivitis sicca, urinary retention, and constipation.[30,42]

In severe cases, the respiratory musculature can be affected, with decreased abdominal tone and primary diaphragmatic respiration. The diaphragm is more resistant to botulism toxin and only is affected in very severe cases.[30] Death can result from paralysis of the respiratory muscles or secondary to aspiration pneumonia and complications resulting from prolonged recumbency.

Diagnosis

The diagnosis of botulism is primarily based on the history and suggestive clinical presentation. Due to the dietary origin of the toxin, multiple cases can occur within the same group of animals and there may be a history of exposure to carrion.[30,34,36] Differential diagnoses for the clinical presentation include acute polyradiculoneuritis, tick paralysis, fulminant myasthenia gravis, acute polymyositis, coral snake envenomation, lasalocid poisoning and rabies poliomyelitis. In many cases of botulism in domestic animals and human patients, the underlying organism is not identified.

The results of routine investigation (including CBC, serum biochemistry profile, urine and cerebrospinal fluid analyses) are usually normal or reflect secondary complications of recumbency and paralysis. Conscious thoracic radiographs should be performed to assess for evidence of megaesophagus and secondary aspiration pneumonia.

Definitive diagnosis is based on the demonstration of botulinum toxin early in the course of the disease, either in blood (10 mL of serum should be collected) or intestinal contents (50 g of feces, vomitus, or food sample should be collected) using a mouse protection assay.[43] Alternatives to the mouse biological assay include enzyme-linked immunosorbent assays and PCR to detect botulism toxin in food, but many of these tests currently are still being validated.[41] The more rapidly the sample is collected after the onset of signs, the higher the likelihood of confirming the diagnosis. The samples should be refrigerated, but not frozen (freezing affects the vegetative form of *C. botulinum,* but does not affect the toxin). The sample should be labeled as a biological hazard, particularly as people are considerably more susceptible to botulism toxin than are dogs or cats. Culture of the organism from food or the environment is not helpful, but culture of the organism from a patient's feces or gastric contents could be very helpful in supporting the diagnosis. *C. botulinum* can be successfully cultured from the feces or gastric contents of ≈60% of human patients, but this requires strict anaerobic handling.

Electrodiagnostic evaluation of muscle and nerve function can assist in the diagnosis, but is not definitive (see ch. 117).[35,42,44-47] The typical electrodiagnostic feature of botulism is a marked reduction in compound motor action potential amplitude during motor nerve conduction, in the presence of normal nerve conduction velocity and no evidence of temporal dispersion of the compound motor action potential.[34,35,42,44,46,47] The reduction in amplitude reflects the decrease in transmission at the neuromuscular junction. In addition to the reduction in amplitude, there are some reports of identification of mild fibrillation potentials and increased insertional activity on electromyography after prolonged periods of paralysis (around 2 weeks), followed by positive sharp waves on recovery, and subtly decreased motor nerve conduction velocities in some canine patients.[35,42] Repetitive nerve stimulation at low frequency rates (3 Hz) can produce a small decrement in compound motor action potentials; rapid stimulation rates (50 Hz) are likely to produce an increment in successive compound motor action potentials and this increment is highly supportive of botulism, although it has not been reported in dogs.[35,42]

Treatment

Supportive care represents the mainstay of treatment in botulism, in particular the avoidance of problems associated with prolonged recumbency, namely bladder management (including prevention of retention cystitis; see ch. 106), avoiding the development of pressure sores, access to food and water, cleanliness, support while patients return to normal exercise, and physical therapy (see ch. 355 and 356). In more severe cases, respiratory support might also be required. In cases that have recently presented and where toxin could still be present within the GI tract, an attempt should be made to remove the material, taking care to avoid aspiration pneumonia. This may include using gastric lavage (see ch. 112), enemas (see ch. 114), and cathartics.

Bladder management is important, as recumbent animals will tend to retain urine and can develop retention cystitis. The bladder should be kept as empty as possible to minimize residual urine volume, either through support for urination, manual expression, intermittent catheterization, or indwelling closed collection systems. Intermittent catheterization is associated with the lowest incidence of urinary tract infections, followed by manual expression and finally indwelling closed urinary collection systems.

All recumbent patients should be maintained on soft bedding in order to avoid the development of pressure sores, and they should be turned frequently. Physical therapy (massage and passive range of joint movement) will also help to maintain joint movement (see ch. 355). The animals should also be kept clean in order to avoid urine and fecal scald and contamination of any pressure sores with fecal material.

Antitoxin Administration

Antitoxin administration currently is the only specific therapy for botulism. Antitoxin only is effective in limiting the severity of the clinical signs if administered early in the disease course. Antitoxin administration will not reverse established weakness or paralysis. Most canine cases are due to type C botulism and the human trivalent antitoxin acts against types A, B and E; therefore the available antitoxin is not effective. If type C antitoxin is available, then anaphylaxis and other hypersensitivity reactions are possible; a small subcutaneous or intradermal test dose should therefore first be administered.

Prognosis

Animals with botulism have the potential for complete recovery with no long-term deficits if they can be supported through the period of flaccid paralysis, and secondary complications can be avoided. Most dogs will recover within 2 to 3 weeks. Despite an apparently full recovery, muscle weakness still can be present for up to a year after recovery. The overall mortality in human patients with botulism is around 7 to 10%, but this is doubled in patients over 60 years of age. No such data are available in veterinary medicine. There are substantial costs associated with the duration of nursing required, and the owner should be made aware of these at the outset.

CHAPTER 215

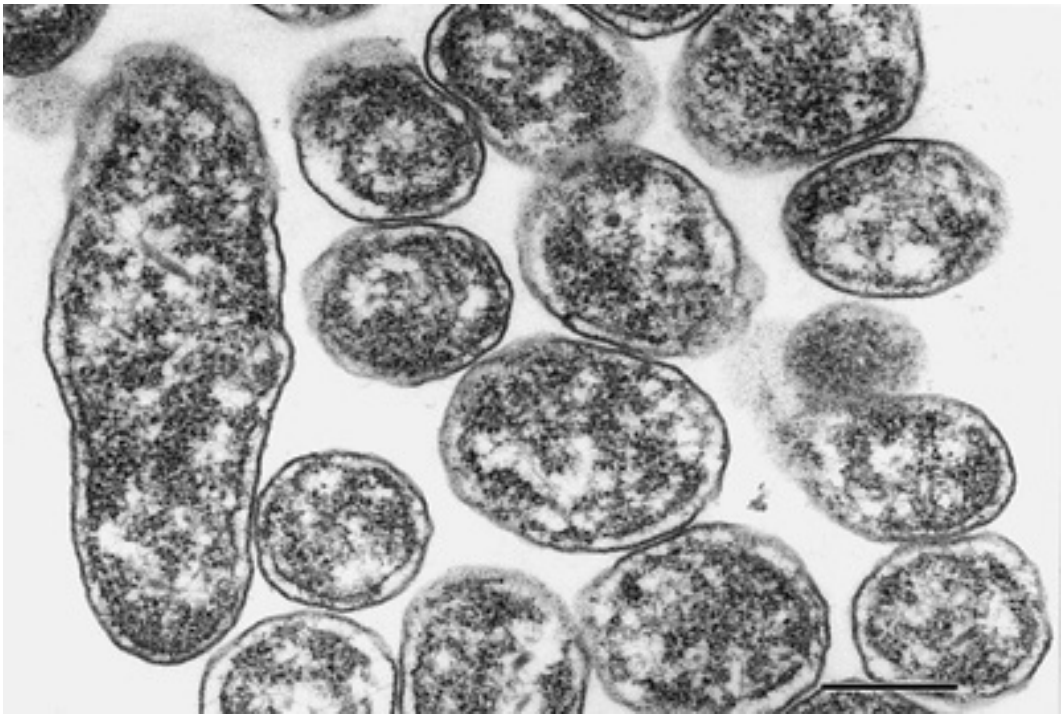
Bartonella—Canine

Pedro Paulo V.P. Diniz

Client Information Sheet: *Bartonella*—Canine

Introduction

Bartonella species are fastidious Gram-negative bacteria transmitted by blood-sucking arthropods and capable of infecting many domestic and wild animal host species (E-Figure 215-1). Genetically, members of the genus *Bartonella* are closely related to the genus *Brucella* and plant pathogens from the genus *Agrobacterium.*[1] *Bartonella* species can cause a long-lasting infection by targeting primarily erythrocytes (E-Figure 215-2), endothelial cells and bone marrow progenitor cells.[2] *Bartonella* species have coevolved and adapted to a primary mammalian host, where persistent bacteremia may occur without clinical signs. Some examples include *B. henselae* and *B. clarridgeiae* in cats; *B. vinsonii* subsp. *berkhoffii* and *B. rochalimae* in domestic dogs and wild canids; *B. bovis* in cattle; *B. washoensis* in ground squirrels; and *B. quintana* and *B. bacilliformis* in humans. However, when *Bartonella* infect a non-adapted incidental host, clinical manifestations are more commonly seen, especially in immunocompromised hosts. To date, over 14 species, subspecies or species candidatus of *Bartonella* have been described in dogs. Of note, most of the species detected in dogs can also infect humans. In people, *Bartonella* species are an important cause of fever of unknown origin, endocarditis, arthritis, lymphadenitis, and encephalitis, among several other medical conditions. Professionals with frequent exposure to animals and blood-sucking arthropods, such as veterinarians, are at high risk of infection with *Bartonella* species.[3,4]



E-FIGURE 215-1 Electron photomicrograph of *Bartonella henselae.* Gram-negative cell wall structures including outer membrane, peptidoglycan layer and the inner cell wall are visible. Magnification ×66,000. Bar = 0.25 micron. (From Guptill L, Wub C-C, Glickman L, et al: Extracellular *Bartonella henselae* and artifactual intraerythrocytic pseudoinclusions in experimentally infected cats. *Vet Microb* 76(3):283-290, 2000. Transmission and Risk Factors

Cat fleas *(Ctenocephalides felis)* are considered one of the main vectors of *Bartonella* in companion animals and humans. It has been shown that *B. henselae* can multiply in the digestive system of the cat flea and survive several days in flea feces.[5] In shelters, fleas from cats are frequently infected with *Bartonella* species (generally above 40% of fleas), whereas *C. felis* from dogs have a lower frequency of infection (2.8% to 11.3% of fleas).[6,7] This difference is associated with the lower level of persistent bacteremia in dogs when compared to cats, which are the natural reservoirs for several *Bartonella* species (see ch. 216). *Bartonella* DNA was also detected in other canine blood-sucking arthropods, such as *Pulex* flea species, *Ixodes* spp. and *Rhipicephalus sanguineus* ticks.[7,8] Epidemiological evidence indicates that dogs infested with ticks have higher chances of being seropositive for *Bartonella* species.[9] However, experimental studies have not yet confirmed the capacity of ticks to transmit *Bartonella* to dogs. Lice and biting flies are also suspected vectors for transmission to dogs. Other risk factors for canine exposure to *Bartonella* species include living in rural environments or multi-dog households, having outdoor access, and being a herding breed.[9,10] Wildlife reservoirs may play a significant role in the ecology of *Bartonella* species. Coyotes, foxes, raccoons and other mammals can be infected with the same species of *Bartonella* detected in dogs and humans.[11-13] In California, coyotes are a major reservoir for *Bartonella* species, and are often asymptomatic despite 21% to 28% of them being bacteremic.[11,13] Cats and rodents may also serve as reservoirs for *Bartonella* transmission to dogs by sharing infected fleas. Circumstantial case-based evidence also suggests that cats may transmit *Bartonella* species to dogs by way of a scratch or bite, as they do to humans.

Epidemiology

Bartonella species have been described in all continents except Antarctica. Subtropical regions tend to have lower prevalence than tropical areas, but the frequency of seroreactive or infected dogs varies widely among countries. The two most frequent *Bartonella* species in dogs are *B. henselae* and *B. vinsonii* subsp. *berkhoffii* (E-Table 215-1). *B. vinsonii* subsp. *berkhoffii* and *B. rochalimae* can establish prolonged bacteremia in dogs, which may serve as natural reservoir hosts. Based on serologic testing of 14,430 dogs suspected of having vector-borne diseases in the United States, the overall seroreactivity to *Bartonella henselae* and *B. vinsonii* subsp. *berkhoffii* was 3.8% and 1.5%, respectively, but varied among regions from 1.7% to 4.2% of dogs that were seroreactive to *B. henselae* and from 1% to 1.6% for *B. vinsonii* subsp. *berkhoffii.* The highest percentage of seroreactive samples was observed from Northeast, mid-Atlantic and Southern regions of the United States.[14] However, serologic tests may underestimate the real prevalence of *Bartonella* species in the canine population because over half of the infected dogs do not mount a detectable antibody response.[2] Based upon enrichment culture coupled with polymerase chain reaction (PCR), the presence of *Bartonella* species in blood samples of sick dogs suspected of vector-borne diseases in the United States was 9.2% of 663 dogs.[15] Asymptomatic dogs may also be infected with *Bartonella* species, with two studies in the United States reporting 18% to 20% of clinically healthy dogs as being infected with *B. henselae* or *B. vinsonii* subsp. *berkhoffii.*[16,17] In other countries, the frequency of dogs that are bacteremic with *Bartonella* species varies widely, from 16.7% of 54 healthy dogs in Korea, 11.6% of 60 healthy dogs in southern Italy, and 6.3% of 80 dogs in Algeria, to 1.4% of 73 dogs in Grenada, and 1% of 198 sick dogs in Brazil.[2] Although seemingly less frequently, dogs can be infected with other *Bartonella* species for which the cat, the rat, and squirrels serve as reservoir hosts.

E-TABLE 215-1

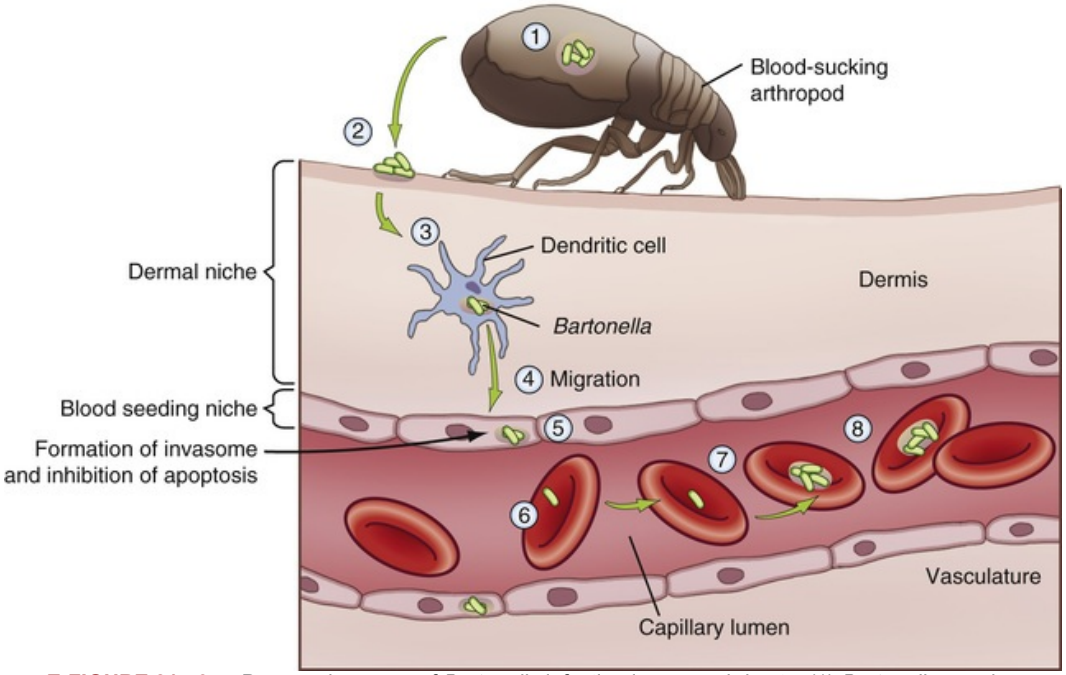
***Bartonella* Species Detected in Dogs and Reported Hosts**

MOST COMMON SPECIES	PRIMARY HOST	OTHER HOSTS
B. henselae	Cat	Human, dog, horse, rat, sea turtle, porpoise, beluga, wild felids, mockingbird, blackbird, woodpecker
B. vinsonii berkhoffii	Dog, coyote	Human, cat, fox, sea turtle
UNCOMMON SPECIES	**PRIMARY HOST**	**OTHER HOSTS**
B. bovis	Cattle	Dog, cat, deer, elk
B. clarridgeiae	Cat	Human, dog
B. elizabethae	Rat	Human, dog
B. grahamii-like	Rat	Dog, human
B. koehlerae	Cat	Human, dog
B. quintana	Human	Human, dog, cat, monkey
B. rochalimae	Dog, gray fox, red fox	Human, coyote, raccoon
B. taylorii	Wild mouse	Dog
B. vinsonii subsp. *arupensis*	Wild mouse, vole	Dog, human
Candidatus B. merieuxii	Dog	Not reported
Candidatus B. volans	Squirrel	Dog, human, sea otter
Candidatus B. washoensis	Squirrel	Human, dog, chipmunk

Pathogenesis

The pathophysiologic mechanisms of *Bartonella* infection have been investigated in detail based on

experimental rodent models or cell cultures, but information derived from experimental infection in dogs is still limited. Recent reviews have detailed the molecular and cellular mechanisms of *Bartonella* pathogenesis[18-21] that go beyond the scope of this chapter, but the main steps and factors are summarized as follows (E-Figure 215-3). While in the vector, *Bartonella* species replicate in the midgut of the arthropod and are excreted in the feces. *Bartonella* species are then inoculated through the bite or scratching associated with the arthropod bite. Once in the dermis, *Bartonella* species will start invading targeted cells, most likely dendritic and endothelial cells, which are called "dermal and blood seeding niches," respectively.[21] *Bartonella* species can also infect microglial cells, macrophages and CD34+ progenitor cells in the bone marrow.[22] This invasion is mediated by two groups of virulence factors: adhesins and type IV secretion systems (T4SS). Adhesins, such as *Bartonella* adhesin A (E-Figure 215-4), mediate bacterial adherence to endothelial cells and extracellular matrix proteins,[18] whereas T4SS are capable of transporting DNA and effector proteins to the targeted host cell. Two T4SS are present in *B. henselae* and *B. vinsonii* subsp. *berkhoffii:* the Trw and VirB/D4 systems, while *B. rochalimae* only has VirB/D4 T4SS.[19] Using these T4SS, these pathogens translocate *Bartonella*-effector proteins (Beps) into the targeted cells. At least seven Beps associated with inhibition of host cell apoptosis, cell invasion, bacterial persistence in erythrocytes and endothelial cells, and endothelial sprouting have been described to date.[18,21] The invasion of endothelial cells by *Bartonella* species is characterized by the formation of the *invasome,* a large well-organized bacterial aggregate that is engulfed and internalized by the targeted cell mediated by Beps and other pathogenicity factors.[18,23] Once *Bartonella* species establish persistent infection of the blood seeding niche by inhibiting cell apoptosis, they are periodically seeded into the bloodstream. Bacteria are released from the blood seeding niche, where they bind to and invade mature erythrocytes, and they replicate until they reach a critical number without causing hemolysis. Continuous replication of the pathogen in the blood seeding niche causes release into circulation at approximately five-day intervals, causing persistent bacteremia to facilitate the acquisition of the organism by the vector.[21] Experimental infection of dogs with *B. vinsonii* subsp. *berkhoffii* induced immunosuppression characterized by sustained suppression of peripheral blood CD8+ lymphocytes.[24] Immunosuppression caused by *Bartonella* infection may predispose the host to opportunistic infections, including infection by other pathogens transmitted by the same vector.



E-FIGURE 215-3 Proposed process of *Bartonella* infection in reservoir hosts. (1) *Bartonella* species replicate first in the midgut of the arthropod vector and are excreted in its feces. (2) *Bartonella* species are inoculated by scratching infected insect feces into the dermis. (3) *Bartonella* species colonize the "dermal niche." (4) Bacteria colonize endothelial cells mediated by *Bartonella*-effector proteins. (5) From this "blood seeding niche," the bacteria are periodically seeded into the bloodstream where they invade erythrocytes and spread the infection (6). After limited replication (7), they persist for the remaining lifespan of the red blood cell (8) and are thus competent for transmission by a bloodsucking

arthropod. (From Siamer S, Dehio C: New insights into the role of *Bartonella* effector proteins in pathogenesis. *Curr Opin Microbiol* 23:80-85, 2015. Reprinted with permission.)

Clinical Manifestations and Physical Examination Findings

From a clinical perspective, *Bartonella* species can be disseminated throughout all of the tissues in the body, which can result in disease in a single organ or multiple organs. Lesions have been described in the heart, liver, lymph nodes, joints, eye, nasal cavity, central nervous system (CNS), skin, and subcutaneous tissue. While a wide array of clinical signs is seen in dogs naturally infected with or exposed to *Bartonella* species experimental infection of dogs with *B. henselae, B. vinsonii* subsp. *berkhoffii* or *B. rochalimae* generally does not cause clinical signs or hematological abnormalities.[25-27] One study reported severe necrotic lesions at the site of inoculation associated with high inoculum doses while another study reported transient pyrexia.[24,28] Despite the lack of experimental models, clinical and epidemiological evidence supports the association between *Bartonella* infection and clinical manifestation in dogs. The described signs and lesions may be potentially associated with five intrinsically related mechanisms: intravascular infection, host immune-mediated response, lymphatic infection, pyogranulomatous lesions and abnormal vascular proliferation. (E-Box 215-1).

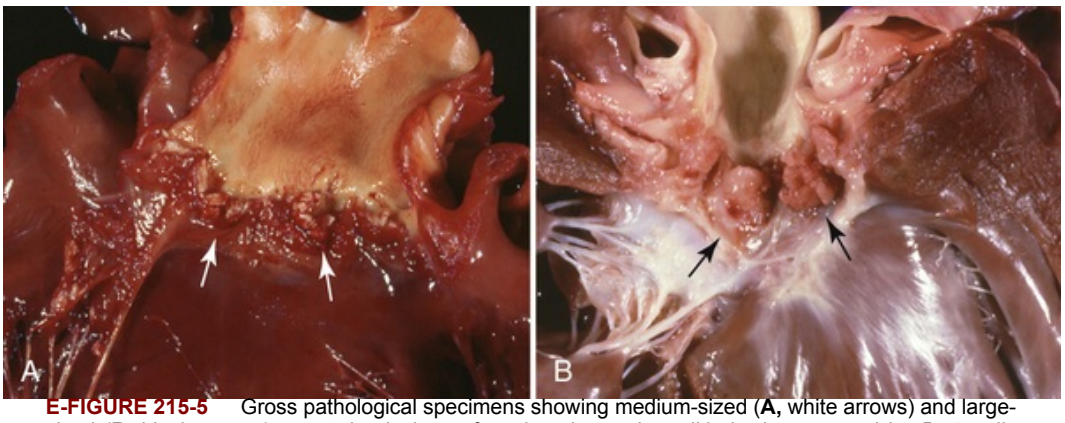
E-Box 215-1

Potential Mechanisms Associated with Disease Manifestations in Dogs Infected with *Bartonella* Species

POTENTIAL MECHANISM	CLINICAL MANIFESTATION OR DISEASE PROCESS
Intravascular infection	Endocarditis, fever of unknown origin, thromboembolic disease, polyarthritis

Host immune-mediated response	Polyarthritis, immune-mediated thrombocytopenia, immune-mediated hemolytic anemia, uveitis, vasculitis, meningoencephalitis, hyperviscosity syndrome
Lymphatic infection	Pleural effusion, pericardial effusion, abdominal effusion, seroma
Pyogranulomatous lesions	Dermatitis, panniculitis, lymphadenitis, chronic lymphocytic hepatitis, granulomatous hepatitis, meningoencephalomyelitis, systemic pyogranulomatous disease
Abnormal vascular proliferation	Peliosis hepatis, hemangiopericytoma, bacillary angiomatosis

Endocarditis is the most recognized consequence of *Bartonella* infection in dogs, with *B. vinsonii* subsp. *berkhoffii* being the most commonly identified species by molecular methods.[29-31] Approximately 19% to 28% of canine cases of infective endocarditis are caused by *Bartonella* infection,[32,33] with five of 11 dogs (45%) with culture-negative blood culture being seroreactive for *Bartonella* species in one study.[33] *Bartonella* endocarditis differs from endocarditis caused by other bacteria by affecting the aortic valve more frequently (E-Figure 215-5), and commonly being paired with concomitant congestive heart failure (see also ch. 251).[32] Frequent findings include murmur (89%), lameness (43%), respiratory abnormalities (28%), and weakness and collapse (17%).[33] Fever is a commonly reported finding, but it was less frequent in endocarditis caused by *Bartonella* species than by other bacteria in one study.[32] Endocarditis predisposes to septic thromboembolic disease, which can be associated with lameness, recumbency, anisocoria, and obtundation, among other neurologic signs.[29,34] Cardiac arrhythmias, secondary to myocarditis, can be detected in dogs lacking echocardiographic evidence of endocarditis. Dogs with *Bartonella* endocarditis have 2.7 times higher the risk of death than dogs with endocarditis caused by other bacteria.[32] Therefore, clinicians should always consider *Bartonella* infection in the differential diagnosis of infective endocarditis, as early introduction of specific therapy may increase survival.



E-FIGURE 215-5 Gross pathological specimens showing medium-sized (**A,** white arrows) and large-sized (**B,** black arrows) vegetative lesions of aortic valve endocarditis in dogs caused by *Bartonella clarridgeiae*. (Photo courtesy Bruno Chomel, DrSc, DVM, MS, PhD, Department of Population Health and Reproduction, University of California, Davis School of Veterinary Medicine, Davis, USA.)

The association of *Bartonella* infection and arthritis has been described in dogs and humans.[10,35] Dogs seroreactive to *Bartonella* species have three times the chance for presenting arthritis-related lameness compared to seronegative dogs.[10] In addition, *Bartonella* species have been implicated in dogs with granulomatous inflammation involving the skin, lymph nodes, liver, spleen or in association with disseminated granulomatous lesions.[36-39] Signs vary with the tissues and organs affected. Diverse neurologic signs have also been reported in dogs infected with *Bartonella* species. We also detected infection in dogs that were diagnosed with pleural, pericardial (restrictive pericarditis), and abdominal effusions and subcutaneous seroma,[40,41] suggesting that *Bartonella* species can cause lymphatic infection and potentially lead to obstruction of lymph flow. Despite the fact that no direct cause-and-effect association can be implicated in these cases, the detection of these pathogens in effusions considered "aseptic" based upon conventional

culture approaches may prove to be clinically relevant when facing a suspected case of idiopathic effusion.

Based on review of medical records of 47 dogs tested at North Carolina State University and confirmed to be infected with *Bartonella* species by enrichment blood culture, PCR and DNA sequencing, the most frequent signs were: fever (40% of dogs), lethargy (40%), weight loss (34%), anorexia (32%), lymphadenopathy (30%), diarrhea (23%), neurological signs (21%), heart murmurs (21%), respiratory signs (21%), polyuria/polydipsia (21%), lameness (19%), vomiting (15%), and splenomegaly (13%).[42] Weight loss occurred more frequently in sick dogs infected with *Bartonella* species than in dogs suspected of other vector-borne diseases.[43] However, such signs are of limited help in distinguishing *Bartonella* infection from other causes of special vector-borne diseases in dogs; therefore, other vector-borne pathogens should always be ruled out in any cases suspected of *Bartonella* infection.

Diagnosis

Because *Bartonella* species can be detected or isolated from clinical specimens of asymptomatic dogs, positive culture or PCR results do not necessarily indicate disease causation. Consequently, the diagnosis of canine bartonellosis relies on the presence of clinical abnormalities (see E-Box 215-1), histopathologic findings, and positive culture or PCR results on blood and affected tissues. For life-threatening illnesses such as endocarditis, myocarditis and neurologic disease, the presence of *Bartonella* species should be promptly investigated and patients should be presumptively treated with specific antibiotic therapy (see therapy section below). In all cases of suspected canine bartonellosis, other possible causes of disease must be investigated. For dogs presented with other local abnormalities (such as organomegaly, lymphadenopathy, panniculitis, etc.) or systemic disease (vasculitis, immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, systemic lupus erythematosus, polyarthritis, etc.), an extensive work-up should be performed to rule out other causes such as fungal, bacterial (including mycobacterial) infections, parasites, neoplastic, genetic, degenerative or immune-mediated disorders. Of note, if immunosuppressive therapy is necessary to address immune-mediated causes, concomitant *Bartonella* infection should be ruled out by serology, enrichment culture and PCR prior to therapy, as immunosuppression may predispose to *Bartonella* endocarditis and poor outcome.[44] An algorithm of the diagnostic approach is provided in Figure 215-6.

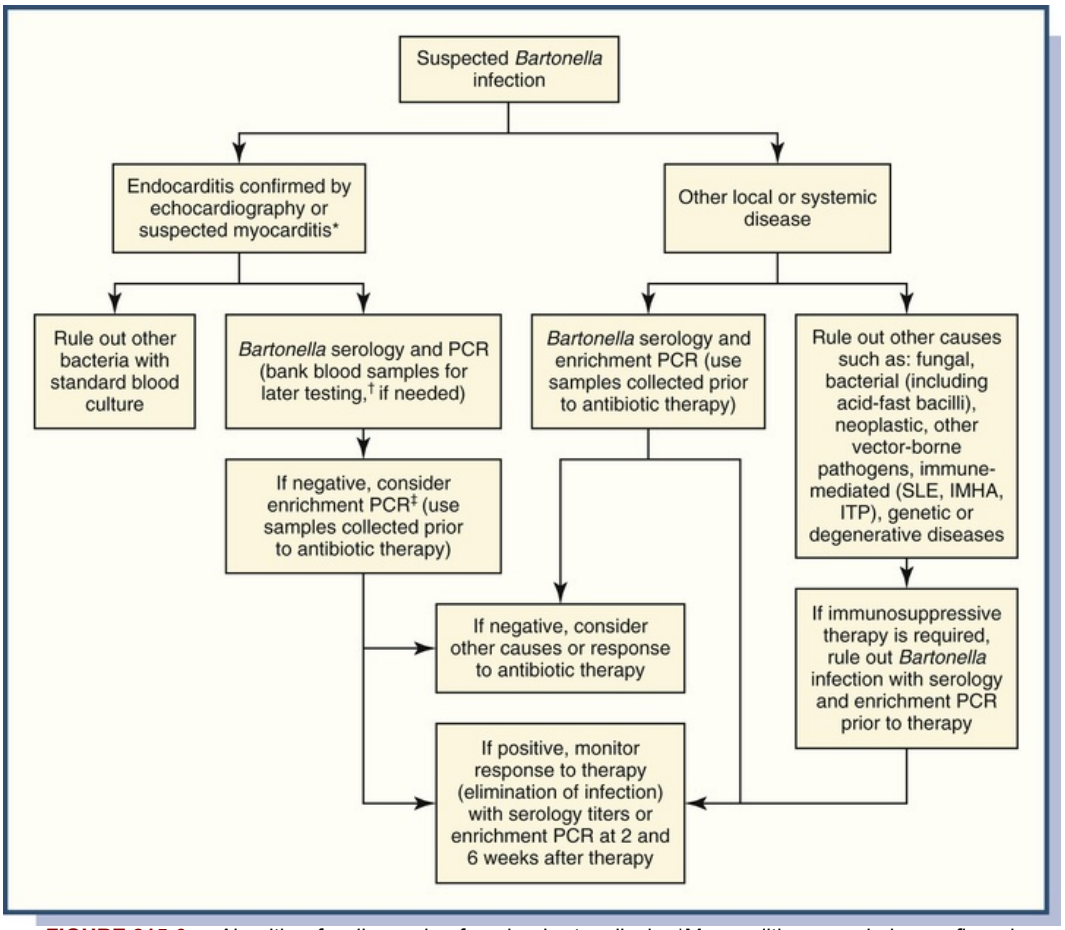


FIGURE 215-6 Algorithm for diagnosis of canine bartonellosis. *Myocarditis can only be confirmed by histopathology, but it may be suspected by elevated cardiac troponin I levels, abnormal echocardiographic findings and the presence of cardiac arrhythmias. †Samples can be refrigerated at 2–8°C for up to a week or frozen at −20°C for longer periods of time. ‡Diagnostic platform comprised of BAPGM enrichment culture coupled with PCR. See text for details. *BAPGM*, *Bartonella* alpha-Proteobacteria growth medium; *IMHA*, immune-mediated hemolytic anemia; *ITP*, immune-mediated thrombocytopenia; *PCR*, polymerase chain reaction; *SLE*, systemic lupus erythematosus.

Laboratory Abnormalities

Frequently, infected dogs have no hematologic abnormalities, and when present, they are nonspecific and often mild. In a recent study, the most common laboratory findings among 47 dogs confirmed to be infected with *Bartonella* species were: proteinuria (40%), anemia (38%), leukocytosis (36%), thrombocytopenia (34%), elevated liver enzymes (32%), hyperbilirubinemia (30%), hyperglobulinemia (26%), hypoglobulinemia (23%), azotemia (21%), monocytosis (17%), abnormal coagulation panel (PT/PTT) (13%), leukopenia (11%), and lymphocytosis (11%).[42,43] Cylindruria, bilirubinuria, and isosthenuria may be present in some dogs. When the frequency of laboratory findings was compared to dogs suspected of other vector-borne diseases, dogs presented with hypoglobulinemia (not associated with protein-losing nephropathy or enteropathy) had four times higher risk of being infected with *Bartonella* species than those who did not present with it.[43] These findings may be associated with potential immune suppression, since experimental infection with *B. vinsonii* subsp. *berkhoffii* in dogs was associated with defects in monocytic phagocytosis, cyclic CD8+ T lymphopenia, and impaired antigen presentation within lymph nodes.[24,27] Dogs infected with *Bartonella* species may have a positive Coombs' test associated with immune-mediated hemolytic anemia (see ch. 198). Antinuclear antibodies also may be present, which can result in a misdiagnosis of systemic lupus erythematosus (SLE; see ch. 205). In dogs with *Bartonella* endocarditis, myocarditis or cardiac arrhythmias, other common hematologic and biochemistry abnormalities include eosinophilia and neutrophilia (rarely accompanied by left shift).[45]

Electrocardiography

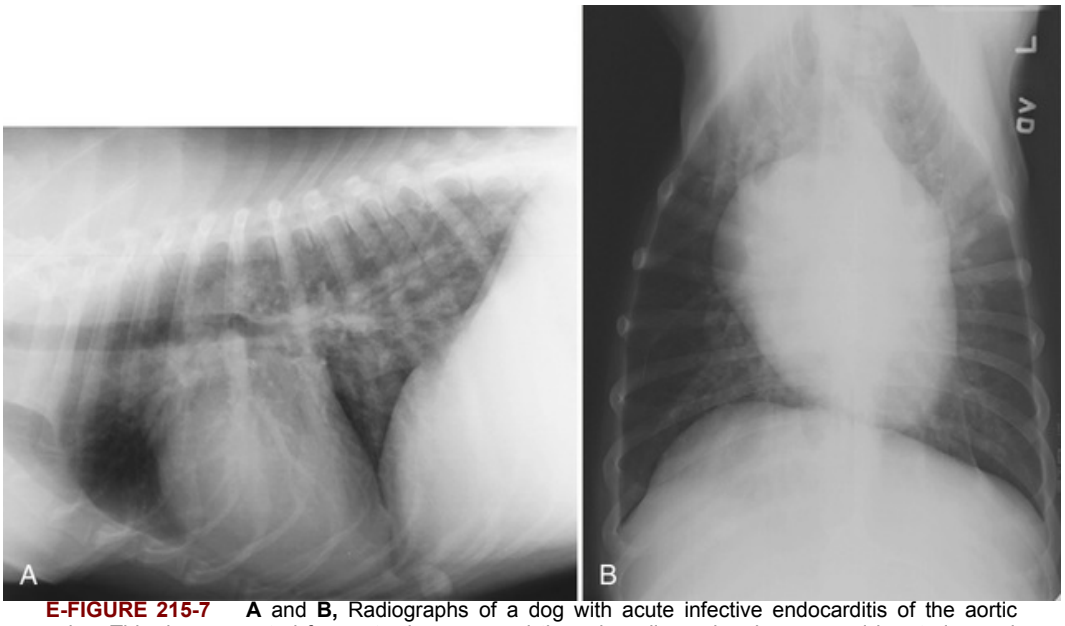
Cardiac arrhythmias can be detected in 9% to 60% of dogs infected with *Bartonella* species (see ch. 103).[15,42,45] Higher frequency of arrhythmias was seen in cases with endocarditis or myocarditis, characterized by sinus tachycardia, atrial fibrillation, intermittent ventricular premature complexes, ventricular tachycardia or third-degree atrioventricular block (see ch. 248).[45]

Cardiac Biomarkers

Cardiac troponin I (cTnI) was elevated (0.28 to 3.05 ng/mL, normal ≤0.11 ng/mL) in three out of eight dogs infected or exposed to *B. henselae* or *B. vinsonii* subsp. *berkhoffii* in Brazil; these dogs also presented other cardiovascular abnormalities such as hypotension and myocardial dysfunction.[46] Since other vector-borne diseases such as ehrlichiosis and babesiosis can also cause increases in cTnI levels,[47] it is important to rule out other infectious and non-infectious causes of myocardial injury (see ch. 246).[48]

Diagnostic Imaging

Dogs with *Bartonella* endocarditis often present with cardiogenic pulmonary edema, identified on thoracic radiographs by perihilar to caudodorsal interstitial to alveolar pulmonary infiltrates with absence of left atrial enlargement or global cardiomegaly (E-Figure 215-7).[34] Echocardiography is very sensitive for detecting abnormalities suggestive of endocarditis, such as hyperechoic, oscillating, and irregular-shaped valvular vegetations or thickened and hyperechoic valve leaflets (E-Figure 215-8 and Video 215-1; see ch. 251). Insufficiency of the affected valve is always present, and most often is moderate to severe.[34] In dogs with *Bartonella*, decreased systolic function (characterized by decrease in fractional shortening) and left ventricular enlargement or eccentric hypertrophy have been reported.[46] Ultrasonography should be used to evaluate the presence of lymphadenopathy, organomegaly, peritoneal fluid or suspected pyogranulomatous disease (see ch. 88). The ultrasound findings reported in a dog infected with *B. henselae* and presenting with peliosis hepatis included hepatomegaly with multiple, small, nodular masses and fluid-filled cyst-like structures.[49] Granulomatous disease can be identified on ultrasound by the presence of enlarged lymph nodes, but must be confirmed by histopathology.[39]



E-FIGURE 215-7 **A** and **B,** Radiographs of a dog with acute infective endocarditis of the aortic valve. This dog presented for acute dyspnea, and thoracic radiographs show normal heart size and diffuse interstitial pulmonary infiltrates of the caudal lung lobes. The pulmonary veins are mildly distended. Because of the lack of cardiomegaly, there was debate about whether the infiltrates were cardiogenic, and measurement of markedly elevated pulmonary capillary wedge pressure confirmed left heart failure as the cause of the infiltrates. This dog had acute aortic insufficiency from *Bartonella* endocarditis of the aortic valve, causing acute cardiogenic pulmonary edema without overt

cardiomegaly. (From MacDonald K: Infective endocarditis in dogs: diagnosis and therapy. *Vet Clin North Am Small Anim Pract* 40(4):665-684, 2010. Reprinted with permission.)

Specific Techniques

Molecular Diagnostic Methods

In all cases of suspected bartonellosis, clinical samples (EDTA-blood, serum, plasma, tissues, etc.) should always be collected prior to antibiotic therapy and stored in −20°C, as antimicrobials rapidly decrease the chances of detection of *Bartonella* species by culture or PCR assays. Samples from tissue and non-blood fluids (effusion, synovial fluid, etc.) from affected organs should be preferentially tested by culture and PCR, as they may provide better clinical sensitivity than blood samples. Molecular diagnostic tests such as PCR assays are highly sensitive and specific for the targeted pathogens and have faster turnaround time (1 to 3 days) than culture. PCR assays for the genus *Bartonella* or selected species are available at private veterinary reference laboratories and at selected university laboratories in the United States as part of vector-borne PCR panels; however, analytical sensitivity and specificity among laboratories may vary. The diagnostic value of PCR assays depends upon the type of sample tested. Dogs generally maintain very low bacteremic levels of *Bartonella* species (<1 to 10 organisms/mcL),[2] that can be below the limit of detection of the PCR assay. Therefore, in cases other than endocarditis, blood samples may not be the optimal diagnostic clinical specimen. In addition, negative PCR or culture results do not rule out *Bartonella* infection in dogs. Formalin-fixed paraffin-embedded tissues can be used for the detection of *Bartonella* species; however, stringent procedures must be established to avoid cross-contamination of *Bartonella* DNA in the necropsy room and during the processing of tissue samples.[50]

Serologic Methods

The detection of antibodies to *Bartonella* species can be performed by immunofluorescent antibody (IFA), enzyme-linked immunosorbent assay (ELISA) or Western immunoblot assays.

High *Bartonella* serologic titers (>1 : 512) are useful to diagnose aortic valve endocarditis due to *Bartonella* species.[33] However, in dogs with other local or systemic disease, serology results alone may be of limited diagnostic value as bacteremia may occur in the absence of detectable antibodies in over half of the dogs.[43] Species-specific assays for *B. henselae, B. vinsonii* subsp. *berkhoffii* and *B. rochalimae* and *B. clarridgeiae* are available. However, some degree of cross-reactivity was initially suggested based on the frequent number of naturally exposed dogs seroreactive to more than one antigen.[10] Conversely, a recent experimental study in dogs demonstrated that canine antibody response was not only species specific for *B. henselae* or *B. vinsonii* subsp. *berkhoffii* but also genotype or serotype specific within each species.[51] Therefore, a dog infected with a specific *Bartonella* type may not mount a detectable antibody response to other bacterial types under the same species, which may explain the discrepancy between serology and culture/PCR results. With four distinct genotypes of *B. vinsonii* subsp. *berkhoffii* reported in dogs (I-IV), as well as two serotypes of *B. henselae* (I and II), these new findings may indicate that the use of serologic methods may be problematic unless extensive serology panels are made available for several *Bartonella* species, genotypes and serotypes.[51] At the time of writing, no commercially available *Bartonella* serology panel provides differentiation among genotypes and serotypes of *Bartonella* species.

Culture Methods

The gold standard for microbiologic detection of *Bartonella* species is achieved by obtaining isolates in solid culture media, which may take 4 to 8 weeks. However, some wild types of *Bartonella* do not easily adapt to laboratory conditions. Often, PCR-positive samples fail to yield isolates and can only be characterized based on DNA amplification and sequencing. In addition, the low level and cyclic bacteremia in dogs and the slow growth of *Bartonella* species limit the diagnostic value of culture methods.

A combined approach using enrichment culture coupled with DNA amplification and sequencing (so-called "enrichment PCR") is available in the United States.* This combined approach uses a chemically modified insect-based cell liquid media (*Bartonella* alpha-Proteobacteria Growth Medium [BAPGM])[52] to increase the number and variety of organisms for PCR detection and solid media isolation. This approach provides results in 3 weeks, with a broader spectrum of *Bartonella* species detected.[2] However, similar to serology and PCR assays, negative results do not rule out infection. Currently, this is one of the most successful diagnostic techniques available, detecting 55% more dogs infected with *Bartonella* species than a single PCR assay from blood or tissue.[43] In humans, higher clinical sensitivity was reported when blood samples were drawn on three separate days over the course of a week (so-called "triple draw") because of relapsing bacteremia.[53] A similar approach may be considered in dogs suspected of bartonellosis that are chronically and systemically ill when serology and single enrichment PCR tests fail to identify exposure to or infection with *Bartonella* species.

Microscopy

Blood smear examination for detection of intraerythrocytic *Bartonella* species has very limited diagnostic value due to the size of the bacterium and intermittent bacteremia. *Bartonella* species can only be visualized on tissue samples stained with modified silver stains (e.g., Warthin-Starry stain or Dieterle's stain) but other pathogens can also be stained. At research laboratories, immunohistochemistry and fluorescent *in situ* hybridization has been used for specific identification of *Bartonella* species in tissue samples.

Treatment

To date, an optimal protocol has not been established for the treatment of *Bartonella* infections in cats, dogs, or people.[2,54] Randomized controlled trials using sensitive diagnostic tools and evaluating several outcomes of interest (persistent bacteremia, clinical cure, adverse effects, development of endocarditis, relapse rate, and mortality) are needed to support antimicrobial protocols.[54] Current recommendations are based upon limited case series, experimental studies, clinical experience and data extrapolated from the human literature. Single-agent therapy with doxycycline or azithromycin is no longer recommended because of treatment failure and the risk of rapid development of antimicrobial resistance.[40,41,55] Currently, long-term therapy with a combination of two antibiotics with different modes of action, one achieving high plasma concentrations and the other achieving high intracellular concentrations (E-Table 215-2), is the best available recommendation

until other antibiotics or antibiotic combinations are proven to be effective. A third-generation fluoroquinolone (pradofloxacin) has demonstrated better antimicrobial activity against human and feline *Bartonella* isolates than enrofloxacin,[55] but to date this drug has only been approved for use in cats in the United States. Minocycline could be considered in case of doxycycline shortage, since it has demonstrated good *in vitro* antimicrobial activity against *B. henselae* isolates from cats and humans in one study,[56] but its activity against *Bartonella* isolates from dogs is unknown. For seroreactive dogs, response to therapy can be monitored based upon decrease in antibody titers after weeks to several months with effective antimicrobial therapy. Monitoring bacteremia by enrichment PCR at two and six weeks after completion of antibiotic therapy may also be used to infer about therapeutic cure. However, it is unclear if true elimination of the pathogen can be achieved with any antibiotic regimen. If the patient is reasonably stable, the second antibiotic should be started five to seven days after the first antibiotic, in order to decrease the risk of Jarisch-Herxheimer reaction.[57] The reaction, characterized by lethargy, fever, and vomiting (signs similar to bacterial sepsis), tend to occur within the first week after starting antibiotics. It is caused by rapid death of bacteria caused by the adequate intracellular and intravascular drug concentrations, with consequent release of endotoxins triggering the systemic inflammatory response syndrome (SIRS; see ch. 132). Clinicians should avoid interrupting antimicrobial therapy or switch antibiotics based on a suspected adverse drug reaction in such cases. A short-term course of corticosteroids at anti-inflammatory dosages can be used for alleviating these signs.

E-TABLE 215-2

Current Recommended Antibiotic Dosages for Canine Bartonellosis

ANTIBIOTIC COMBINATION	DOSE	INTERVAL (HOURS)	ROUTE	MINIMUM DURATION (WEEKS)	RECOMMENDED SCENARIO
Doxycycline with enrofloxacin*	5–10 mg/kg 5 mg/kg	12 12	PO PO	6 6	Long-term home therapy
Doxycycline with rifampin	5–10 mg/kg 5 mg/kg	12 24	PO PO	6 4–6	CNS infections
Azithromycin with rifampin	5–10 mg/kg 5 mg/kg	24 24	PO PO	6† 6	CNS infections
Doxycycline with amikacin	5–10 mg/kg 15–20 mg/kg	12 24	PO IV/IM/SC	6 See notes‡	Endocarditis or during hospitalization

*Other fluoroquinolones might be considered, but experimental or clinical data are not available. See text for details.

†Initially given every 24 hours for 7 days, followed by every other day for an additional 5 weeks.

‡It should be used only during inpatient treatment, because it requires parenteral administration and renal function monitoring.

CNS, Central nervous system.

Prevention

Currently, there are no available vaccines against *Bartonella* species for dogs, cats or humans; therefore, the prevention of infection is based on vector control. Veterinarians should educate clients about the importance of year-around ectoparasite control for dogs and cats to prevent the transmission of *Bartonella* species, as well as other vector-borne pathogens.

Public Health Considerations

The most commonly recognized manifestation of *Bartonella* infection in humans is cat scratch disease, a syndrome characterized by a cutaneous papule or pustule associated with regional lymphadenopathy ipsilateral to the inoculation site (E-Figure 215-9), and fever caused by *B. henselae* and potentially *B. clarridgeiae.* However, similar to dogs, *Bartonella* infection in humans can cause an array of clinical manifestations. An increasing number of publications has suggested *Bartonella* as a newly recognized occupational hazard for veterinarians and veterinary technicians, among other professions with frequent

contact with animals and exposure to blood-sucking arthropods.[4,58] In a recent report on 114 veterinary subjects, over one in four of those was infected with *Bartonella* species, with headaches and irritability being more frequently reported among infected subjects than uninfected veterinarians.[4] Other reports describe infected veterinarians experiencing chronic fatigue, frequent headaches, chronic undulant fever, persistent back pain, and lymphadenopathy.[59,60] Consequently, veterinarians not only must be aware of their risk of infection with *Bartonella* species, but also must play an important role in public health by advising clients about the disease and the steps towards minimizing or eliminating exposure.[61] Precautions should be taken to avoid exposure to fleas and other potential vectors, contact with arthropod feces, bites and scratches from animals, and direct contact with bodily fluids from sick animals.[2] Direct transmission of *Bartonella* species from dogs to humans through bites or scratches has not yet been clearly established, but dogs should not be allowed to lick open human wounds, as *Bartonella* DNA was detected in dog saliva.[62]

CHAPTER 216

Bartonella—Feline

Lynn F. Guptill

Client Information Sheet: *Bartonella* Infection in Cats

Background

Bartonella spp. are small, vector-transmitted, facultatively intracellular, Gram-negative bacteria. Most *Bartonella* species appear to be highly adapted to mammalian reservoir hosts. Bartonellae often cause a long-term, intermittent bacteremia in clinically normal animals.[1,2] The mechanisms that facilitate persistent *Bartonella* bacteremia in mammals are not yet completely understood. Intracellular localization, frequent genetic rearrangements, and alteration of outer membrane proteins are strategies for immune system evasion and bacterial persistence.[1-5] Location in erythrocytes (RBCs) may facilitate efficient vector transmission and potentially contribute to decreased antimicrobial efficacy.[6] *Bartonella* species are also reported to colonize vascular endothelial cells, and, based on work done in a rodent model, may be periodically released from these cells into the circulation, where they may be found extracellularly and within RBCs.[3,7] This discussion will focus on *B. henselae,* the *Bartonella* species most commonly isolated from domestic cats. Other species that may naturally infect cats, *Bartonella clarridgeiae, B. koehlerae, B. bovis,* and *B. quintana,* are also discussed.

Epidemiology

Since the first recognition of feline *B. henselae* infection in 1992, results of serologic, blood culture, and polymerase chain reaction (PCR) tests indicate that exposure to *Bartonella* spp., most frequently *B. henselae,* is prevalent among cats in the United States and throughout most temperate regions of the world.[8] Prevalence is higher in areas with warmer temperatures and higher humidity, in feral cats, and in cats infested with fleas. Older cats appear more likely to be seropositive and younger cats to be bacteremic.[9-14] *B. henselae* bacteremia affects about 5% to 40% of domestic cats in the United States depending on geographic location.[10,12,15-17] A prevalence of over 90% was reported in one cat colony.[18] *B. clarridgeiae* infections accounted for about 10% of cats with *Bartonella* bacteremia evaluated in the United States, and 16% to 31% of cats with *Bartonella* bacteremia in France and the Philippines.[19,20] *Bartonella koehlerae* was recently detected in approximately 4% of cats tested in Israel. *Bartonella bovis* and *B. quintana* have been isolated or detected by PCR in a few healthy domestic cats.[21-23]

Domestic cats are considered the primary reservoir and vector for human infection with *B. henselae.* Cats are also likely reservoirs for *B. clarridgeiae* and *B. koehlerae.* Cattle appear to be the reservoir for *B. bovis.* Molecular methods have detected *B. quintana, B. koehlerae, B. henselae, B. clarridgeiae,* and a range of other *Bartonella* species in cat fleas, along with rickettsial pathogens.[24,25] While this may suggest flea involvement in transmission of all of these *Bartonella* species, the fleas may have just fed on an infected host. Flea competence for transmitting some *Bartonella* species has not yet been verified. Wild felids, including panthers, bobcats, mountain lions, pumas, African lions, and cheetahs, are also exposed to *Bartonella* species.[23]

There are multiple genetically diverse strains of *B. henselae.* Two recognized 16S rRNA types of *B. henselae* exist, with at least two subgroups within each type.[26,27] Other methods of classifying *B. henselae* include multilocus sequence typing and amplified fragment length polymorphism. Each method has identified multiple genetic types of *B. henselae.*[28] Cats can be co-infected with multiple genetic types of *B. henselae* and multiple *Bartonellas,* with regional differences.[15,19,28-31] All molecular methods also show remarkable genetic

diversity among *Bartonella* isolates and evidence of genomic variations during the course of infection.[5,32-40] Such variation may enhance the ability of *B. henselae* to persist in infected cats for prolonged periods. Genetic variation makes vaccine development difficult, but is useful in epidemiologic studies, and in further understanding the pathogenicity of various *Bartonella* isolates.

Pathogenesis

Bartonella henselae is naturally transmitted among cats by cat fleas. *Bartonella henselae* was transmitted among cats by transferring fleas fed on naturally infected cats to specific pathogen–free (SPF) cats and by intradermal (ID) inoculation of excrement collected from fleas fed on *B. henselae*–infected cats.[41-43] Transmission via flea saliva has not been documented.[41] However, a recent study suggests that *B. henselae* may be transmitted via flea regurgitation during feeding, similar to what is described for *Yersinia pestis* transmission.[44] Ticks may also have a role in transmission; *B. henselae* and other *Bartonella* spp. were detected by PCR in questing ticks.[45-47] Transstadial transmission of *B. henselae* has been demonstrated in *Ixodes ricinus* ticks, likely competent vectors for *B. henselae.* Blood-feeding arthropods have been proposed as vectors for transmission of *Bartonella* infections in cats, human beings, dogs, and other mammals.[48-52]

Cats may become infected through IV or IM inoculation with infected cat blood or by IV, SC, ID, or oral routes of inoculation with plate-grown bacteria. Infection did not occur when cats were injected with urine of bacteremic cats.[53-59] *Bartonella henselae* transmission fails when infected cats cohabit with uninfected cats in a flea-free environment. Thus, transmission among cats does not normally occur through cat bites, scratches, grooming, or sharing of food dishes and litterboxes. Transmission does not occur between bacteremic females and males during mating, or to kittens of infected females during gestation or in the neonatal period in flea-free environments.[53,57,60] Chronic, relapsing bacteremia is believed to facilitate transmission of *Bartonella* by blood-feeding arthropods. Experimentally infected cats maintained relapsing *B. henselae* or *B. clarridgeiae* bacteremia for as long as 454 days.[54] Naturally infected cats maintained recurrent bacteremia for up to 3 years; however, reinfection of these cats via fleas likely occurred.[61,62]

While cats mount a strong immune response to *Bartonella* infection, a lack of heterologous protection against reinfection was demonstrated in previously infected cats. Cats previously infected with *B. henselae* 16S rRNA type II were susceptible to infection with *B. henselae* 16S rRNA type I.[63] Cats infected with *B. henselae* type I or II were susceptible to challenge infection with *B. clarridgeiae,* and cats infected with *B. koehlerae* or *B. clarridgeiae* were susceptible to challenge infection with *B. henselae* type I or type II. However, cats infected with *B. henselae* type I were partially or completely protected against challenge infection with *B. henselae* type II.[64] Cats can become immune to challenge with homologous strains of the organism. The level of bacteremia and degree of susceptibility to reinfection following challenge inoculation is likely to vary with *Bartonella* species and strain.[62] Chronic location of *Bartonella* in cats has not been completely determined. Bartonellae have been detected within RBCs of naturally infected cats.[65] *Bartonella* may localize within vascular endothelial cells, as has been suggested for rodents, and may also infect dendritic cells or other cells in SC tissue after ID inoculation.[66,67]

Clinical Findings

Existing data indicate that few cats naturally infected with *Bartonella* have clinical signs. Uveitis may be a manifestation of natural *Bartonella* infection.[68] Natural *Bartonella henselae* type I infection was associated with fatal blood-culture–negative vegetative aortic valve endocarditis in one cat and an experimentally infected cat developed fatal myocarditis.[69,70] Whether *Bartonella* spp. contribute to argyrophilic bacteria in lymph nodes of young cats with persistent lymphadenomegaly is unknown.[71] Naturally infected cats usually have subclinical signs. Clinical signs in cats experimentally infected with *B. henselae* are usually mild. Cats with experimental intradermal inoculation developed areas of induration or abscess at inoculation sites 2 days to 4 weeks later. Pure *B. henselae* cultures were obtained from those sites (Figure 216-1).[54,56,58,59,72]

FIGURE 216-1 Postinoculation abscess 20 days after intradermal inoculation of *Bartonella henselae* in a cat. The size of the papule increased from the time of inoculation and only *B. henselae* was isolated from bacterial culture of an aspirate. Bar = 1 cm. (Courtesy Lynn Guptill-Yoran, Purdue University, West Lafayette. In Greene CE: *Infectious diseases of the dog and cat*, ed 4, St Louis, 2012, Saunders.)

Other transient clinical findings in many experimentally infected cats included generalized or localized peripheral lymphadenomegaly (lasting for about 6 weeks following inoculation), and brief periods of fever (>39.4° C [103° F]) in the first 48 to 96 hours and again about 2 weeks later. Mild neurologic signs (nystagmus, whole body tremors, focal motor seizures, decreased or exaggerated responses to external stimuli, behavior changes) and epaxial muscle pain were seen in a few experimentally inoculated cats. Some cats were lethargic and anorexic during febrile periods.[54,56,58,59] Reproductive failure occurred in some cats experimentally infected with *B. henselae*.[60] Cats experimentally infected with *B. koehlerae* exhibited no clinical signs.[73] A potential causative role of *Bartonella* spp. in chronic diseases of cats seems likely. One study suggested that co-infection of cats with *B. henselae* and feline immunodeficiency virus (see ch. 222) was more likely to be associated with gingivitis or lymphadenomegaly than either infection alone.[74] One study suggested possible associations between *B. henselae* seroreactivity and stomatitis or unspecified urinary tract disorders.[75]

Because of the high *Bartonella* prevalence in cats, extensive, controlled, epidemiologic studies are needed to determine whether particular clinical conditions are associated with infection. Some studies have investigated potential associations between *Bartonella* infection or exposure and clinical conditions such as neurologic disease, stomatitis, uveitis, plasmacytic pododermatitis, anemia, hyperglobulinemia, high serum pancreatic lipase immunoreactivity, inflammatory polyps, chronic rhinosinusitis, peliosis hepatis and fever. There was no statistically significant association of *Bartonella* with most of the aforementioned conditions in cats, though power may not have been sufficient to detect some associations.[74-86] *Bartonella* infection may be associated with hyperglobulinemia.[80] Association between oral disease in cats and *Bartonella* exposure has varied among studies; an association between seroreactivity and stomatitis was suggested in one study, no association was reported in another, and then an association was reported between *Bartonella* bacteremia and oral disease, but not between *Bartonella* seroreactivity and oral disease.[74,87,88] There was an inverse relationship between *Bartonella* seroreactivity and pain associated with degenerative joint disease in a group of cats.[89] Studies that rely solely on *Bartonella* seroreactivity to evaluate disease associations should be interpreted with caution. The high prevalence of *Bartonella* exposure among cats makes it difficult to determine which clinical conditions may be truly associated with infection, particularly in cats exposed to arthropod vectors.

Diagnosis

Overview

Most clinical signs or clinical pathological abnormalities attributed to feline *Bartonella* are nonspecific. Determining which cats are likely infected with *Bartonella* and whether that infection is responsible for clinical signs, is difficult. In addition to testing for *Bartonella* infection in sick cats, veterinarians may be asked to test healthy pet cats belonging to clients with *Bartonella*-related illnesses. One may screen healthy cats being considered as blood donors or as pets for people considered most susceptible to *Bartonella* infections (see Public Health). It is important to approach the diagnosis of feline bartonellosis in a careful, systematic manner.

Routine Laboratory and Pathologic Findings

Most experimentally infected cats have no abnormalities on complete blood count (CBC), serum biochemistries, or urinalysis. Some cats had early transient anemia and some had persistent eosinophilia.[54] Mature neutrophilia occurred in some cats during periods of skin inflammation.[56] Hyperglobulinemia has not been reported in experimental *Bartonella* infections of cats, but results of a study on samples collected from a commercial veterinary laboratory reported a potential association between hyperglobulinemia and *B. henselae* seroreactivity.[80] However, no clinical or historical data were available and *B. henselae* DNA was not detected. If cats have unexplained hyperglobulinemia, it may be useful to evaluate for *Bartonella* using culture and PCR.

Visualizing *B. henselae* in RBCs of infected cats has not been effective using conventional staining methods and microscopy. Confocal microscopy and special staining has been effective, and intra-RBC locations of *B. henselae, B. clarridgeiae,* and *B. koehlerae* have been documented in cats using fluorescence methods.[90,91] Acute and chronically infected cats had hyperplasia of lymphoid organs and small foci of lymphocytic, pyogranulomatous, or neutrophilic inflammation in lung, liver, spleen, kidney, or heart (Figures 216-2 and 216-3).[54,56]

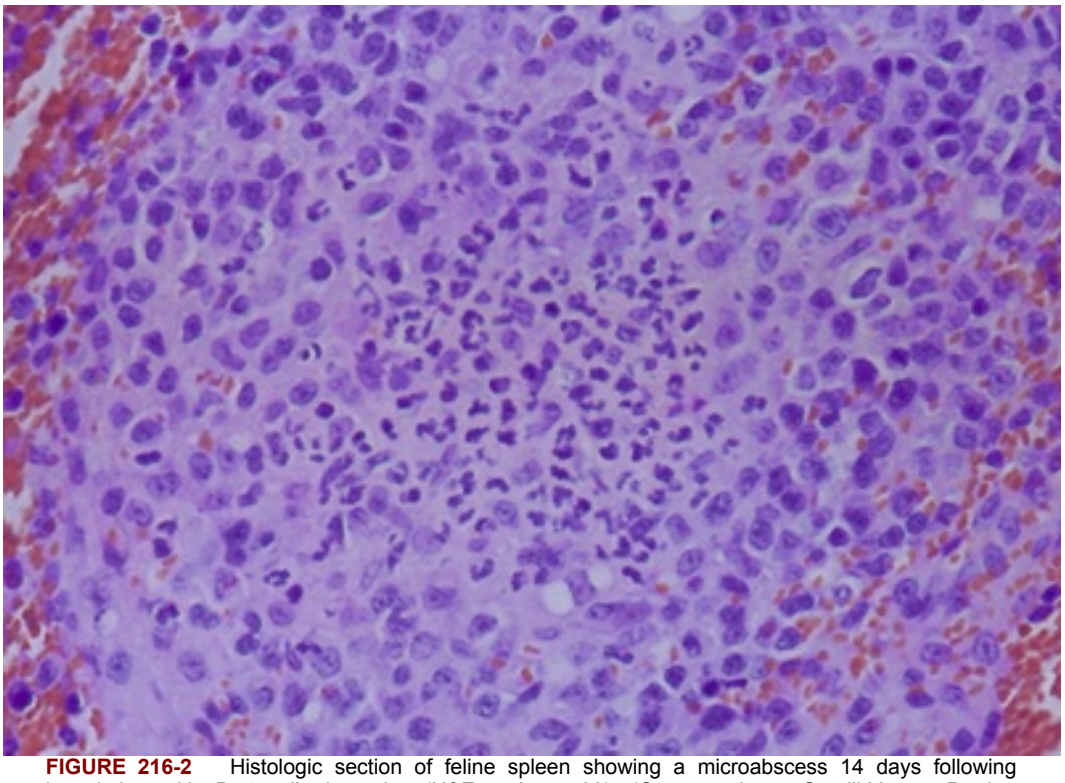

FIGURE 216-2 Histologic section of feline spleen showing a microabscess 14 days following inoculation with *Bartonella henselae* (H&E stain, ×400). (Courtesy Lynn Guptill-Yoran, Purdue University, West Lafayette. In Greene CE: *Infectious diseases of the dog and cat,* ed 4, St Louis, 2012, Saunders.)

(From Guptill L, Slater L, Wu CC, et al: Experimental infection of young specific pathogen-free cats with *Bartonella henselae*. *J Infect Dis* 176:206-216, 1997.)

Bacterial Isolation

A positive blood or other tissue culture is definitive for active *Bartonella* infection. However, because of the relapsing nature of detectable *Bartonella* bacteremia in cats, culture is not always sensitive. Use of enrichment media improves culture sensitivity, as does testing more than one sample.[92,93] Blood culture is indicated for ill cats whose history and clinical presentation suggest *Bartonella* infection or when a client's physician requests testing. Blood for culture should be obtained using sterile technique and the blood placed in EDTA-containing or lysis centrifugation blood culture tubes (Isolator tubes, Wampole, Cranbury, NJ). If collected into EDTA tubes, blood should be chilled or frozen for shipment.[94,95] Blood should be sent to laboratories familiar with culture of these fastidious organisms. The laboratory should be contacted for specific instructions regarding sample collection and submission. *Bartonella* growth from blood or other tissue samples is often slow and may be several weeks.

Serologic Testing

Serum antibodies have limited value for diagnosing active *Bartonella* infection since serologic tests overestimate infection. Serology is useful for epidemiologic surveys. Serum IgG antibodies persist in experimentally infected cats for prolonged periods; how long antibodies persist after clearing infection is not known. Indirect fluorescent antibody (FA), enzyme immunoassay (EIA), and Western blot tests are available. Because of the genetic diversity of *Bartonella* organisms, infections with some strains or species of *Bartonella* may be missed regardless of the method used.[96,97] The positive predictive value of FA or EIA (IgG) serologic tests for bacteremia was only 39%-46%; however, methods used to establish bacteremia were not ideal.[23,28] The utility of a negative serologic result may be greater, as the negative predictive value for these tests is 87%-97%.[10,15,30,31] However, some seronegative bacteremic cats exist. No cutoff values for serologic results have been established as confirmatory of current *Bartonella* infection.[64] In people, variability in Western blot testing results has been problematic.[97,98] No difference in Western blot patterns was noted from infected cats evaluated over the course of infection.[54] Results of one study[99] agree with our findings: antibodies in sera of infected cats react with an increasing number of bands of polyacrylamide gel-separated proteins over the course of infection.

Nucleic Acid Detection

Standard PCR testing for DNA may be no more sensitive than blood culture in detecting active *Bartonella* infection. Detection of DNA does not always equate to presence of living organisms. Use of high resolution melt PCR improves sensitivity for detecting *Bartonella* infections in cats. With either culture or PCR, some infections are missed. Combining these two methods is better than either alone.[23,28] PCR has the added benefit of identifying the species and/or strain of *Bartonella* by sequencing the reaction product. Results of PCR testing are available more quickly than results of blood culture. Blood samples for PCR should be obtained using sterile technique. Care must be taken in sample collection and processing to avoid sample contamination and DNA degradation. Laboratories experienced in molecular diagnostics should be used and should be contacted for submission guidelines and test validation data.

Summary

When testing ill cats for *Bartonella* infection, the combination of bacterial culture and PCR appears to be the most sensitive diagnostic approach. Serology can be sensitive for evaluating exposure to *Bartonella* species, but positive serologic results may not indicate active infection.

Therapy

Antibiotic Review

Documenting clearance of *Bartonella* infections through antibiotic treatment is difficult due to the prolonged and relapsing nature of bacteremia. No antibiotic regimen has proven effective in controlled studies with long-term follow-up.[72,100-102] Enrofloxacin (5.4 to 7.6 mg/kg PO q 12 h) for 14 or 28 days appeared to clear *B. henselae* or *B. clarridgeiae* infection in 4 of 6 or 5 of 7 treated cats, respectively, followed for 12 weeks after treatment.[101] However, enrofloxacin causes retinal degeneration in cats and use of dosages of greater than 5 mg/kg/day is contraindicated.[103] Pradofloxacin was effective *in vitro;* however, resistance to pradofloxacin developed in *B. henselae* after 5 *in vitro* passages.[104,105] This potential for acquired resistance should be taken into consideration when planning treatment. Fluoroquinolones are not recommended for single agent treatment of humans with bartonellosis.[106,107] Doxycycline (4 to 12 mg/kg PO q 12 h) cleared bacteremia in 1 of 6 cats treated for 14 days and 1 of 2 cats treated for 28 days.[101] In some experimental infections, an effective doxycycline dosage in cats was 10 mg/kg q 12 h (Greene CE, personal communication). Antibiotics tested in other studies, including erythromycin, amoxicillin, amoxicillin-clavulanate, and tetracycline, rapidly decreased the level of bacteremia in infected cats. However, in one study, treated and untreated cats became blood-culture negative after the same period of time, making proof of antibiotic efficacy challenging. In some studies, cats were not followed for more than 8 weeks, making it difficult to assess drug efficacy due to the possibility of chronic relapsing bacteremia.[72,102] Azithromycin was previously recommended for treatment of infected cats, but data from controlled efficacy studies with long-term follow-up are lacking. One study indicated *in vitro* resistance to azithromycin develops quickly.[108]

Treatment Recommendations

Treatment of people with *Bartonella* infections varies depending on the clinical manifestation and the patient's immunocompetence.[107] There are not enough data regarding different clinical forms of feline bartonellosis to allow development of guidelines specific to particular clinical conditions. Currently, doxycycline and pradofloxacin may be preferred initial antibiotics to consider for cats thought to have *Bartonella* infection. Successful treatment of endocarditis was reported in one cat with a treatment regimen including marbofloxacin and azithromycin.[109]

Because treatment with antibiotics may induce resistant strains, treatment should be reserved for use only in *Bartonella*-positive cats showing clinical signs. Although treatment reportedly decreases the level of bacteremia, there is little evidence that treatment will decrease probability of *Bartonella* transmission to fleas, other cats, or humans. Client education regarding the uncertainty of treatment efficacy, the need for prolonged follow-up, and the possibility of reinfection following treatment is essential. The importance of flea control and other means of preventing transmission (see Prevention) should be strongly emphasized.

Prevention

Prevention of *Bartonella* infections in cats is best accomplished by avoiding exposure to infected animals and fleas. Since *Bartonella* can be transmitted through inoculation of infected cat blood, cats should not receive blood transfusions from untested cats or cats known to be PCR-, culture-, or serologically positive for *Bartonella*.[55,110] No vaccine to prevent *Bartonella* infection in cats is available. Flea and tick control programs are of utmost importance in preventing infection. Flea control products have shown excellent efficacy in preventing transmission of *Bartonella henselae* via fleas.[70,111,112]

Public Health

Cat owners should be informed of the current understanding regarding how cats acquire *Bartonella* infections, how infection may be transmitted to people, the possibility of transmission by ticks, and the association of flea infestation with transmission. Multiple *Bartonella* species or subspecies are considered zoonotic or likely zoonotic.[113] Cats are the reservoir for several zoonotic *Bartonella* species, and may serve as a vector for transmission of *Bartonella* species to people. Transmission of *B. henselae* from cats to people is believed to occur most commonly through contamination of cat scratches or other wounds with flea excrement. Further study will determine whether flea bites may also be a source of zoonotic *Bartonella* transmission.[44] Transmission may also occur through cat bites, particularly if cat blood or flea excrement contaminate the bite site.[48,49]

Bartonella spp. cause a wide variety of clinical syndromes in people, including cat scratch disease (typical and atypical forms, including encephalopathies); bacillary angiomatosis and peliosis; parenchymal bacillary peliosis; relapsing fever with bacteremia; endocarditis; retinitis; pulmonary, hepatic, and splenic granulomas; osteomyelitis; and others.[107] Immunocompetent individuals usually have more localized infection, whereas infections in immunocompromised individuals may more often be systemic and can be fatal. *Bartonella* exposure is much greater in individuals that have exposure to animals than among individuals in the general population. Exposure to fleas and flea excrement should be considered a risk for transmission of *Bartonella*. Two reports suggest that needle-stick injuries, in addition to exposure to fleas, flea excrement, cat scratches, and cat bites may also represent risks for *Bartonella* transmission.[114,115]

Individuals working in the veterinary medical professions should consider bartonellosis an occupational hazard and take appropriate precautions (e.g., wearing gloves when handling animals infested with fleas and samples collected from these animals, avoiding needle-stick injuries, avoiding animal bites and scratches, washing hands after all animal encounters).[116,117] Common sense precautions to share with pet owners regarding avoiding transmission of *Bartonella* spp. from pets to people include: ongoing flea and tick control, avoiding interactions that result in scratches or bites, thoroughly washing bite or scratch wounds, washing hands after handling pets (particularly when pets are infested with fleas), seeking medical attention when necessary, and acquiring new pets of known good health status that are and have been ectoparasite-free.

Stray or shelter cats less than 1 year old are more likely to be *Bartonella* bacteremic. There is no evidence that declawing cats decreases the probability of transmission of *B. henselae* between cats and human beings. Guidelines from the Centers for Disease Control and Prevention, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America recommend the following when acquiring a new cat: adopt a cat older than 1 year of age that is in good health, avoid rough play with cats, maintain flea control, wash any cat-associated wounds promptly, and do not allow a cat to lick wounds or cuts.[106] The Guidelines note that there is no evidence to indicate any benefit to cats or their owners from routine culture or serologic testing of cats for *Bartonella* infections.[106]

Summary

Bartonella infections are zoonotic and have the potential to cause serious illness in people. Veterinarians must make it a priority to educate staff, volunteers, and clients regarding the risks for transmission of *Bartonella.* A large proportion of domestic cats harbor persistent *Bartonella* spp. infections. Ongoing and future studies will help to ascertain possible ramifications of chronic *Bartonella* bacteremia for feline health. Veterinarians should be aware of the high prevalence of feline *Bartonella* bacteremia and carefully consider their approach to evaluating cats for possible *Bartonella*-related clinical conditions. Based on current knowledge, healthy cats should not be routinely tested for *Bartonella,* and antibiotic treatment should not be recommended for healthy cats. When ill cats are treated, treatment should always be accompanied by comprehensive vector control

measures and client education. Client education should emphasize the role of fleas in *Bartonella* transmission and the importance of vector control programs in preventing transmission. Education should also emphasize other potential avenues for transmission and address the potential risks associated with antibiotic treatment, the likelihood of reinfection of a cat following antibiotic treatment, and the zoonotic potential of *Bartonella.*

CHAPTER 217

Leptospirosis

Simone Schuller

Client Information Sheet: Leptospirosis

Etiology

Leptospirosis is a zoonotic disease of worldwide distribution that affects most mammalian species.[1] It is caused by spirochetes of the genus *Leptospira.* Leptospires are thin, elongated, highly motile, helically coiled organisms that can be differentiated from other spirochetes by their distinct hooked ends[2] (Video 217-1). Leptospires have Gram-negative staining properties but have phenotypic features of both Gram-negative and Gram-positive bacteria.[3] The taxonomy of the genus *Leptospira* is fairly complex and a source of confusion, as serological and genotypic typing are used in parallel. Serological classification is based on differences in the carbohydrate component of leptospiral lipopolysaccharide.[2] Antigenically related serovars are grouped into serogroups. Currently, over 250 known pathogenic serovars have been identified, belonging to 24 serogroups.[4] Genotypic classification based on DNA hybridization has defined 20 species of *Leptospira* including 9 pathogenic, 6 saprophytic, and 5 intermediate species, and new species are being added as they are discovered. Serologic and genotypic classifications do not always concur, in that serovars of the same serogroup can belong to different genomic species. The accepted nomenclature is the name of the genus, followed by species name, followed by serovar, followed by strain (if appropriate). Genus and species are italicized, with the serovar name not italicized and with an upper-case first letter (e.g., *Leptospira interrogans* serovar Australis).

Epidemiology

Leptospires are maintained in the environment by chronically infected reservoir hosts, which harbor leptospires in their renal tubules and shed the organisms via urine. Small rodents are considered the most important reservoir hosts, but it is likely that a large spectrum of animals, including dogs[5] and cats[6] and also humans,[7] can act as reservoir hosts for pathogenic *Leptospira.* Hosts become infected either by direct contact of mucous membranes or broken skin with urine from infected animals, or indirectly, via contact with contaminated soil or surface water (Figure 217-1). In contrast to reservoir hosts, which typically show no clinical signs of illness, incidental hosts can develop acute, severe, and potentially lethal disease.

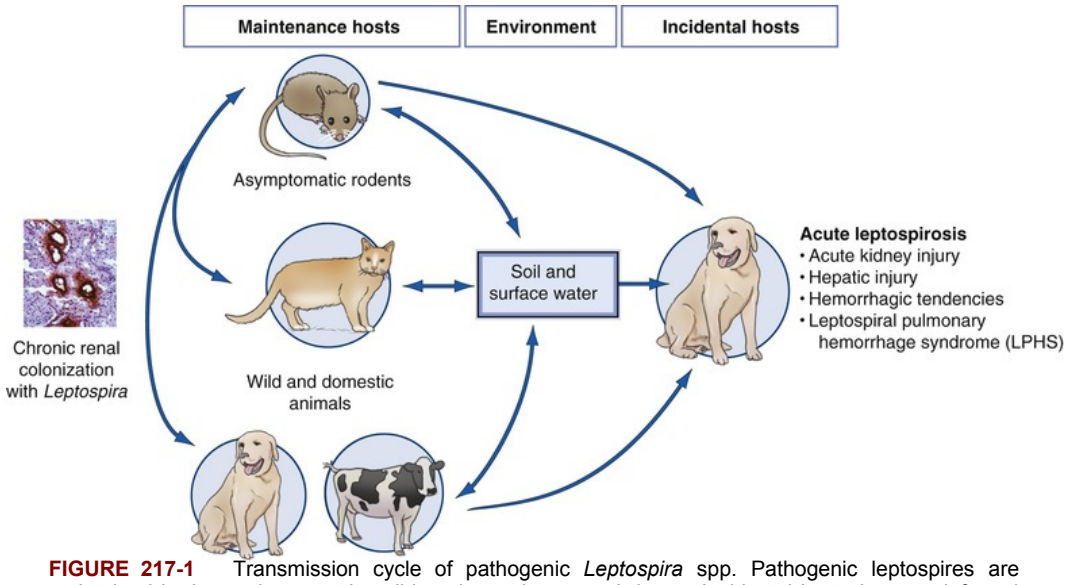

FIGURE 217-1 Transmission cycle of pathogenic *Leptospira* spp. Pathogenic leptospires are maintained in the environment by wild or domestic reservoir hosts. Incidental hosts become infected either via direct contact with reservoir hosts or contaminated soil and surface water. Cats probably are more likely to become infected via contact with prey due to their natural aversion to water. The role of dogs and cats as reservoir hosts requires further study.

In the past, acute infection in dogs most commonly was associated with the presence of antibodies to the serogroups Canicola and Icterohaemorrhagiae, but it is now clear that dogs are susceptible to infection with serovars belonging to a wide range of serogroups, including, but not restricted to, Australis, Grippotyphosa, Pomona, Autumnalis, and Sejroe.[9-11] Leptospirosis is a seasonal disease, with peak incidence during the warmer parts of the year and a link to rainfall or flooding.[12] As a consequence, seasonal patterns of leptospirosis are dependent on regional climate.[13] Dogs living in proximity to outdoor water, who swim or drink from outdoor water sources, and who are exposed to wildlife, have a higher risk of infection.[14] Males, herding dogs, hounds, working dogs, and mixed breeds have been reported to be at increased risk in the USA.[15] In a cohort of dogs from Switzerland, puppies (<1 year) and male dogs were significantly overrepresented compared to the general dog population.[16] However, other studies have not confirmed any sex, age, or breed predispositions.[17,18] Veterinarians therefore should suspect leptospirosis in any dog with suggestive clinical signs regardless of signalment and lifestyle.

Pathogenic Mechanisms of Leptospirosis

After entering the host, pathogenic leptospires quickly establish a systemic infection via hematogenous spread. Unlike bloodstream infections with other Gram-negative bacteria, leptospires do not cause fulminant septic disease shortly after the onset of infection. This has been attributed to the low endotoxic potential of leptospiral lipopolysaccharide.[19] During this initial phase, leptospires evade the host immune response by binding inhibitors of complement activation on their surface.[20,21] Leptospiremia continues until the host mounts an effective acquired immune response, which clears the organism from the bloodstream and most tissues. Thereafter, leptospires can persist in immune-privileged sites, such as the eye and the renal tubules.[8] Leptospirosis is a multisystemic disease, particularly affecting the kidneys and liver, but also many other organs, such as the lungs, spleen, endothelial cells, uvea/retina, skeletal and heart muscle, meninges, pancreas, and the genital tract. The exact mechanisms through which pathogenic leptospires cause organ dysfunction and tissue damage are not known and can vary among different organ systems. While vasculitis can be a feature in some cases of leptospirosis, most studies in humans and experimental animals do not support vasculitis as a consistent primary event responsible for tissue damage.[22]

During the acute phase, the predominant renal lesions are those of an acute interstitial nephritis, with tubular cell necrosis, apoptosis, and regeneration.[23,24] Tubular lesions are assumed to be due to direct effects of the organisms because they are generally associated with the presence of *Leptospira.* Leptospiral outer membrane components also have been shown to induce cell damage and inflammation in tubular epithelial

cells *in vitro*.[25] Glomerular abnormalities have been described in both dogs and experimental animals with leptospirosis and indicate structural and functional glomerular involvement.[26,27] Leptospires can cause a specific hypokalemic, nonoliguric form of acute kidney injury due to inhibition of the tubular Na^+-K^+ ATPase (see ch. 322).[28] Hyposthenuria can occur due to an acquired vasopressin resistance of the inner medullary collection ducts.[29]

Hepatic lesions described in humans and animals with leptospirosis include a cholestatic hepatitis with complete or partial liver-plate disruption, hepatocellular necrosis, binucleation of hepatocytes, periportal edema with inflammatory cell infiltration, and proliferation of Kupffer cells along the sinusoidal lining (see ch. 282).[23,24] Hyperbilirubinemia does not appear to be correlated with hepatocellular necrosis in humans.[30] In experimentally infected hamsters, hyperbilirubinemia coincided with the invasion of hepatic intercellular junctions by migrating leptospires and subsequent disruption of bile canaliculi.[31] In human patients, both icteric and nonicteric forms of leptospirosis have been described, the icteric form being considered more severe and rapidly progressive.[32] Similarly, a serum bilirubin of ≥0.6 mg/dL (≥10 micromole/L; reference range 0.03-0.2 mg/dL [0.5-4.0 micromole/L]) was strongly associated with death or euthanasia in a cohort of 254 dogs with acute leptospirosis.[16]

Leptospiral pulmonary hemorrhage syndrome (LPHS) increasingly has been recognized in humans, dogs, and many other species in recent years and has become a major cause of mortality.[16,33] LPHS lung tissue shows various degrees of intra-alveolar hemorrhage in the absence of a marked inflammatory cell infiltrate or vasculitis (Figure 217-2).[34] Intra-alveolar edema, fibrin, and hyaline membranes, which are characteristic of disorders with diffuse alveolar damage, such as acute respiratory distress syndrome (ARDS), also can be present but are not a predominant feature.[34,35] In contrast to what is seen in liver and kidney, few leptospires are observed in affected lung tissue in immunocompetent hosts and they do not colocalize with the pulmonary lesions.[24] Several hypotheses, including systemic inflammatory, immune-mediated, and direct leptospiral effects, currently are under investigation. It is likely that the pathogenic mechanisms of LPHS are multifactorial, with both host- and pathogen-related factors playing a role.[22] It has been suggested that introduction of clones with enhanced virulence might be a contributing factor to the recent emergence of LPHS.[4] However, at present, available evidence to link specific leptospiral serovars with particular clinical manifestations in both humans and animals is weak.[36-38] This might be partially due to the limitations of current serological tests to correctly identify the infecting serogroup or serovar in acutely infected patients.[39,40]

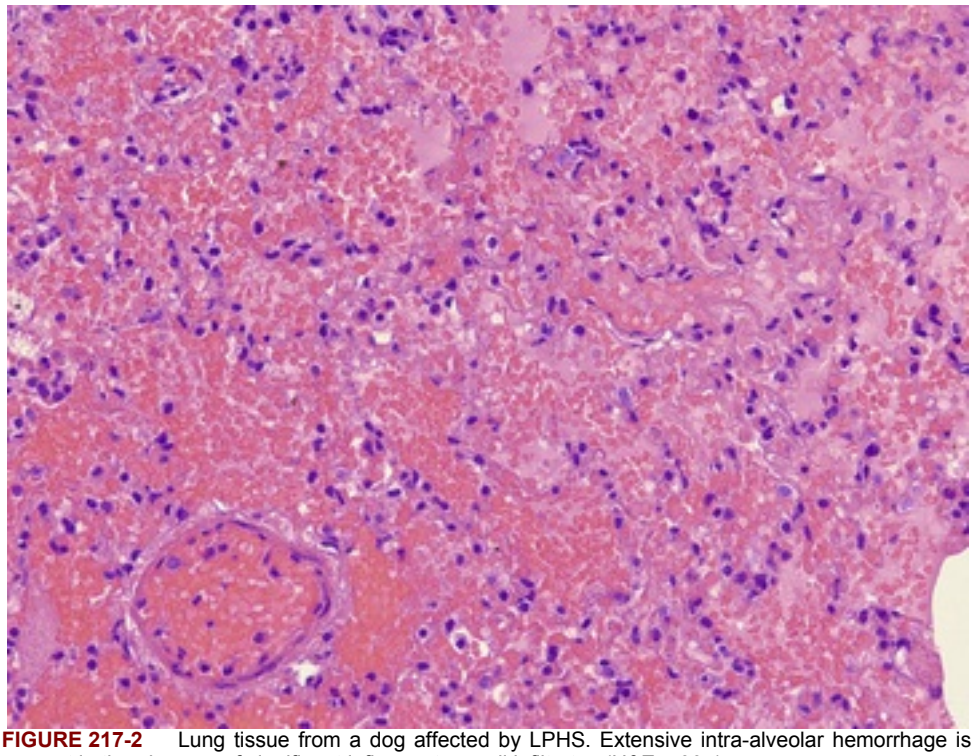

FIGURE 217-2 Lung tissue from a dog affected by LPHS. Extensive intra-alveolar hemorrhage is present in the absence of significant inflammatory cell infiltrates (H&E, 400×).

Diagnosis

Clinical Findings

The clinical signs of leptospirosis are nonspecific and most commonly relate to acute renal and hepatic injury. The most common clinical signs reported in dogs are anorexia, vomiting, lethargy, abdominal pain, diarrhea, jaundice, dehydration, stiffness and musculoskeletal pain, fever or hypothermia, dyspnea and tachypnea, weakness, and weight loss.[16,26,33,36,41-48] Polyuria and polydipsia are common, while oliguria or anuria were present in approximately 30% of dogs with acute leptospirosis in a referral population.[16] In a recent study of a large cohort of dogs with acute leptospirosis, the predominant clinical syndromes were renal (99.6%), hepatic (26%), and pulmonary (76.7%). Signs consistent with disseminated intravascular coagulation (DIC) were present in 18.2% of dogs. This study reflects the recent emergence of LPHS as a common complication in acute canine leptospirosis. Isolated hepatic involvement was very uncommon in this cohort but has been described in 14% of dogs diagnosed with acute leptospirosis by others.[48]

Other clinical abnormalities can include ventricular tachyarrhythmias, abdominal pain due to intussusception,[49-51] ocular signs,[52-54] and skin calcifications.[55,56] In contrast to large animal species, dogs rarely appear to develop reproductive disorders associated with leptospiral infection.[57,58]

The role of chronic leptospiral infection as a cause of chronic kidney disease in both cats and dogs requires further studies. Progression of tubulointerstitial nephritis to tubular atrophy and renal fibrosis has been described in dogs infected with serovar Canicola and rats infected with serovar Icterohaemorrhagiae.[59,60] In a recent study, cats with kidney disease (acute and chronic) were more likely to have antibodies against *Leptospira* spp. and to shed pathogenic leptospires in their urine than were cats without kidney disease.[6]

Chronic hepatitis has been described in case reports in association with infection by serovar Grippotyphosa and serovar Australis.[61,62] Amplification of leptospiral DNA from liver biopsies of dogs with chronic hepatitis was, however, unrewarding.[63] Therefore, at present, it is not clear whether *Leptospira* spp. can be the causative agent of chronic hepatitis in dogs.

Hematology, Clinical Biochemistry, Urinalysis

Mild to moderate anemia is present in approximately half of dogs with leptospirosis. Causes of anemia can be

blood loss via the respiratory or gastrointestinal (GI) tract and anemia of inflammatory disease. Hemolysis due to the effect of leptospiral toxins on erythrocytic membranes appears to be less common in dogs compared to cattle.[64] Neutrophilic leukocytosis, with neutrophilia, left shift, lymphopenia, and monocytosis are often present. Mild to severe thrombocytopenia is common in dogs with leptospirosis and can be caused by platelet or endothelial activation, immune-mediated destruction, or splenic sequestration.[65,66]

Blood urea nitrogen and creatinine concentrations are increased in the majority of dogs at presentation or during the course of disease. Hepatic injury as evidenced by increases in the activity of serum alanine aminotransferase (ALT), aspartate aminotransferase, alkaline phosphatase (ALP), and hyperbilirubinemia occurs almost exclusively in conjunction with azotemia.[16] Increases in serum activity of ALP and total bilirubin are more frequent than are increases in serum ALT activity.

Electrolyte abnormalities, such as hypo- and hyperkalemia, hyper- and hypophosphatemia, hyponatremia, and hypochloremia, are common in canine leptospirosis and usually parallel the degree of renal and GI dysfunction. Hypokalemia can occur due to renal and/or GI losses, as well as potassium wasting due to the leptospiral-induced inhibition of Na^+-K^+-ATPase.[28] Hemostatic disorders in dogs with leptospirosis vary widely in severity and are multifactorial. Hypocoagulable conditions from DIC, failure of coagulation factor synthesis, thrombocytopenia, and thrombocytopathy compete with prothrombotic conditions associated with inflammation and renal disease (see ch. 197).[67] Urinalysis reveals isosthenuria in the majority of dogs with leptospirosis, but hyposthenuria also has been described.[26,37,41,44] Glucosuria, hematuria, pyuria, and granular casts can be present. Proteinuria is present in many affected dogs and can be due to glomerular and/or tubular dysfunction.[26,68] The width of leptospires is below the resolution of light microscopy and therefore, the organisms are not typically visible by routine urinary sediment examination.

Diagnostic Imaging

Radiographic and computed tomographic changes in dogs with LPHS have been described. Initially, pulmonary changes appear in the caudodorsal parts of the lung fields and range from a mild interstitial to severe reticulonodular pattern with focal alveolar infiltrates.[69] Mild mediastinal and/or pleural effusion can be present.[70]

The most common abdominal sonographic findings relate to the kidneys and include cortical hyperechogenicity, renomegaly, mild pyelectasia, a medullary band of hyperechogenicity, and mild perirenal fluid accumulation.[71] Other findings can include hepatomegaly, splenomegaly, ascites, enlargement and hypoechogenicity of the pancreas, thickening of the gastric and (rarely) intestinal walls, and mild lymphadenomegaly.[26,33,41,43,44]

Confirmatory Testing

Leptospirosis is a zoonotic disease. Therefore, confirmation of a clinical suspicion of leptospirosis in veterinary patients is important from a public health perspective. A positive culture of biological samples (blood, urine, tissue) is the definitive proof of infection, but culturing leptospires is difficult, requiring up to six months, and is not routinely performed by diagnostic laboratories. Darkfield microscopy to identify intact leptospires in urine (see Video 217-1) has poor sensitivity and specificity and needs to be performed on fresh urine. Testing for antileptospiral antibodies via the microscopic agglutination test (MAT) or ELISA and polymerase chain reaction (PCR) to detect leptospiral DNA currently are the most useful diagnostic tools available for practitioners.

Serologic Tests

Microscopic Agglutination Test (MAT)

Despite marked limitations, the MAT still is considered the gold standard test for confirmation of acute leptospirosis. The MAT is based on determining the ability of serial dilutions of patient serum to agglutinate live leptospiral serovars *in vitro.* MAT reactivity to a serovar suggests exposure to a serovar within the broader serogroup, but not necessarily to the serovar tested. The panel of serovars ideally should be based on antibody prevalence data in the relevant geographic location, as failure to include the infecting serogroup can lead to false-negative results. MAT results are strongly dependent on quality control in the laboratory, with considerable interlaboratory variability.[40] Therefore, practitioners are encouraged to submit diagnostic

samples to laboratories that adhere to a proficiency scheme.[72] The MAT has marked limitations with regards to sensitivity, specificity, and repeatability, especially if single titers are interpreted.[40,73] Infected dogs can be antibody negative in the acute phase of the disease, due to the normal delay in appearance of serum antibodies. On the other hand, noninfected dogs vaccinated with bi- or quadrivalent whole-cell antileptospiral vaccines can have postvaccinal titers of 1:6400 or higher to both vaccinal and nonvaccinal serovars.[74-76] While the majority of vaccinated dogs has been shown to become antibody-negative by week 15 postvaccination, vaccinal titers can persist for 12 months in a small percentage of dogs.[75] Reactivity of antileptospiral antibodies with multiple serogroups often prevents the determination of the infecting serogroup. Moreover, the serogroup with the highest MAT titer can vary over time, indicating that the MAT does not reliably predict the infecting serogroup in acutely infected animals.[40]

For a dog with consistent clinical signs vaccinated with a bivalent vaccine against Canicola and Icterohemorrhagiae, a single titer ≥ 1:800 for one or more serogroup(s) has in the past generally been considered suggestive of leptospirosis. However, the best way to confirm a recent infection using MAT is to test paired samples, collected one or two weeks apart, which greatly increases the sensitivity of the MAT.[40,48,73] Obtaining a sample for a follow-up titer at the time of discharge from the hospital can be a practical approach. A fourfold or greater rise in MAT is highly suggestive of leptospirosis (for example, a titer of 200 rises to 800, corresponding to the fact that the serum is positive for two more consecutive dilutions) or when an initially antibody-negative dog exhibits a convalescent titer ≥ 800 to one or multiple serovars. An algorithm summarizing the confirmatory diagnostics in dogs suspected to have leptospirosis is presented in Figure 217-3.

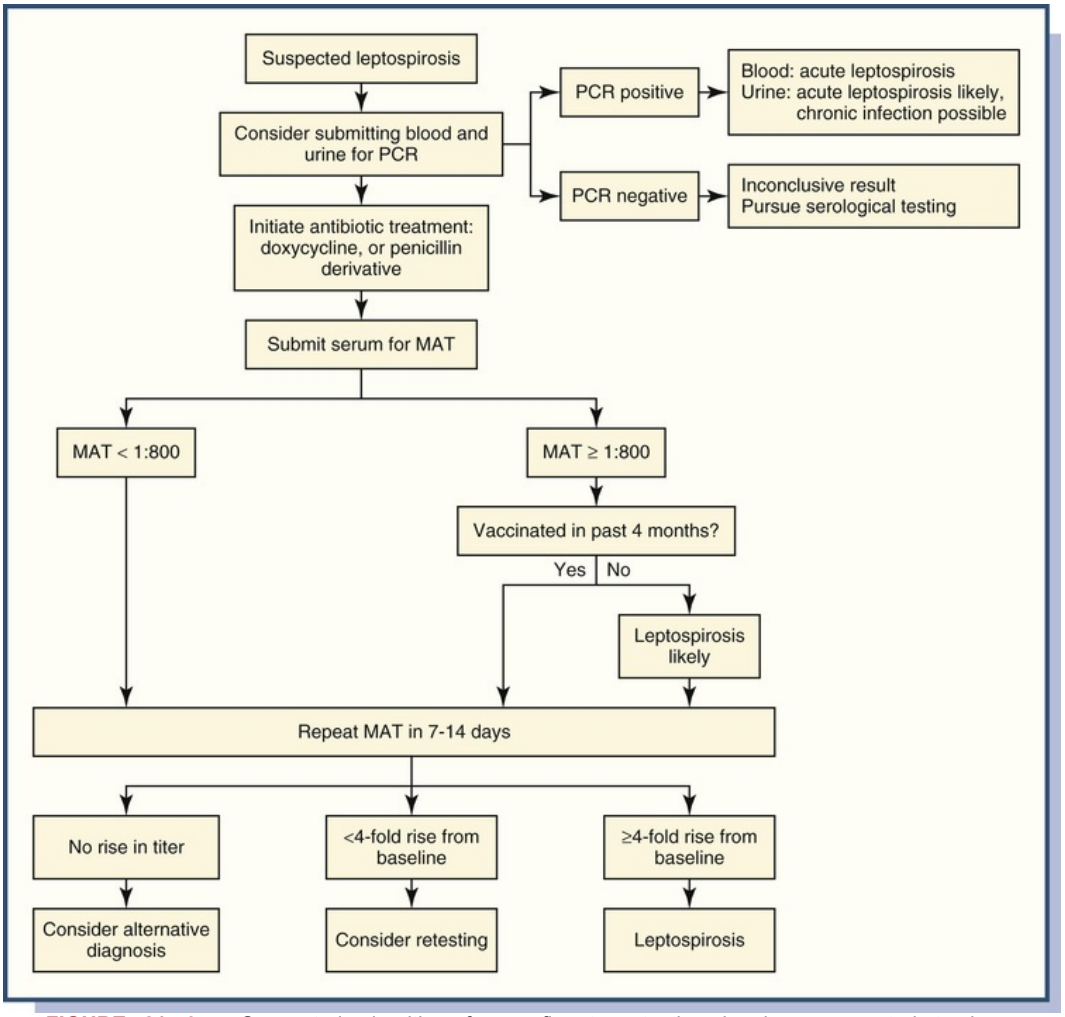

FIGURE 217-3 Suggested algorithm for confirmatory testing in dogs suspected to have leptospirosis. The interpretation of MAT titers can be particularly difficult in recently vaccinated dogs because in these dogs, vaccinal titers cannot be reliably distinguished from acute infection. In dogs

that have received early antibiotic treatment, a rise in titer can be blunted due to early eradication of the pathogen. *MAT*, Microscopic agglutination test; *PCR*, polymerase chain reaction.

Enzyme Linked Immunosorbent (ELISA) and Immunofluorescence Assays (IFA)

Detection of antileptospiral IgM and/or IgG via ELISA is gaining popularity, as more patient-side assays are becoming commercially available. These assays provide results within minutes but suffer from the same limitations as the MAT with regard to the possible absence of antibodies in early infection or their presence due to recent vaccination. Measurement of antileptospiral IgG and IgM via IFA can be helpful in differentiating vaccination from recent infection, but correct interpretation of these tests can be challenging. Retesting of initially antibody-negative animals within a few days is advised. Further studies assessing the diagnostic performance of these tests in well-characterized patient populations are needed. In the meantime, it is advised to use these tests in conjunction with paired MAT titers.

Polymerase Chain Reaction (PCR) Tests

PCR assays for detection of leptospiral DNA can be performed on blood, urine, or tissue specimens. In experimentally infected dogs, leptospiral DNA can be found in blood during the first week of infection and thereafter in urine.[77] Because the exact time of infection typically is unknown in naturally infected dogs, PCR testing of both blood and urine should be performed, ideally before antibiotic administration. The stability of leptospiral DNA in canine blood and urine has not been examined systematically. In the absence of well-established general recommendations, clinicians are encouraged to follow the guidelines of their specific laboratories with regards to sample collection, storage, and shipment conditions. Several PCR assays for diagnosis of canine leptospirosis have been described, targeting the *lipL32/hap1* gene, which is specific for pathogenic *Leptospira* spp.[5,77,78] or 23S rDNA.[79] These PCRs provide no information on the infecting serovar. Diagnostic performances of all PCR assays are not equivalent, and PCR assays validated for use in human clinical specimens, probably used by some veterinary diagnostic laboratories, might not perform similarly when applied to specimens from dogs.[80,81]

As long as there is a lack of data on sensitivity, specificity, and positive and negative predictive value of different PCR assays in dogs, MAT remains the preferred confirmatory test for leptospirosis. PCR can be used in conjunction with MAT in patients with high vaccinal titers because previous vaccination does not lead to positive results by PCR.[76]

Treatment

Effective treatment of canine leptospirosis consists of appropriate antimicrobial therapy and supportive care for the different organ systems involved. Leptospires are susceptible to a wide range of antibiotics *in vitro*, but the capacity of antibiotics to completely eradicate infection *in vivo*, in particular renal carriage, varies.[82] Penicillin and its derivatives have been shown to reduce leptospiremia but fail to reliably clear the organisms from the kidney.[8,83,84] Doxycycline has been shown to clear leptospires from blood and organs including kidneys in rodent models.[83] Therefore, currently it is recommended to treat dogs with leptospirosis with oral doxycycline (5 mg/kg PO q 12 h or 10 mg/kg PO q 24 h) for 14 days. Unfortunately, doxycycline often is not well tolerated in the early phase of treatment because GI signs are common in acute leptospirosis. In these cases, initial therapy with an intravenous penicillin derivative (e.g., penicillin G, ampicillin, amoxicillin) often is recommended until doxycycline can be used. Macrolide antibiotics such as azithromycin and third-generation cephalosporins have been assessed in animal models and have been proposed as alternative treatment in humans who cannot tolerate doxycycline treatment.[84-86]

Treatment of LPHS largely is supportive. Radiographic screening is recommended even in the absence of respiratory signs, in order to detect early lesions and implement precautionary measures (see ch. 242). These include avoidance of stress and overhydration/hypervolemia (see ch. 129) and control of systemic hypertension (see ch. 99 and 158). Depending on the severity of pulmonary hemorrhage, oxygen therapy and in severe cases, mechanical ventilation may be required (see ch. 131 and 139). Based on the hypothesis of an immune-mediated mechanism of LPHS, the efficacy of immunomodulatory treatments has been assessed. Results of small and often not well-controlled clinical trials in humans suggest that immunosuppressive treatment with methylprednisolone,[87] dexamethasone alone or in combination with desmopressin,[88] or plasmapheresis,[89] can improve survival in patients with LPHS. Further studies have to be performed in order to determine whether immunosuppression is an effective treatment for LPHS in dogs.

After initial stabilization (see ch. 322 and 110), renal recovery can continue for several months. A follow-up study of dogs with leptospirosis indicated that ≈50% of dogs surviving the acute phase of the disease displayed impairment of renal function more than one year after hospital discharge.[90] Long-term monitoring of renal function therefore is strongly recommended in these dogs.

Concurrent infection of other dogs that reside in the same household can occur, probably following infection from the same environmental source. Treatment of dogs living with dogs diagnosed with leptospirosis with doxycycline for 2 weeks therefore is currently recommended.

Leptospirosis in Cats

Cats can become infected with leptospires and can shed leptospires in their urine, but clinical signs of acute disease are rarely described.[6,91-97] In experimentally and naturally infected cats, interstitial nephritis is the most consistent histopathologic finding,[92,95,98,99] and in one study, cats with kidney disease (acute and chronic) were more likely to have serum antibodies against *Leptospira* spp. and to shed pathogenic leptospires in their urine.[6] Therefore, the role of healthy cats as reservoir hosts, as well as the role of leptospirosis as a clinical disease in cats, deserves further study and might have been underestimated in the past.

Prevention of Leptospirosis

Vaccination

Prior to 1960, serovars Icterohaemorrhagiae and Canicola were thought to be responsible for most cases of canine leptospirosis. Since the introduction of a bivalent vaccine against serogroups Icterohaemorrhagiae and Canicola, infection with serovars that belong to these serogroups likely have become rare based on MAT antibody testing, and acute infections in dogs vaccinated with bivalent vaccines now are commonly caused by other serogroups, such as Grippotyphosa and Australis.[9,100] Quadrivalent vaccines that contain serogroups Canicola, Icterohaemorrhagiae, Grippotyphosa, and Pomona have been available in the USA since 2001. Recently, new vaccines containing serovars belonging to three (Icterohemorrhagiae, Canicola, and Grippotyphosa) or four (Icterohemorrhagiae, Canicola, Grippotyphosa, and Bratislava) serogroups have been developed in Europe in an effort to increase the spectrum of protection.[101] However, more data are required to determine whether addition of these serovars will protect more dogs from leptospirosis than the available bivalent vaccines, as limited data suggest in the USA.[100]

Public Health Considerations

Leptospirosis is a zoonotic disease, and humans are at increased risk of infection if they perform activities that involve animal contact, such as hunting, abattoir work, dairy farming, and veterinary practice.[32] Recreational activities, such as swimming, canoeing, fishing, potholing, and caving, also are associated with a significant risk of exposure due to intense contact with water or soil.[102,103] Dog-to-human transmission of leptospirosis has been suggested by several authors.[104-106] However, seropositivity to *Leptospira* spp. was uncommon in pet owners exposed to dogs with confirmed acute leptospirosis and staff in a veterinary referral hospital with a very high leptospirosis caseload.[107] Appropriate precautions should be taken when handling dogs suspected to have leptospirosis. Owners should be informed that their dog likely contracted leptospirosis through direct or indirect contact with wild or farm animals, which could represent an ongoing risk for humans and animals. Owners should be instructed to wash hands after handling their pet and to wear gloves when cleaning up urine spills until the course of antimicrobial drug therapy is completed. Routine household disinfectants should be used for cleaning urine spills, and dogs should be taken outside to urinate in places that are not intensely frequented by humans and other animals.

CHAPTER 218

Ehrlichiosis, Anaplasmosis, Rocky Mountain Spotted Fever, and Neorickettsiosis

Jane E. Sykes

Client Information Sheet: Ehrlichiosis, Anaplasmosis, Rocky Mountain Spotted Fever, and Salmon Poisoning Disease

General Considerations

The primary causes of canine ehrlichiosis are the intracellular Gram-negative bacteria *Ehrlichia canis, Ehrlichia ewingii,* and *Ehrlichia chaffeensis,* belonging to the family Anaplasmataceae. Other bacteria within this family are *Anaplasma platys* and *Anaplasma phagocytophilum,* which cause canine thrombocytic and granulocytic anaplasmosis, respectively, and *Neorickettsia helminthoeca,* the agent of salmon poisoning disease (SPD). *Rickettsia rickettsii,* the cause of Rocky Mountain spotted fever (RMSF), and other spotted fever group (SFG) rickettsiae belong to the family Rickettsiaceae. The families Rickettsiaceae and Anaplasmataceae are related through the order Rickettsiales (Table 218-1).

TABLE 218-1

Members of the Order Rickettsiales That Are Established Pathogens in Dogs and Cats

FAMILY	GENUS	SPECIES
Anaplasmataceae	*Ehrlichia*	*E. canis* *E. chaffeensis* *E. ewingii*
	Anaplasma	*A. phagocytophilum* *A. platys*
	Neorickettsia	*N. helminthoeca*
Rickettsiaceae	*Rickettsia*	*R. rickettsii*

These organisms are transmitted to dogs and cats by arthropod or trematode vectors (Table 218-2). They are maintained in nature through infection of wild animal reservoir hosts and can also be transmitted by blood transfusion. Their geographic distribution is restricted to that of their vectors and intermediate hosts. Several of these pathogens cause human disease. Dogs, therefore, serve as potential sentinels for human infection and precautions should be taken to prevent transmission while handling engorged ticks, blood, and tissue from dogs with suspected infections. Because of shared arthropod vectors and/or concurrent exposure to multiple vector ticks, coinfections with more than one of these pathogens (as well as other vector-borne pathogens) can occur and may complicate the clinical picture. Severity of clinical signs depends on the size of the inoculum, host immunity, and pathogen strain virulence.

TABLE 218-2

Important Ticks Involved in Transmission of Members of the Order Rickettsiales

TICK SPECIES	COMMON NAME	VECTORED AGENTS	GEOGRAPHIC DISTRIBUTION
Rhipicephalus sanguineus	Brown dog tick	*Ehrlichia canis* *Anaplasma platys?* *Rickettsia rickettsii*	Worldwide, primarily between latitudes 35 degrees south and 50 degrees north
Amblyomma americanum	Lone star tick	*Ehrlichia chaffeensis* *Ehrlichia ewingii*	West-central Texas, north to Iowa, and eastward in a broad belt spanning the southeastern United States; Atlantic coast up to Maine
Ixodes scapularis	Black-legged tick, deer tick	*Anaplasma phagocytophilum*	Northeastern, north central, and southeastern United States
Ixodes pacificus	Western black-legged tick	*Anaplasma phagocytophilum*	West coast of the United States
Ixodes persulcatus	Taiga tick	*Anaplasma phagocytophilum*	Eastern Europe and Asia
Ixodes ricinus	Castor bean tick	*Anaplasma phagocytophilum*	Europe, including the United Kingdom
Dermacentor variabilis	American dog tick	*Rickettsia rickettsii*	East of the Rocky Mountain states as far north as Massachusetts and Nova Scotia, west coast of the United States to southwestern Oregon
Dermacentor andersoni	Rocky Mountain wood tick	*Rickettsia rickettsii*	Rocky Mountain states of the United States, primarily Montana, Idaho, and Oregon

The Ehrlichioses

Ehrlichia canis

Etiology and Epidemiology

Ehrlichia canis causes canine monocytic ehrlichiosis (CME), an important disease of dogs exposed to ticks worldwide. The organism infects circulating monocytes and forms morulae (Latin for "mulberry"), a cluster of bacteria, within the monocyte cytoplasm. *E. canis* is transmitted by *Rhipicephalus sanguineus* ticks. Infection has been reported in dogs from Asia, Africa, Europe, and the Americas. In the United States, disease is diagnosed most frequently in dogs living in the southeastern and southwestern states, but because of chronic, subclinical infection, dogs can be incidentally transported to nonendemic regions before developing the condition. Ticks acquire infection by feeding as larvae or nymphs on infected dogs. Jackals, foxes, and possibly coyotes may also act as reservoir hosts. The organism is transmitted transstadially but not transovarially within the tick.[1] No age, breed, or sex predilection for CME has been clearly documented. Cross-bred dogs may be less likely to develop disease.[2]

Pathogenesis and Clinical Signs

The course of CME has been divided into acute and chronic phases, although these phases are not always clinically distinguishable. Transmission can occur within hours of tick attachment and acute signs of disease occur 8 to 20 days after infection.[3] Common vague signs include lethargy, inappetence, fever, and weight loss. Replication of the organism in reticuloendothelial tissues is associated with generalized lymphadenopathy and splenomegaly. Ocular and nasal discharge, peripheral edema, and less commonly, petechial and ecchymotic hemorrhages may occur. Neurologic signs include twitching, ataxia, seizures, vestibular signs, hyperesthesia, and cranial nerve deficits. These signs are likely caused by meningeal inflammation or hemorrhage. Thrombocytopenia and sometimes mild leukopenia and anemia occur 1 to 4 weeks after infection. Transient proteinuria has also been reported, which resolves within 6 weeks of infection.[4,5] Dogs may recover from the acute phase after 2 to 4 weeks without treatment.

After the acute phase, some dogs remain subclinically infected for months to years. They may have mild persistent thrombocytopenia. Organisms may sequester within the spleen and evade host immune systems through antigenic variation.[6] This phase may persist for months to years.

Chronic ehrlichiosis ranges in severity from mild to life-threatening, with signs that include lethargy,

inappetence, bleeding tendencies, pallor, fever, weight loss, lymphadenopathy, splenomegaly, anterior uveitis, retinal hemorrhage, retinal detachment, polyuria/polydipsia, and edema[7-10] (Figure 218-1). Bleeding tendencies result from thrombocytopenia and platelet dysfunction.[11] Cutaneous and mucosal petechial or ecchymotic hemorrhages, epistaxis, melena, hematochezia, hematuria, and prolonged bleeding from venipuncture sites have been reported (see ch. 197).[9] Polymyositis may develop, with muscle atrophy and tetraparesis (see ch. 354).[12] Secondary opportunistic infections such as viral papillomatosis, protozoal infections, and bacteriuria have also been described, although the precise underlying mechanism of immune suppression and how it relates to persistence of *E. canis*, has not yet been elucidated (Figure 218-2).[13,14]

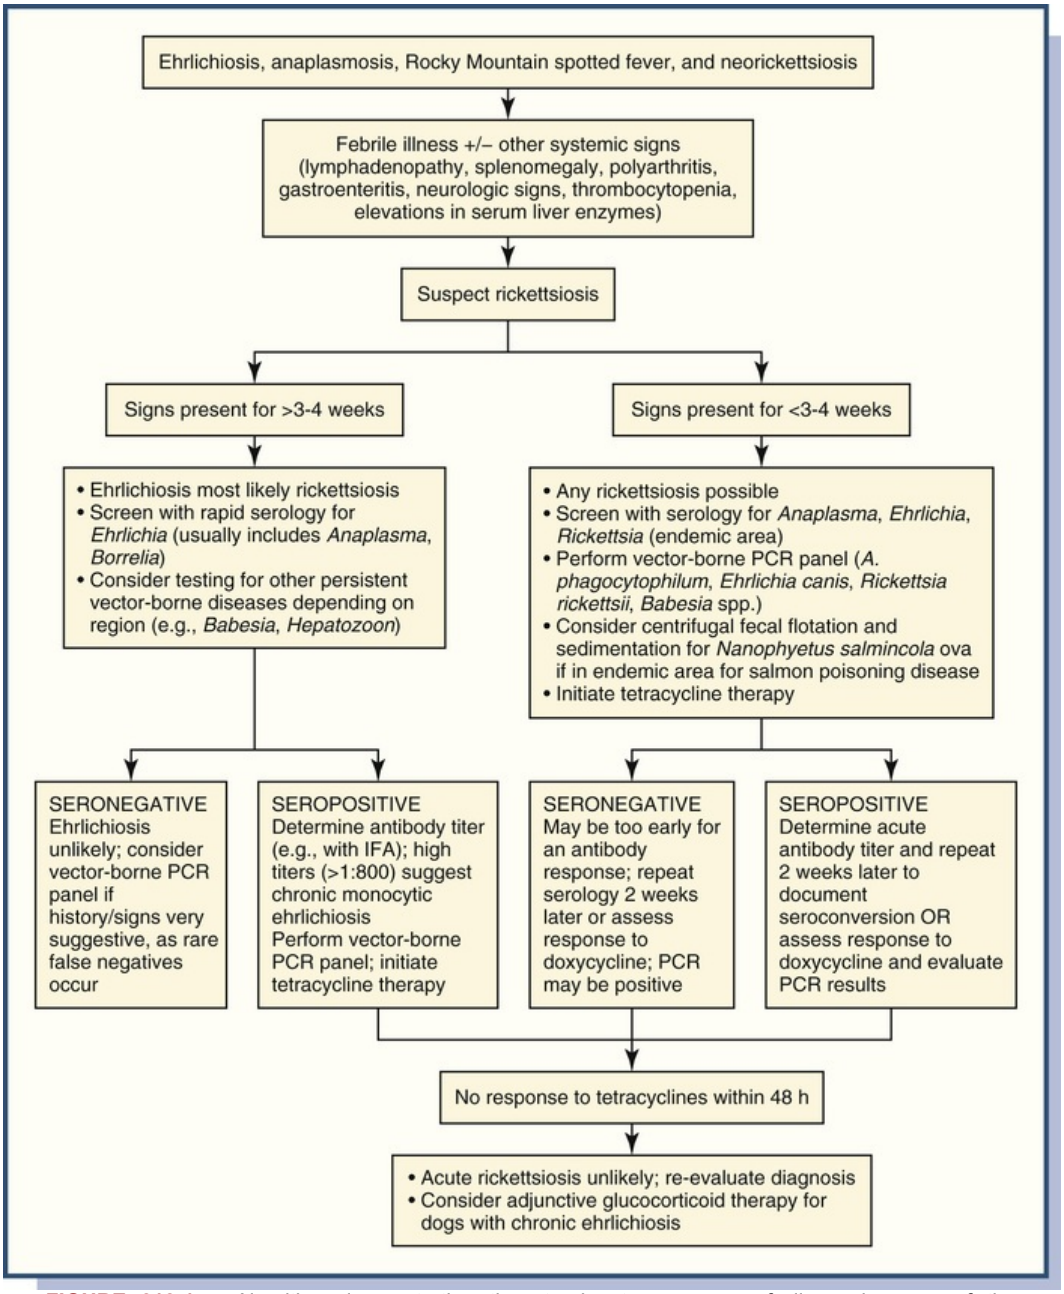

FIGURE 218-1 Algorithm demonstrating the step-by-step process of diagnosing one of the rickettsial diseases in dogs. *IFA*, Indirect fluorescent antibody test; *PCR*, polymerase chain reaction test.

FIGURE 218-2 Secondary viral papillomatosis in a dog naturally infected with *Ehrlichia canis*. (Image courtesy University of California, Davis, Internal Medicine Service.)

Pancytopenia on results of a complete blood count (CBC) typifies the severe chronic form of ehrlichiosis (see ch. 58 and 202). It is caused by hypoplasia of all bone marrow cells.[9] Thrombocytopenia and nonregenerative anemia are common. Moderate to marked granular lymphocytosis (up to 17,000/mcL) and bone marrow plasmacytosis may occur. Some dogs have a monoclonal gammopathy, similar to that seen with some lymphocytic leukemias or multiple myelomas (see ch. 60). Dogs with well-differentiated lymphocytosis or an otherwise unexplained monoclonal gammopathy should be tested for *E. canis* infection.[15] Serum chemistry abnormalities in chronic ehrlichiosis include hypoalbuminemia, hyperglobulinemia, and elevated alanine aminotransferase (ALT) and alkaline phosphatase (ALP) activities. The hyperglobulinemia is usually due to a polyclonal gammopathy.[7] A protein-losing nephropathy may develop as a result of an immune-complex glomerulonephritis, which can be associated with azotemia (see ch. 325). Dogs with central nervous system (CNS) involvement may have increased cerebrospinal fluid (CSF) protein concentrations and cell counts.[16]

Diagnosis

Detection of morulae within monocytes using cytologic evaluation is diagnostic for monocytic ehrlichiosis but is insensitive. It is important to note that the morulae of *E. canis* and *E. chaffeensis* cannot be discriminated. In one study, morulae were found in 2 of 19 dogs with chronic monocytic ehrlichiosis.[9] Diagnosis of ehrlichiosis is usually confirmed with serology, using indirect fluorescent antibody (IFA) or enzyme-linked immunosorbent assay (ELISA). Antibodies can be detected between 7 and 28 days after initial infection. Therefore, dogs with acute ehrlichiosis may have negative test results if antibody production has not yet occurred. Retesting should be performed after 2 to 3 weeks to demonstrate seroconversion. A positive serum antibody titer for *E. canis* may occur with previous exposure and does not equate with diagnosis. Serology results must be interpreted in the context of the clinical signs and results of testing for other conditions. Dogs with chronic *E. canis* infection typically have extremely high IFA titers, sometimes >1 : 600,000. Antibodies may persist despite treatment, suggesting persistence of the organism.[9] These test results do not correlate with severity of hyperglobulinemia or disease. Serologic cross-reactivity to other *Ehrlichia* species occurs, including *E. ewingii* and particularly *E. chaffeensis*. Cross-reactivity to *Anaplasma phagocytophilum* antigens can occur but is minor.[15]

A variety of ELISA assays detect antibodies to *E. canis*.[17-19] A point-of-care lateral flow ELISA device

detects canine heartworm antigen, antibodies to *E. canis* or *E. ewingii,* antibodies to *Borrelia burgdorferi,* and antibodies to *A. phagocytophilum* in canine serum, plasma, or whole blood (SNAP 4Dx Plus, IDEXX Laboratories, Westbrook, ME.). This test includes recombinant surface proteins of *E. canis* and *E. ewingii.* The antigens of *E. canis* and *E. ewingii* are combined together in a single spot, so a positive result reflects either seroreactivity to *E. canis, E. ewingii,* or both pathogens. The sensitivity of this assay for detection of antibodies to *E. canis* when compared with IFA was 131/134 (97.8%) and specificity was 217/235 (92.3%).[20] Other point-of-care ELISA assays detect *E. canis* antibodies. In addition, a diagnostic laboratory-based ELISA assay detects antibodies to *E. canis, B. burgdorferi, A. phagocytophilum* and *D. immitis* (Accuplex 4, Antech Laboratories). It is recommended that dogs incidentally identified to have *E. canis* seroreactivity when screened using ELISA assays that simultaneously detect heartworm antigen should undergo a thorough physical examination and have a complete blood count, chemistry panel, and urinalysis to evaluate for thrombocytopenia, hyperglobulinemia, and proteinuria. Treatment of seroreactive clinically healthy dogs is controversial, since it does not change their outcome and has the potential to lead to antimicrobial resistance or adverse effects of drug therapy (see ch. 169).

PCR is widely available for routine diagnosis of *E. canis* infection as part of "vector-borne pathogen" panels offered by veterinary diagnostic laboratories. Assay results must be interpreted in the context of the history, clinical signs, and serologic assay results. *E. canis* DNA can be detected using PCR on blood, lymph node aspirates, splenic aspirates, or bone marrow. However, sensitivity of PCR from bone marrow for diagnosis of chronic ehrlichiosis can be as low as 25%.[9] Thus, PCR alone is not suitable for screening potential blood donors for infection but may be useful for confirming infection in the first week of illness, when serologic assays are often negative.

Treatment

The recommended treatment for CME is doxycycline (10 mg/kg PO q 24 h) for 28 days.[15] Shorter periods of treatment (e.g., 16 days) may be effective for dogs with acute CME.[21] Most dogs show clinical improvement within 24 to 48 hours, but those with severe chronic disease may not respond to therapy or their "cytopenias" may gradually resolve over several months. Platelet counts generally improve and normalize within 2 weeks of initiating therapy. Following therapy, titers may decline and become negative over 6 to 9 months, while some retain high titers for years. Treatment for such dogs should be based on resolution of platelet counts and decreases in hyperglobulinemia. Hyperglobulinemia may take months to resolve after treatment is discontinued. Platelet counts should be reassessed 1 and 3 months after discontinuation of therapy because of the potential for relapse or reinfection. Other causes of illness should be considered in dogs that fail to respond to treatment.

Alternative drugs, used with variable success, include chloramphenicol, imidocarb dipropionate, and enrofloxacin.[15,22-25] Members of the *E. canis* genogroup appear to have intrinsic gyrase-mediated resistance to fluoroquinolones.[26] While enrofloxacin therapy may lead to clinical improvement, its use is not recommended. The efficacy of imidocarb diproprionate has been controversial.[22-24]

For dogs that are dehydrated or anemic, intravenous fluids (see ch. 129) or blood products (see ch. 130) may also be required. Use of darbepoetin or granulocyte colony-stimulating factor could be considered for dogs with severe chronic ehrlichiosis.[27] If thrombocytopenia fails to respond to doxycycline administration, adding a short course (up to a week) of immunosuppressive doses of glucocorticoids may be beneficial.

Prevention and Public Health Significance

Prevention of canine monocytic ehrlichiosis relies on tick control combined with careful searching for and prompt removal of attached ticks (see ch. 211). DNA of an *E. canis*-like organism has been detected in people with clinical signs of monocytic ehrlichiosis.[28] Appropriate precautions are indicated when handling engorged ticks, blood, or tissue specimens from infected dogs.

Ehrlichia ewingii

Ehrlichia ewingii has caused granulocytic ehrlichiosis in people and dogs in North America and, possibly, dogs from Brazil and Cameroon.[29-31] Infection has been primarily identified in south-central and southeastern areas of the United States, where exposure is widespread and *E. ewingii* is the predominant cause of canine ehrlichiosis.[32] Like *E. chaffeensis, E. ewingii* is transmitted primarily by *Amblyomma americanum* ticks from the reservoir white-tailed deer, whose expanding population has likely contributed to the emergence of these

pathogens.[33] Like *Anaplasma phagocytophilum, E. ewingii* infects and forms morulae within granulocytes. Infection causes fever, headache, and cytopenias in people and dogs may be subclinically affected or may exhibit lethargy, anorexia, vomiting, diarrhea or neurologic signs.[34] Dogs may have fever and a neutrophilic polyarthritis (see ch. 203). Persistent *E. ewingii* infection lasting more than a year has been reported in laboratory-infected dogs without clinical signs of illness. This may support dogs acting as a reservoir.[35-37] Laboratory testing may reveal anemia, mild leukopenia or leukocytosis, thrombocytopenia, hyperglobulinemia and elevated activities of serum ALP.[34,35,37-39]

E. ewingii has yet to be cultivated. Antibodies to *E. ewingii* can be detected using a point-of-care lateral flow ELISA device (SNAP 4Dx Plus, IDEXX Laboratories, Westbrook, ME.). This assay's sensitivity for detection of *E. ewingii* antibodies, as compared with a plate ELISA, was 109/113 (96.5%) and its specificity was 154/164 (93.9%).[20] Granulocytic morulae are commonly detected in blood smears and synovial fluid from affected dogs. *E. ewingii*–specific PCR assays have been developed, providing the only method for confirming infection. Treatment with doxycycline for 2 to 4 weeks results in rapid clinical improvement and may be sufficient to eliminate infection.

Other *Ehrlichia* Species

Ehrlichia chaffeensis causes human monocytic ehrlichiosis in North America, a disease that is characterized by fever, headache, myalgia, thrombocytopenia, leukopenia, and increases in liver enzyme activities[40] (see Figure 218-1). In the United States, human monocytic ehrlichiosis occurs primarily in the south-central, southeastern and mid-Atlantic states, coinciding with the distribution of *Amblyomma americanum* and the reservoir, white-tailed deer. Experimental infection of dogs with *E. chaffeensis* results in prolonged fever, mild anemia, leukopenia, and thrombocytopenia, or the infection is subclinical.[41,42] Naturally infected dogs have developed lymphadenopathy and epistaxis.[43] Dogs maintain high antibody titers and are PCR-positive for months after infection, supporting their role as a reservoir.[42] As for *E. canis* infection, diagnosis of *E. chaffeensis* infection may be made using acute and convalescent serology or PCR. Serologic cross-reactivity has the potential to occur with other *Ehrlichia* species. Although clinical improvement occurs following doxycycline therapy, doxycycline may not completely eliminate infection.[43] Treatment for a minimum of 28 days is suggested.

Other *Ehrlichia* species detected include an *Ehrlichia muris*–like organism in dogs from the upper Midwest[44] and an *Ehrlichia ruminantium*–like organism in dogs from South Africa.[45] The significance of these infections is unknown.

Anaplasmosis

Anaplasma phagocytophilum

Etiology and Epidemiology

Anaplasma phagocytophilum causes canine granulocytic ehrlichiosis. The organism infects a variety of domestic and wildlife host species and is an important emerging pathogen in people worldwide. Clinical infections have been documented in dogs, horses, cats, and people. In Europe, infections have also been documented in domestic ruminant species (sheep, cattle, goat). Different strains of *A. phagocytophilum* exist worldwide and differ in their host tropism and virulence.[46] *A. phagocytophilum* forms morulae in neutrophils more frequently than in eosinophils (Figure 218-3). *A. phagocytophilum* is spread by several Ixodid tick species, is transmitted only transstadially within ticks (see Table 218-2), and ticks must be attached for 24 to 48 hours for transmission to occur. *Ixodes scapularis* is the vector in the upper midwestern and northeastern United States and southeastern Canada. *Ixodes pacificus* is a vector on the west coast of North America, from California to British Columbia. In Europe, including the United Kingdom, the vector is *I. ricinus.* Ticks (commonly *I. persulcatus*) with *A. phagocytophilum* have been detected in Asia and Russia.[47] Ticks with molecular evidence of *A. phagocytophilum* have been noted in the Middle East, South Africa, and South America.[48-50] Small mammals, including mice, woodrats, chipmunks, voles, shrew, and deer, serve as reservoir hosts for *A. phagocytophilum.* Because *Borrelia burgdorferi* is transmitted by the same Ixodid ticks, coinfections with *B. burgdorferi* and *A. phagocytophilum* are frequently detected and, together, pathogenicity is enhanced (see ch. 211).[51] In the upper midwest and northeastern United States, infection is most common from spring to early summer and in the fall. Labrador and Golden Retrievers account for half of reported cases, possibly reflecting

their popularity for outdoor activities.[52] The median age of infected dogs was 8 years, although dogs of any age are at risk.[52,53]

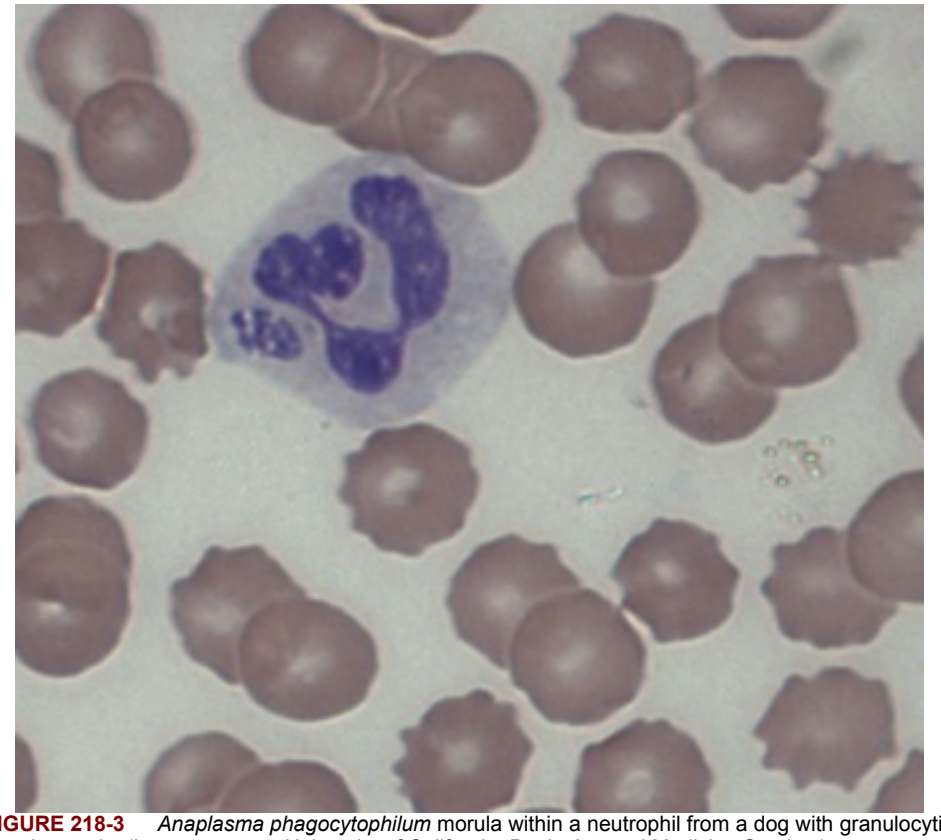

FIGURE 218-3 *Anaplasma phagocytophilum* morula within a neutrophil from a dog with granulocytic anaplasmosis. (Image courtesy University of California, Davis, Internal Medicine Service.)

Clinical Signs

In many dogs, infection is subclinical. Common signs, when seen, occur after an incubation period of 1 to 2 weeks and are nonspecific: fever, lethargy, inappetence, scleral injection, lameness, stiffness and reluctance to move. Infrequent soft and nonproductive coughing may be noted.[54,55] Mild lymphadenomegaly, splenomegaly (see ch. 206), and neutrophilic polyarthritis (see ch. 203) may occur.[53,55] Less common signs include polydipsia, vomiting, diarrhea, CNS signs (abnormal placing reactions), and cervical pain.[52-55] Infection appears to be self-limiting in dogs, since chronic disease (>30 days) has not been described. Thrombocytopenia is documented in >80% of infected dogs. Less common abnormalities include lymphopenia, eosinopenia, or mild nonregenerative anemia.[52,54,55] Serum chemistries may reveal hypoalbuminemia and mild to moderately increased activities of serum ALT and ALP.

Diagnosis and Treatment

The finding of morulae within neutrophils in an endemic area is highly suggestive of infection with *A. phagocytophilum,* although the morulae cannot be distinguished from those of *E. ewingii* (see Figure 218-1). Morulae, when present, are found in 7% to 37% of circulating neutrophils.[52,53] Diagnosis can also be accomplished using acute and convalescent phase serology using IFA or ELISA assays. A point-of-care lateral flow ELISA device (SNAP 4Dx Plus, IDEXX Laboratories, Westbrook, ME.) can also be used to detect antibodies to *A. phagocytophilum,* with a reported sensitivity of 93% and specificity of 99% when compared with IFA.[39] However, many acutely ill dogs with granulocytic anaplasmosis have negative serologic test results because they have not had sufficient time for an antibody response when first brought to a veterinarian. Further, positive titers may reflect previous subclinical exposure (within 8 to 10 months) so demonstration of a fourfold rise in titer is required.[56] With all current serologic assays, serologic cross-

reactivity with other *Anaplasma* species, especially *A. platys* and possibly other *Ehrlichia* species, can occur.[15,43] PCR on whole blood (usually as part of a panel designed to simultaneously test for multiple vector-borne pathogens) can be used to identify infection in acutely ill dogs and allows *A. phagocytophilum* to be distinguished from *E. ewingii* when morulae are seen in granulocytes. Treatment of choice for granulocytic anaplasmosis is a 2-week course of doxycycline (5 mg/kg PO q 12 h). Most dogs show rapid improvement, with signs abating within 12 to 48 hours. Prevention relies on tick control.

Public Health Significance

Anaplasma phagocytophilum causes human granulocytic anaplasmosis, a febrile disease that resembles the disease in dogs. Death is rare but has occurred as a result of complications due to secondary infections. Dogs are an important sentinel for human infection. Dogs may be a source of infection by bringing infected ticks into contact with humans. Precautions should be taken when handling blood or tissue from infected dogs, or during tick removal.

Anaplasma platys

A. platys, the cause of canine thrombocytic anaplasmosis, is yet to be cultured. *Rhipicephalus sanguineus* is the likely vector, although attempts to transmit infection using this tick were unsuccessful.[57] The organism has been reported in South America, Australia, Asia, Africa, Europe, and North America.[58-63] After an incubation period of 1 to 2 weeks, thrombocytopenia occurs and then normalizes within days. Morulae within platelets may be seen in blood smears shortly after infection and in megakaryocytes within bone marrow specimens.[64] The majority of infections reported in the United States have been mild or subclinical. Cases reported from Europe and South America have had more severe clinical manifestations, including fever, splenomegaly, and hemorrhage. However, coinfection with other tick-borne pathogens may have contributed to clinical signs. Diagnosis is based on visualization of morulae within platelets together with acute and convalescent phase serology. Because of cross-reactions with *A. phagocytophilum,* serology is not specific for *A. platys. A. platys*–specific PCR assays have been developed.[65] Treatment of canine thrombocytic anaplasmosis is as for granulocytic anaplasmosis. Recently, persistent human infection with *A. platys* has been documented.[66,67] The extent to which *A. platys* can cause disease in humans is unknown.

Neorickettsioses

Neorickettsia helminthoeca

Etiology and Epidemiology

Neorickettsia helminthoeca causes salmon poisoning disease (SPD), a condition diagnosed from the western slopes of the Cascade Mountains of northern California to southern Vancouver Island, Canada.[68] Disease may occur elsewhere following transportation of infected fish for feeding or in dogs that travel to and from a nonendemic area to a site containing infected fish. Recently, a similar disease was described in Brazilian dogs.[69]

The vector of SPD is *Nanophyetus salmincola,* a fluke that harbors the organism throughout its life cycle. Fluke eggs transform into miracidia, which infect small snails, *Oxytrema silicula,* that live in both fresh and brackish stream water. Cercariae leave the snail and penetrate a fish, most commonly a salmonid fish, although certain nonsalmonid fish have also been reported to be infected.[70,71] Hatchery-reared fish may also be infected. The cercariae transform into metacercariae, usually within the kidneys but also in the muscle and other tissues. Fish may retain the infection for several years.[71,72] Dogs become infected with the rickettsia after ingesting parasitized fish. Following ingestion, the metacercariae transform into adult flukes. Labrador Retrievers and intact male dogs are overrepresented, but dogs of either gender and of any age or breed may be affected.[73] Foxes and coyotes may also become infected, and SPD has also been reported in captive bears.[74] Domestic cats are not susceptible to SPD, but the flukes mature to adults within feline intestinal tracts. SPD may also be acquired after ingesting adult flukes (which could potentially occur following coprophagy), infected snails, and fluke eggs.[75]

Clinical Signs

After the fluke matures and attaches to the intestinal tract, *N. helminthoeca* infects and replicates within cells of

the mononuclear-phagocyte system. Rapid dissemination of the organism to the lymph nodes, spleen, liver, lungs, and brain occurs. After an incubation period ranging from 5 to 33 days, the earliest clinical observations include anorexia and fever as high as 42° C (107.6° F). Later signs include lethargy, weight loss, mild to severe lymphadenomegaly, vomiting, and diarrhea, sometimes containing blood.[71,73,76] Rarely, a history of vomiting or diarrhea is absent. The presence of adult flukes may contribute to the gastrointestinal signs. Dogs lacking peripheral lymphadenomegaly have abdominal lymphadenomegaly on ultrasound examination. Associated laboratory abnormalities include neutrophilia, sometimes a mild to moderate left shift, lymphopenia, and monocytosis. Thrombocytopenia occurs in approximately 90% of affected dogs and may be as low as 16,000/mcL. Serum chemistry abnormalities include hyponatremia, hypokalemia, increased liver enzyme activities, and hypoalbuminemia, which can be profound and sometimes accompanied by hypocholesterolemia and hypoglobulinemia.[71,73,76]

Diagnosis

Diagnosis of SPD may be inferred by finding characteristic trematode eggs in the feces using fecal sedimentation or sugar flotation (see Figure 218-1). Eggs appear 5 to 8 days after infected fish ingestion. A combination of fecal sedimentation and centrifugal flotation increases the sensitivity for detection of fluke ova. In one study, 93% of dogs with SPD tested positive for *N. salmincola* ova using a combination of fecal flotation and fecal sedimentation.[73] The finding of fluke ova on fecal examination may not be diagnostic of SPD, as dogs may be infected with trematodes that do not harbor the rickettsia, and ova may be shed for months after recovery. Nevertheless, *N. salmincola* ova were detected in only 0.2% of over 1800 fecal flotations in dogs seen at a teaching hospital in an endemic area, and all positive test results were in dogs suspected to have SPD. Thus, specificity of fecal flotation is high.[73] Neorickettsiae may also be visible using cytologic examination of lymph node aspirates (Figure 218-4), together with moderate to marked histiocytic inflammation and lymphocytic-plasmacytic reactivity.[77] Organisms may appear as granular to amorphous material filling infected cells, best visualized using Giemsa stain.[77] The use of PCR-based assays on lymphoid tissue to identify infection has been reported.[73]

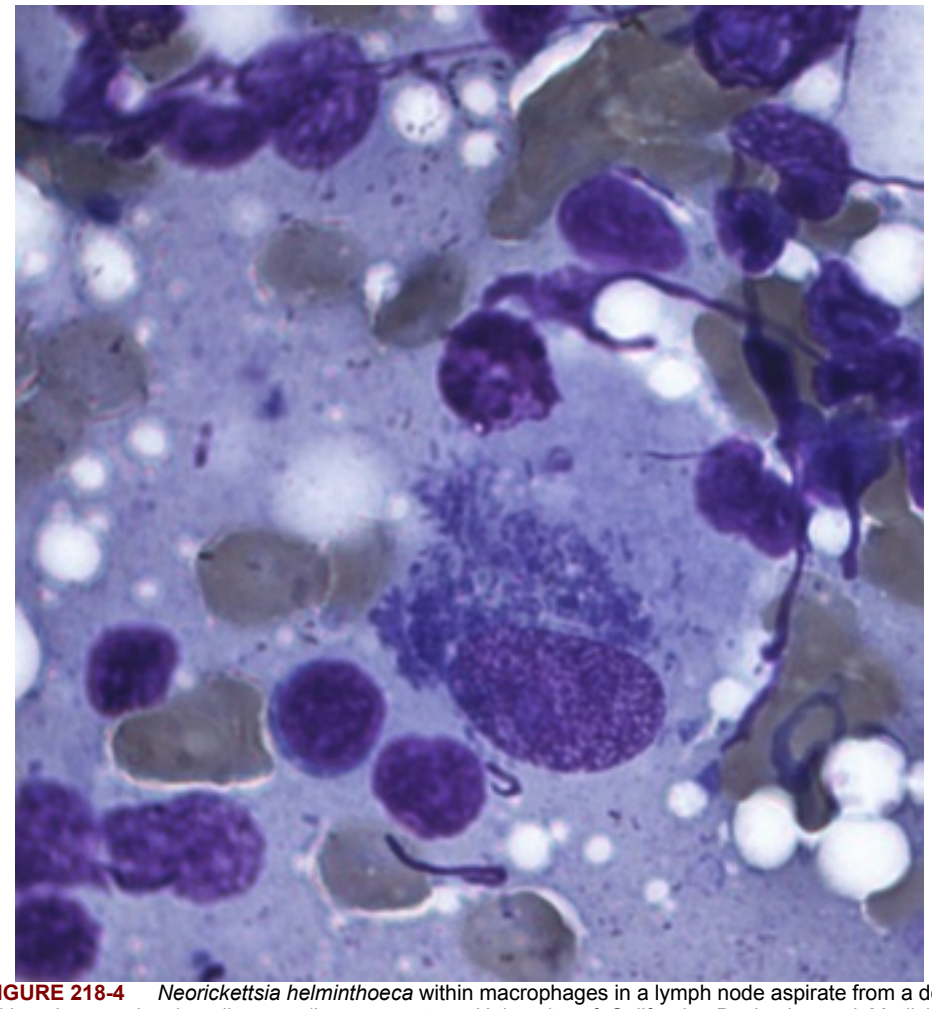

FIGURE 218-4 *Neorickettsia helminthoeca* within macrophages in a lymph node aspirate from a dog with salmon poisoning disease. (Image courtesy University of California, Davis, Internal Medicine Service.)

Treatment and Prevention

The treatment of choice is doxycycline. Parenteral administration may be necessary in vomiting dogs. In addition, supportive therapy using fluids, blood products, and antiemetics may be necessary. Praziquantel should also be administered to treat the helminth infection (see ch. 163). Prevention involves avoiding access to fish and feeding only thoroughly cooked fish. Freezing fish for 24 hours also effectively destroys the metacercariae and rickettsiae.

Neorickettsia risticii

Neorickettsia risticii is the cause of Potomac horse fever. The life cycle of this organism likely involves the trematode vector, *Acanthatrium oregonense.*[78] The fluke miracidia infect aquatic snails (*Juga* spp.) and parasitize caddisflies. Horses may become infected following accidental ingestion of infected caddisflies containing metacercariae. *N. risticii* has been identified using culture and PCR in dogs from the western and southwestern United States with signs mimicking ehrlichiosis.[79] The dogs were seroreactive to *N. risticii* antigens using IFA. Further studies are required to determine the significance of this organism in dogs and cats.

Tick-Borne Rickettsioses

General Considerations

Rickettsia rickettsii, the cause of Rocky Mountain spotted fever (RMSF), belongs to the Rickettsiaceae, a family

that contains a number of pathogenic and nonpathogenic *Rickettsia* species. Many novel species of rickettsiae have been recently characterized using molecular methods.[80] Clinical signs in humans caused by these organisms include fever, lymphadenopathy, headache, eschar formation (tissue slough), and rash. Formation of an eschar at the inoculation site does not usually occur in RMSF.[80] The ability of novel *Rickettsia* species to cause disease in dogs and cats, and the role of dogs and cats as reservoirs, requires further study. Tick-borne SFG rickettsiae cause disease after infecting vascular endothelial cells and increasing microvascular permeability.[81] Organisms inhibit apoptosis, favoring rickettsial growth. Widespread endothelial injury is associated with production of proinflammatory cytokines and activation of the coagulation cascade without disseminated intravascular coagulation.[81]

Rocky Mountain Spotted Fever (RMSF)

Etiology and Epidemiology

RMSF is a severe, life-threatening illness of humans and dogs caused by *Rickettsia rickettsii,* most commonly diagnosed in the south-central, southeastern, and south Atlantic United States. It also occurs in Central America and parts of South America (Brazilian spotted fever).[80] Approximately 2000 cases of RMSF are reported annually in people in the United States.[82]

Rickettsia rickettsii is transmitted primarily by *Dermacentor* ticks in North America, although transmission by *R. sanguineus* occurs in Arizona.[83,84] The American dog tick *(Dermacentor variabilis)* is the primary vector in the southeastern states, and the Rocky Mountain wood tick *(Dermacentor andersoni)* transmits the rickettsia in the Rocky Mountain region and Canada (see Table 218-2). *R. sanguineus* and *Amblyomma* spp. ticks have been implicated as vectors in Central and South America, respectively.[85,86] The organism is transmitted transstadially and transovarially within ticks. Uninfected larvae and nymphs also become infected when they feed on small wild mammals, such as ground squirrels. In the United States, most cases occur between March and October. In humans, the highest incidence has been reported in Caucasian males <10 years and 40-64 years of age.[85] Most cases originate from rural or wooded areas. Exposure to dogs is a risk factor.[87,88] The disease occurs sporadically, but may cluster in small geographic regions. Rarely, familial clusters occur, sometimes including the family dog.[89,90] A history of a tick bite is present in <70% of infected people and is even less common in dogs.[91,92]

Pathogenesis and Clinical Signs

Following tick attachment, a reactivation period lasting 4 to 24 hours is necessary. Disease in humans and dogs is similar with incubation periods of 2 to 14 days (mean: 7). Common nonspecific observations include fever, lethargy, anorexia, and lymphadenopathy. Extreme headaches may occur early in the course of human illness and be accompanied by myalgia, vomiting, anorexia, and abdominal pain.[85] Early RMSF is often misdiagnosed as a viral illness in humans.[85] About 60% to 70% of infected people, within 2 weeks of the tick bite, have the characteristic triad of rash, fever, and headache. The rash initially appears as small macules on the wrists and ankles and spreads to involve the arms, legs, and trunk, eventually becoming maculopapular with central petechiae.[85] Dogs may develop edema and erythema of extremities, including the lips, muzzle, scrotum, penile sheath, pinnae and, rarely, the ventral abdomen.[92-94] Continued tissue damage in these regions may lead to necrosis and gangrene, requiring amputation in some cases.[89,93] Stiffness and reluctance to walk may be apparent.[91] Ocular manifestations are common, including conjunctivitis, mucopurulent ocular discharge, scleral injection, uveitis, hyphema, iridal and retinal hemorrhage, and retinal edema (see ch. 11).[95] Petechial and ecchymotic hemorrhages have been noted.[91,96] Epistaxis, melena, and hematuria may occur in severely affected dogs. Neurologic signs (ataxia, tremors, vestibular signs, hyperesthesia, opisthotonus, seizures) have been reported in up to 80% of dogs with RMSF.[89,91,92,96,97] Other signs include respiratory distress and cough due to pulmonary edema, cardiac arrhythmias due to myocarditis, hepatomegaly, icterus, and development of acute kidney injury (see ch. 322). Death can result from progressive neurologic signs, acute oliguric renal failure, or cardiovascular collapse and shock.[85,91] Death is reported in 2-10% of humans, although a study from Mexico reported a mortality rate of 22% in children.[88] The median time from onset of illness to death is only 8 days, making early recognition and treatment crucial.

Laboratory abnormalities include leukocytosis, sometimes with a left shift, anemia, and thrombocytopenia.[91,92,94,96] Serum chemistry abnormalities may include increased liver enzyme activities and

creatine kinase concentrations, hypoalbuminemia, and electrolyte disturbances. In severe cases, azotemia and hyperbilirubinemia are noted. Cerebrospinal fluid analysis may reveal increases in protein concentration (usually <100 mg/mcL) and in neutrophil and mononuclear cell counts (see ch. 115).[89] Neutrophilic polyarthritis has been documented using synovial fluid analysis (see ch. 94 and 203). Thoracic radiography may reveal an interstitial pattern.

Diagnosis

Antibody detection using microimmunofluorescence is the serologic reference method, but ELISA assays are also used.[98] Wide antigenic cross-reactions exist among pathogenic and nonpathogenic SFG rickettsiae. Thus, positive titers are not specific for *R. rickettsii.* Because antibodies are generally not detectable until 7 to 10 days after disease onset, a fourfold rise in IgG titer using acute and convalescent phase sera is necessary to confirm recent infection. A single titer exceeding 1 : 1024 is also considered diagnostic of recent infection, if associated with clinical signs.[91] Given the acute nature of RMSF, serology is of limited usefulness for early diagnosis.

Direct immunofluorescence or immunoperoxidase staining of infected tissues, including biopsies of affected skin, can be used to detect *R. rickettsii* antigen in tissue early in the course of disease or at necropsy, with high specificity and a sensitivity of about 75%.[97,99-101] PCR assays for *R. rickettsii* can be used on blood or tissue. The number of rickettsiae circulating in blood is generally low with poor PCR sensitivity.[102,103] Use of PCR together with immunohistochemistry on skin biopsy specimens in acute disease improves laboratory confirmation of RMSF (see ch. 86 for skin biopsy procedure). Real-time PCR assays that differentiate between SFG rickettsiae–infecting dogs are available.[104] *R. rickettsii* has been classified as a biosafety level-3 agent, and cultivation requires special facilities and is not routine. Laboratory-acquired infections have been reported.[105]

Treatment

Doxycycline is recommended for RMSF and it results in rapid (12-24 h) clinical response. Other tetracyclines, chloramphenicol, and fluoroquinolones are effective.[106,107] Treatment should be continued for at least 7 days. Parenteral antimicrobial drug therapy may be needed if vomiting or neurologic signs are present. Treatment delays have been correlated with more severe disease and increased mortality in humans. Treatment should not be delayed while awaiting results of diagnostic testing. Other supportive therapy may be required for dogs in shock, including IV fluids (see ch. 129) and blood products (see ch. 130). Care may be required to avoid pulmonary or cerebral edema after IV crystalloids.[91] Residual neurologic signs, renal insufficiency or cutaneous scarring may persist despite treatment, especially if treatment is delayed.

Prevention

Natural infection is followed by development of solid immunity, and reinfection has not been documented in naturally infected dogs. Prevention relies on tick control (see above). Prophylactic antibiotic administration is not indicated to prevent RMSF after a tick bite, as this only appears to delay onset of illness.[85]

Public Health Aspects

Dogs are important sentinels for human infection with *R. rickettsii.* Recognition of the disease in dogs has contributed to prompt diagnosis and treatment of RMSF in humans interacting with those dogs.[89] Veterinarians that manage dogs with RMSF should educate their clients about the disease and their potential for infection and should contact human health care providers should humans become ill in association with canine disease. Dogs may carry unattached infected ticks, which may subsequently attach to people. People may become infected through improper removal of attached ticks from their dogs. Guidelines for safe removal of ticks have been published (also see video, ch. 211).[85] Ticks should be lifted from the skin using fine forceps. Gloves should be worn. Hands should be washed with soap and water after removal. The skin should be thoroughly examined for attached ticks after these activities.

Feline Rickettsial Disease

Cats are rarely infected with rickettsial agents.[108-130] The DNA of *E. canis*–like organisms has been detected in cats from North America, Europe and South America.[108-111] One of the three North American cats showed signs of polyarthritis and the other two had cytopenias. None of these three cats was seroreactive in an IFA assay using *E. canis* antigens. *Ehrlichia*-like morulae have been identified in mononuclear cells in cats from the

United States, Kenya, France, Brazil and Thailand.[112-116] Clinical signs including fever, lethargy, anorexia, pallor, and splenomegaly were reported in these cats, although some had coinfections with hemoplasmas or retroviruses. The most consistent laboratory abnormalities in infected cats have been nonregenerative anemia and hyperglobulinemia. Many infected cats respond rapidly to treatment with doxycycline. Cats infected with monocytic ehrlichiae should be treated with doxycycline at 10 mg/kg PO q 24 h for a minimum of 28 days.[15]

Several case series of cats with suspected or proven *A. phagocytophilum* infection have been described from Europe and the United States. The diagnosis was based on cytologic evaluation of morulae within circulating granulocytes with or without PCR confirmation of infection.[117,118,126-130] Clinical abnormalities in these cats included lethargy, anorexia, fever, pallor, epistaxis, hyperesthesia, lameness, lymphadenopathy, hepatomegaly, ataxia, vomiting, and thrombocytopenia. Experimental infection of cats with *A. phagocytophilum* has resulted in development of morulae within granulocytes and clinical illness.[131] These cats showed signs of fever, anorexia, and lethargy, and some had thrombocytopenia. Signs in cats infected with *A. phagocytophilum* resolve following treatment with doxycycline.[126,128]

CHAPTER 219

Hemotropic Mycoplasmas

Séverine Tasker

Client Information Sheet: Hemotropic Mycoplasma *(Haemoplasma)* Infections

The hemotropic mycoplasmas (hemoplasmas) are small (0.3-1 micron) wall-less bacteria that parasitize erythrocytes, living on the surface of the erythrocyte membrane (Figure 219-1). They infect a variety of hosts including cats, dogs, rodents, pigs, cattle, deer, horses and beetles. Infections also have been described in humans with novel hemoplasma species,[1,2] as well as species that possibly have originated in animals such as the cat,[3] pigs,[4-6] sheep,[1,7] or dogs,[8] raising the possibility of zoonotic infections. Hemoplasma infections have been reported throughout the world. Please note that *Babesia* infections are described in ch. 221 and *Bartonella* infections are described in ch. 215 and 216.

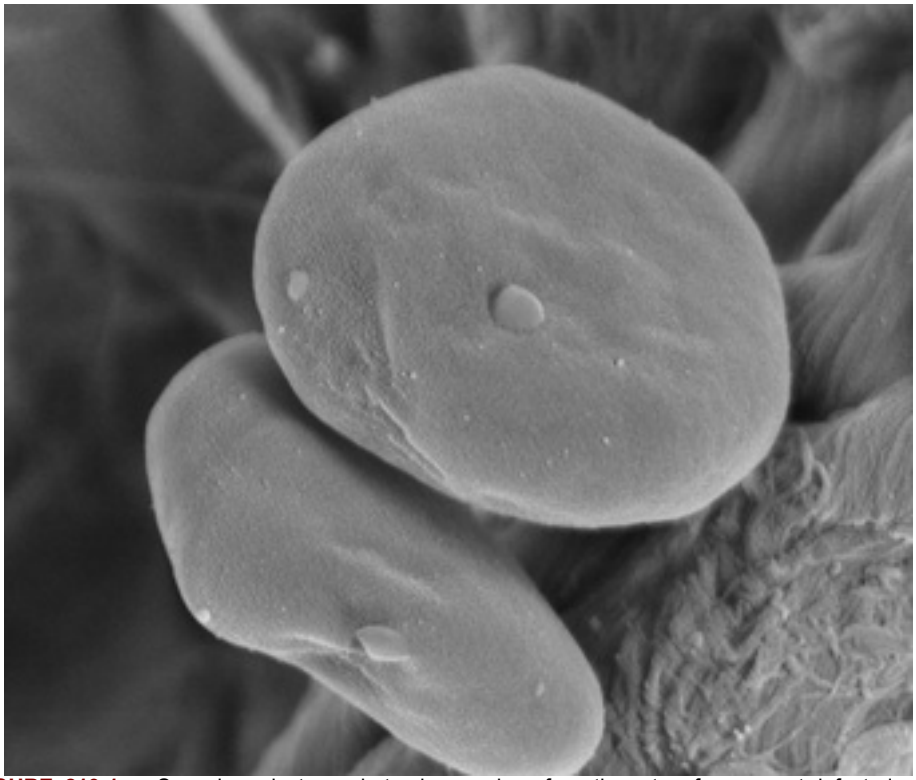

FIGURE 219-1 Scanning electron photomicrography of erythrocytes from a cat infected with *Mycoplasma haemofelis*, showing a rounded organism within an indentation on the erythrocyte surface (×1000).

Initially, the hemoplasmas, as members of the genus *Haemobartonella,* were classified as rickettsial organisms, but gene (mainly 16S rRNA-based) sequencing analysis and phylogenetic studies resulted in their reclassification within the genus *Mycoplasma.*[9-11] Though similarities between the hemoplasmas and mycoplasmas are recognized, such as the absence of a cell wall, their small (including genome) sizes, and their fastidious growth requirements, the hemoplasmas' niche environment of the blood is not one that is

commonly recognized for *Mycoplasma* species, which are most commonly found on the mucosal surfaces of the respiratory and urogenital tracts.[12] Indeed, recent work using non-16S rRNA gene-based phylogeny suggests that, although the hemoplasmas probably rightly belong to the family *Mycoplasmatales*, they should reside in a genus separate to that of the *Mycoplasma* species.[13,14]

Gene sequencing analysis also has revealed the existence of different species of hemoplasmas, and five major hemoplasma species are now known to infect cats and dogs (Table 219-1). Renaming of the hemoplasmas accompanied their reclassification as mycoplasmal organisms. In renaming, some of the species were assigned the status *Candidatus;* this status is used in bacterial nomenclature for newly described organisms for which sequence data are available, but which cannot be phenotypically characterized to meet the needs of the International Code of Nomenclature of Bacteria[15] due to the inability to grow them *in vitro.* Although none of the hemoplasmas can be grown *in vitro,* only newly described hemoplasma species were given the *Candidatus* status as those species previously defined and named (in the genus *Haemobartonella*) could not be assigned the *Candidatus* status as a rule in bacterial nomenclature exists that forbids the demotion of any bacterial species.

TABLE 219-1

Feline and Canine Hemoplasma Species, Their Prevalence (Using PCR as Method of Detection), and a Summary of Each Species' Pathogenicity

SPECIES NAME	HOST	REPORTED PREVALENCE	PATHOGENICITY
Mycoplasma haemofelis	Cat	Up to 46.6%	Acute infection often results in hemolytic anemia
'*Candidatus* Mycoplasma haemominutum'	Cat	Up to 46.7%	Acute infection can induce a drop in erythrocyte parameters but not usually severe enough to cause anemia unless cat has concurrent disease or is immunocompromised (e.g., retrovirus infection)
'*Candidatus* Mycoplasma turicensis'	Cat	Up to 26%	
Mycoplasma haemocanis	Dog	Up to 52.4%	Infection can result in hemolytic anemia, primarily in splenectomized dogs
'*Candidatus* Mycoplasma haematoparvum'	Dog	Up to 33.3%	Anemia not usually reported unless the dog has concurrent disease or is immunocompromised (e.g., chemotherapy)

In addition to the five main feline and canine hemoplasmas described in Table 219-1, the feline hemoplasma species' '*Candidatus* M. haemominutum' also has been detected occasionally in dogs,[16,17] as has the ovine hemoplasma *Mycoplasma ovis*[18] and the bovine hemoplasma '*Candidatus* M. haemobos.'[19,20] A '*Candidatus* M. haematoparvum'-like organism also been reported in a small number of cats in two studies.[21,22] The clinical importance of these additional hemoplasma species in dogs and cats remains unclear.

Prevalence and Risk Factors for Infection

Prevalence studies for feline hemoplasma species have been performed worldwide, with very varied results (see Table 219-1). '*Candidatus* M. haemominutum' is usually the most common species found in prevalence studies, with prevalences ranging from 0 to 46.7% (median 14.4%) of cats being infected.[21-51] *M. haemofelis* and '*Candidatus* M. turicensis' infections generally are less common, although occasionally, high prevalences are reported. Reported prevalence for *M. haemofelis* have ranged from 0 to 46.6% (median 4.8%)[21-43,45-51] and for '*Candidatus* M. turicensis' have ranged from 0 to 26% (median 2.0%).[21,22,28,31,32,38,39,43,45,48-52] Variable numbers of cats infected with more than one hemoplasma species are also reported in different studies, and one recent study of Brazilian cats reported that over 80% of hemoplasma-infected cats harbored more than one hemoplasma species.[45] '*Candidatus* M. turicensis'–infected cats often are coinfected with another hemoplasma species, particularly '*Candidatus* M. haemominutum,' and indeed, in some studies, no cats were

found to be infected with '*Candidatus* M. turicensis' alone.[31,45,51]

The characteristics of the cats sampled for these different prevalence studies have varied enormously, from healthy cats to anemic cats suspected of having hemoplasmosis or retrovirus-infected cats, and from client-owned indoor cats to outdoor feral cats, which likely explains the wide differences in prevalences reported. Additionally, geographic variation in prevalence appears to exist, with cats in warmer countries having a higher prevalence of infection. Different polymerase chain reaction (PCR) methods, likely with differing sensitivities and specificities, were also used, likely contributing to the variation, too.

In most studies, feline hemoplasma infections are found more commonly in male, nonpedigree cats with access to the outdoors.[21,24-26,28,32,34,39,41,43,45,48,50-53] Infection with '*Candidatus* M. haemominutum' usually is more prevalent in older cats, presumably because the chance of acquiring chronic subclinical infection increases with time. Some studies have shown an association between hemoplasma infection with any species and feline immunodeficiency virus (FIV),[33,38] whereas others have not,[28] but these same studies failed to show an association between hemoplasma infection with any species and feline leukemia virus (FeLV) infection.[28,33,38] (Table 219-2). However, studies looking at individual hemoplasma species infections and retroviral status have shown variable results (see Table 219-2).

TABLE 219-2

Overview of Retrovirus Infection as Risk Factors for Hemoplasma Infections in a Selection of Published Studies

STUDY NAME (NUMBER AND TYPE OF CATS)	HEMOPLASMA SPECIES (SPECIES DETECTED BY PCR METHODS USED ARE LISTED IN BRACKETS)	FeLV INFECTION	FIV INFECTION
Luria et al. 200426 ($_n$ = 484, feral cats, northern Florida)	• '*Candidatus* M. haemominutum'	✓	✓

Tanahara et al. 201050 ($_n$ = 1770 cats with outdoor access in Japan)	• Any hemoplasma species ('*Candidatus* M. haemominutum' and/or *M. haemofelis* and/or '*Candidatus* M. turicensis')	✗	✓
Georges et al. 201251 ($_n$ = 152 rescue cats presenting	• Any hemoplasma species ('*Candidatus*	✓	✓

for euthanasia or neutering, or samples submitted to a diagnostic laboratory, Trinidad and Tobago)	M. haemominutum' and/or *M. haemofelis* and/or '*Candidatus* M. turicensis')		
	• '*Candidatus* M. haemominutum'	✓	✓
	• *M. haemofelis*	✗	✗

✓, Identified as risk factor; ✗, not identified as risk factor.

Reported prevalences for canine hemoplasma infection also vary widely in different studies (see Table 219-1); generally *M. haemocanis* is more prevalent (0 to 54.4% of dogs infected, median 5.9%),[18-20,35,39,46,54-61] but occasionally '*Candidatus* M. haematoparvum' (0 to 33.3% of dogs infected, median 1.5%)[18-20,35,39,46,55-57,59-61] is found in higher numbers. Geographic variation is marked, possibly due to the presence of the proposed canine hemoplasma tick vector *Rhipicephalus sanguineus*,[56,60] and kenneled dogs, young dogs, crossbreeds, and dogs with mange were more likely to be infected in one study,[60] whereas other studies found no association with age.[39,56,59]

Pathogenesis

Mycoplasma haemofelis is the most pathogenic of the feline hemoplasma species. Cats do not need to be immunocompromised or splenectomized to succumb to clinical disease with *M. haemofelis*, and splenectomized cats infected with '*Candidatus* M. haemominutum' do not seem to show increased pathogenicity with this organism.[62]

Acute infection often results in severe hemolytic anemia (primarily extravascular, but occasionally intravascular hemolysis is reported), although in some cases, only mild anemia results. In experimental studies, clinical signs typically occur around 2 to 34 days after infection, with anemia lasting from around 18 to 30 days. The onset of anemia usually is followed by a significant regenerative response with reticulocytosis. Chronic infection usually is not associated with significant anemia.[28] Experimental infections have shown that *M. haemofelis* blood organism numbers can fluctuate greatly over short periods of time, especially in the first few weeks of infection (Figure 219-2). Antigenic variation to evade the host immune system could mediate these *M. haemofelis* organism number fluctuations,[63] as a very large portion (62%) of the *M. haemofelis* genome encodes a set of uncharacterized hypothetical proteins arranged in series of paralogous repeats that could mediate differing expression of hemoplasma surface proteins over time. Young cats could be more likely to develop severe clinical disease due to *M. haemofelis* compared to older cats.[32,64] Epidemiological studies have, however, only variably demonstrated associations between anemia and *M. haemofelis* infection.[23,34] This might be because these studies usually include asymptomatic, chronically *M. haemofelis*–infected cats.

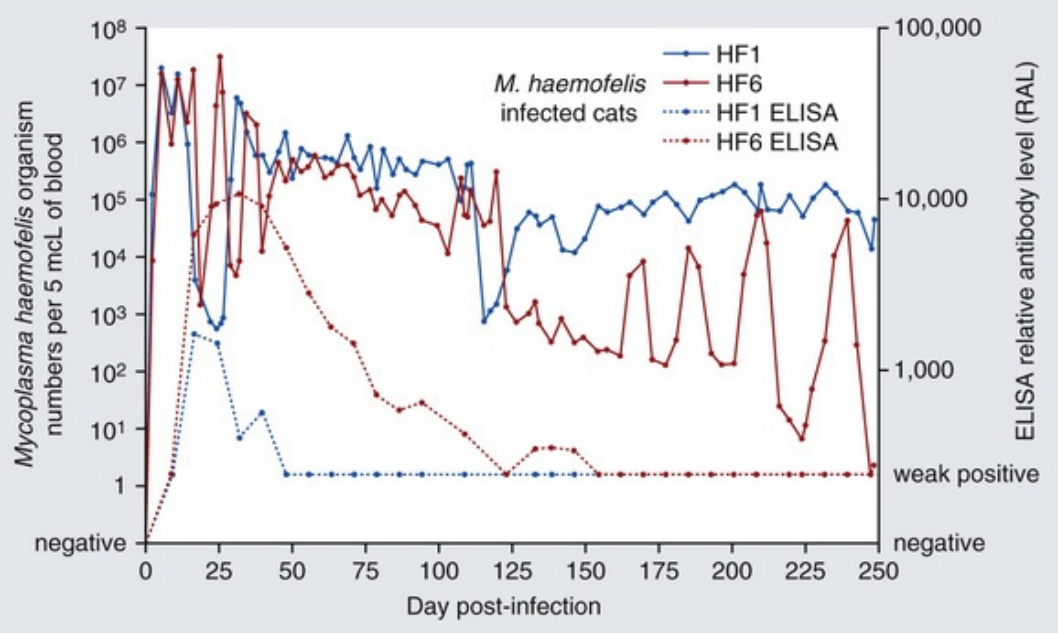

FIGURE 219-2 Graph made from data collected from two cats in the study by Barker et al. in 2010.[97] The solid lines indicate *M. haemofelis* organism numbers in the blood (detected by quantitative PCR) whilst the hashed lines indicate the relative levels of antibodies against a recombinant dnaK *M. haemofelis* protein present in the blood (detected by an enzyme linked immunosorbent assay). The marked fluctuations in *M. haemofelis* organism numbers in the blood over time is evident in both cats, but especially Cat HF6. Antibody levels peak, and are quantifiable, during acute infection only, after which they are detectable but nonquantifiable; antibody assays may be useful in the future to differentiate acute and chronic hemoplasma infection but are currently only available as a research tool.

Persistent autoagglutination or positive Coombs' testing, indicating the presence of erythrocyte-bound antibodies, has been demonstrated in anemic cats with acute *M. haemofelis* infection.[64-66] One detailed study[64] showed that erythrocyte-bound antibodies reactive at 4° C (cold reactive antibodies; both IgM and IgG) appeared a few days earlier than those reactive at 37° C (warm reactive antibodies, primarily IgG). However, in most cats, these antibodies appeared only *after* the development of anemia had started. The absence of erythrocyte-bound antibodies at the onset of development of anemia could reflect a problem with the sensitivity of their detection or that erythrocyte-bound antibodies appear as a result of hemoplasma-induced hemolysis rather than initiating it. In line with the latter, it has been found that these antibodies disappear with antibiotic and supportive treatment alone, without the need for specific glucocorticoid treatment.[64] Osmotic fragility[66,67] and reduced erythrocyte lifespan[68] also have been reported with *M. haemofelis* infection.

Although acute '*Candidatus* M. haemominutum' infection is associated with a fall in red blood cell parameters,[64] anemia usually is not induced except in cats with concurrent diseases or infections (e.g., lymphoma or FeLV infection).[69,70] '*Candidatus* M. haemominutum' also has been associated with the development of myeloproliferative disease in cats with FeLV infection in one experimental study.[70] Although concurrent problems usually are present in '*Candidatus* M. haemominutum'–infected cats that develop anemia, cases of so-called primary '*Candidatus* M. haemominutum' anemia (i.e., without any apparent concurrent disease or infection present) also have been reported,[71] so infection with this species cannot be ruled out as a cause of anemia in an individual case. However, conflicting data exist, as one US study actually documented that '*Candidatus* M. haemominutum'–infected cats were less likely to be anemic than non–'*Candidatus* M. haemominutum'–infected cats.[21]

'*Candidatus* M. turicensis' infection has resulted in anemia[67] or a small fall in red blood cell parameters in some experimental studies,[64] but generally anemia is uncommon following infection. Both concurrent disease and immunosuppression are thought to be involved in the pathogenesis of '*Candidatus* M. turicensis' disease,[52] in a similar way to the pathogenesis described for '*Candidatus* M. haemominutum.' Determining the pathogenicity of '*Candidatus* M. turicensis' in naturally infected cats has been difficult in epidemiological studies because cats often are coinfected with other hemoplasma species, which confounds disease associations.

It is possible that different strains of each of the feline hemoplasma species reported exist, and that these also vary in pathogenicity. This might explain some of the conflicting data reported in different studies. However, other factors, such as the underlying health status of the cat, and possibly even the transmission route of infection, might play a role in the outcome of hemoplasma infection.

Studies regarding the pathogenicity of canine hemoplasmas are sparse. Hemoplasma infection in dogs usually results in hemolytic anemia only in splenectomized or immunocompromised dogs,[72-75] and asymptomatic latent *M. haemocanis* infections can be reactivated following splenectomy. However, recognition of the possibility of hemoplasma infection is important to differentiate such cases from cases of primary immune-mediated hemolytic anemia, as some cases show evidence of erythrocyte-bound antibodies in positive Coombs' tests.[76,77]

Carrier Status

Long-term carrier status can occur with feline hemoplasma infection, with infected cats often being asymptomatic.[24,78] The author's experience is that this is particularly common with '*Candidatus* M. haemominutum' infection, although suspected clearance of infection has been reported by others with and without antibiotic treatment.[28] We have observed that a large proportion of *M. haemofelis*–infected cats spontaneously clear infection from peripheral blood a few months following acute infection; this also has been reported with '*Candidatus* M. turicensis' infection. However, generalized statements regarding long-term carrier status cannot be made since great variation exists, likely because of differences in the host-organism interaction and hemoplasma isolates. Often, carrier cats have subclinical infections, but reactivation of infection can occur and could result in clinical disease[79,80]; this is uncommon in our experience.

Little work has been done regarding the time course of carrier status with canine hemoplasmas, but asymptomatic carrier dogs infected with '*Candidatus* M. haematoparvum' and *M. haemocanis* are thought to exist.[56]

Transmission

The natural route of transmission of hemoplasma infection between cats and dogs in the field has not yet been determined, and it could be that different routes predominate for the different hemoplasma species that exist.

Canine and feline hemoplasma DNA has been found in fleas and ticks,[42,49,53,81-85] although this does not equate with vectors mediating transmission, as it could reflect their hematophagous activity on infected hosts. The clustered geographical distribution of infection in some studies supports the role of an arthropod vector in hemoplasma transmission.[21] The cat flea, *Ctenocephalides felis,* has been implicated in feline hemoplasma transmission, but only very transient *M. haemofelis* infection has been reported in cats infected experimentally via the hematophagous activity of fleas, and clinical and hematological signs of *M. haemofelis* infection were not induced in the recipient cat.[86] Additionally, a recent study found no evidence of hemoplasma transmission by fleas in an experiment involving the introduction of fleas into groups of cats housed together.[87] Transmission of *M. haemocanis* by the brown dog tick, *Rhipicephalus sanguineus,* has been demonstrated experimentally, although this was before PCR was available to confirm diagnosis of infection.[82]

The association between hemoplasma infection and male gender and/or retrovirus status (particularly FIV) seen in some studies could suggest that cat fights are involved in transmission of infection. Studies in Switzerland have found that subcutaneous inoculation of '*Candidatus* M. turicensis'–containing blood resulted in infection transmission, whereas the same inoculation method using '*Candidatus* M. turicensis'–containing saliva did not. This suggests that hemoplasma transmission by social contact (e.g., saliva via mutual grooming) is less likely than transmission by aggressive interaction (e.g., blood transmission during a cat bite incident).[88] However, a recent study[87] on '*Candidatus* M. haemominutum' and *M. haemofelis* transmission found evidence of horizontal transmission of '*Candidatus* M. haemominutum,' but not *M. haemofelis,* by direct contact between cats in the absence of aggressive interaction and vectors. Vertical transmission has not been definitively shown using molecular methods with canine or feline hemoplasma infections but has been suggested for other hemoplasma species.[89] Blood transfusion is another potential route of transmission, and blood donors should be screened for hemoplasma infection.[90]

Clinical Presentation and Laboratory Abnormalities

The clinical disease that follows hemoplasma infection is influenced by the stage of infection, the host response to the organism, the health status of the host, and which species of hemoplasma is involved. *M. haemofelis* and *M. haemocanis* in splenectomized dogs are most likely to be associated with clinical signs during acute infection. On the other hand, '*Candidatus* M. haemominutum,' '*Candidatus.* M. turicensis' and '*Candidatus* M. haematoparvum' generally are not associated with clinical signs unless concurrent disease or immunosuppression is present.

Common clinical signs associated with hemoplasmosis are lethargy, pallor, and weakness. Inappetence, dehydration, weight loss and intermittent fever also are reported. Splenomegaly also can be evident in cats with feline hemoplasmosis; in contrast, this is not commonly seen in dogs with clinical hemoplasmosis because such dogs usually no longer have a spleen due to a previous history of splenectomy, the latter increasing their susceptibility to clinical hemoplasmosis.

Affected animals with severe anemia can have tachycardia, tachypnea, and weak or bounding femoral pulses with hemic cardiac murmurs. Icterus is very rare, despite the severe nature of the anemia involved. Moribund cats can be hypothermic.

Pathogenic hemoplasma infections typically cause a regenerative anemia that is macrocytic and hypochromic, although pronounced reticulocytosis is not always evident.[91] Normoblasts can be present. Positive Coombs' test results, particularly with cold agglutinins, and persistent autoagglutination, have been reported in acute hemoplasmosis, indicating the presence of erythrocyte-bound antibodies. Hyperbilirubinemia is seen occasionally, due to hemolysis, and hypoxic liver injury can result in increased activities of alanine aminotransferase (ALT). Hyperproteinemia is sometimes seen in affected cats. Retrovirus testing can be positive in cats.

Differential Diagnoses

Hemoplasmosis should be considered as a differential diagnosis in cats or dogs presenting with regenerative (although occasionally nonregenerative) anemia and possibly associated fever. Other diagnoses to consider are primary immune-mediated hemolytic anemia (see ch. 198), secondary immune-mediated hemolytic anemia (e.g., secondary to drugs, neoplasia, infections; see ch. 198), cytauxzoonosis (cats; see ch. 221), retroviral infection (cats; see ch. 222 and 223), babesiosis (see ch. 221), Heinz-body–associated hemolysis (cats; see ch. 152 and 198), hypophosphatemia (see ch. 69), and inherited red blood cell disorders such as pyruvate kinase deficiency (see ch. 198).

Diagnosis

Cytology

Cytologic examination of blood smears can show hemoplasmas on the surface of erythrocytes (Figure 219-3) (occasionally in chains, especially with *M. haemocanis* [Figure 219-4]), but this is known to be very insensitive for diagnosis (0 to 37.5%),[23,24,48,92] with huge numbers of organisms needed in the blood before they can be visualized cytologically. Additionally, cytologic evaluation cannot differentiate easily between hemoplasma species,[93] despite reports in cats suggesting that '*Candidatus* M. haemominutum' organisms are smaller than *M. haemofelis.*[94] '*Candidatus* M. turicensis' has never been visualized cytologically,[95] probably due to the low numbers of organisms seen in blood during infection with this species.[64] As well as having poor sensitivity, specificity can be an issue for cytological diagnosis of hemoplasma infection, as the untrained eye can fail to distinguish stain precipitate from true hemoplasma organisms, and careful staining with a properly prepared, filtered Romanowsky-type stain solution (e.g., Wright Giemsa or Diff-Quik) is essential. Organisms also need to be differentiated from Howell-Jolly bodies and basophilic stippling. In experienced hands (e.g., board-certified clinical pathologists, with whom specificity is reported as 84 to 98%),[23,24,48,92] the finding of epicellular organisms on the surface of erythrocytes in association with clinical signs of hemoplasmosis can be supportive of the diagnosis, but PCR testing should be performed for confirmation.

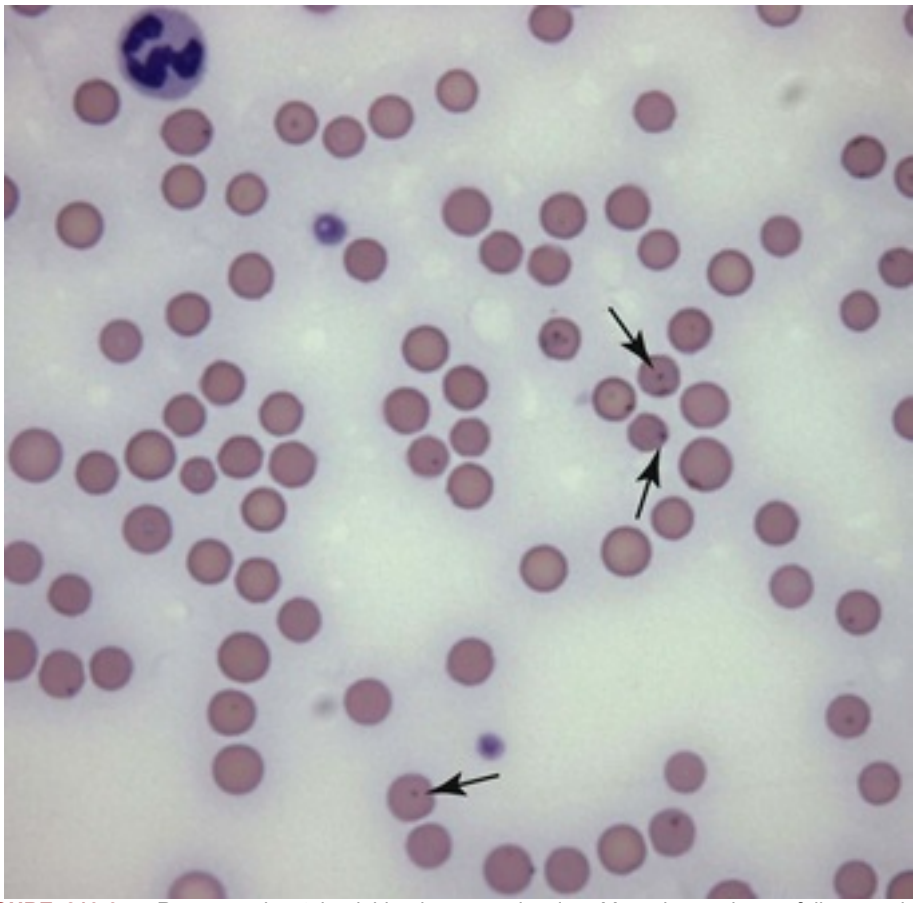

FIGURE 219-3 Romanowsky-stained blood smear showing *Mycoplasma haemofelis* organisms (arrows) on the surface of erythrocytes. Cytology is, however, an insensitive method for diagnosing hemoplasma infections. (Image courtesy Dr. Jane Sykes.)

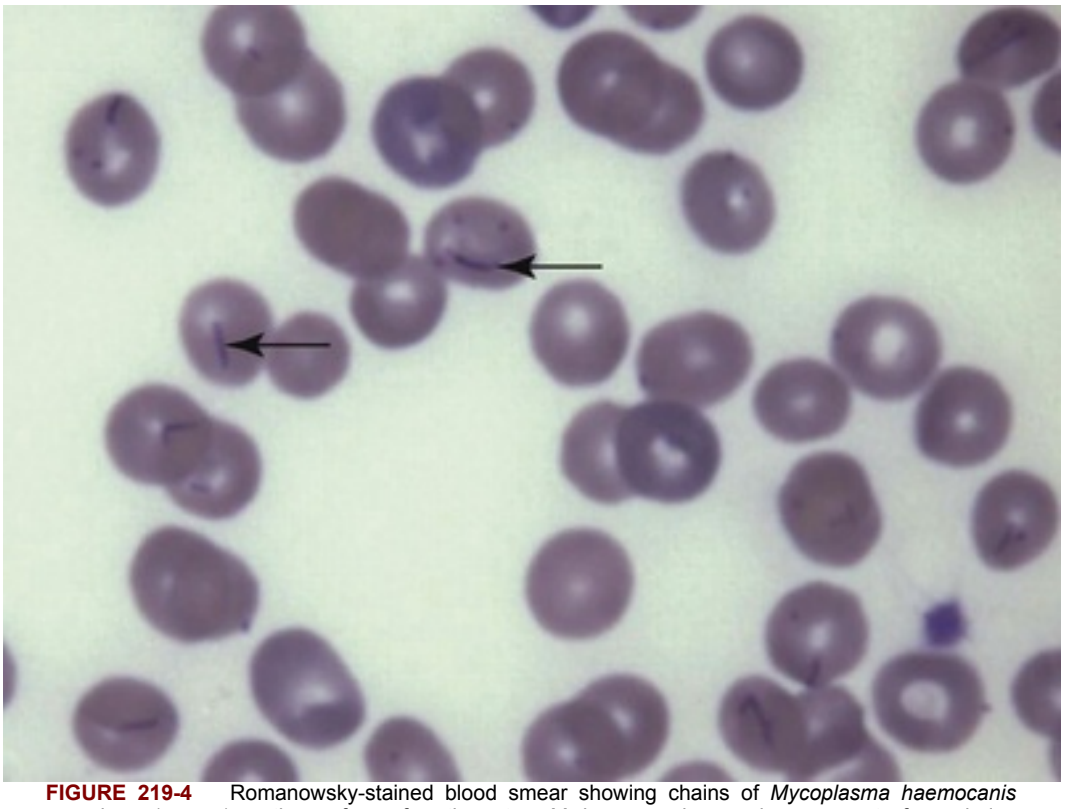

FIGURE 219-4 Romanowsky-stained blood smear showing chains of *Mycoplasma haemocanis* organisms (arrows) on the surface of erythrocytes; *M. haemocanis* organisms seem to form chains more commonly than other species but cytology is still insensitive for diagnosis. (Image courtesy Dr. Jane Sykes.)

Polymerase Chain Reaction Assays

PCR is now the diagnostic method of choice for hemoplasma infection. When properly designed and executed, PCR is far more sensitive than cytologic examination of blood smears, although PCR might not detect organisms in some asymptomatic carrier cats that have very low numbers of organisms in the blood, below the detection limit of the PCR assay. Some hemoplasma PCRs have been duplexed with a host housekeeping gene (such as the 28S rRNA gene) PCR[96]; the inclusion of such an internal control is important in order to prevent false-negative results for hemoplasma infection due to the failure of DNA extraction, presence of PCR inhibitors, or qPCR setup errors. Specificity also is a valuable feature, with diagnostic PCRs being available for each of the feline and canine hemoplasma species. Real-time quantitative PCR (qPCR) assays also exist that allow quantification of hemoplasma DNA in the patient's blood; this can allow one to monitor the course of hemoplasma infection and evaluate any response to treatment, such as a decrease in the level of hemoplasma DNA in the blood following institution of effective antibiotic treatment. The fluctuations in blood organism numbers that can occur during *M. haemofelis* infection (see Figure 219-2) should be considered when interpreting qPCR results, as decreases in organism number cannot always be deemed a consequence of effective antibiotic treatment or host immune response. When a positive PCR result is obtained for hemoplasma infection, the result must always be interpreted with the clinical signs, clinicopathological results, and any concurrent disease or immunosuppression present because asymptomatic carrier cats exist. The pathogenicity of the agent detected also should be considered when deciding whether the positive result represents the cause of the animal's signs.

Serology

Serologic assays to detect antibodies to feline hemoplasma proteins currently are only available for research (see Figure 219-2). One study, using an ELISA based on recombinant *M. haemofelis* DnaK, suggested that serologic assays could differentiate acute from chronic *M. haemofelis* infection,[97] and another study found that a similar serologic assay was more sensitive than PCR in detecting exposure to '*Candidatus* M. turicensis.'[98]

Further work is required to determine the specificity of these assays before they can be used commercially in naturally infected cats.

Treatment

Antibiotic treatment is indicated for cats and dogs with clinical signs and clinicopathological abnormalities consistent with hemoplasmosis. Treatment also should be considered for cats that test positive for *M. haemofelis* in view of the potential for recrudescence of disease with this hemoplasma species. However, no antibiotic treatment regime exists that is known to predictably eliminate hemoplasma infection with any species of these organisms. Antibiotics typically are given for 4 weeks.

Several antibiotics, notably tetracyclines[75,99] and fluoroquinolones,[99-103] have been shown to be effective in reducing hemoplasma organism numbers in reports in cats and dogs, although the vast majority of studies are with *M. haemofelis* only. Doxycycline (10 mg/kg PO q 24 h for 4 weeks) often is used as a first-line agent for treating hemoplasmosis; longer treatment courses (e.g., 6-8 weeks) are recommended by some clinicians to increase the likelihood of elimination of infection, although longer treatment courses do not guarantee elimination. Because of the possibility of esophagitis in cats, administration of the hyclate preparation of doxycycline always should be followed by food or water. Marbofloxacin (2 to 5.5 mg/kg PO q 24 h [please note different licensed dosages exist in different countries]) or pradofloxacin (3 to 5 mg/kg PO q 24 h [depending on drug formulation]), both fluoroquinolones, can be used as second-line agents. Pradofloxacin could be more effective at clearing *M. haemofelis* infection than doxycycline.[103] Enrofloxacin also is usually effective, but permanent retinotoxicosis has been reported in cats, and so, although this adverse effect is rare, great caution must be exercised with the use of enrofloxacin in cats. Azithromycin was not effective in one study of cats infected with *M. haemofelis* and/or '*Candidatus* M. haemominutum.'[92]

Different hemoplasma species respond to antibiotic treatments differently. Although marbofloxacin resulted in a marked and sustained lowering of blood *M. haemofelis* organisms in cats in one study,[102] a similarly designed study showed only a temporary lowering of numbers of '*Candidatus* M. haemominutum' organisms in blood.[101] Another study suggested that '*Candidatus* M. haemominutum' infection was not treated as effectively with doxycycline as was *M. haemofelis*,[62] and PCR-positive results for '*Candidatus* M. haemominutum' infection were reported in five cats following either enrofloxacin or doxycycline treatment.[22] Little work has been done on the response of '*Candidatus* M. turicensis' infection to antibiotics, but one report described a successful response to doxycycline in a case.[28] Some cases appear to be refractory to antibiotic treatments, and in one *M. haemocanis* case report, oxytetracycline, and then enrofloxacin, treatment, did not markedly reduce organism numbers, although clinical signs did improve.[74] One isolate of the porcine hemoplasma *M. suis* was able to penetrate porcine erythrocytes and its subsequent intracellular location was associated with marked resistance to antibiotic therapy[104]; it is possible that this could occur with hemoplasmas in other species. Occasionally, dual antibiotic therapy (typically doxycycline and marbofloxacin) has been tried, with variable success; it may be worth considering introduction of an additional agent if monotherapy with doxycycline or a fluoroquinolone is inadequate.

Ideally, response to antibiotics should be monitored by qPCR to ensure organism numbers are decreasing with therapy because response to treatment is not predictable. However, repeat qPCR might not be necessary if the patient shows a rapid and favorable clinical response to treatment. Repeated complete blood counts also should be performed. Affected dogs and cats also could require supportive treatment with crystalloids or blood products (blood transfusion or treatment with an oxygen-carrying hemoglobin compound, if available; see ch. 130). Clinical improvement usually occurs within 2 to 3 days of effective treatment.

The use of immunosuppressive dosages of glucocorticoids to suppress the associated immune-mediated hemolytic process is controversial, because treatment with antibiotics and supportive care alone usually is adequate, even in animals with erythrocyte-bound antibodies.[64] Glucocorticoids have the potential to cause reactivation of hemoplasma infection, and in one case, negative PCR results for *M. haemocanis* were only obtained once prednisolone therapy for presumed immune-mediated hemolytic anemia had stopped.[75] However, in cases with a lack of response to antibiotics and persistent erythrocyte-bound antibodies, cautious use of glucocorticoids (e.g., prednisolone 1-2 mg/kg PO q 24 h) can be considered.

Prevention

Blood donors should be screened via PCR for hemoplasma infection to help prevent inadvertent transmission

from asymptomatic carrier cats or dogs. Keeping cats indoors also is likely to prevent infection, as outdoor status has been identified as a risk factor and, in view of the potential for vector transmission, preventive flea and tick treatment is recommended.

CHAPTER 220

Enteric Bacterial Diseases

Stanley Leon Marks

Overview

The Quandary in Confirming a Diagnosis of Enteric Bacterial Diseases

Veterinarians face a quandary when attempting diagnosis of dogs and cats with enteric bacterial disease because isolation rates for putative bacterial enteropathogens are similar in diarrheic and nondiarrheic animals and the incidence of bacterial-associated diarrhea is extremely variable.[1-3] Indications for performing a "fecal enteric panel" in a dog or cat are poorly defined, causing indiscriminate testing and misinterpretation of results. Specific practice guidelines have been published for diagnosis and management of infectious diarrhea in people to improve the cost effectiveness of diagnostic testing and to maximize the diagnostic yield for detection of bacterial enteropathogens.[4]

Although fecal cultures are commonly submitted in people with diarrhea, their usefulness has been questioned because, in part, their diagnostic yield is low.[5,6] 28/260 dogs with diarrhea (10.8%) had positive fecal bacteriologic panels ($650/positive test result).[2] The 28 positive results may have included false-positives, as causality was not established. These tests are relatively insensitive for the most likely pathogens, and results were likely affected by the poor selection of specimens for culture. The advent of real-time polymerase chain reaction (PCR) panels for dogs and cats with diarrhea has provided a new paradigm for rapid and sensitive detection of toxin genes or organisms associated with disease. However, interpretation of these panels can also be problematic because virtually all of these bacterial organisms have been frequently isolated from the feces of clinically healthy dogs and cats. *Bona fide* bacterial enteropathogens of dogs and cats include *Clostridium difficile, Clostridium perfringens, Salmonella, Campylobacter jejuni,* and *Escherichia coli* associated with granulomatous colitis (GC). Available methodologies to detect these enteropathogens lack sensitivity and, in some cases, specificity. Determining etiology in cases of bacterial-associated gastroenteritis is a problem magnified by the challenges of defining what exactly constitutes a pathogen. Many strains of non-*jejuni Campylobacter* spp., *C. difficile, C. perfringens,* and *E. coli* can be detected in the absence of diarrhea.[2,5,6]

Recommendations Regarding Fecal Enteric Panels

The specific indications for performing fecal enteric panels consisting of fecal cultures, toxin analysis, and genotyping are poorly defined. Most veterinary microbiologists recommend enteric panels for dogs and cats developing diarrhea after kenneling or show attendance, in animals with an acute onset of bloody diarrhea in association with evidence of sepsis, and in diarrhea outbreaks occurring in more than one household pet. Since *C. difficile, Campylobacter jejuni,* and *Salmonella* spp. are zoonotic, judicious screening for these organisms is warranted when an immunocompromised person is in close contact with a potentially infected animal or the animal is in contact with children.

Clostridium perfringens

Description

Clostridium perfringens is an anaerobic, spore-forming, Gram-positive bacillus associated with outbreaks of acute, often severe diarrhea in humans, horses, dogs, and cats. The elaboration of four major toxins (alpha, beta, epsilon, and iota) is the basis for typing the organism. There are 5 toxigenic phenotypes, A-E. Each

biotype may also express a subset of at least 10 other established toxins, including *C. perfringens* enterotoxin (CPE), a well-characterized virulence factor whose production is coregulated with sporulation.[7] In recent years, it was shown that a novel toxin, NetB, was produced by most type A isolates from chickens with necrotic enteritis (NE) and to play an important role in the pathogenesis of NE.[8] There is increasing evidence that related necrotizing genes such as *netF* are associated with canine acute hemorrhagic diarrhea syndrome (AHDS).[8a] CPE was detected in the feces of 8/12 dogs that had clinical signs consistent with AHDS. Each of 4 dogs with peracute clinical signs died, and each had fecal specimens positive for CPE. Although several studies have shown an association between immunodetection of CPE in fecal specimens and canine diarrhea, the pathogenesis of *C. perfringens*–associated diarrhea in the dog and cat is not fully understood, as CPE is also detected in up to 14% of nondiarrheic dogs.[1,9] In our experience, no CPE was detected in fecal specimens collected from 51 healthy nondiarrheic cats but was positive in 9/62 (14%) specimens from diarrheic cats. It is important to use caution when interpreting results of fecal enzyme-linked immunosorbent assays (ELISAs) for CPE and *C. difficile* toxin A and B in neonatal kittens, due to the high incidence of positive ELISAs (up to 50%) documented by the author in apparently healthy kittens.

Pathogenesis

CPE is a 35-kDa protein encoded by the *cpe* gene, whose expression is coregulated with sporulation of the organism.[7,9] *Clostridium perfringens* strains that carry a chromosomal *cpe* have primarily been associated with human foodborne disease, whereas strains with a plasmid *cpe* gene have been associated with human nonfoodborne diseases and animal diseases, including canine diarrhea. Nonfoodborne diseases associated with CPE are thought to involve commensal enterotoxigenic strains that are triggered to undergo massive sporulation. The trigger may be one of several factors, including sudden change in diet, antibiotic administration, or coinfection with another intestinal pathogen. Once released into the intestinal lumen, CPE interacts with specific epithelial tight junction proteins, forming a small protein complex of ≈90 kDa, where it then becomes trapped on membrane surfaces.[10] Small CPE complexes then interact with additional host proteins, forming larger complexes. Studies have suggested a ≈155 kDa complex is responsible for the cytotoxic and histopathological damage, which provides CPE access to occludin, causing alterations in tight junction structure and function, leading to paracellular permeability changes that contribute to diarrhea.[10]

Diagnosis

Signs

No gold standard exists for confirming a diagnosis of canine or feline *C. perfringens*–associated diarrhea. Diagnosis in dogs and cats is optimally based on detection of CPE in fecal specimens in conjunction with PCR detection of the enterotoxin gene *(cpe)*.[1] There are no pathognomonic clinical signs for *C. perfringens*–associated diarrhea in dogs. Infection can cause small intestinal, large intestinal, or diffuse clinical signs (see ch. 40).[2] Dogs with *C. perfringens*–associated diarrhea typically have large-bowel diarrhea characterized by increased frequency, tenesmus, fecal mucus, and hematochezia. However, clinical signs of enteritis or enterocolitis are also commonly seen.[2]

CPE, Hematocrit

There appears to be a strong association between ELISA-detected CPE and AHDS.[2] *C. perfringens* warrants consideration in a dog with acute hemorrhagic diarrhea, as a causative or associative enteropathogen. Many dogs with acute hemorrhagic diarrhea associated with CPE have increased hematocrits and low-normal total protein concentrations.

Fecal Culture

Quantitative fecal culture and fecal spore counts are of little diagnostic value, as the organism is isolated from more than 80% of healthy dogs. There is no correlation between spore counts and detection of CPE, or between fecal consistency and detection of CPE.[1,11] A commercially available ELISA kit (Techlab Inc., Blacksburg, VA) for detecting CPE in fecal specimens has not yet been validated in the dog or cat. Further, as many as 14% of healthy dogs have detectable concentrations of CPE, based on this ELISA's results.[1]

Polymerase Chain Reaction (PCR)

PCR detection of enterotoxigenic *C. perfringens (cpe)* was shown to be a valuable diagnostic test when combined with immunodetection of CPE. In that study, fecal specimens from nondiarrheic dogs were far less likely to be positive for both CPE and *cpe* (4%) compared to diarrheic dogs (28%).[1] Quantitation of the alpha toxin gene of *C. perfringens* via RT-PCR is performed to help diagnose *C. perfringens*–associated diarrhea in dogs and cats; however, the alpha toxin gene is often detected and increased in healthy nondiarrheic animals, decreasing the diagnostic utility of this particular test.

Treatment

Animals that are systemically ill (e.g., fever, hemorrhagic gastroenteritis, inflammatory or toxic leukogram) merit appropriate antimicrobial therapy. There is no evidence supporting use of antimicrobial therapy in dogs with uncomplicated diarrhea associated with *C. perfringens.* Antibiotics that have been recommended for the treatment of canine *C. perfringens*–associated diarrhea include ampicillin (22 mg/kg q 8 h for 5 days), metronidazole (10 mg/kg q 12 h for 5 days), and tylosin (5-10 mg/kg q 24 h for 5 days). Tetracycline use should be avoided due to a high incidence (21%) of *in vitro* resistance.[12] Reports touting the benefits of increasing dietary fiber or administering probiotics to infected animals to alter the commensal microflora have not been validated.

Clostridium difficile

Description

Clostridium difficile is a fastidious Gram-positive, anaerobic spore-forming bacillus. It is the most common cause of antibiotic-associated pseudomembranous colitis in people. *Clostridium difficile* has also been associated with diarrhea and enterocolitis in foals, adult horses, and dogs. An outbreak of *C. difficile* infection (CDI) was reported in dogs at a veterinary teaching hospital with an incidence of 19 cases per 1000 admissions.[13] There is far less information about CDI in cats, although it less prevalent than in dogs. ELISA testing for *C. difficile* toxin A was negative in all of 219 diarrheic cats.[14] Two toxins, toxin A (TcdA, an enterotoxin) and toxin B (TcdB, a cytotoxin), are thought to be primarily responsible for the disease, although other toxins may also play a role. In addition, a small percentage of healthy individuals can carry *C. difficile* in their intestinal tracts without any signs of disease.

Pathogenesis

Clinical disease begins with intestinal growth of toxin-producing strains of *C. difficile* followed by release of toxins and subsequent development of disease. In people, antimicrobials may disrupt normal commensal microflora with subsequent overgrowth of toxigenic strains of *C. difficile.* There is no convincing evidence of a similar pathogenesis in dogs or cats. The primary virulence factors involved in the pathogenesis of CDI are TcdA and TcdB.[15] Some *C. difficile* strains can produce a binary toxin (CDT), although its role is unclear.

Diagnosis

Fecal Culture

There are no pathognomonic clinical signs in dogs and cats, although a strong association was found between the detection of *C. difficile* TcdA and the presence of AHDS in dogs, similar to that described for *C. perfringens*.[2] Selective culture media, such as cycloserine cefoxitin fructose agar or *C. difficile* moxalactam norfloxacin agar, should be used, with fecal-direct inoculation or after-broth enrichment. Isolation of the organism alone is not sufficient for diagnosis due to the presence of nontoxigenic strains; however, appropriately processed and cultured specimens that are culture-negative have good negative predictive value. Detection of common antigen (glutamate dehydrogenase), an enzyme produced constitutively by toxigenic and nontoxigenic strains, is a sensitive but nonspecific test commonly performed in human and veterinary laboratories. A recent study evaluating the performance characteristics of the common antigen test in dogs showed a sensitivity of 100% but low specificity. The value of this test is to screen dogs suspected of having CDI.[16]

ELISA and Cell Culture Cytotoxicity Assay (CTA)

Traditionally, diagnosis of CDI is based on detection of TcdA and/or TcdB in fecal specimens via ELISA. Commercially available ELISAs are commonly used in veterinary reference laboratories; however, the performance characteristics of these human-based assays are inconsistent and poor in dogs, with sensitivities ranging from 7-60%.[16] The current gold standard test for CDI is the CTA, which detects TcdB activity.[17] Due to expense and time, it is not routinely used.

Recommended Approach

Diagnosis of CDI in dogs and cats should be based on combination testing, including a positive fecal culture and/or common antigen test, followed by ELISA for detection of TcdA and TcdB. Antigen- or culture-positive but toxin-negative results are difficult to interpret because of the marginal sensitivity of available tests. Positive results indicate a *possible* diagnosis of CDI in an animal with diarrhea and no other identifiable cause, but such testing cannot be considered definitive. There are currently no validated PCR tests for *C. difficile* in dogs and cats. Performing direct PCR from stool can be associated with false-negative results due to PCR inhibitors. Direct PCR for diagnosis of CDI in dogs and cats is not recommended.

Treatment

In general, CDI is treated like any other diarrheal disease. Supportive therapy should be administered based on clinical signs. If CDI is suspected to be antimicrobial-associated, antimicrobial therapy should be stopped if possible. Parenteral antimicrobial therapy rarely is indicated for CDI unless the animal is systemically ill. Metronidazole (10 mg/kg q 12 h for approximately 5 days) is the therapy of choice for dogs and cats with suspected CDI. Although metronidazole-resistant *C. difficile* isolates obtained from foals and adult horses have been reported, a study evaluating the susceptibilities of 70 canine *C. difficile* isolates showed all were susceptible to ≤1 mcg/mL.[12] The second drug of choice in humans and occasionally in horses is vancomycin; however, it is used only in cases of nonresponsive CDI or when metronidazole-resistant strains have been demonstrated.

Campylobacter spp.

Description

Campylobacter spp. are small (0.2 to 0.5 micron × 0.5 to 5 micron), microaerophilic, Gram-negative, curved, slender, rod-shaped bacteria with more than 37 species and subspecies in the genus. Most are thought to be nonpathogenic. *Campylobacter* species implicated in canine enteric disease include *C. jejuni, C. coli, C. helveticus,* and *C. upsaliensis. Campylobacter helveticus* and *C. upsaliensis* are the most common isolates identified in cats. Some selective media have an inhibitory effect on a number of *Campylobacter* spp. This increases the possibility of more sensitive species (*C. upsaliensis* or other catalase-negative or weakly-positive species) being missed.[18] Fecal shedding of *C. jejuni* is significantly greater in puppies <6 months old and during the summer and autumn.[19] The higher prevalence of infection in pups versus adult dogs may reflect their confinement and increased exposure to excrement. In addition, naïve puppy immune systems may increase susceptibility to intestinal colonization by *C. jejuni.* Other enteric pathogens, such as parvovirus, *Giardia,* or *Salmonella* may have synergistic roles. Isolation of *Campylobacter* spp. from a diarrheic animal does not necessarily implicate *Campylobacter* as a cause of the diarrhea. *Campylobacter* spp. was isolated from 21 of 219 (9.6%) diarrheic cats versus 15/54 (27.8%) of nondiarrheic cats, similar to other studies.[14,20,21]

Pathogenesis

Campylobacter spp. have a fecal-to-oral route of transmission either through direct contact or via objects contaminated with feces. Various virulence factors are associated with colonization, adhesion, invasion, persistence within the host, and host cell damage. The cause of diarrhea due to *Campylobacter* infection is poorly understood, and the only exotoxin characterized in *Campylobacter* is cytolethal distending toxin, or CDT.[22] This toxin has 3 proteins, CdtA, CdtB, and CdtC, all of which are required for cellular damage. A bowel neutrophilic inflammatory response has been described in association with *Campylobacter* infection, and active intestinal fluid secretion may be due to *Campylobacter* products that increase cAMP, prostaglandin E_2, and leukotriene B_4.

Diagnosis

Fecal Examination

Dogs and cats are often healthy carriers of *Campylobacter* species. If ill, clinical signs include anorexia, occasional vomiting, and watery to bloody diarrhea with mucus. The animal can be febrile, and severely affected animals can be lethargic and dehydrated. Diagnosis is confirmed via several different methodologies, beginning with examination of a direct-stained fecal smear (Gram stain or Romanowsky-type stain) for the organism's characteristic appearance (slender, curved rods with an "S" shape or seagull–shaped appearance). The major limitation of direct examinations is that the procedure fails to differentiate among *Campylobacter* spp. or between it and related organisms including *Helicobacter* spp., and *Anaerobiospirillum* spp. In addition, identification of *Campylobacter*-like organisms (CLOs) alone on a stained fecal smear is not sufficient to warrant a diagnosis of *Campylobacter*-associated diarrhea, as many healthy dogs and cats can harbor CLOs in their intestinal tract.[2]

Fecal Culture

For optimal recovery of *Campylobacter* spp., feces or fecal swabs should be fresh or placed immediately into anaerobic transport medium before refrigeration at 4° C. For isolation, use of a formulated selective medium containing antimicrobial agents (e.g., Campy-CVA containing cefoperazone, vancomycin, and amphotericin B) is recommended over other direct-plating selective media. Microaerophilic incubation conditions should be maintained, and the plates incubated at 37° C, or at 42° C, when isolation of *C. jejuni* and *C. coli* from feces is attempted. Suspect colonies should be Gram-stained and subcultured to 5% SBA. Biochemical tests can then be performed to speciate all *Campylobacter*-like organisms isolated. The selective medium containing cefoperazone should be used when attempting to isolate *C. upsaliensis*, as the organism is more resistant to cefoperazone than to cephalothin.[23]

Molecular Techniques

Several molecular techniques have been used to identify and differentiate *Campylobacter* spp. These assays include direct sequencing of the 16S rDNA and comparison with databases such as GenBank, DNA hybridization with probes specific for different species, PCR amplification of specific regions of 16S rDNA or the *lpx*A gene, and amplified fragment length polymorphism. These tests may aid in differentiating a variety of *Campylobacter* species, such as *C. coli, C. jejuni, C. lari,* and *C. upsaliensis*.[21]

Treatment

The majority of cases are uncomplicated, self-limiting and resolve with supportive therapy. Because isolation of *Campylobacter* does not confirm causation, treatment may not be warranted. Antibiotics may further disrupt intestinal microflora. However, in animals that are immunocompromised, febrile, or with evidence of hemorrhagic diarrhea, antimicrobial treatment may be indicated. It is now recognized that *Campylobacter* are a leading cause of enteric disease in people and that diarrheic and nondiarrheic dogs can serve as sources of infection for humans.[24] The drugs of choice are the macrolides (erythromycin at 10 to 15 mg/kg q 8 h) or fluoroquinolones (enrofloxacin at 10 mg/kg q 24 h). Fluoroquinolones are not used initially due to their high rate of mutational resistance. The macrolides such as erythromycin (10-20 mg/kg q 8 h for 7 days, despite possible gastrointestinal side-effects) or azithromycin (5-10 mg/kg q 24 h for 7 days) are the drugs of choice.[25] Bacterial shedding can last as long as 4 months. Infected animals should be quarantined away from children for this period.

Salmonella spp.

Description

The salmonellae are Gram-negative, motile, non–spore-forming facultative anaerobic bacilli belonging to the family *Enterobacteriaceae.* The genus *Salmonella* consists of only 2 species, *Salmonella enterica* and *Salmonella bongori. S. enterica* is divided into 6 subspecies: *S. enterica* subsp. *enterica, S. enterica* subsp. *salamae, S. enterica* subsp. *arizonae, S. enterica* subsp. *diarizonae, S. enterica* subsp. *houtenae* and *S. enterica* subsp. *indica.*[26] *Salmonella* spp. are among the most common causes of human foodborne disease: an estimated 1.4 million cases occur annually in the United States.[27] Clinical salmonellosis in dogs and cats is rare, although the prevalence is

higher in puppies and kennel populations. Isolation of *Salmonella* spp. from adult dogs range from 0 to 2% in nondiarrheic and 0 to 1% in diarrheic dogs.[2] Isolation rates are similar in nondiarrheic and diarrheic cats. *Salmonella* was isolated from 80% of raw chicken diet samples and from 30% of the stool samples from dogs fed these diets.[28]

Pathogenesis

Salmonella infections begin with ingestion of organisms in contaminated food or water, followed by invasion of M-cells in the Peyer's patches. *Salmonella* express several fimbriae that contribute to their ability to adhere to intestinal epithelial cells.[29] *Salmonella* pathogenicity islands (SPI-1 and SPI-2) encode the genes necessary for the invasion of intestinal epithelial cells, induction of intestinal secretory and inflammatory responses, intracellular replication, and establishment of systemic infection.[30] *Salmonella* spp. inject an array of bacterial effector molecules into host cytoplasms, triggering reorganization of actin cytoskeletons and resultant membrane ruffling. Cell internalization of *Salmonella* occurs within minutes of bacterial contact. Invasion is followed by inflammation, influx of neutrophils and macrophages, and consequent secretory diarrhea. This is likely mediated by activation of inositol-signaling pathways within affected host cells. The presence or absence of additional virulence factors plays an important role in determining whether septicemia occurs.

Clinical Signs

Signs of clinical salmonellosis in dogs and cats are typically acute and characterized by fever, malaise, anorexia, diarrhea, and vomiting. The diarrhea is frequently watery or mucoid and can be bloody. Most *Salmonella*-infected dogs and cats are asymptomatic, although some animals may manifest clinical signs of sepsis (see ch. 132).

Diagnosis

The traditional diagnosis of salmonellosis is made based on isolation of the organism in conjunction with clinical signs and assessment of potential risk factors such as hospitalization, age, environmental exposure, and antibiotic administration. However, isolation of *Salmonella* is not necessarily indicative of its involvement, as similar isolation rates can be detected in healthy nondiarrheic animals.[2] Hematological abnormalities are variable and include a nonregenerative anemia, lymphopenia, thrombocytopenia, and neutropenia with a left shift. Toxic neutrophils may be seen in animals with systemic disease and endotoxemia, findings similar to those documented with canine parvovirus (see ch. 225). Fresh fecal specimens should be placed onto one or more selective media, including MacConkey agar, XLD agar, and brilliant green agar. For enrichment, selenite F broth, tetrathionate broth, or Gram-negative (GN) broth is recommended. Biochemical testing can be used to identify presumptive *Salmonella* colonies, followed by serological testing of isolates for further discrimination. Conventional and real-time PCR are promising diagnostic tools that are increasingly used by reference laboratories.

Treatment

It is widely accepted (although supportive scientific evidence is lacking) that the administration of antimicrobials is not warranted for uncomplicated episodes of *Salmonella* infection. Only supportive therapy is recommended. Intravenous fluid therapy may be required depending on the severity of the diarrhea. Antibiotics reported to be effective against *Salmonella* include fluoroquinolones, chloramphenicol, trimethoprim-sulfonamide, and amoxicillin.[31] Salmonellosis is a disease of major zoonotic importance, and all *Salmonella* organisms with the exception of those causing human typhoid fever infect humans and animals.

Enteric *Escherichia coli (E. coli)* Infections

Description

E. coli is a pleomorphic, Gram-negative, non–spore-forming bacillus. It is a member of the family *Enterobacteriaceae*. *E. coli* is among normal intestinal microflora but can be associated with gastroenteritis in the presence of bacterial virulence factors and impaired local or systemic immunity. Seven distinct pathogenic categories (pathovars) of diarrheagenic *E. coli* are recognized, each defined by a characteristic set of virulence

factors acquired by horizontal gene transfer that act in concert to determine the clinical, pathologic, and epidemiologic features of the diseases they cause. The 7 pathovars include enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enterohemorrhagic *E. coli* (EHEC), necrotoxigenic *E. coli* (NTEC), enteroinvasive *E. coli* (EIEC), enteroaggregative *E. coli* (EAEC), and adherent-invasive *E. coli* (AIEC) strains.[32-34] Many strains have been isolated from dogs with and without diarrhea, and the role of many of these strains in ill dogs and cats is poorly defined. In contrast, there is evidence for the role of AIEC strains in susceptible dog breeds such as the Boxer, French Bulldog, and the Border Collie. Little is known about pathogenic *E. coli* in cats, although EPEC was isolated from approximately 5% of samples from cats with diarrhea, enteritis or septicemia.

Escherichia coli Associated With Granulomatous Colitis

Overview

Granulomatous colitis (histiocytic ulcerative colitis; GC) of Boxer dogs was first described by Van Kruiningen in 1965.[35] The colonic lesion also has been described infrequently in the French Bulldog and the Border Collie. Historically, GC of Boxer dogs was considered an idiopathic immune-mediated disease with a poor prognosis. Poor response to immunosuppression, however, led to reassessment of antibiotic therapy, and there is now convincing evidence documenting dramatic improvement in clinical signs and histological lesions of Boxer dogs treated with enrofloxacin.[36,37] Documentation of periodic acid–Schiff (PAS)-staining positive macrophages in people with Whipple's disease together with the dramatic response to antibiotics in Boxer dogs with a similar enteropathy precipitated the search for an infectious agent.

Diagnosis

Affected Boxer dogs typically have a history of severe large bowel diarrhea often accompanied by marked weight loss, inappetence, and loss of body condition. Hematological changes often are mild and nonspecific, but dogs with severe GC can develop microcytic anemia caused by chronic blood loss. Boxer dogs with GC commonly are hypoalbuminemic. Histopathologic lesions in Boxers with GC are pathognomonic and include mucosal infiltration with large numbers of PAS-positive macrophages, evidence of mucosal ulceration and loss of goblet cells.[35] Colonic biopsies are warranted in Boxer dogs with signs of colitis to eliminate other causes of colitis and to optimize therapy when culture and sensitivity testing of mucosal biopsies is feasible. The identification of Gram-negative coccobacilli within macrophages can be confirmed using fluorescent in situ hybridization (FISH) probes.[35] Colonic tissue culture can be used to isolate *E. coli* and optimize antibiotic selection given the increasing incidence of antibiotic resistance in Boxers.[36]

Treatment

Dogs with GC can show dramatic responses to treatment with enrofloxacin (10 mg/kg q 24 h for 8 weeks). Administration of fluoroquinolones is usually associated with rapid resolution of both clinical signs and the cellular infiltrative nature of this disorder. Antimicrobials that penetrate intracellularly, such as chloramphenicol and trimethoprim-sulfonamides, are potentially viable alternatives for management of dogs with GC, particularly in resistant cases. Drugs should be selected based on results of susceptibility testing.

Zoonotic Implications of Enteric Bacteria

Clostridium Perfringens

There have been no documented cases of zoonotic transmission from dogs or cats. Contaminated food products can lead to enterotoxemia, underscoring the importance of adequate hygiene.

Clostridium Difficile

The risk of zoonotic transmission is currently unclear, and transmission of *C. difficile* from animals to humans has not been documented. Nevertheless, it is recommended to assume that *C. difficile* is potentially zoonotic because the strains of *C. difficile* that infect dogs are often indistinguishable from those found in people with CDI.

Campylobacter spp.

Campylobacter spp. are potentially zoonotic from dogs to humans with subsequent development of diarrhea.[38] An estimated 6.3% of 218 human cases of *C. jejuni* or *C. coli* enteritis was attributed to exposure to diarrheic animals. Other sources of infection in people include consumption of contaminated food and food products, water and raw milk. Pasteurization of milk and thorough cooking of meats and poultry carcasses destroys *C. jejuni.*

Salmonella spp.

Most human *Salmonella* infections are acquired by handling or consuming contaminated food products, particularly foods of animal origin. Infections also are acquired by direct and indirect contact with farm animals, reptiles, chicks, and occasionally, pets. Infected animals usually shed *Salmonella* organisms in their feces.

Escherichia Coli

The potential for zoonotic transmission is unclear; however, some of the strains of pathogenic *E. coli* found in dogs and cats are indistinguishable from those found in people. While this does not confirm a zoonotic risk, it is prudent to treat cases of *E. coli* diarrhea as potentially zoonotic. This is particularly true for *E. coli* O157 because of the potential for severe disease in humans and the very low infective dose. Careful attention to hand hygiene, the use of contact precautions and proper cleaning and disinfection is important.

Hospital Infection Control (see ch. 209)

Dogs and cats diagnosed with *C. perfringens, C. difficile, Campylobacter jejuni, Salmonella* spp., or *E. coli*–associated diarrhea should be housed under contact precautions in an isolation area. Direct and indirect contact should be prevented between infected animals and all other animals. Barrier precautions, consisting of a gown and gloves, should be used when handling infected animals. Hands should be washed thoroughly with bactericidal soap and water after any contact with the animal or the isolation environment, even when gloves have been worn. Hand washing is recommended over alcohol-based hand sanitizers, especially when working with *C. difficile*–infected animals, because the spores are alcohol-resistant. Spores can survive up to 70 days in the environment and can be transported on the hands of staff members who have direct contact with other patients.

Strict adherence to hand washing techniques and the proper handling of contaminated wastes are effective in preventing the spread of the disease. Infected animals should be walked in an area separate from other patients, and feces should be promptly removed. *Clostridium difficile* spores are highly resistant to most disinfectants. Bleach (1 : 10 to 1 : 64 dilution of regular household bleach) has good sporicidal activity, as long as there is minimal organic debris and there has been adequate contact time. Bleach is an effective disinfectant for *Salmonella* and *Campylobacter,* and one can make a solution of household bleach and water by adding ¼ cup bleach to 1 gallon of water, or to make a smaller amount in a spray bottle, add 1 tablespoon bleach to 1 quart of water. Saturate area with solution. DO NOT rinse. Air dry.

Protozoal Diseases

OUTLINE

Chapter 221 Protozoal Infections

CHAPTER 221

Protozoal Infections

Michael R. Lappin

Multiple pathogenic protozoans infect dogs and cats. The group can be divided into amoeba, ciliates, coccidians, flagellates, Microspora, and Piroplasmida. Protozoans generally cause either gastrointestinal (GI) tract disease (enteric protozoans)[1,2] or polysystemic disease.[3]

Enteric Protozoal Diseases

The most common protozoal agents infecting the GI tract of dogs and cats are:

- The flagellates, *Giardia* spp. *Tritrichomonas foetus (blagburni),* and *Pentatrichomonas hominis;*
- The coccidians, *Besnoitia* spp., *Cryptosporidium* spp., *Cyclospora cayetanensis, Cystoisospora* spp., *Hammondia* spp., *Neospora caninum, Sarcocystis* spp., and *Toxoplasma gondii;*
- The ciliate, *Balantidium coli;* and
- The amoeba, *Entamoeba histolytica*.

Cystoisospora spp., *Sarcocystis* spp., *Besnoitia* spp., *Hammondia* spp., *N. caninum,* and *T. gondii* complete the intestinal cycle in only one species. Some isolates of *Cryptosporidium* spp., *C. cayetanensis, Giardia* spp., *E. histolytica,* and *B. coli* will replicate in multiple warm-blooded vertebrates and therefore can potentially be zoonotic. In addition, *N. caninum* antibodies have been detected in some people[4,5] and DNA of *T. foetus* was amplified from the feces of a person,[6] findings that also suggest zoonotic transmission.

With the exception of *C. cayetanensis,* for which the route of transmission is unknown, fecal-oral transmission occurs with the enteric protozoans. The coccidians produce oocysts. *Cryptosporidium* spp. oocysts are immediately infectious when passed by the host; *T. gondii, N. caninum,* and *Cystoisospora* spp. must sporulate outside the host to be infectious (Figure 221-1).

FIGURE 221-1 Sporulated oocysts of *Toxoplasma gondii* from feces of a cat. The oocysts measure approximately 8 microns × 10 microns.

In the flagellate group, both trophozoites and cysts of *Giardia* spp. are potentially infectious; however, transmission occurs most frequently after ingestion of cysts because gastric secretions generally kill trophozoites. Only trophozoites are detected in cats or dogs with *T. foetus* or *P. hominis* infections. Ingestion of the organism in the tissues of transport hosts can also result in infection by *Cystoisospora* spp., *Besnoitia* spp., *Hammondia* spp., *N. caninum,* and *T. gondii* (Figure 221-2).

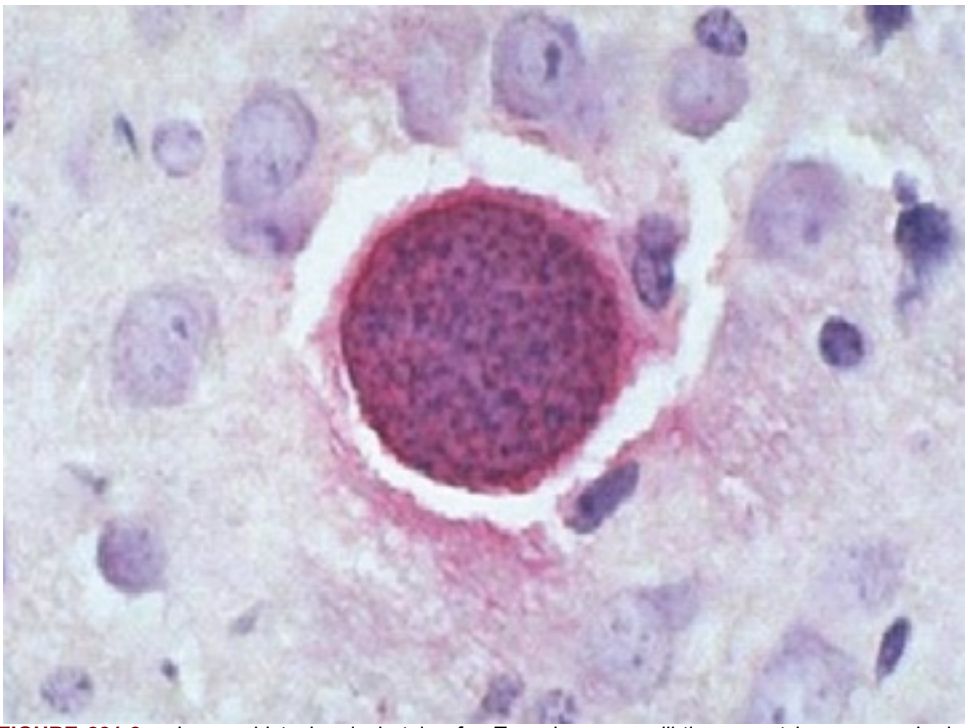

FIGURE 221-2 Immunohistochemical stain of a *Toxoplasma gondii* tissue cyst in a mouse brain. The cyst is approximately 100 microns in diameter and contains approximately 500 organisms.

Carnivorism can result in infection by other enteric protozoans like *Cryptosporidium* spp., *Giardia* spp., *E. histolytica,* and *B. coli* if the organisms are present in the intestines of the prey species. The gastrointestinal phase of infection can be self-limiting for each of the agents; however, fecal shedding periods are variable. After tissue cyst ingestion, infected cats rarely shed oocysts of *T. gondii* for more than 2 weeks.[7] For the other enteric protozoans, fecal shedding can be of longer duration. For example, cats infected with *T. foetus* or *Cryptosporidium* spp. can shed the organisms continuously or intermittently for months.

The enteric protozoans have worldwide distribution. Because they are maintained in nature primarily by fecal-oral transmission, more cases are associated with crowded and unsanitary environments. In general, *Giardia* spp., *T. gondii, N. caninum, Cystoisospora* spp., *Cryptosporidium* spp., and *T. foetus* (cats) infections are common[8-18] and *E. histolytica, B. coli,* and *C. cayetanensis* infections are thought to be rare.[19-22] However, in a 2015 study in Pakistan, *Entamoeba* spp. cysts were identified in 94 of 600 dog fecal samples[23] and *E. histolytica* cysts are found in public parks in Spain.[24] Currently it is unknown how many dogs and cats harbor *P. hominis.*[25,26] Antibodies against *T. gondii* (30%) and *Cryptosporidium* spp. (8.3%) are commonly detected in serum from client-owned cats, suggesting that exposure is common (Figure 221-3).[27,28] Prevalence of the agents varies by region in coprologic studies.

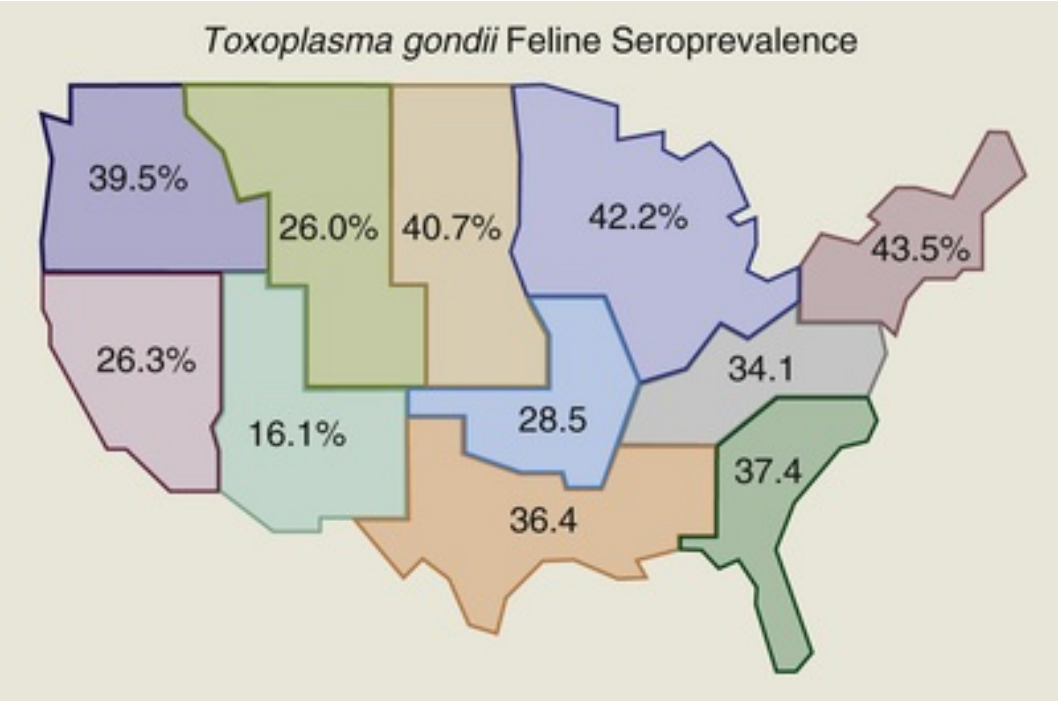

FIGURE 221-3 Map of the United States showing the distribution of *Toxoplasma gondii* antibody test results in cats. (From Vollaire MR, Radecki SV, Lappin MR: Seroprevalence of *Toxoplasma gondii* antibodies in clinically ill cats in the United States. *Am J Vet Res* 66:874-877, 2005.)

Pathogenic mechanisms have not been ascertained for each of the enteric protozoans. *Cystoisospora* spp. and *T. gondii* replicate in intestinal cells and may result in clinical illness from cell destruction. Tissue invasion also can occur with *E. histolytica.*[21,22] *Giardia* spp. and *Cryptosporidium* spp. are found on the surface of enterocytes, so pathogenesis is unlikely secondary to direct cell damage. Some of the pathogenic mechanisms proposed for these enteric agents include production of toxins, disruption of normal flora, induction of inflammatory bowel disease (IBD), inhibition of normal enterocyte enzymatic function, blunting of microvilli, and induction of motility disorders. *Cystoisospora* spp. and *T. foetus* infections are more commonly associated with clinical GI disease in puppies or kittens. *Sarcocystis* spp., *Besnoitia* spp., *Hammondia* spp., *T. gondii,* and *N. caninum* are almost never associated with GI disease. Clinical illness associated with *T. gondii, N. caninum,* and *Sarcocystis* spp. generally results from the tissue phase of the infections.[7,29-32] *Giardia* spp. and *Cryptosporidium* spp. infections are common in young animals, but GI signs can occur in animals of any age. Clinical disease is more common, and duration of organism shedding into the environment may be prolonged in dogs and cats with immunodeficiency-inducing concurrent diseases.

Owner concerns in dogs or cats with enteric protozoal infections generally are vomiting, inappetence, or diarrhea; fever is uncommon. *Giardia* spp., *Cryptosporidium* spp., and *T. gondii* infections are most commonly associated with small-bowel diarrhea; *E. histolytica, B. coli,* and *T. foetus* infections are most commonly associated with large-bowel diarrhea. *Cystoisospora* spp. infections can cause clinical signs of large- or small-bowel diarrhea. Physical examination findings in dogs or cats with enteric protozoal infections are nonspecific but can include abdominal discomfort, increased gas or fluid in the intestinal tract, or thickened intestinal loops.

All dogs and cats with large-, small-, or mixed-bowel diarrhea should be assessed for enteric protozoal infections. Diagnosis of GI protozoal infection is based primarily on documentation of oocysts, trophozoites, or cysts on direct fecal examination or fecal flotation (see ch. 81).

A direct smear of diarrheic stool can be used to examine for trophozoites of *E. histolytica, B. coli, Giardia* spp., *P. hominis,* or *T. foetus*. More frequently, a small quantity of fresh feces or mucus is mixed with a drop of 0.9% NaCl on a clean microscope slide and examined at 100× after placing a coverslip. When a motile organism is noted, examining at 400× assesses structural features. Application of a stain such as Lugol's solution, methylene blue, or acid methyl green to the wet mount at the edge of the coverslip will aid in visualizing internal structures of protozoa. Trophozoites are rarely found in formed stools. Duodenal aspiration for cytologic examination for *Giardia* trophozoites is effective for the diagnosis of giardiasis in the dog. However, this technique is not effective in the cat because the organism lives in the distal small intestine.

Protozoal cysts or oocysts are best demonstrated after fecal concentration; Sheather's sugar centrifugation and zinc sulfate centrifugation are inexpensive techniques commonly used in clinical practice (see ch. 81).[33] These solutions are inexpensive and generally effective. Sugar solution is hypertonic and will distort *Giardia* spp. cysts; the cytoplasm is pulled to one side and appears as a half- or quarter-moon.

Due to small size and limited number in feces of infected dogs and cats, *Cryptosporidium* spp. oocysts are almost never seen when concentrated feces are examined at 100×. Acid-fast staining or fluorescein-labeled monoclonal antibody staining of a fecal smear and fecal polymerase chain reaction (PCR) assay can aid in the diagnosis of cryptosporidiosis in dogs and cats.[34,35] Oocysts stain pink with acid-fast stain (Figure 221-4).

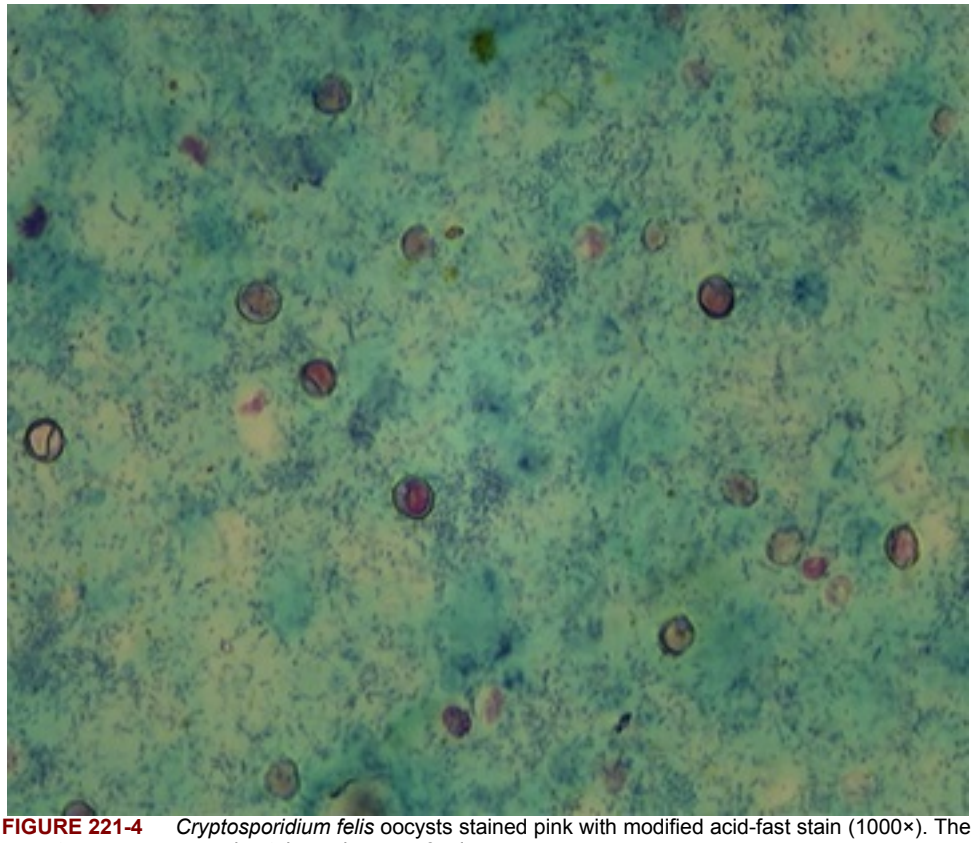

FIGURE 221-4 *Cryptosporidium felis* oocysts stained pink with modified acid-fast stain (1000×). The oocysts measure approximately 4 microns × 6 microns.

The fluorescein-labeled monoclonal antibody system also detects *Giardia* spp. cysts of dogs and cats, and so this test is an excellent screening procedure for dogs or cats with small-bowel diarrhea. Enzyme-linked immunosorbent assay (ELISA) for detection of *Cryptosporidium* spp. antigens in feces is generally inaccurate as it is based on antibodies against *C. parvum;* it is now known most dogs are infected with *C. canis* and most cats are infected with *C. felis*.[36,37] In addition, while zoonotic assemblages of *Giardia* are occasionally amplified from dog or cat feces, most small animals carry dog or cat assemblages.[36-38] Antigens of *Giardia* spp. can be detected in feces by ELISA, and these assays appear to be accurate for use with dog and cat feces.[39,40] However, *Giardia* antigen assays are best used in combination with fecal flotation, which detects more parasites overall.[40] PCR assays for the amplification of *Giardia* spp. and *Cryptosporidium* spp. DNA from feces are offered by multiple diagnostic laboratories in the United States. However, the sensitivity, specificity, and predictive values of these assays are generally unknown and there is no standardization between laboratories at this time. In general, these assays are not indicated unless the animal is known to be positive and the clinician or owner wishes to determine the genotype of the organism. PCR assays are also available for *T. foetus* and *P. hominis*. While fecal culture can also be used to identify *T. foetus (blagburni),* PCR assay results are returned more quickly.

The presence of enteric protozoans in diarrheic stool does not prove that disease was due to the organism. Some enteric protozoans, especially *Giardia* spp., *Cryptosporidium* spp., *T. foetus,* and *Cystoisospora* spp., live chronically in the intestinal tract of normal animals; other conditions causing GI tract disease can induce repeat shedding. Thus, animals with enteric protozoal infections that do not respond to therapy should be evaluated for underlying causes of disease. *Giardia* spp., *Cryptosporidium* spp., *Cystoisospora* spp., and *Sarcocystis* spp. are commonly found in animals with normal stools.

Withholding food for 24 hours is indicated for animals with acute vomiting but feeding is initiated as soon as possible (see ch. 39). Highly digestible, bland diets are used most frequently if vomiting and small-bowel diarrheas are the primary manifestations of disease (see ch. 276). High-fiber diets are generally indicated if large-bowel diarrhea is occurring (see ch. 277). However, feeding a high-fiber diet may also aid in the treatment of giardiasis due to inhibition of trophozoite attachment to duodenal epithelial cells. Use of probiotics may also have clinical benefit in some cases (see ch. 167).[41-44]

Optimal treatments for *E. histolytica* and *B. coli* infections in dogs or cats are unknown. *Giardia* spp. infections of dogs and cats generally respond clinically to the administration of metronidazole, fenbendazole, or febantel-pyrantel-praziquantel, but infection is usually not eliminated.[45-53] Metronidazole also helps correct the anaerobic bacterial overgrowth or *Clostridium perfringens* overgrowth that commonly accompanies giardiasis. In addition, metronidazole may also be beneficial due to inhibition of lymphocyte function. In a recent study of cats, administration of liquefied metronidazole benzoate at 25 mg/kg PO q 12 h for 7 days was 100% effective during the time period studied.[48] Central nervous system (CNS) toxicosis occasionally occurs with this drug; it is unlikely if no more than 50 mg/kg is given orally per day.[54,55] Secnidazole was used at 30 mg/kg PO once for the treatment of *Giardia* in 17 cats; increased liver enzyme activities were reported for 1 cat.[56] This drug could be an option for difficult-to-treat cats but more controlled studies should be performed to evaluate safety. Fenbendazole (50 mg/kg PO q 24 h for 3 to 5 days) and albendazole are commonly prescribed alternate anti-*Giardia* spp. drugs; albendazole is associated with neutropenia in dogs and cats and so should not be used.[57,58] Furazolidone (cats), paromomycin (dogs or cats), and nitazoxanide (dogs or cats) are other drugs with anti-*Giardia* effects. Lastly, use of the commercially available *Giardia* spp. vaccines as immunotherapy has given variable treatment responses; this vaccine is still available in some countries but not the United States (see ch. 208).[59,60]

The majority of drugs prescribed to cats with diarrhea due to *T. foetus (blagburni)* has failed. Recently, ronidazole and tinidazole have been evaluated, with ronidazole administered at 25 mg/kg PO q 24 h for 14 days appearing to be the most likely to eliminate infection.[61-65] However, ronidazole can be neurotoxic.[66] In addition, some *T. foetus (blagburni)* are resistant to tinidazole and ronidazole is not always effective.[63,65] In one case series of 104 cats, only 64% were graded as good responses to ronidazole.[65]

Paromomycin, tylosin (10 to 15 mg/kg PO q 12 h), azithromycin (10 mg/kg PO q 24 h), and nitazoxanide (25 mg/kg PO q 12 h) have all been used to lessen diarrhea in dogs, cats, calves or people with cryptosporidiosis, but no treatment has consistently stopped *Cryptosporidium* spp. oocyst shedding.[67-72] The drugs are generally prescribed initially for 7 to 10 days. However, it sometimes takes as long as 4 to 6 weeks to achieve total resolution of diarrhea. The most commonly prescribed drugs to treat *Cystoisospora* spp. infections of dogs and cats are trimethoprim-sulfonamide, sulfadimethoxine, furazolidone, amprolium, or amprolium-sulfadimethoxine. Quinacrine, spiramycin, toltrazuril, roxithromycin, and ponazuril have been

used on a limited basis. Ponazuril appears to be safe in most puppies and kittens and can eliminate infection after one dose (50 mg/kg PO). However, administration of ponazuril daily for 3 days at 50 mg/kg was the most effective protocol in one study.[73]

Cryptosporidium spp., *T. gondii, Giardia, E. histolytica,* and *B. coli* are potentially zoonotic (see ch. 210). *Entamoeba histolytica* and *B. coli* infections are extremely uncommon, and pets are unlikely sources of human infections.[74-80] Most people are infected with *Cryptosporidium* spp. or *Giardia* spp. from contaminated food or water, not contact with pets.[74] It is now known that *Cryptosporidium* spp. and *Giardia* spp. exist that are specific to people or pets. However, most people, cats, and dogs are infected with host-specific genotypes, so zoonotic transmission appears to be unlikely. However, some dogs and cats are infected with human genotypes, suggesting shared infection can occur.[77,78] Therefore, infected animals, particularly those with diarrhea, should be managed as a potential zoonotic risk. Genotyping for both *Cryptosporidium* spp. and *Giardia* spp. is commercially available (Veterinary Diagnostic Laboratory, Colorado State University, Fort Collins, CO). As no drugs eliminate *Cryptosporidium* spp., treatment of subclinical carriers is likely of no benefit. Whether to treat normal dogs or cats with *Giardia* infection continues to be controversial.[80]

Polysystemic Protozoal Diseases

The most common protozoal agents inducing disease in dogs or cats are the coccidians *Hepatozoon americanum, Neospora caninum,* and *Toxoplasma gondii,* the flagellates *Leishmania* spp. and *Trypanosoma cruzi,* and the piroplasms *Cytauxzoon felis* and *Babesia* spp. *Acanthamoeba castellanii* and *A. culbertsoni* are free-living amoebae rarely associated with disease in dogs.[81-85] *Encephalitozoon cuniculi* is a microspora that may be common based on seroprevalence.[86] The organism has been detected in some clinically ill dogs and cats, but infection appears to be uncommon.[87-90] Uveitis potentially associated with *E. cuniculi* has been detected in dogs and cats and further study in this area is indicated.[88a,88b,89] *Encephalitozoon cuniculi* was not associated with feline chronic kidney disease in one study.[90] *Pneumocystis carinii* (see ch. 202 and 242) is a saprophytic organism with worldwide distribution that has characteristics of protozoans, yeast, and fungi that has been detected in diseased dogs that generally have some form of immune function deficit.[91-96]

Coccidians

Hepatozoonosis

Hepatozoon canis and *H. americanum* both infect dogs.[97-102] In North America, *H. americanum* predominates, but *H. canis* and mixed infections have been detected.[102] *Hepatozoon americanum* is transmitted by *Amblyomma maculatum* and is most common in the Texas Gulf Coast, Mississippi, Alabama, Georgia, Florida, Louisiana, and Oklahoma.[98,101-103] In Africa, southern Europe, and Asia, *H. canis* predominates and is transmitted by *Rhipicephalus sanguineus*. A *Hepatozoon* species is occasionally found in the blood of cats in Europe.[104-106] The tick ingests the organism from infected dogs during a blood meal and oocysts develop. After a dog ingests an infected tick, sporozoites are released and infect mononuclear phagocytes and endothelial cells of the spleen, liver, muscle, lungs, and bone marrow, and they ultimately form cysts containing macromeronts and micromeronts. *Hepatozoon americanum* can also be transmitted to dogs by predation.[107,108] Clinical disease results from pyogranulomatous inflammation; glomerulonephritis or amyloidosis may occur secondary to chronic inflammation and immune-complex disease.

H. americanum has resulted in illness in all age groups, but disease is most commonly recognized in puppies.[109-113] Fever, weight loss, and severe hyperesthesia over the paraspinal regions are common findings. Anorexia, pale mucous membranes from anemia, depression, oculonasal discharge, and bloody diarrhea occur in some dogs. Clinical signs can be intermittent and recurrent.

Neutrophilic leukocytosis (20,000 to 200,000 cells/mcL) with a left shift and normocytic, normochromic nonregenerative anemia are the most common hematologic findings. Thrombocytopenia is unusual unless coinfection with *Ehrlichia canis* or *Anaplasma* spp. occurs. Increased activity of alkaline phosphatase, hypoalbuminemia, hypoglycemia, and, rarely, polyclonal gammopathy occur in some dogs. Inflammatory reactions directed at tissue phases in muscle result in periosteal reactions that can occur in any bone except the skull. These reactions do not occur in every case and are most common in young dogs. Presence of serum antibodies against *H. americanum* were compared with tissue biopsy; the sensitivity and specificity were 93% and 96%, respectively.[114] Definitive diagnosis is based on identification of gamonts in neutrophils or

monocytes in Giemsa- or Leishman-stained blood smears or by demonstration of the organism in muscle biopsy sections (Table 221-1). In one study, DNA of *H. americanum* (27.2%), *H. canis* (2.3%), or DNA of both organisms (2.3%) were amplified by PCR assay from blood of 614 dogs suspected hepatozoonosis.[115]

TABLE 221-1

Characteristic Cytologic Morphology of Small Animal Systemic Protozoal Agents

AGENT	MORPHOLOGIC CHARACTERISTICS
Babesia canis	Paired piroplasms (2.4 × 5 micron) in circulating red blood cells
Babesia gibsoni	Single piroplasms (1 × 3.2 micron) in circulating red blood cells
Cytauxzoon felis	Piroplasms (1 × 1.5 micron "signet ring" form; 1 × 2 micron oval form; 1 micron round form) in circulating red blood cells; macrophages or monocytes of lymph node aspirates, splenic aspirates, or bone marrow
Hepatozoon canis and *H. americanum*	Gamonts in circulating neutrophils and monocytes
Leishmania spp.	Ovoid to round amastigotes (2.5-5 × 1.5-2 micron) in macrophages found on imprints of exudative skin lesions, lymph node aspirates, or bone marrow aspirates
Neospora caninum	Free or intracellular (macrophages or monocytes) tachyzoites (5-7 × 1-5 micron) in cerebrospinal fluid, airway washings, or imprints of cutaneous lesions
Toxoplasma gondii	Free or intracellular (macrophages or monocytes) tachyzoites (6 × 2 micron) in pleural effusions, peritoneal effusions, or airway washings
Trypanosoma cruzi	Flagellated trypomastigotes (1 flagellum; 15-20 microns long) free in whole blood, lymph node aspirates, and peritoneal fluid

While clinical signs of hepatozoonosis rapidly resolve with drug therapy, no therapeutic regimen has been shown to eliminate *H. canis* or *H. americanum* infection from tissues. For treatment of *H. americanum,* the combination of trimethoprim-sulfadiazine (15 mg/kg PO q 12 h), pyrimethamine (0.25 mg/kg PO q 24 h), and clindamycin (10 mg/kg PO q 8 h) for 14 days is very successful in the acute stage.[112] Use of decoquinate (10 to 20 mg/kg q 12 h) with food lessens the likelihood of recurrence of clinical disease and prolongs survival time. Imidocarb dipropionate (5 to 6 mg/kg IM or SC once or twice, 14 days apart) is the drug of choice for treatment of *H. canis* and may also be effective for *H. americanum.* Administration of nonsteroidal antiinflammatory agents may lessen discomfort for some dogs (see ch. 164).

Tick control is the best form of prevention. Glucocorticoid administration should be avoided because it may exacerbate clinical disease. No evidence exists for zoonotic transfer of *H. americanum* or *H. canis* from infected dogs to people.

Neosporosis

Neospora caninum is a coccidian previously confused with *T. gondii* due to similar morphology.[116-119] The sexual cycle is completed in the GI tract of dogs and results in the passage of oocysts in feces.[120-129] Sporozoites develop in oocysts within 24 hours of passage. Tachyzoites (rapidly dividing stage) and tissue cysts containing hundreds of bradyzoites (slowly dividing stage) are the other two life stages. Infection has been documented after ingestion of infected bovine placental tissue and tissue from naturally infected deer.[130] In one study, *N. caninum* antibodies were most common in dogs living on dairies.[131] Transplacental infection has been well documented; dams that give birth to infected offspring can repeat transplacental infection during subsequent pregnancies.[132] Although organism replication occurs in many tissues, clinical illness primarily reflects neuromuscular infection in dogs. Although encephalomyelitis and myositis develop in experimentally infected kittens and some naturally exposed cats are seropositive for *N. caninum* antibodies, clinical disease in naturally infected cats has not been reported.[133-135] Canine neosporosis has been reported in many countries around the world.

Several clinical syndromes associated with neosporosis have been reported in dogs.[134-150] Congenitally infected puppies develop ascending paralysis with hyperextension of the hindlimbs; muscle atrophy occurs

in many cases (Figure 221-5). Polymyositis and multifocal CNS disease can occur alone or in combination. Clinical signs can be evident soon after birth or may be delayed for several weeks. Neonatal death is common. Although disease tends to be most severe in congenitally infected puppies, dogs as old as 15 years have been clinically affected. In some dogs, myocarditis, dysphagia, ulcerative dermatitis, pneumonia, central nervous system disease, and hepatitis occur. Dogs on immunosuppressive therapy for other conditions can have activated subclinical infections or severe clinical illness if exposed to *N. caninum* for the first time while immune suppressed (see ch. 165).[143-146] Dogs with central nervous system neosporosis generally have multifocal disease, which can affect the cerebellum, cerebral cortex, and brainstem (see ch. 261). If not treated, most affected dogs die.[146,149,150]

FIGURE 221-5 Puppy with the characteristic extensor rigidity associated with *Neospora caninum* infection. (Courtesy Dr. Paul Cuddon.)

No specific hematologic or biochemical findings exist, but increased creatine kinase and aspartate transaminase activities are common in dogs with myositis. Cerebrospinal fluid (CSF) abnormalities (see ch. 115) include increased protein concentration (20 to 50 mg/dL) and a mild, mixed inflammatory cell pleocytosis (10 to 50 cells/dL) consisting of monocytes, lymphocytes, neutrophils, and, rarely, eosinophils. Interstitial and alveolar patterns can be noted on thoracic radiographs. Demonstration of the organism in CSF or tissues gives a definitive diagnosis. Tachyzoites are rarely identified on cytologic examination of CSF, imprints of dermatologic lesions, and bronchoalveolar lavage (see Table 221-1).[146] Dogs with central nervous system neosporosis usually have multifocal disease on magnetic resonance imaging.[149,150] *Neospora caninum* tissue cysts have a wall thickness greater than 1 micron; *T. gondii* tissue cysts have a wall thickness less than 1 micron. The organism can be differentiated from *T. gondii* by electron microscopy, immunohistochemistry, and PCR.[139,151-154] Molecular techniques have also been used to show that varying strains of *N. caninum* exist and could be one explanation for variability of clinical signs of disease.[154]

A presumptive diagnosis of neosporosis is made by combining appropriate clinical signs of disease and positive serology with the exclusion of other causes inducing similar clinical syndromes, in particular *T. gondii.*[155] Immunoglobulin G antibody titers greater than or equal to 1 : 200 have been detected in most dogs with clinical neosporosis; minimal serologic cross-reactivity with *T. gondii* occurs at titers greater than or equal to 1 : 50 when measured by indirect fluorescent antibody (IFA) testing. Antibodies of *N. caninum* DNA

can also be detected in CSF of some affected dogs.[152]

The prognosis for dogs with severe neurologic involvement is grave. Some have survived after treatment with trimethoprim-sulfadiazine combined with pyrimethamine, sequential treatment with clindamycin hydrochloride, trimethoprim-sulfadiazine, and pyrimethamine, or clindamycin alone.[136-139,141] Newer drugs have been studied *in vitro* and should be evaluated *in vivo* in an attempt to improve clinical outcomes.[156] Glucocorticoids or other immune-suppressive drugs may exacerbate clinical disease.

Neospora caninum antibodies have been detected in people, including those with acquired immunodeficiency syndrome (AIDS) and neurologic disease.[157-160] However, in one study there was no link to repeated abortion in women.[159] Overall, the zoonotic link is unclear, but it seems prudent to avoid ingesting canine feces or undercooked meat. There has been an epidemiologic link between dogs and cattle; therefore, efforts should be made to lessen dog fecal contamination of livestock feed, and dogs should not be allowed to ingest bovine placentas or venison.[131,161-163] Bitches that whelp clinically affected puppies should not be bred.

Toxoplasmosis

Toxoplasma gondii is one of the most prevalent parasites infecting warm-blooded vertebrates.[164-166] Only cats complete the coccidian life cycle and pass environmentally resistant oocysts in feces. Dogs can mechanically pass oocysts after the ingestion of feline feces but new oocysts are not produced by dogs.[167] Sporozoites develop in oocysts after 1 to 5 days of exposure to oxygen and appropriate environmental temperature and humidity (see Figure 221-1). Tachyzoites disseminate in blood or lymph during active infection and replicate intracellularly rapidly until the cell is destroyed (Figure 221-6).

FIGURE 221-6 *Toxoplasma gondii* tachyzoites.

Bradyzoites are the slowly dividing, persistent, tissue stage that form in the extraintestinal tissues of infected hosts as immune responses attenuate tachyzoite replication. Tissue cysts form readily in the CNS, muscles, and visceral organs. Infection of warm-blooded vertebrates occurs after ingestion of any of the three life stages of the organism or transplacentally.[168] Most cats are not coprophagic and are usually infected by ingesting *T. gondii* bradyzoites during carnivorous feeding; oocysts are shed in feces from 3 to 21 days. Sporulated oocysts can survive in the environment for months to years and are resistant to most disinfectants. Bradyzoites may persist in tissues for the life of the host. *Toxoplasma gondii* has also been shown to be transmitted in semen of dogs.[169] Approximately 30% to 40% of cats and 20% of the dogs in the United States

are seropositive and therefore presumed to be infected (see Figure 221-3).[164-166,170]

Clinical disease associated with the GI phase of infection is rare, and detection of *T. gondii* oocysts in feces is rarely reported in studies of naturally exposed cats with diarrhea.[171-173] Most clinical signs are systemic and can include death in dogs and cats that develop overwhelming intracellular replication of tachyzoites after primary infection; hepatic (see ch. 283), pulmonary (see ch. 242), CNS (see ch. 261), and pancreatic tissues are commonly involved (Figure 221-7).[174-178]

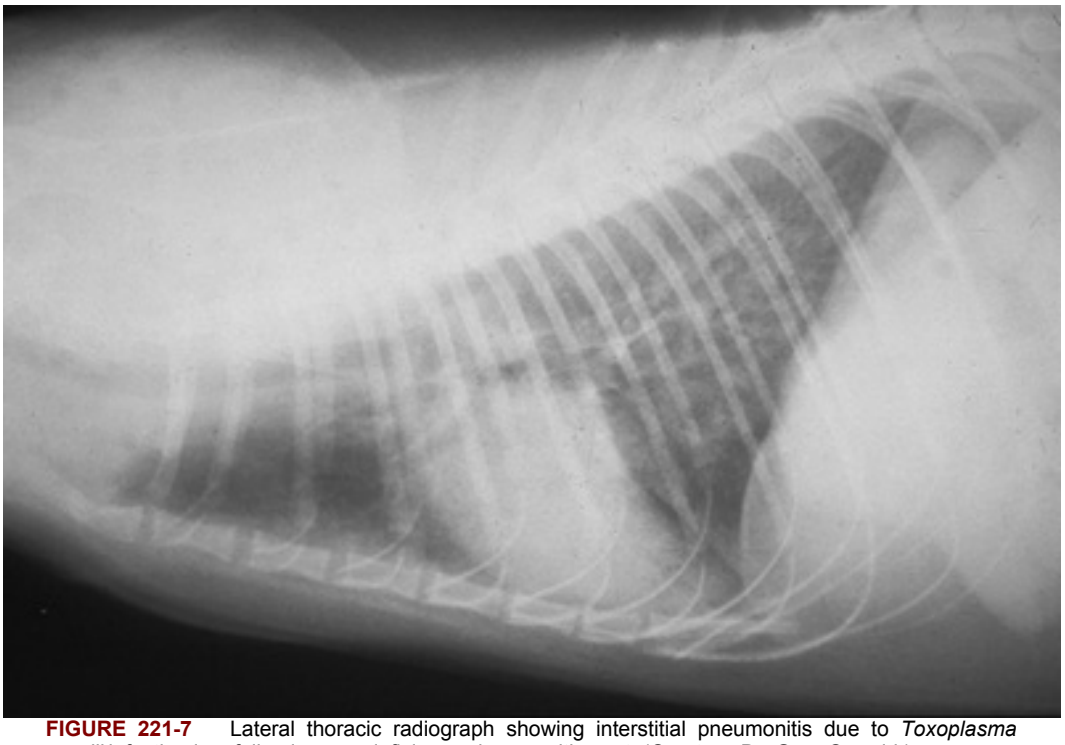

FIGURE 221-7 Lateral thoracic radiograph showing interstitial pneumonitis due to *Toxoplasma gondii* infection in a feline immunodeficiency virus–positive cat. (Courtesy Dr. Gary Oswald.)

Immune deficiency secondary to viral infection or immune-suppressive therapy can also induce fatal toxoplasmosis.[179-183] Common clinical findings in cats with disseminated toxoplasmosis include depression, anorexia, and fever followed by hypothermia, peritoneal effusion, icterus, and dyspnea.

Chronic toxoplasmosis occurs in some dogs and cats. *Toxoplasma gondii* infection should be on the differential diagnoses list for cats with anterior or posterior uveitis, fever, muscle hyperesthesia, weight loss, anorexia, seizures, ataxia, icterus, diarrhea, cutaneous disease, and pancreatitis.[184-189] However, in one study there was no association between *T. gondii* antibodies and chronic kidney disease in cats.[90]

In dogs, respiratory, GI, or neuromuscular infection resulting in fever, vomiting, diarrhea, dyspnea, cutaneous disease, and icterus are most common and occur most frequently in immune-suppressed dogs, such as those with canine distemper virus (CDV) infection (see ch. 228) or those receiving cyclosporine to prevent rejection of a transplanted kidney (see ch. 323).[180,190-195] Neurologic signs are dependent on the location of the primary lesions and include ataxia, seizures, tremors, cranial nerve deficits, paresis, and paralysis. Dogs with myositis have weakness, stiff gait, or muscle wasting. Rapid progression to tetraparesis and paralysis with lower motor neuron dysfunction can occur. Some dogs with suspected neuromuscular toxoplasmosis probably had neosporosis.[116] Myocardial infection resulting in ventricular arrhythmias occurs in some infected dogs. Dyspnea, vomiting, or diarrhea can occur in dogs with polysystemic disease. Retinitis, anterior uveitis, iridocyclitis, and optic neuritis occur in some dogs with toxoplasmosis but are less common than in the cat (see ch. 11). Keratitis due to *T. gondii* infection has also been reported.[194]

Dogs or cats with clinical toxoplasmosis can have a variety of clinicopathologic and radiographic abnormalities but none documents the disease.[170,196] Nonregenerative anemia, neutrophilic leukocytosis, lymphocytosis, monocytosis, neutropenia, eosinophilia, proteinuria, bilirubinuria, increases in serum proteins and bilirubin concentration, as well as creatinine kinase, alanine aminotransferase, alkaline phosphatase, and

lipase activities occur in some animals. Pulmonary toxoplasmosis most commonly causes diffuse interstitial to alveolar patterns or pleural effusion (see ch. 242).[197] CSF protein concentrations and cell counts are often higher than normal (see ch. 115 and 261). The predominant white blood cells (WBCs) in CSF are small mononuclear cells, but neutrophils also are commonly found.

The antemortem definitive diagnosis of toxoplasmosis can be made if the organism is demonstrated; however, this is uncommon. Bradyzoites or tachyzoites are rarely detected in tissues, effusions, bronchoalveolar lavage fluids, aqueous humor, or CSF (see Table 221-1). Detection of 10 × 12 micron oocysts in feces in cats with diarrhea suggests toxoplasmosis but is not definitive, because *Besnoitia* and *Hammondia* infections of cats produce morphologically similar oocysts.

Toxoplasma gondii–specific antibodies (dogs or cats), antigens (cats), immune complexes (cats), and DNA (dogs or cats) can be detected in the blood of normal animals, as well as in those with clinical signs of disease; therefore, it is impossible to make an antemortem diagnosis of clinical toxoplasmosis based on these tests alone.[198-204] Of the serum tests, IgM correlates the best with clinical toxoplasmosis because this antibody class is rarely detected in serum of healthy animals. Because the organism cannot be cleared from the body, most animals will be antibody-positive for life; therefore, repeating serum antibody titers after clinical disease has resolved is of little use. The combination of aqueous humor or CSF *T. gondii*–specific antibody detection and organism DNA detection by PCR is the most accurate way to diagnose ocular or CNS toxoplasmosis in cats (Diagnostic Laboratory, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO).

Clindamycin hydrochloride, trimethoprim-sulfonamide combination, and azithromycin have been used successfully for the treatment of clinical toxoplasmosis.[170,184,205] Pyrimethamine combined with sulfa drugs is effective for the treatment of human toxoplasmosis but commonly results in toxicosis in cats. Ponazuril was used successfully for the treatment of *T. gondii* keratitis in one dog.[194] Cats or dogs with uveitis should be treated with topical, oral, or parenteral glucocorticoids to avoid secondary glaucoma and lens luxations.[170,206] Optimal treatment duration for clinical toxoplasmosis in dogs or cats is unknown but generally is recommended for at least 4 weeks.

Toxoplasmosis is associated with a large number of clinical abnormalities in people that are most severe in the fetus and immune-suppressed individuals (see ch. 210). Recently, several studies have identified associations between *T. gondii,* cats, and behavioral abnormalities in people and these associations are being studied further.[207-209] However, it is clear that avoiding *T. gondii* would be prudent for all people. Risk factors associated with *T. gondii* infection in humans in the United States have been studied.[210] Avoiding tissue cysts in undercooked meat, including chicken, can lessen the risk of acquiring toxoplasmosis.[211] Based on detection of antibodies against *T. gondii* sporozoites in human sera, it is now known that a high percentage of *T. gondii* infections occur in humans from ingestion of sporulated oocysts.[212] Thus, at-risk people should also avoid old feline feces by cleaning the litterbox daily, washing hands or wearing gloves while gardening or otherwise coming in contact with soil, and washing (or cooking) produce well before it is eaten.

Although owning a pet cat is occasionally epidemiologically associated with acquiring toxoplasmosis,[213] touching individual cats is probably not a common way to acquire toxoplasmosis for the following reasons:

- Cats generally shed oocysts only for days to several weeks after primary inoculation.
- Repeat oocyst shedding is rare, even in cats receiving glucocorticoids or cyclosporine, and in those infected with feline immunodeficiency virus (FIV) or feline leukemia virus (FeLV).[214-216]
- Cats with toxoplasmosis inoculated with tissue cysts 16 months after primary inoculation did not shed oocysts.[217]
- Cats are fastidious and usually do not allow feces to remain on their skin for time periods long enough to lead to oocyst sporulation; the organism was not isolated from the fur of cats shedding millions of oocysts 7 days previously.[217]
- Increased risk of acquired toxoplasmosis was not associated with cat ownership in human immunodeficiency virus (HIV)–infected people or in veterinary health care providers.[218]

Because humans are not commonly infected with *T. gondii* from contact with individual cats, testing healthy cats for toxoplasmosis is not recommended. No serologic assay accurately predicts when a cat shed *T. gondii* oocysts in the past, and most cats that are shedding oocysts are seronegative. Most seropositive cats have completed the oocyst shedding period and are unlikely to repeat shedding. Most seronegative cats would shed the organism if infected. If owners are concerned that they may have toxoplasmosis, they should see their doctor for testing.

Flagellates

Leishmaniasis

Leishmania spp. are flagellates that cause cutaneous, mucocutaneous, and visceral diseases in dogs, humans, and other mammals. Rodents and dogs are primary reservoirs of *Leishmania* spp.; people are incidental hosts. Leishmaniasis was considered unimportant in the United States until recently, with cases reported only occasionally.[219-226] In 2000, *Leishmania donovani* infection was confirmed in multiple dogs in a Foxhound kennel in New York State.[221] Further investigation documented *L. donovani* or *Leishmania* spp. infection in 30 other Foxhound kennels in 20 states and Ontario, Canada. Infection of dogs other than Foxhounds in the United States appears to be uncommon.[223] Transmission appears to be primarily from dog to dog in Foxhounds in the United States, but transmission by shared needles, blood transfusions, breeding, and congenital transmission can occur.[221,225-230] In other countries, the sandfly is the primary vector. Flagellated promastigotes develop in the sandfly and are injected into the vertebrate host when the sandfly feeds. Promastigotes are engulfed by macrophages and disseminate through the body. After an incubation period of 1 month to 7 years, amastigotes (nonflagellate) form and cutaneous lesions develop; sandflies are infected during feeding. The intracellular organism induces extreme immune responses; polyclonal (and occasionally monoclonal) gammopathies, proliferation of macrophages, histiocytes, and lymphocytes in lymphoreticular organs and immune complex formation resulting in glomerulonephritis and polyarthritis are common in dogs. In endemic areas, *Leishmania infantum* DNA has been amplified and the organism grown from *Rhipicephalus sanguineus* suggested a potential role of this tick as a vector.[231,232]

Cats have been infected experimentally with some *Leishmania* spp.[233] Cats in endemic areas are commonly seropositive or PCR-positive.[234-240] A cat with naturally occurring *Leishmania infantum* infection was capable of infecting sandflies.[241] Most clinically affected cats in Europe or the United States *(Leishmania mexicana)* have dermatological abnormalities, many consisting of nodular, ulcerative lesions on the ear pinna or muzzle.[239,240] The primary histopathological abnormalities are diffuse granulomatous inflammation with macrophages containing numerous amastigotes.

Visceral leishmaniasis is most common in dogs. Subclinical infection may persist for months or years. When clinical signs occur, weight loss, normal to increased appetite, polyuria, polydipsia, muscle wasting, depression, vomiting, diarrhea, cough, epistaxis, sneezing, and melena are common presenting complaints. Splenomegaly, lymphadenopathy, facial alopecia, fever, rhinitis, dermatitis, increased lung sounds, icterus, swollen painful joints, uveitis, and conjunctivitis are commonly identified on physical examination.[242] Cutaneous lesions are characterized by hyperkeratosis, scaling, thickening, mucocutaneous ulcers, and intradermal nodules on the muzzle, pinnae, ears, and footpads (Figure 221-8 and ch. 10). Subclinical *Leishmania* infection was associated with infertility and chronic prostatitis in a dog.[243]

FIGURE 221-8 Characteristic skin lesion from *Leishmania* infection in a dog. (Courtesy Dr. Arturo Font.)

Hyperglobulinemia, hypoalbuminemia, proteinuria, increased liver enzyme activities, thrombocytopenia, azotemia, lymphopenia, and leukocytosis with left shift are common in dogs. Hyperglobulinemia is usually polyclonal, but an IgG monoclonal gammopathy was reported in a dog.[244] *Leishmania*-infected dogs can be positive for antinuclear antibodies in serum, which may lead to the erroneous diagnosis of primary immune-mediated disease.[245]

Leishmaniasis can be confirmed by detecting the organisms by cytology, histopathology, PCR assay, or laboratory animal inoculation, or by detecting antibodies against *Leishmania* in serum.[246-256] Demonstration of amastigotes (2.5 to 5 microns × 1.5 to 2 microns in lymph node aspirates, bone marrow aspirates, or skin imprints stained with Wright's or Giemsa stain gives a definitive diagnosis (Figure 221-9). PCR assays can be performed on EDTA-anticoagulated blood, bone marrow aspirates (see ch. 92), lymph node aspirates (see ch. 95), splenic aspirates (see ch. 89), cells collected on conjunctival swabs, or tissue samples. Dogs are unlikely to eliminate *Leishmania* infection spontaneously, and so a true positive antibody test indicates infection. However, serological cross reaction amongst antibodies against *Leishmania* and antibodies against other common vector-borne diseases like *Trypanosoma cruzi, Ehrlichia canis, Toxoplasma gondii, Neospora caninum* and *Babesia canis* occurs in some assays.[248]

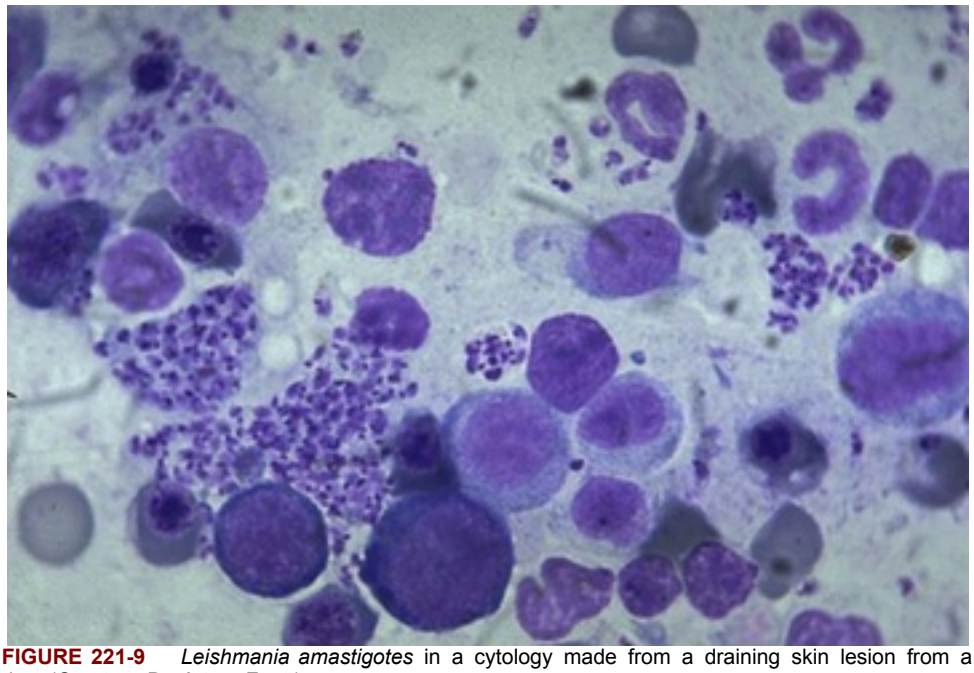

FIGURE 221-9 *Leishmania amastigotes* in a cytology made from a draining skin lesion from a dog. (Courtesy Dr. Arturo Font.)

Many treated dogs respond clinically, but *Leishmania* cannot be eliminated from the body with drugs.[246,251,256-263] The combination of antimony and allopurinol was superior to treatment with either drug alone.[257,264] As antimonial drugs are not routinely available in the United States, affected dogs could be treated with allopurinol, marbofloxacin, or liposomal amphotericin B initially.[247,260,262] The prognosis is variable; many cases given monotherapy are recurrent.

Avoidance of infected sandflies is the only means of prevention.[265-267] If in endemic areas, pet owners should house animals during nighttime hours, control breeding places of sandflies, and consider use of an insect repellent.[266,267] A vaccine is available for use in some countries.[268,269] Foxhounds and other dogs from endemic areas to be used as potential blood donors should be screened serologically or by PCR assay on blood.[227,270] The primary zoonotic risk for canine leishmaniasis is from dogs acting as a reservoir host for the organism. Direct contact with amastigotes in draining lesions is unlikely to result in human infection. In one study in the United States, none of the 185 persons with potential exposure to infected Foxhounds had evidence of infection.[221]

Trypanosomiasis

Trypanosoma cruzi infection of mammals is diagnosed primarily in North and South America, including the Caribbean Islands.[271-281] Infected reservoir mammals (dogs, cats, raccoons, opossums, armadillos) and vectors (reduviid bugs, kissing bugs) are found in the United States, but clinical infections in dogs or people are not commonly reported; this may relate to differences in vector behavior and sanitation standards in the United States. A number of studies have evaluated risk factors for acquiring trypanosomiasis.[277-281] As dogs and cats can be reservoirs, housing them separate from human sleeping quarters and reducing their exposure to triatomine bugs were predicted to strongly reduce transmission risks.[279] It appears that connatal transmission can occur in dogs as it does in humans.[282]

The organism should be on the differential list for dogs in endemic areas with cardiomyopathy, conduction disturbances, ventricular arrhythmias, and supraventricular arrhythmias (see ch. 252).[271,283-291] Laryngeal paralysis and neurologic disease may occur occasionally. Laboratory abnormalities include lymphocytosis and increased activities of liver enzymes and creatine kinase. Thoracic radiographic, abdominal radiographic, and echocardiographic findings are consistent with cardiac disease and failure, but they are not specific for trypanosomiasis. The primary electrocardiogram (ECG) findings are ventricular premature contractions, heart block, and T-wave inversion (see ch. 248).

Definitive diagnosis is based on organism demonstration. Trypomastigotes (1 flagellum, 15- to 20-microns long) can be identified during acute disease on thick blood film or buffy coat smears stained with Giemsa or

Wright's stain (see Table 221-1). The organism is sometimes detected in lymph node aspirates or in abdominal effusions. Histopathologic evaluation of cardiac tissue may reveal amastigotes (1.5 to 4 microns). Trypomastigotes can also be cultured from blood or grown by bioassay in mice. In North American cases, positive serologic test results correlate with infection.[292-294] However, there can be serological cross-reaction amongst antibodies against some vector disease agents in some assays.[248] PCR assay can also be used to amplify *T. cruzi* DNA from fluids or tissues.[278,291] *Trypanosoma caninum* is a related but nonpathogenic organism that can be cultured or amplified by PCR from the skin of dogs in some regions of Brazil.[295]

There are no approved drugs available for *T. cruzi* infection in the United States, but in a recent study of allopurinol in an experimentally infected mouse model, a positive response was noted.[296] Ravuconazole was safe in one experimental dog model and suppressed *T. cruzi* infection, lessening cardiac inflammation.[297] Administration of benznidazole temporarily suppressed *T. cruzi* infection in dogs but did not prevent the development of cardiomyopathy.[298] Simvastatin administered at 20 mg/dog lessened heart expression and serum levels of interferon-gamma (IFN-gamma) and tumor necrosis factor-alpha (TNF-alpha) improving cardiac parameters in a dog *T. cruzi* model.[299] Glucocorticoid therapy may improve survival of infected dogs. Therapy for arrhythmias (see ch. 248) or heart failure (see ch. 247) should be instituted as needed.

Dogs in endemic areas should be kept from other reservoir hosts such as opossums and should not be fed raw meat. Vector control is the primary means of prevention.[300-302] Potential blood donors from endemic areas should be serologically screened. Infected dogs can serve as a reservoir of *T. cruzi* for vectors, and blood from infected dogs can be infectious to humans. Research on a vaccine against *T. cruzi* infection is promising.[303-305]

Piroplasmida

Babesiosis

Multiple *Babesia* spp. infect dogs throughout the world.[306-323] *Babesia canis* can be subgenotyped by PCR and the various genotypes differ in geographical distribution and disease inducing potential.[307-310] *Babesia canis* subgenotypes have worldwide distribution including Africa, Asia, Australia, Europe, Central America, South America, Japan, and the United States. *Babesia rossi* is transmitted by *Haemaphysalis leachi* and is the most pathogenic. *Babesia canis* is transmitted by *Dermacentor reticulatus* and is moderately pathogenic. *Babesia vogeli* occurs in the United States, is the least pathogenic, and is transmitted by *Rhipicephalus sanguineus*. A separate large *Babesia* spp. and *B. conradae* also infect dogs in the United States.[312-314]

Babesia gibsoni infects dogs in most countries of the world and the organisms differ between regions.[315-325] In the United States, the vector for *B. gibsoni* is unknown but the organism is known to be transmitted by biting and is common in American Pit Bull Terriers.[319,320,324] *Babesia* spp. can also be transmitted by blood transfusion.[325]

None of the *Babesia* spp. that infect cats—*B. cati* (India), *B. felis* (South Africa and Sudan), *B. herpailuri* (South America and Africa), or *B. pantherae* (Kenya)—is found in the United States. However, *B. vogeli* DNA has been amplified from the blood of cats in Brazil, a country with high prevalence rates for *R. sanguineus*.[311]

While *Babesia* spp. can be associated with many clinical signs of disease and laboratory abnormalities in dogs, in the United States,[306,316,321,323,326-331] subclinical *Babesia* spp. infections are most common.[322,332] Following infection with pathogenic strains of *B. canis, B. conradae,* or *B. gibsoni,* the incubation period varies from several days to several weeks. The degree of parasitemia varies by the organism studied, but parasitemia can be detected transiently in some dogs as soon as day 1.[306,326] In some infected dogs, the intracellular replication in red blood cells (RBCs) results intravascular hemolytic anemia (see ch. 198). Immune-mediated reactions against the parasite or altered self-antigens worsen the hemolytic anemia and commonly result in a positive Coombs' test. Severity of disease depends on the species and strain of *Babesia* and the host immune status; chronic, subclinical infection can occur. Presence of coinfections, such as *Bartonella* spp., may increase the pathogenic potential.[328,331] Clinical manifestations are those of acute anemia and include fever, pale mucous membranes, tachycardia, tachypnea, depression, anorexia, and weakness. Icterus, petechiation, azotemia, and hepatosplenomegaly are present in some dogs depending on the stage of infection and the presence of disseminated intravascular coagulation (DIC). Administration of glucocorticoids or splenectomy may activate chronic disease. Common laboratory abnormalities include regenerative anemia, hyperbilirubinemia, bilirubinuria, hemoglobinuria, thrombocytopenia, metabolic acidosis, azotemia,

polyclonal gammopathy, and renal casts.[306,321,326]

A presumptive diagnosis of clinical babesiosis can be based on historical findings, physical examination findings, test results, and positive serology. Many dogs are seropositive but clinically normal; therefore, serology alone cannot be used to make a definitive diagnosis.[306,326,327] Demonstration of increasing antibody titers over 2 to 3 weeks are consistent with recent or active babesiosis. Definitive diagnosis is based on organism demonstration in RBCs using Wright's or Giemsa stains on thin blood smears. *Babesia vogeli* and *B. canis* are typically found as paired, piriform bodies measuring 2.4 × 5 microns. *Babesia gibsoni* is typically found as single, annular bodies measuring 1.0 × 3.2 microns (see Table 221-1). PCR assays for *Babesia* spp. are now available commercially and can be used to document organism presence, but positive results do not always correlate to clinical illness.[333-335]

Supportive care, including blood transfusions (see ch. 130), should be administered as indicated. Several drugs including diminazene aceturate, phenamidine, pentamidine isethionate, parvaquone, atovaquone, and niridazole have also been used in an attempt to treat different *Babesia* spp. infections.[314,336-343] In the United States, dogs with suspected *B. canis* associated clinical illness often respond to imidocarb dipropionate administered at 5 to 6.6 mg/kg SC or IM twice, 14 days apart or 7.5 mg/kg SC or IM once.[326,336] Adverse effects include transient salivation, diarrhea, dyspnea, lacrimation, and depression. Imidocarb is not as effective for the treatment of *B. gibsoni* infection. In the United States, dogs with suspected *B. gibsoni* or *B. conradae* associated clinical illness often respond to azithromycin (10 mg/kg PO q 24 h for a minimum of 10 days) combined with atovaquone (13.3 mg/kg PO q 8 h for at least 10 days). If these drugs are not available, the combination of doxycycline (7-10 mg/kg q 12 h), enrofloxacin (2-2.5 mg/kg q 12 h), and metronidazole (5-15 mg/kg q 12 h) for 6 weeks had 85.7% efficacy in one study in Taiwan.[343] The addition of diminazene did not improve response rates in this study.[343] Clindamycin administered at 12.5 mg/kg PO q 12 h for at least 10 days may control clinical signs.[339] However, treatment of *Babesia* spp. infections is unlikely to eliminate the carrier state.[338] As there are no drugs available that are known to consistently eliminate infection, treatment of healthy, seropositive dogs is unlikely to be of benefit and prevention is of utmost importance. In addition, since infection may not be cleared, following antibody titers or PCR may be of minimal benefit.[344] Following the clinical and laboratory abnormalities is probably of great importance. For example, the proteinuria associated with babesiosis can lessen following treatment.[330]

Ticks should be controlled if possible (see ch. 163).[345-348] If it is difficult to control ticks in a *B. canis* or *B. vogeli*–infected kennel, one dose of imidocarb at 7.5 mg/kg IM may eliminate the carrier state. Dog fights should be avoided. Administration of immunosuppressive drugs and splenectomy should be avoided in previously infected dogs. Dogs in high-risk breeds (Greyhound, American Pit Bull Terrier) and dogs from endemic areas to be used as blood donors should be assessed for infection by PCR assay or serologic screening and positive dogs eliminated from the program.[270] Vaccines for *B. canis* have been studied in some countries.[349] Currently no evidence exists to suggest that *Babesia* spp. infecting dogs and cats can cause human disease.

Cytauxzoonosis

Cytauxzoon felis infects cats, pumas, and bobcats in many regions of the United States and is occasionally identified in cats in Europe.[350-368] In one study of 961 cats in Florida, North Carolina, and Tennessee, the prevalence rate was 0.3%.[355] When first discovered, *C. felis* infection was thought to be uniformly fatal. It is now apparent that less virulent strains exist and many cats will survive and be subclinical carriers.[355-358,361,366] Bobcats and pumas are usually subclinically affected and approximately 50% of the strains evaluated were identical to domestic cats and the others were unique.[367] The organism can be passed experimentally from infected bobcats to domestic cats by *Dermacentor variabilis;* clinical illness occurs after an incubation period of 5 to 20 days.[368] However, *Amblyomma americanum* is also a competent vector, and based on the distribution of cases in the United States, is the most likely vector to cats.[350,353] Perinatal infection of kittens appears to be unlikely.[354]

Cytauxzoon felis–infected macrophages line the lumen of veins throughout the body, and merozoites released from the infected macrophages infect erythrocytes. Clinical disease results from obstruction of blood flow through tissues by mononuclear infiltrates and from hemolytic anemia. Some infected cats develop coagulation abnormalities, and cats that died in one study had greater concentrations of tumor necrosis factor-alpha and interleukin-1 beta, suggesting an immune-pathogenic component to disease.[369,370]

Most cases of cytauxzoonosis are in cats allowed to go outdoors that live by wooded areas that support the presence of ticks.[350,352] Fever, anorexia, dyspnea, depression, icterus, pale mucous membranes, and death are the most common clinical findings.[350,351,371] A primary differential diagnosis is hemoplasmosis (see ch. 219). Ticks are generally not identified on affected cats. Cytauxzoonosis is suspected in cats with regenerative anemia and neutrophilic leukocytosis; thrombocytopenia occurs in some cats. Hemoglobinemia, hemoglobinuria, bilirubinemia, and bilirubinuria are uncommon. Antemortem diagnosis is based on demonstration of the erythrocytic phase on thin blood smears stained with Wright's or Giemsa stains. Infected macrophages can be detected cytologically in bone marrow, spleen, liver, or lymph node aspirates.

The organism is easily identified on histologic evaluation of most organs. Serologic testing is not commercially available but PCR assay can be used to amplify organismal DNA from blood, aspirates, or tissue samples.[350,372]

Supportive care should be administered as indicated. However, stress can exacerbate death in clinically ill cats and so minimal manipulations should be used. Administration of atovaquone (15 mg/kg PO q 8 h) and azithromycin (10 mg/kg PO q 24 h) is currently the treatment protocol of choice; in one study, 14 of 22 cats survived.[373,374] Treatment with diminazene or imidocarb is inferior to this protocol.[375,376] Ticks should be controlled, and cats in endemic areas should be housed during periods of peak tick activity. The use of an imidacloprid 10%/flumethrin 4.5% collar (Seresto, Bayer) that repels ticks was effective in one study.[377] This collar was accepted without significant side-effects by approximately 95% of cats owned by veterinary students or employees of a teaching hospital.[378] Vaccine research is currently ongoing. *Cytauxzoon felis* is not known to be zoonotic.[379]

Feline Immunodeficiency Virus Infection

Julia A. Beatty

Client Information Sheet: Feline Immunodeficiency Virus Infection

Feline immunodeficiency virus (FIV) is a common infection of domestic cats worldwide. Transmission occurs primarily during aggressive territorial encounters and results in lifelong infection. Although the immunological consequences of FIV infection in cats mirror many of those seen in human immunodeficiency virus (HIV)–infected humans, the clinical manifestation of most FIV infections is mild or absent. In those cats that do succumb to FIV-associated diseases, there are no pathognomonic signs, so assigning clinical relevance to FIV infection in an individual cat is challenging. Diagnostic investigation of sick, FIV-infected patients frequently reveals specific, treatable problems. Screening diagnostic tests detect circulating antibodies to the virus. Depending on the circumstances, additional serology or molecular testing can assist in determining a cat's true infection status. Confinement of uninfected cats is the most effective way to prevent transmission. FIV presents no known zoonotic risk.

Etiology and Epidemiology

FIV, family *Retroviridae*, subfamily *Orthoretrovirinae*, genus *Lentivirus*, describes a large group of closely related viruses that are endemic in domestic cats and other carnivores including lions, leopards and spotted hyenas.[1,2] Antibodies to FIV are found in domestic cat populations across the globe. Seroprevalence varies from <5% to >30% depending on the region and the population tested.[3] Risk factors for FIV infection include age, sex, environment, breed and health status; adult, male, free-roaming, crossbred cats and sick cats at high risk (Table 222-1).[4-6] The average age of FIV-infected cats in epidemiological studies is 5 to 6 years.[7]

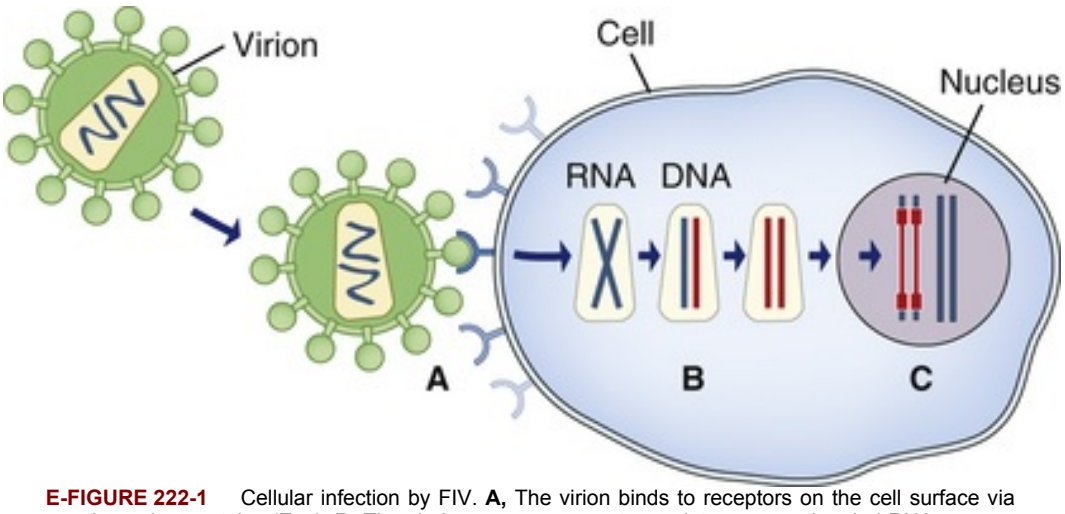
TABLE 222-1

Risk Factors for FIV Infection

VARIABLE	HIGH RISK	LOW RISK
Sex	Male	Female
Neuter status	Unneutered	Neutered
Breed	Mixed breed	Pure breed
Environment	Free roaming	Confined
Health status	Sick	Healthy
Age	Adult	Juvenile

An understanding of virus structure and replication cycle informs the basis for diagnostic testing methodologies as well as persistent infection as an invariable outcome. Each FIV virion contains a duplicate, single-stranded RNA genome (E-Figure 222-1). Three major genes *gag*, *pol* and *env* encode viral core proteins (matrix [p15], capsid [p24] and nucleocapsid [p10]), enzymes (reverse transcriptase, protease, integrase) and envelope glycoproteins (transmembrane [gp41], surface [gp120]), respectively.[8] Env binds the primary receptor for FIV, CD134, to initiate infection. A conformational change in Env exposes the binding site for the co-receptor CXCR4, triggering cell entry.[9] The viral genome is released and copied into DNA by the viral

RNA-dependent DNA polymerase, reverse transcriptase. This DNA copy, once integrated into the host chromosomal DNA and flanked by long terminal repeats which control its transcription, is known as provirus (see E-Figure 222-1). Provirus can either remain latent or form the template for the production of new virions.



E-FIGURE 222-1 Cellular infection by FIV. **A,** The virion binds to receptors on the cell surface via envelope glycoproteins (Env). **B,** The viral enzyme, reverse transcriptase, uses the viral RNA genome as a template to make a DNA copy. **C,** The DNA copy becomes integrated into the infected host cell DNA as provirus. (Reproduced with permission, Wiley. Hosie MJ, Beatty JA: Vaccine protection against feline immunodeficiency virus: setting the challenge. *Aust Vet J* 85:5-12, 2007.)

Within an infected cat, FIV mutates frequently, creating a pool of variant viruses. The principal underlying mechanisms are point-mutations introduced during reverse transcription and recombination between viruses co-infecting a single cell. Variable regions in *env* form the basis for the phylogenetic classification of FIV into major subtypes or clades, A to E. Regional variation in the prevalence of subtypes exists with subtypes A, B and C being most common.[10,11] Classification of FIV subtypes has become complex. Sequences used for subtyping do not detect all recombinations within *env* and variants with *gag, pol* and *env* sequences that are not consistent with a single subtype occur.[12,13] The clinical relevance of subtype classification is uncertain, as subtype does not consistently predict biological properties, such as virulence, or vaccine protection.

FIV is transmitted by direct inoculation of saliva or blood during fighting.[4,14] Other routes of transmission are of minor epidemiological significance. Horizontal transmission of FIV between cats in stable households is rare, in sharp contrast to the major feline retroviral pathogen, feline leukemia virus (FeLV; see ch. 223), which spreads rapidly between housemates.[7,15,16] Vertical or perinatal transmission of FIV in the field is documented infrequently, although primary infection of the queen during pregnancy may increase the risk of transmission.[16-19] Natural sexual transmission of FIV is not documented.

In veterinary hospitals, no special precautions over and above those for any feline patient are necessary for dealing with FIV-infected cats. Virus shed in secretions is rapidly inactivated in dry conditions and routine cleaning and disinfection procedures to prevent the spread of feline herpesvirus-1 (FHV-1), feline calicivirus (FCV), and feline panleukopenia virus (FPV) (see ch. 225 and 229) effectively eliminate any residual risk of environmental contamination. Nosocomial FIV infection is virtually impossible unless there is parenteral inoculation of contaminated blood or saliva from an FIV-infected cat. Cats used as blood donors should be demonstrated to be free from FIV infection since iatrogenic transmission by this route is inevitable.[20] Cats should not be housed in isolation facilities solely on the basis of their FIV status since this places potentially immunosuppressed cats at risk.

FIV strains are highly host-specific. Cross-species transmission, even between carnivore hosts, is rare.[21] One group has been able to demonstrate productive infection of human cells *in vitro* and experimental infection of non-human primates with FIV.[22,23] Owners can be counseled that any zoonotic risk posed by FIV is minimal; a serosurvey of veterinary workers with occupational exposure found no evidence of FIV infection and human CD134 does not support cellular entry by the virus.[24,25] However, immunosuppressed human patients, such as transplant recipients, should avoid FIV-infected cats or observe meticulous hygiene

precautions to avoid the possibility of exposure to shared opportunistic pathogens.

Pathogenesis

FIV infection can be broadly considered to progress in three stages: a transient "primary stage," a chronic "asymptomatic stage" and a terminal "second stage" (Figure 222-2). In contrast to HIV where, without antiretroviral treatment, patients progress through predictable, well-characterized clinical stages to the terminal acquired immunodeficiency syndrome (AIDS) stage, the consequences of FIV infection are not predictable.[5,26,27] It is expected that a large proportion of FIV-infected cats will remain free from significant disease and have a normal life expectancy.[15,27-29]

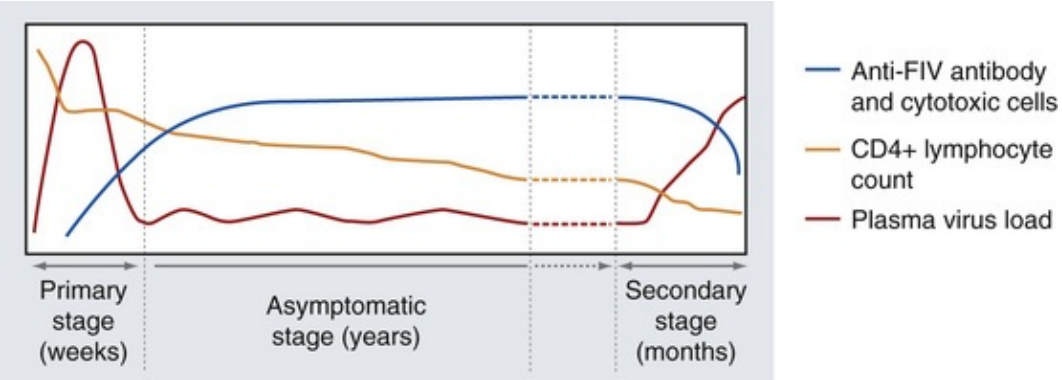


FIGURE 222-2 Course of FIV infection. Following infection, there is an initial burst of virus replication. This may be accompanied by a transient, non-specific "primary stage" illness. Strong cellular and humoral immune responses dramatically reduce plasma virus load but fail to clear infection and the "asymptomatic stage" begins. A fall in CD4+ lymphocyte numbers, the primary target of early FIV infection, begins early and progresses throughout infection. After several years, in a minority of cats, lymphoid tissues become depleted, antiviral immunity wanes and plasma virus levels rise again. "Second-stage" disease is characterized by clinical signs of immune dysfunction, lymphoma, unexplained wasting or neurological signs.

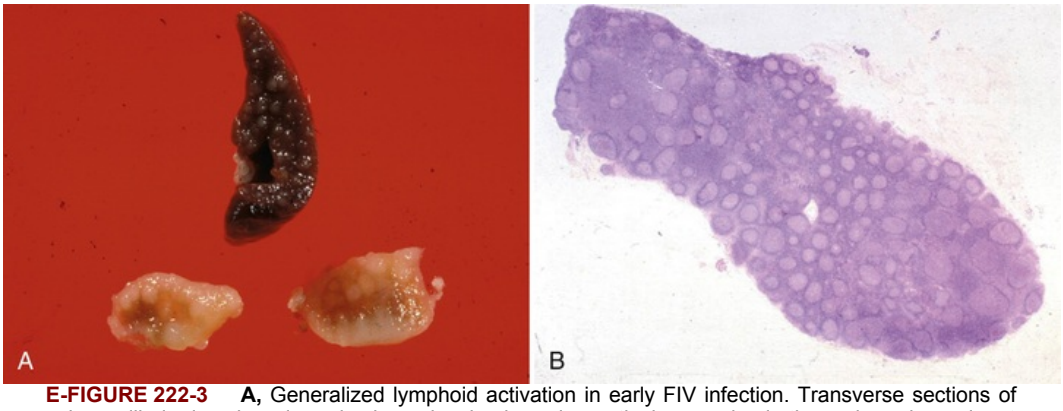
During the primary stage, which lasts for 6 to 8 weeks, virus replicates rapidly and viremia is detectable by virus isolation and polymerase chain reaction (PCR).[30] Dissemination to lymphoid tissues follows and virus can be detected in saliva within 3 weeks of experimental infection.[31,32] A robust immune response comprising CD8+, cytotoxic T-lymphocytes and antibodies to viral proteins can be detected from 2 to 6 weeks after experimental infection.[33,34] Virus replication is contained but, crucially, not cleared by host immunity. Clinical signs accompanying the primary stage, such as transient fever, neutropenia and lymphadenopathy, are sometimes seen after experimental infection of young cats, but are rare following natural exposure.[31,35]

The asymptomatic stage—which lasts for years and, often, for the cat's lifetime—is characterized by a low level or absent viremia. Hence, antigen testing is not used for FIV diagnosis (see Diagnosis). Importantly, immune dysfunction begins early after FIV infection and progresses during the asymptomatic stage. Mild or intermittent clinical signs can be seen during the asymptomatic stage. The main targets of early FIV infection, lymphocytes (T-helper cells), which promote cell-mediated and humoral immunity, decline progressively in number.[36,37] Deficits in lymphocyte function begin early and progress.[38-40] T-cell priming to novel antigens is disrupted within 5 weeks following experimental infection.[38] In clinically normal FIV-infected cats, impaired immunity to opportunistic pathogens has been demonstrated. Primary challenge with *Toxoplasma gondii* resulted in severe, systemic toxoplasmosis in FIV-infected cats compared with only mild, transient signs in FIV-uninfected cats.[41] Innate as well as adaptive immunity is affected; delayed clearance of *Listeria monocytogenes* in experimental FIV infection was attributed to defective natural killer (NK)-cell function.[42]

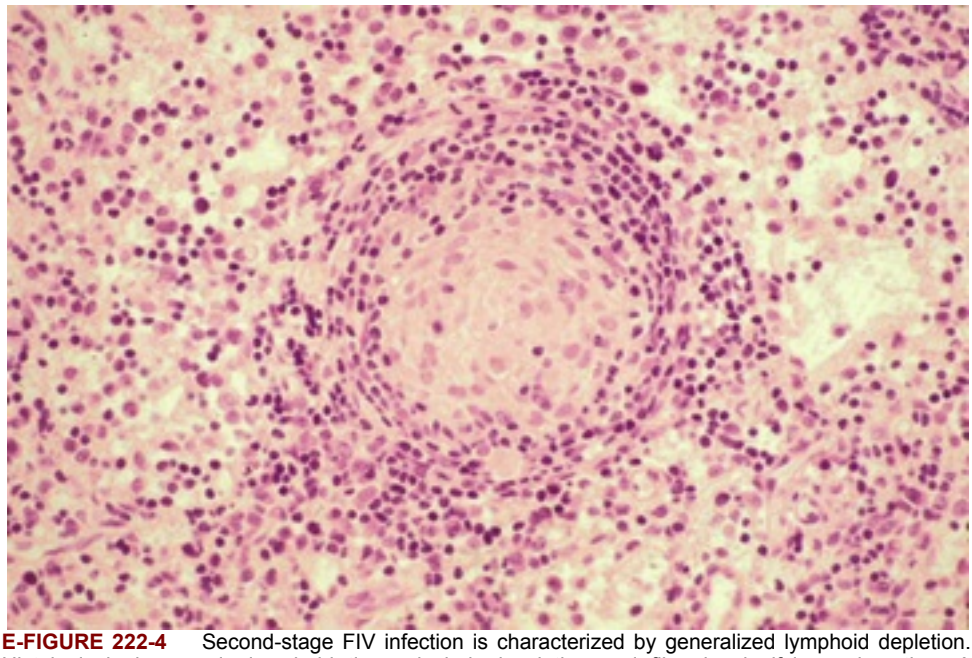
Immune hyperactivation, as well as suppression, contributes to overall immune dysfunction in FIV infection. An early rise in an activated subpopulation of lymphocytes expressing low levels of CD8, CD8(low), exacerbates a reduced CD4:CD8 ratio.[43] Lymphoid hyperplasia, follicular dysplasia and expansion of B- and T-cell areas develop in lymph nodes and other organs including spleen, tonsils and mucosa-associated lymphoid tissue (E-Figure 222-3).[33,35,44] Polyclonal B-lymphocyte stimulation results in hypergammaglobulinemia.[45] Chronic antigenemia activates T-cell subpopulations which function as immune

suppressors. These include CD4+ and CD8+ lymphocytes expressing B7 and CTLA4, which contribute to immune anergy and apoptosis in lymph nodes, as well as CD4+CD25+ T-regulatory cells, which function as non-specific suppressors, thereby impacting immunity to FIV and to opportunistic pathogens.[46,47]



E-FIGURE 222-3 **A,** Generalized lymphoid activation in early FIV infection. Transverse sections of submandibular lymph node and spleen showing irregular cortical expansion in the node and prominent white pulp in the spleen 2 months after experimental infection. **B,** Prominent and irregular follicular expansion in the submandibular lymph node from the same cat (H&E). (Courtesy Professor John (Sean) J. Callanan.)

Eventually, in some cats, second-stage infection ensues. Second-stage FIV is characterized by profound lymphoid depletion (E-Figure 222-4), escape of virus from immunological control and terminal disease.[44,48,49] The term "second-stage" FIV infection is preferred to "feline-AIDS," as criteria to define AIDS in cats are not determined. Further, "feline AIDS" carries negative connotations for some owners and the term is frequently misused to apply to any FIV-infected cat.



E-FIGURE 222-4 Second-stage FIV infection is characterized by generalized lymphoid depletion. Histological changes in lymphoid tissue include involution and fibrosis signifying exhaustion. A depleted secondary follicle and an overall decrease in cell density are shown (H&E). (Courtesy Professor John (Sean) J. Callanan.)

Clinical Signs

All FIV-infected cats should be considered to be at risk from immune dysfunction which can manifest as

immune deficiency or immune-mediated disease. Healthy FIV-infected cats should be carefully examined and even apparently minor problems fully investigated. Immune dysfunction can manifest clinically as atypical and refractory bacterial, viral or protozoal infections and parasitoses (Figures 222-5 through 222-9). Respiratory infections, bacterial pyoderma, generalized demodicosis, mycobacterial infection, disseminated cowpox, pulmonary cryptococcosis and lungworm infections are reported.[4,50-52] Persistent cytopenias, particularly neutropenia or lymphopenia are described in advanced FIV infection.[27,53-55] FIV infection has been linked to feline chronic gingivostomatitis (FCGS), a painful and debilitating condition that can greatly impact quality of life (Figure 222-10).[56]

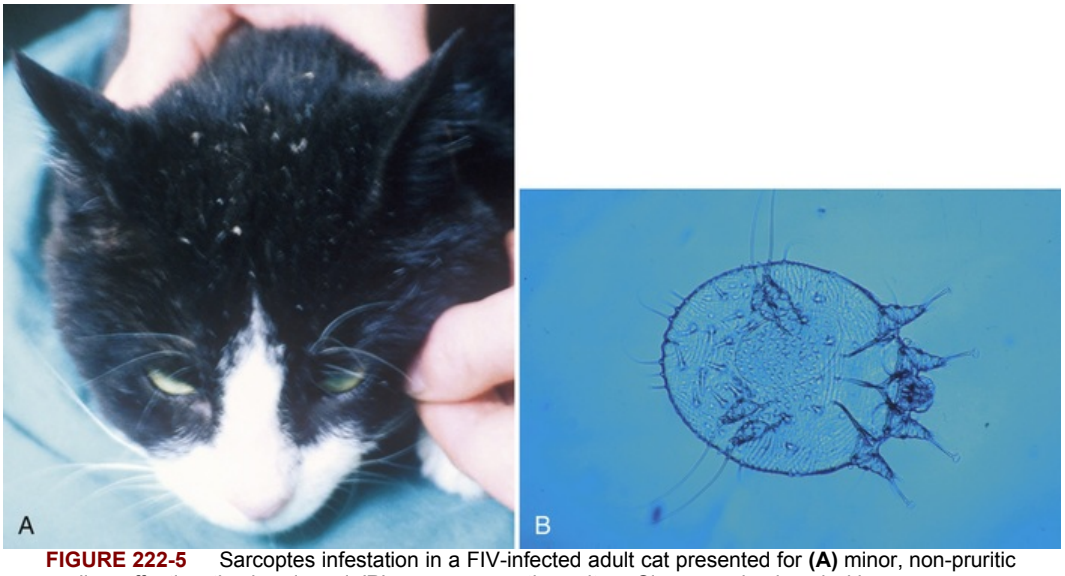


FIGURE 222-5 Sarcoptes infestation in a FIV-infected adult cat presented for **(A)** minor, non-pruritic scaling affecting the head, and **(B)** numerous active mites. Signs resolved and skin scrapes were negative within 1 week of ivermectin treatment.

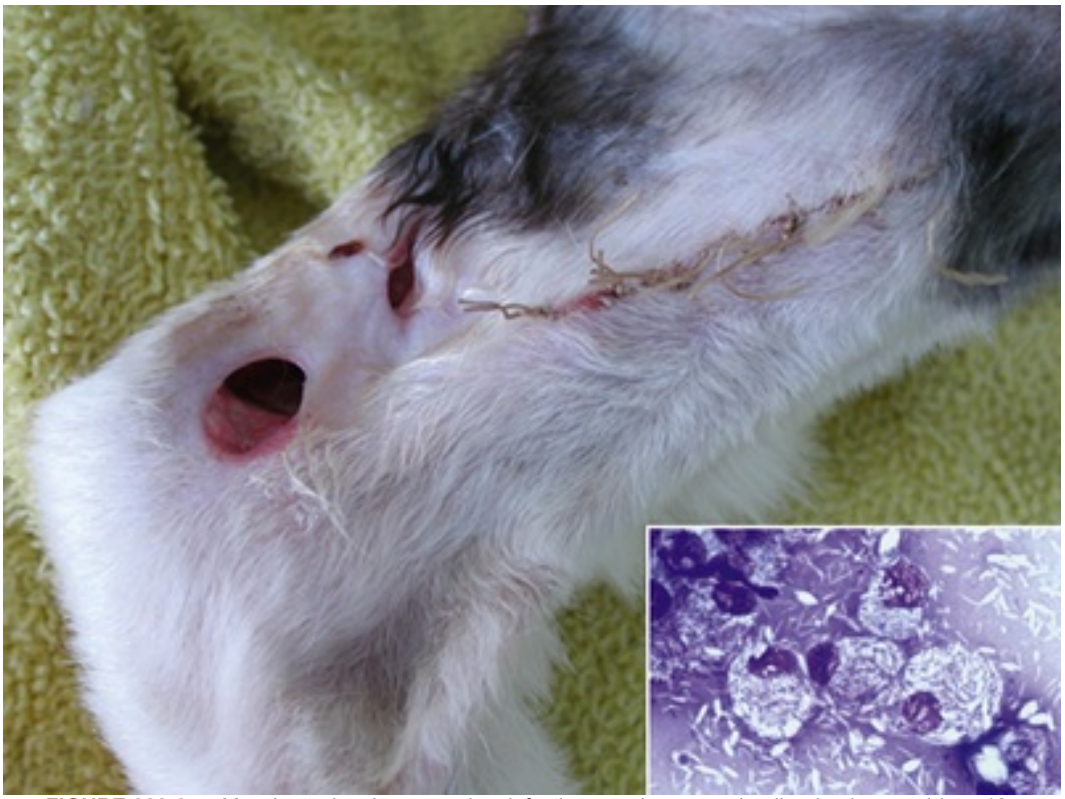

FIGURE 222-6 *Mycobacterium lepraemurium* infection causing a non-healing hock wound in a 12-year-old cat with second-stage FIV infection. Inset: Fine-needle aspiration and cytology shows numerous negatively staining intracellular bacilli. Modified Wright-Giemsa. (Courtesy Professor Vanessa Barrs.)

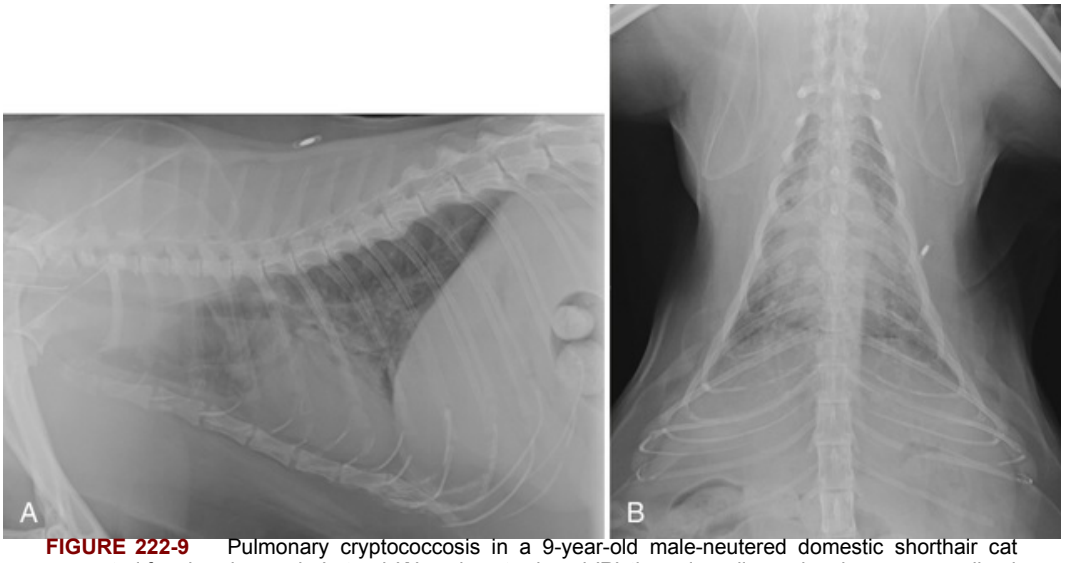

FIGURE 222-9 Pulmonary cryptococcosis in a 9-year-old male-neutered domestic shorthair cat presented for chronic cough. Lateral **(A)** and ventrodorsal **(B)** thoracic radiographs show a generalized mixed, predominantly bronchointerstitial, pulmonary pattern. *Cryptococcus neoformans* was cultured from bronchoalveolar lavage fluid (BAL). No yeasts had been identified on cytology of the BAL.

FIGURE 222-10 Gingivostomatitis with marked caudal oral cavity involvement.

The risk of lymphoma is increased in FIV infection by 5 to 6-fold.[59] This risk is small in comparison to the 60-fold increased risk of lymphoma in FeLV infection. FIV-associated lymphomas are typically high-grade, extranodal, B-cell tumors, similar to HIV-associated diffuse large B-cell lymphoma (Figure 222-11).

FIGURE 222-11 Lymphoma involving extranodal sites from two FIV-infected cats. **A,** Renal lymphoma. **B,** Intraocular lymphoma.

The etiology of FCGS is ill-defined and it is likely to be multifactorial. Epidemiological evidence identifies FIV as a risk factor in some studies and, while FIV is clearly not causal, a role for the virus in disease manifestation and severity in infected cats seems likely.[57,58] Immune stimulation triggered by FIV may contribute to chronic oral inflammation while immune suppression may delay clearance of other pathogens, such as feline calicivirus or secondary bacterial infections.

Direct oncogenesis by FIV is rare: integration site mapping in a single case demonstrated truncation of a gene on chromosome B3 and down-regulation of the unaffected allele consistent with a loss of function mutation.[60] FIV-induced immune dysfunction may play a role in lymphomagenesis. Reduced CD4+ lymphocyte counts, a known risk factor for HIV-associated lymphoma, have been demonstrated in cats developing FIV-associated lymphoma.[61] Interestingly, in HIV-associated lymphomas, co-infecting gammaherpesviruses are causal in over 80% of cases. The oncogenic potential of the recently identified widely endemic, gammaherpesvirus of domestic cats, *Felis catus* gammaherpesvirus 1, is under

investigation.[62,63] Hyperstimulation of the B-cell compartment in FIV infection might also contribute to oncogenesis, with amplification of normal somatic mutations predisposing to B-cell tumors. Increased numbers of circulating B-cells, plasma immunoglobulin and interleukins 1 and 6 (IL-1 and IL-6), which stimulate B-cell proliferation and differentiation, have been documented in FIV-infected cats that develop lymphoma.[61] Many other neoplasms are described in FIV-infected cats but the role of FIV, if any, in these cancers is unknown.

Wasting syndrome is multifactorial with changes in protein and lipid metabolism, altered energy requirements, anorexia, cytokine derangements, malabsorption, endocrinopathies and myopathies all contributing.[64] An increased risk for renal diseases in FIV infection is suspected but a causal association has been difficult to prove. Renal proteinuria but not renal azotemia has been associated with natural FIV infection.[65]

Following experimental infection, FIV provirus can be detected in the central nervous system from 2-4 weeks. The virus targets non-neuronal cells, primarily macrophages and microglia, resulting in a progressive encephalitis.[69] Histopathological lesions are generally less severe in FIV than in HIV infection. This might be partly due to FIV being less macrophage-tropic than HIV, since macrophages carry virus across the blood-brain and blood–cerebrospinal fluid barriers. However, some FIV isolates induce severe neuropathology.[70] These lesions may be clinically silent or induce progressive neurological deficits including behavioral changes, stereotypic motor behaviors, increased aggression and delayed righting and pupillary light reflexes.[68] In natural FIV infection, compulsive roaming, changes in sleeping patterns, aggression, seizures, ataxia, tremors, movement disorders and paraparesis have been reported but the extent to which other etiologies were excluded is unclear.[4,71,72] Some deficits accompanying HIV-associated neurodegeneration, such as cognitive impairment (reduced concentration, memory, learning) and psychological problems, cannot be routinely diagnosed in cats.[67]

Severe unexplained weight loss can occur in second-stage disease (Figure 222-12). This presentation resembles "wasting syndrome," an AIDS-defining condition in HIV infection, indicating weight loss of 10% or more over 30 days with no identifiable cause other than HIV infection.

FIGURE 222-12 Severe, unexplained wasting in second-stage FIV infection.

FIV-associated neuropathology has been studied extensively as an experimental model for neurodegenerative diseases in HIV infection.[66-68] The incidence of neurological signs accompanying natural FIV infection is unknown.

Diagnosis

FIV-infected cats should be identified to optimize individual health care and to prevent new infections. Ideally, the current retrovirus status of all cats should be known. Priorities for FIV-testing include free-roaming cats, sick cats, cats presenting with fight-wounds, blood donors, adult cats being rehomed, kittens born to FIV-infected queens and any cat prior to FIV vaccination (Figure 222-13).[73,74]

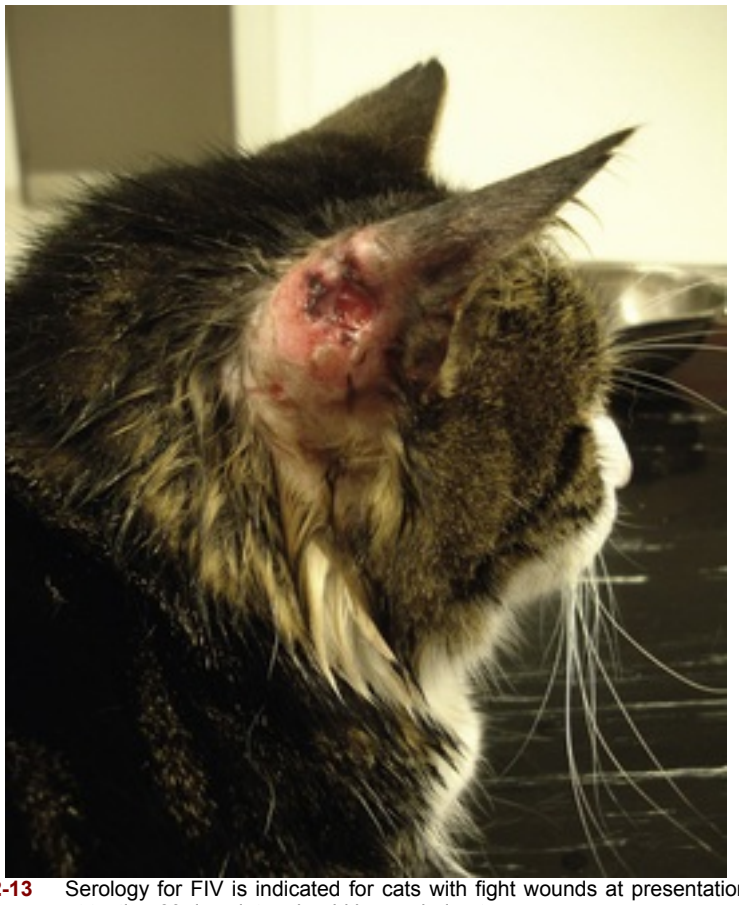

FIGURE 222-13 Serology for FIV is indicated for cats with fight wounds at presentation. If the cat tests negative, repeat testing 60 days later should be carried out.

Commercial FIV tests detect either anti-FIV antibodies by serology or viral nucleic acid by PCR. Virus isolation from peripheral blood mononuclear cells is not commercially available. Serology is the first line for testing. FIV causes a persistent infection so antibody is a marker of infection. Kits designed for in-clinic use capture antibodies from plasma, serum or whole blood using enzyme-linked immunosorbent assay or rapid immunomigration technologies. The antigens used vary between manufacturers and include p15, p24 and gp41. The diagnostic sensitivity and specificity of in-clinic kits was compared using 536 randomly selected serum samples.[75] Confirmatory testing using Western blot was performed on positive samples and a random selection of negative samples. Six of 7 FIV test kits had diagnostic sensitivities >92% and specificities >99%. The interpretation of results from serological screening tests requires the integration of clinical findings from the individual cat to guide whether repeat serology or a PCR test is indicated and what the timing of any repeat testing should be (Figure 222-14).

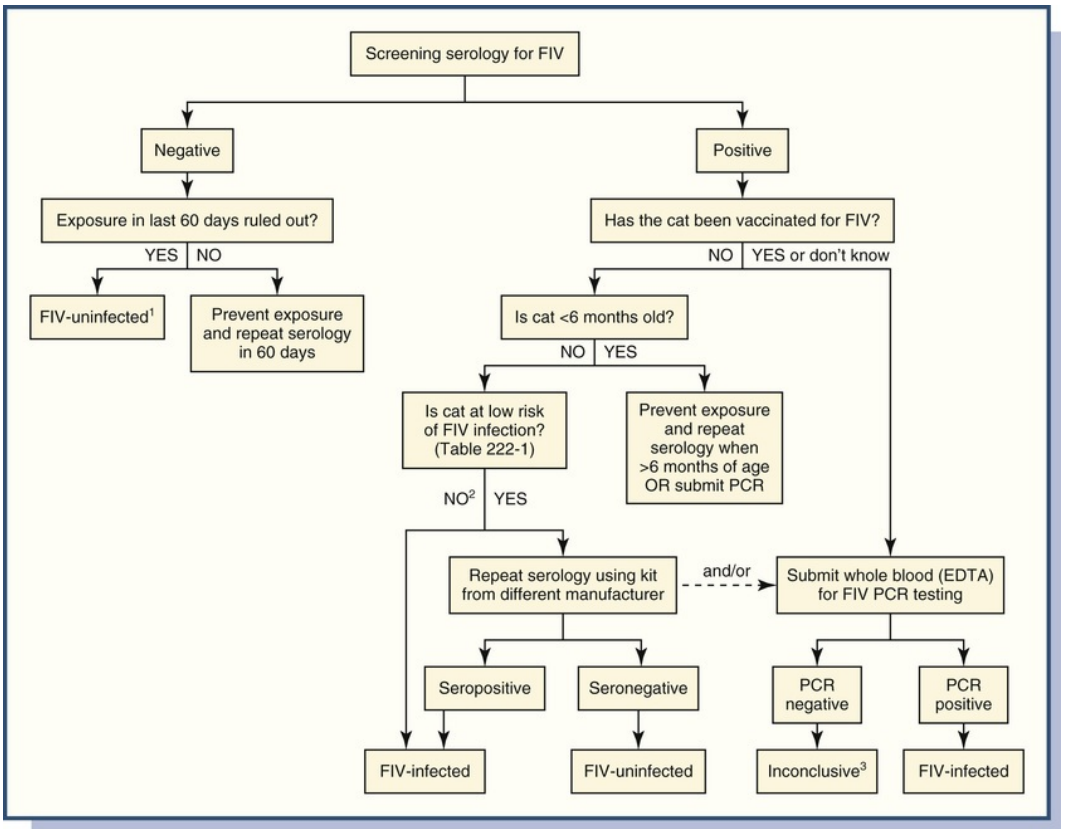

FIGURE 222-14 Determining FIV status using serology and PCR. No single test is 100% accurate. The infection status derived from this algorithm gives a working diagnosis. [1]False negative serology results are rare. Confirmation by repeating serology, preferably using a kit from a different manufacturer, could be considered for high-risk cats. No delay is necessary before repeating serology. Rarely, cats with advanced FIV infection can be seronegative, so consideration should be given to the clinical findings. [2]Repeat serology (no delay necessary) can be considered for high risk cats but positive serology in a high risk cat is highly likely to indicate infection. [3]In this scenario, the cat may be uninfected, or infected with an FIV variant not recognized by the PCR assay or the FIV load may be below limit of detection of the assay. NOTE: At the time of writing, new data on point-of-care serology tests became available. The reader is referred to the section on diagnosis.

Molecular tests target DNA provirus and some also detect viral RNA in plasma. Data to assess the performance of FIV PCR tests are limited and variability in performance between laboratories has been demonstrated.[76] Diagnostic sensitivity that is 5-15% lower than serology and specificity comparable with serology have been reported for commercial PCR tests.[77-79] Sequence variability between isolates likely contributes to the lower sensitivity of PCR because primers may not detect all field isolates. Low provirus or virus load, poor sample quality and technical issues may also contribute. FIV PCR is recommended as an adjunct to serology to determine the true FIV status of cats in certain circumstances. PCR is not indicated as a screening test for FIV.

Interpretation of FIV Serology

Negative serology results are generally reliable because the sensitivity of serological tests is high (Table 222-2). Even in cats at high risk of FIV infection, the risk of a false negative result is low. The time to seroconversion following natural infection is variable and can be prolonged. A seronegative cat that may have been recently exposed should be isolated from FIV-infected cats or cats of unknown FIV status and retested after 60 days.

TABLE 222-2

Interpretation of a Negative FIV Serology Result

INTERPRETATION OF NEGATIVE SEROLOGY RESULT	COMMENTS
The cat is NOT infected with FIV.	This is the most likely explanation.
The cat is FIV-infected, but has not yet seroconverted.	If recent exposure has not been ruled out, repeat serology in 60 days.
False negative	This is unlikely because the diagnostic sensitivity is high BUT the higher the risk of FIV infection in the cat being tested, the higher the risk of a false negative result. If the cat is from a high risk group, repeat serology is optional.
Terminal FIV-related disease	Rarely, cats with terminal disease can be seronegative because FIV-antibody production falls or antibody is complexed. Infection may be detected with PCR.

The following considerations apply when interpreting positive serology results for an individual cat (Table 222-3).

TABLE 222-3

Interpretation of a Positive FIV Serology Result

INTERPRETATION OF POSITIVE SEROLOGY RESULT	COMMENTS
The cat is infected with FIV.	Infection-induced antibody is a marker of FIV infection (not recovery from infection).
False positive	The positive predictive value of serology is reduced in cats at low risk from FIV infection. If the cat is from a low-risk group, repeat the serology using an alternative kit or submit PCR.
The cat is NOT infected, but maternal anti-FIV antibodies are being detected on serology.	Maternal antibodies can persist for months. Repeat serology when the cat is over 6 months of age. If this is not practical, submit PCR.
The cat has been vaccinated for FIV.	Cats vaccinated with Fel-O-Vax FIV test positive on some serological tests.[82,83]

Cats at Low Risk of Infection

The possibility that a positive result is a false positive is increased in cats at low risk of infection because the positive predictive value of the test is reduced. The reason for this is that, in a cat from a low risk group, the prevalence of FIV in that (low risk) population approaches the expected frequency of false positives. So for each positive test result obtained in cats at low risk, there is a higher chance that the result is a false positive.

Maternal FIV Antibodies

Absorbed from colostrum of vaccinated and infected queens, may result in false positive results in kittens. Maternally derived anti-FIV antibodies can persist for months. Young cats returning positive results on serology should be retested after 6 months.

Prior Vaccination with Fel-O-Vax FIV (Boehringer Ingelheim, Germany)

A commercial FIV vaccine is available in regions including the United States, Canada, Australia, New Zealand and Japan. Vaccinated cats seroconvert, requiring that anti-FIV antibodies associated with vaccination be differentiated from the serological response to natural infection. On Western blot testing, vaccine-induced antibodies to all major virus proteins have been detected.[80] Vaccine-induced antibodies are also detected using point-of-care serology tests and, for many years, this has created difficulties in determining whether seropositive cats are vaccinated, infected or both.[81] However, in a recent study of vaccinated (n = 119) and unvaccinated (n = 239) cats, two point-of-care kits, Witness FeLV/FIV (Zoetis Animal

Health, France) and Anigen Rapid FIV/FeLV (BioNote, Korea), accurately detected infection regardless of vaccination status.[82] However, subsequently, in a prospective study of 19 kittens using one of these tests (Witness FeLV/FIV), transient vaccine-induced antibodies were detected in almost half of vaccinates.[83] Further clarification of the utility of point-of-care kits from different manufacturers in detecting true infection status is expected. The reliability of a negative serology result is unchanged by the introduction of FIV vaccination.

PCR can be used with serology to assist in determining the true infection status of seropositive cats that may be vaccinated against FIV, seropositive cats less than 6 months of age and seronegative cats that have been recently exposed to FIV. After experimental exposure, PCR can detect viral RNA within 1 to 2 weeks and DNA within 3 weeks but differences in virus strain, dosage and assay sensitivities mean that it is hard to predict how long after natural exposure PCR can be used to detect FIV infection. Positive PCR test results indicate that the cat is almost certainly infected, whereas negative PCR results are inconclusive.

Prognosis

Controlled studies demonstrate comparable survival time between FIV-infected and uninfected cats.[5,27-29,84] In a study of almost 10,000 retrovirus-tested pet cats, including 1100 seropositive for FIV, the survival rate at 6 years was 65% compared to 90% for uninfected cats.[28] In the same study, if deaths during the first 100 days were excluded, survival of FIV-infected cats was 94% and 80% at 3 and 6 years, respectively, compared with controls. There is no justification for the euthanasia of healthy cats on the basis of FIV status. Regrettably, this practice does occur.[29,85,86]

Even though a negative effect of FIV infection on survival is minor or non-existent when groups of cats are studied, the effect of FIV on morbidity is potentially underestimated. The progressive immune dysfunction that accompanies FIV infection means that the clinician should "expected the unexpected" in FIV-infected cats, even when they are reported to be healthy.

Management

Comprehensive international guidelines for the management of FIV-infected cats from the American Association of Feline Practitioners and the European Advisory Board on Cat Diseases are available to download.[87,88]

Healthy FIV-Infected Cats

FIV-infected cats are the source of new infections and they should be prevented from contacting uninfected cats. This means confining FIV-infected cats indoors or in an enclosure, singly or with other FIV-infected cats. Where a cat in a multicat household is identified as FIV-infected, all cats in the household should be tested. If the household is stable and closed, the benefits of belated segregation may be small as the virus is unlikely to spread, although owners should be made aware of this possibility.

Veterinary check-ups of FIV-infected cats every 6 months will facilitate early detection of any emerging health problems. Evidence on which to base recommendations for vaccination of FIV-infected cats against FHV-1, FCV and FPV is limited.[89,90] Killed products should be selected over modified-live vaccines for FIV-infected cats because of the potential for reversion to virulence with the latter in cats at risk from immunosuppression (see ch. 208).[91,92] Individual risk assessment will guide the frequency of vaccination and the choice of immunogens.[92,93] Control of ectoparasites, endoparasites and the importance of dental prophylaxis and a balanced diet should be stressed to owners.

Sick FIV-Infected Cats

In the absence of surrogate markers that reliably predict disease progression, the prognosis for an individual FIV-infected cat should be determined without regard to its FIV status. Many sick FIV-infected have treatable diseases. Knowing that a cat is FIV-infected is not a reason to curtail the investigation but, rather, will inform the list of differentials and help to guide the diagnostic investigation and treatment selection.

Where antibiotics are indicated, selection should be based on the results of sensitivity testing, and bactericidal agents and dosing protocols used. Clinicians should be vigilant for drug reactions (see ch. 169). Severe drug-induced neutropenia following griseofulvin administration has been reported in FIV-infected

cats.[94] Glucocorticoids may be indicated to treat intercurrent inflammatory or immune-mediated problems arising in FIV-infected cats. Glucocorticoids should be used judiciously, only where specifically indicated, and patients should be monitored closely.

Investigation of chronic gingivostomatitis includes consideration of a range of contributing etiologies, including feline calicivirus-associated disease, inflammation associated with dental disease, immune-mediated and neoplastic causes, and eosinophilic granuloma complex (see ch. 36 and 272).[56] The degree and duration of response to symptomatic and supportive treatments such as teeth cleaning, antibiotics such as amoxicillin clavulanate, interferons and anti-inflammatory doses of glucocorticoids are variable.[95] Extraction of premolars and molars is reported to improve signs in 60-80% of affected cats.[96,97]

In cats presenting with intermediate or high-grade lymphoma, there is no evidence that FIV infection *per se* is a negative prognostic indicator for response to multiagent chemotherapy, although data are limited.[98] Close monitoring of the neutrophil count during therapy is warranted. Where neurological impairment is identified and localized in FIV-infected cats, investigation for potentially treatable causes is indicated (see ch. 261).

Management of FIV-associated wasting (see ch. 177) involves investigation for treatable diseases including enteropathies (see ch. 276) and exocrine pancreatic insufficiency (see ch. 292), supportive care, nutritional support and appetite stimulation.

Severe or persistent cytopenias in FIV-infected cats should be investigated for treatable causes, since cytopenias are common in sick cats regardless of their FIV status.[27,54] There is currently no suitable supportive treatment for FIV-associated neutropenia. Recombinant human granulocyte colony-stimulating factor (rHuG-CSF) increased neutrophil counts in the short term in young cats experimentally infected with FIV, but this effect ceased with the development of antibodies to rHuG-CSF.[99] Further, cross-neutralization with feline (Fe)G-CSF risks refractory agranulocytosis. Pegylated FeG-CSF showed promising results with less frequent dosing, but this compound is not commercially available.[100] Anemia is associated with FIV infection, although less commonly than neutropenia, and supportive care may be indicated. Recombinant human erythropoietin (rhEPO) was effective at increasing PCV in FIV-infected cats without inducing anti-rhEPO antibodies in one small study.[101] Darbepoetin, which is longer-acting and less antigenic than rhEPO, is effective in cats, although studies in FIV-infected cats specifically are not reported.[102]

Immune Modulation and Antiviral Therapies

Before embarking on any treatment trial using immunomodulators or antiviral drugs, the owners' expectations should be carefully managed. FIV infection cannot be cured. The small chance of improving clinical signs should be balanced against the potential risks and costs, including monitoring costs, involved.

Data to support the use of immunomodulators in FIV infection are very limited.[103,104] Non-specific immune stimulation risks unintended outcomes including increased virus replication and the activation of immune suppressor cells. In a placebo-controlled study using human recombinant interferon-alpha (rHuIFN-alpha) (oral transmucosal, 50 IU/cat q 24 h, 7 days on, 7 days off for 6 months) in natural FIV infection, no effect on plasma virus or provirus load was detected although improved clinical signs were reported.[105] Improvements in clinical parameters were also reported using recombinant feline interferon-omega (rFeIFN-omega,Virbagen Omega, Virbac) at 1 MU/kg SC q 24 h for 5 days, repeated on days 14 and 60 or a lower-dosage oral protocol (0.1 MU/cat rFeIFN-omega PO q 24 h for 90 days).[106,107]

Antiretroviral therapies have dramatically improved the prognosis for HIV-infected humans. Combinations of drugs that inhibit HIV reverse transcriptase, protease or integrase avoid the rapid emergence of drug-resistant mutants. Virus load and CD4 count are used to guide the timing of initiation of treatment and to assess response in asymptomatic HIV-infected patients. In contrast, there are limited data to evaluate antiretrovirals in FIV infection and there are no licensed products.[108] Combination therapy for FIV to avoid the emergence of resistant mutants is hampered by the limited choice of drugs; most inhibitors of HIV protease are ineffective against FIV and data on potential inhibitors of FIV integrase are limited to *in vitro* activity.[109,110] Several nucleoside analogues can inhibit FIV reverse transcriptase, including zidovudine (AZT, 3'-azido-3'-deoxythymidine), lamivudine (3TC, 2',3'-dideoxy-3'-thiacytidine) and adefovir (PMEA, 9-[2-phosphonomethoxyethyl]adenine). Improvements in clinical scores, virus load and CD4 counts are reported in some studies but adverse effects, including anemia, neutropenia and gastrointestinal signs are common and can be severe. The pharmacokinetics of AZT have been studied in cats and this drug was associated with improvement in stomatitis in a blinded, placebo-controlled study.[111,112] Precautions for AZT use are shown in

E-Box 222-1.

E-Box 222-1

Precautions for AZT (Reverse Transcriptase Inhibitor) Use in FIV-Infected Cats

- Cats with bone marrow suppression should not be treated.
- Dosage: 5-10 mg/kg q 12 h PO or SC.
- Side-effects are more common at the higher dosage.
- For SC injection, reconstitute with 0.9% NaCl.
- Monitor for anemia; complete blood count weekly × 4, then monthly if stable.
- Mild, transient anemia in the first 3 weeks usually resolves even if treatment is continued.
- Discontinue treatment if hematocrit falls below 20%. Resolution of anemia after withdrawal is expected.
- Long-term use for months or years is reported.

Data from European Advisory Board on Cat Diseases. Hosie MJ, Addie D, Belák S, et al: Feline immunodeficiency. ABCD guidelines on prevention and management. *J Feline Med Surg* 11:575-584, 2009.

In an alternate approach, CXCR4 antagonist AMD3100 (1,1'-bis-1,4,8,11-tetraazacyclotetradekan), which blocks the co-receptor for FIV entry, has been evaluated in client-owned, FIV-infected cats. A prospective, placebo-controlled, double-blind trial showed a mild reduction in proviral load, minimal side-effects and no emergence of resistance over a 6-week period.[113]

Prevention

The most effective way to prevent FIV infection is to confine uninfected cats. Free-roaming cats are at high risk from FIV infection and they represent an important source of new infections. Confining owned FIV-infected cats is also advised to prevent new infections. Providing an enriched environment that prevents roaming is effective, not just in reducing infectious disease risk, but also in preventing trauma, straying and hunting.

A commercial, inactivated, infected-cell vaccine, Fel-O-Vax FIV, has been available in some regions for over a decade. This vaccine is currently categorized, according to international feline vaccination guidelines, as "non-core."[92,93] There are two principal reasons why the use of the FIV vaccine has been controversial. The first concerns its efficacy. The vaccine contains subtypes A and D and, in most published studies, it performs well. Sterilizing immunity against homologous and heterologous FIV strains including subtype B viruses has been demonstrated.[114,115] In studies performed by the vaccine developers, preventable fractions between 80-100% are demonstrated as well as protection from contact challenge and duration of immunity of 12 months or more.[116,117] In a single independent study, the vaccine provided no protection against challenge with a subtype A isolate.[118] Additional independent data on the efficacy of the vaccine in the field in different regions are awaited.

A second area of concern has been that uninfected cats that are vaccinated will test positive on serological tests for FIV.[81] This situation was partly addressed by the introduction of commercial PCR testing for FIV. However, recent data support that point-of-care FIV serology tests from some manufacturers are able to reliably predict FIV infection regardless of vaccination history (see Diagnosis).[82] The availability of tests or testing combinations for FIV infection that are unaffected by the serological response to vaccination is likely to reduce opposition to FIV vaccination.[82,119,120]

CHAPTER 223

Feline Leukemia Virus Infection

Katrin Hartmann, Julie K. Levy

Client Information Sheet: Feline Leukemia Virus Infection

Background

Feline leukemia virus (FeLV) is a retrovirus present throughout the world's domestic cat population. Infection is associated with a variety of illnesses, including neoplasia, bone marrow suppression, and immunodeficiency. The RNA of FeLV is reverse-transcribed into DNA in infected cells and the DNA copies (provirus) are inserted randomly into the host genome. Cell divisions then result in daughter cells containing this provirus. The viral genome encodes for the major proteins *gag* (group-specific antigens), *pol* (reverse transcriptase), and *env* (envelope). One of the *gag* proteins, p27, is abundant in the plasma of infected cats and is the basis for most currently used diagnostic tests. The envelope protein gp70 defines the virus subgroup and is important for inducing immunity.

The prevalence of progressive FeLV infection is similar world-wide: about 1% of healthy cats and up to 15% of high-risk and sick cats are infected.[1,2] Risk factors for infection include illness, male gender, adulthood, outdoor access, and large-scale cat hoarding. Indoor lifestyle and neutering are associated with low infection rates.[1,3-5] Certain diseases are associated with a high prevalence of progressive FeLV infection, such as lymphoma (12.7%),[43] cutaneous abscesses and bite wounds (8.8%), and oral inflammation (7.3%).[6,7] The prevalence has been decreasing these last decades due to common use of FeLV vaccines and widespread test and removal/separation programs.[1,3,8-11]

Pathogenesis

Outcomes of Infection

When FeLV was first discovered, it was believed that most cats cleared the virus after a period of transient viremia, but polymerase chain reaction (PCR) has revealed that most (or even all) cats remain infected for life.[12] There are 3 major outcomes of FeLV infection: progressive infection (antigen-positive, provirus-positive cats), regressive infection (antigen-negative, provirus-positive cats), and abortive infection (antigen-negative, provirus-negative, but antibody-positive cats).[7,13,14] These 3 outcomes can be distinguished through testing for antigen, proviral DNA, and antibodies (Table 223-1). Infection outcome depends on the cat's immune function and the amount of infective virus to which the cat was exposed. In addition to these 3 outcomes, focal infections have been described as rare events in which FeLV infection is restricted to certain tissues, i.e., spleen, lymph nodes, small intestine, or mammary glands. These focal infections are unlikely to play an important role in naturally infected cats.[15,16]

TABLE 223-1

Feline Leukemia Virus Infections Status Possibilities

	SOLUBLE FeLV P27 ANTIGEN IN BLOOD	PROVIRAL DNA IN BLOOD	ANTIBODIES IN BLOOD	REPLICATING VIRUS IN BLOOD	VIRAL RNA IN BLOOD	VIRAL SHEDDING	FeLV-ASSOC DISEA
	ELISA or other						

Test	immunochromatography test	PCR	available	Viral culture	RT-PCR		
Progressive infection	Positive	Positive	Low or negative	Positive	Positive	Yes	Commor
Regressive infection	Negative	Positive	High	Negative	Negative	No	Uncomm reacti possi
Abortive infection	Negative	Negative	High	Negative	Negative	No	None
Not FeLV-infected	Negative	Negative	Negative	Negative	Negative	No	None

After mucosal or cutaneous inoculation of FeLV, the virus replicates in local lymphoid tissues before infected cells carry the virus to target tissues, such as thymus, spleen, and lymph nodes. The virus then populates salivary glands and mucosal glandular epithelium, the sites that eventually secrete most FeLV responsible for horizontal transmission. At the same time (about 3 weeks after infection), bone marrow cells also become involved, producing infected neutrophils and platelets that circulate in the blood.

FeLV genetic material is usually detectable by PCR within 1 week of infection. In most cats, antigenemia (presence of viral proteins in the blood) correlates with viremia (presence of infectious virus that can be cultured from the blood), although some cats have discordant findings.[17] Infected cats can either remain viremic and antigenemic (progressive infection) or revert to an aviremic state (regressive infection) in which neither antigen nor culturable virus is detected but in which FeLV proviral DNA can still be identified.[13,18] Some cats become negative in antigen and proviral DNA but remain antibody-positive (abortive infection). In the course of infection, regressive and progressive infections can be distinguished by repeated testing for FeLV antigen in peripheral blood. Progressive cats remain antigen-positive, while regressive cats revert to an antigen-negative status.[18] They also can be distinguished by their provirus load.[12] During early infection, all cats have similar proviral loads. After a few weeks, provirus load drops in regressively infected cats while it stays high in progressively infected cats.[13,19]

Progressive Infection

In progressive infection, insufficient FeLV-specific immunity results in extensive virus replication that occurs first in the lymphoid tissues and then in the bone marrow. Spread to mucosal and glandular tissues and excretion of infectious virus occur simultaneously with bone marrow infection. The number of cats developing progressive FeLV infection varies by "infection pressure," which ranges from about 3% (after single contact with a FeLV-shedding cat) to about 30% (when living together for several weeks with a shedding cat).[4] Progressively infected cats have a decreased life expectancy. In a long-term follow-up study on experimentally FeLV-infected cats, progressively infected cats lived an average of 3.1 years (range from 0.6 to 6.5 years).[12] Progressively infected cats are persistently antigenemic, continuously shed the virus, and frequently succumb to FeLV-associated diseases within a few years.

Regressive Infection

In regressive infection, an effective immune response limits virus replication prior to or at the time of bone marrow infection. In recent studies, 2% to 10% of FeLV-antigen-negative cats were positive for FeLV provirus by PCR, and thus, regressively infected.[13,20,21] In these cats, FeLV antigen is sometimes detectable in peripheral blood 2 to 3 weeks after virus exposure but then disappears 2 to 8 weeks later or, in rare cases, after several months. Some regressively infected cats fail to ever develop detectable antigenemia. Cats with regressive infection have persistent integration of FeLV DNA in their genome.[22] Complete clearance of FeLV viral RNA or provirus was never detected in cats with regressive infection, even up to 12 years after exposure.[12] However, regressively infected cats only rarely develop FeLV-associated disease, such as lymphoma or bone marrow disorders.[20,23-27] Even though viral shedding does not occur, it is possible for cats with regressive infection to transmit FeLV via blood and tissue donation since the proviral DNA can be infectious.[28,29] It is also possible that the regressive state can convert to a progressive state (reactivation). In a long-term follow-up study on experimentally infected cats, 5/10 regressively infected cats had infection

long-term follow-up study on experimentally infected cats, 5/10 regressively infected cats had infection reactivated and became antigen-positive at different time points over a period of up to 8.5 years.[12] This is more likely to occur soon after exposure to FeLV, but has been described in cats that were antigen-negative for many years.[30]

Abortive Infection

In abortive infection, cats are negative for culturable virus, antigen, viral RNA, and proviral DNA, but remain antibody-positive.[18,31] The incidence of abortive infection is unclear under natural circumstances, but it is more common than once estimated.[21] These cats are assumed to have lifelong protection against new infection and probably do not need vaccination.

Transmission

Under normal circumstances, only progressively FeLV-infected cats transmit the virus to others. Infectious virus is found in highest concentrations in saliva, but also in milk, nasal secretions, feces, and urine.[16,32] FeLV is mostly transmitted horizontally via the oronasal route and bite wounds. Intimate contact between cats is optimal for transmission, such as mutual grooming, and sharing of dishes and litterpans. Transmission can occur during mating, during intrauterine fetal development, or via milk from infected queens to kittens. A recent study found that indirect transmission through FeLV-containing feces is also possible, but those infected cats only develop abortive infection.[33,34] Blood transfusions are also a mode of transmission from both progressively and regressively infected cats.[29]

Susceptibility to FeLV is much higher for kittens than for adult cats. All newborn kittens and most cats up to 2 months of age experimentally infected with FeLV developed progressive FeLV infection, whereas only 15% of cats inoculated when they were 4 months or older became progressively infected.[35] Some studies, however, have demonstrated efficient natural and experimental infection of adult cats as well.[36] Thus, although the risk is lower than in kittens, adult cats can sometimes become progressively infected.

Clinical Signs

Clinical Signs Described in the Field

Although progressively FeLV-infected cats can remain clinically healthy for years, several disease conditions are associated with FeLV infection, including bone marrow disorders (mainly anemia), neoplasia (mainly lymphoma), and immunosuppression leading to susceptibility to secondary infections.[4,8,37,38] FeLV-infected cats have a reduced life expectancy.[11] A comparison between 823 progressively FeLV-infected cats and 7476 age- and sex-matched controls revealed that the median survival of FeLV-infected cats was 2.4 years from the time of diagnosis compared to 6.3 years for controls.[39] Progressive FeLV infection increases the risk for a wide variety of conditions, but it is not always possible to determine whether concurrent diseases are a consequence of FeLV infection or are independent. In 3712 FeLV-infected cats seen for veterinary care, 29% were free of clinical signs.[3] Weight loss was most common in symptomatic cats (63%), followed by fever (42%), dehydration (35%), rhinitis (18%), diarrhea (17%), conjunctivitis (17%), oral inflammation (15%), lymphadenopathy (13%), and abscesses (12%).[3] In another study of 8756 FeLV-infected cats seen at veterinary medical teaching hospitals, anemia (18%) was the most common concern, followed by upper respiratory infection (11%), lymphoma (10%), myeloproliferative diseases (6%), stomatitis (5%), leukopenia (3%), hemoplasmosis (3%), lymphadenopathy (3%), and uveitis (2%).[8]

Bone Marrow Disorders

Bone marrow suppression, especially anemia, is the most common clinical syndrome associated with FeLV infection, resulting from infection of both hematopoietic stem cells and bone marrow stromal cells.[40] Progressive infection with active viral replication is usually required for bone marrow suppression. Regressive infection is only rarely associated with myelosuppression.[27,41] Thus, in a FeLV antigen-negative cat with bone marrow suppression, testing bone marrow for FeLV by PCR is only sometimes helpful.[27] The most common form of FeLV-induced anemia is pure red cell aplasia, a severe nonregenerative anemia with

finding of a lack of reticulocytes but a high mean corpuscular volume [MCV]). Regenerative anemia in FeLV-infected cats, indicated by increased reticulocytes and, in some cases, nucleated red blood cells (RBCs), is less common than nonregenerative anemia and is often associated with coinfection with *Mycoplasma haemofelis* or other hemotropic *Mycoplasma* spp. (see ch. 199 and 219). Some cats with immune-mediated hemolytic anemia are progressively FeLV-infected, and in some, hemolysis precedes the emergence of myeloproliferative disease or lymphoma.

FeLV is also an important cause of thrombocytopenia and granulocytopenia in cats (see ch. 201 and 202). FeLV and myeloproliferative diseases accounted for 44% of cats with thrombocytopenia in one report.[42] Cyclic and persistent neutropenia can occur due to a secondary immune-mediated condition, since some cats respond to immunosuppressive prednisone therapy. Cytopenias can wax and wane in FeLV-infected cats and some are associated with myelodysplasia that eventually evolve into a terminal myelodysplastic syndrome (see ch. 202) or leukemia (see ch. 344). In addition to FeLV's direct bone marrow suppression, nonregenerative anemia, neutropenia, and thrombocytopenia can be a consequence of effects secondary to FeLV, including bone marrow infiltration with neoplastic cells (e.g., lymphoma), infectious agents, myelofibrosis, and osteosclerosis.

Neoplasia

The most common tumors associated with FeLV infection are those of the lymphoid and hematopoietic systems (see ch. 344). Progressive FeLV infection results in a 60-fold increased risk of lymphoma compared with non-infected cats. About 25% of cats with progressive FeLV infection develop lymphoma within 2 years of diagnosis. Multicentric and mediastinal lymphoma are most common, although spinal, renal, ocular and other forms of lymphoma have been diagnosed in FeLV-infected cats.

As the prevalence of FeLV has decreased since its discovery, so has the incidence of FeLV-associated lymphoma.[10,43] The most important mechanism by which FeLV causes malignancy is by inserting the FeLV genome into the cellular genome near a cellular oncogene (most commonly *myc*), activating and overexpressing that gene and causing uncontrolled proliferation of these cells (clone). FeLV can also incorporate the oncogene to form a recombinant virus (e.g., FeLV-B, FeSV) containing cellular oncogene sequences that are rearranged and activated. Upon entering a new cell, the recombinant viruses are oncogenic. In a study of 119 cats with lymphomas, transduction or insertion of the *myc* locus had occurred in 38 cats (32%).[44] Thus FeLV-induced neoplasms are caused, at least in part, by somatically acquired insertional mutagenesis in which the integrated provirus activates a proto-oncogene or disrupts a tumor suppressor gene. Twelve common integration sites for FeLV associated with lymphoma development have been identified in six loci: c-myc, flvi-1, flvi-2 (contains bmi-1), fit-1, pim-1, and flit-1.[45] Some studies also show that variations in the FeLV surface glycoprotein can determine the development of tumors.[46]

If FeLV is the cause of lymphoma, it is usually through progressive infection, but regressive FeLV infection can also be involved. Cats from FeLV cluster households have a 40-fold higher rate of development of FeLV-negative lymphoma than cats from the general population. FeLV proviral DNA was detected in lymphomas of FeLV antigen-negative cats, and lymphomas have also occurred in FeLV antigen-negative laboratory cats known to have been infected previously with FeLV.[47,48] Results of studies on the incidence of regressive FeLV infection in cats with lymphoma vary significantly. Recent studies found evidence of provirus in only 1/10[41] and in 0/50 FeLV antigen-negative lymphomas[26] suggesting that regressive infection is only rarely involved in tumor development.

Immunosuppression

Diseases associated with immunosuppression account for much of the morbidity and mortality in cats with progressive FeLV infection. Thymic atrophy and depletion of lymph node paracortical zones are common, particularly in cats infected as kittens. Neutropenia and lymphopenia can further exacerbate immunosuppression. Poor response to T cell mitogens, prolonged allograft rejection, reduced immunoglobulin production, depressed neutrophil function, complement depletion, cytokine dysregulation, and poor responses to vaccination are common in FeLV-infected cats.[38] Many FeLV-infected cats have concurrent bacterial, viral, protozoal, or fungal infections. Few studies prove these cats have higher rates of infection than non-infected cats or that they have a less favorable response to therapy. Thus, although FeLV is well known to suppress immune function, it should not be assumed that all concurrent infections are a result of FeLV infection.

of FeLV infection.

Miscellaneous Disorders

Transient generalized lymphadenopathy has been observed in young, progressively infected cats. Abortion due to endometritis or transplacental infection of fetuses has been observed. An FeLV "panleukopenia-like syndrome" mimics feline parvovirus infection with low white cell counts, crypt necrosis, and high mortality. Some cats were identified to be coinfected with parvovirus. Lymphocytic-plasmacytic stomatitis, although more common in cats infected with feline immunodeficiency virus (FIV; see ch. 222), is also common in FeLV-infected cats. Neurologic infection can cause neurologic disorders, such as urinary incontinence and pupillary spasm leading to D-shaped pupils and anisocoria. FeLV-associated myelopathy results in vocalization, hyperesthesia, and paresis progressing to paralysis. It has been suggested that FeLV is disrupting intracellular thiamine uptake by blocking a putative thiamine receptor (THTR1), complicating these conditions further.[49]

Diagnosis

Timepoints of Testing for FeLV

Diagnosis of FeLV infections is important in all cats as identification and segregation of infected cats is considered to be the most effective method for preventing transmission. The American Association of Feline Practitioners recommends testing for retrovirus infection when cats are newly acquired, sick, about to be vaccinated against FeLV, or believed to have been exposed to a potentially infected cat.[7] Diagnosis of progressive and regressive infection requires testing for both FeLV antigen and FeLV provirus (Figure 223-1). Detection of the circulating soluble FeLV p27 antigen is commonly done through in-clinic test kits that use serum, plasma, or whole blood. Some results are positive on whole blood but negative on serum or plasma. Thus, one should repeat testing on serum when positive results are seen on whole blood. Tests usually become positive within 30 days of exposure but might take far longer.[17] If results of soluble FeLV antigen testing are negative but recent exposure cannot be ruled out, testing should be repeated a minimum of 30 days after the last potential exposure. Kittens can be tested at any time because passively acquired maternal antibodies do not interfere with testing for viral antigen. Vaccination against FeLV does not interfere with testing.

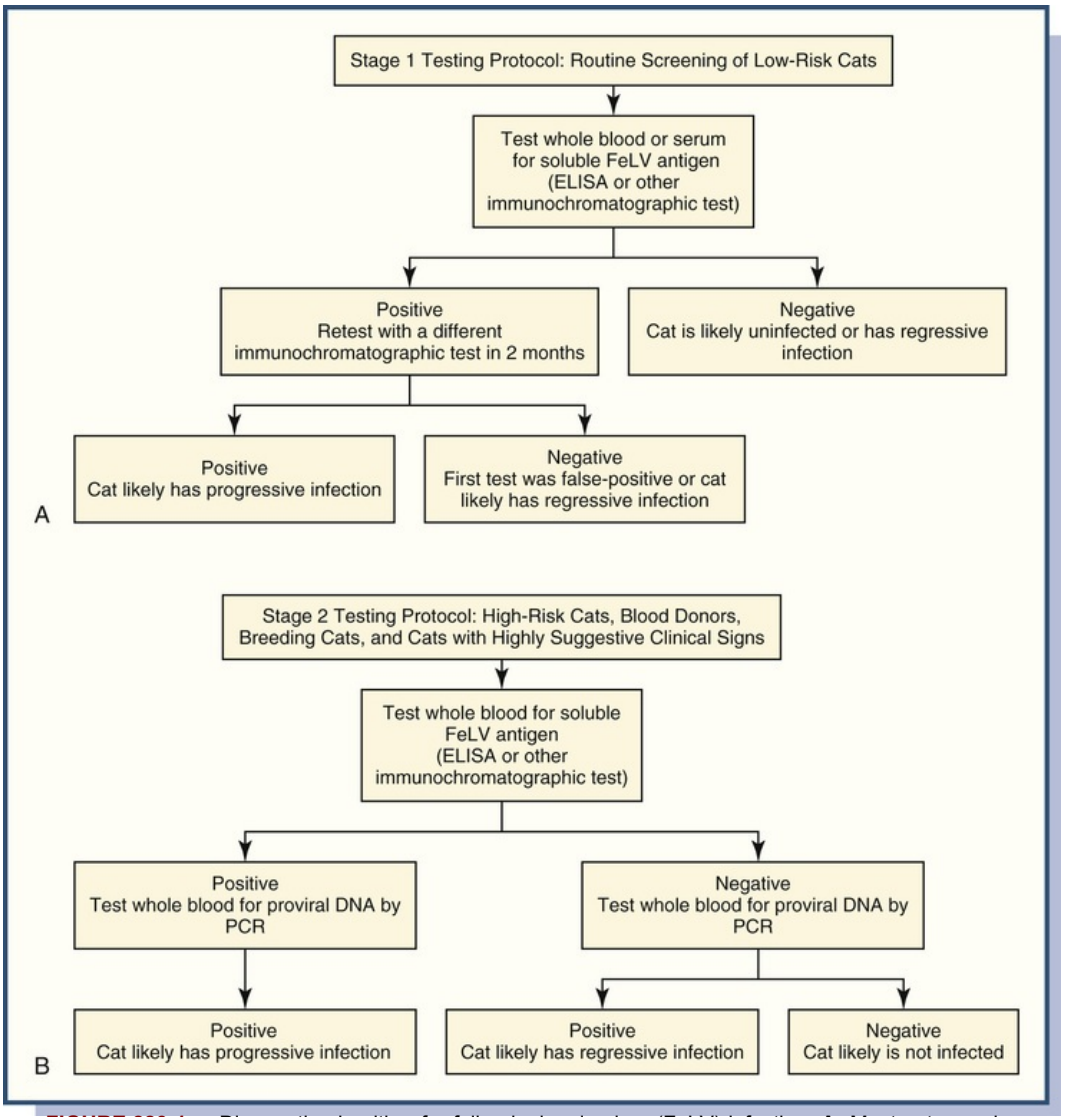

FIGURE 223-1 Diagnostic algorithm for feline leukemia virus (FeLV) infection. **A,** Most cats can be accurately diagnosed with the Stage 1 screening protocol. **B,** The Stage 2 protocol is indicated if Stage 1 test results are unexpected or if there is a need for additional certainty regarding FeLV infection status, such as for blood donors and breeding cats.

In-House Testing for FeLV Antigen

In-house tests for soluble FeLV antigen (such as enzyme-linked immunosorbent assay [ELISA] or similar immunochromatographic tests) are generally highly reliable for detecting progressive FeLV infection. Industrial tests detecting soluble antigen are not superior.[50-52] However, positive results should be confirmed, especially in low-risk and asymptomatic cats in which the predictive value of a positive test is low.[7,53] Due to high test sensitivity and low prevalence of infection (high negative predictive value), a negative test result is highly reliable (see Figure 223-1). Multiple options exist for confirmation of a positive in-house test result, such as IFA or PCR. Ideally, testing for soluble antigen should first be repeated using a test from a different manufacturer.[50,54]

Immunofluorescence Assays (IFA) for FeLV Antigen

IFA detects intracellular FeLV p27 antigen within infected blood cells following bone marrow infection. In blood smears, neutrophils and platelets are most likely to be infected. Thus, this test usually becomes positive several weeks after tests that detect soluble antigen (such as ELISA). False negatives can occur in cats with neutropenia, thrombocytopenia, or lack of bone marrow infection. The IFA is also negative in cats with

regressive infection. Discordant test results in soluble antigen in-house tests and IFA can make determination of the true FeLV status difficult. The most common scenario occurs when the soluble antigen test is positive and the IFA test is negative. This can be due to an early stage of infection (<3 weeks), the variability of host responses, technical problems with testing, or the lower sensitivity of the IFA. Cats with discordant test results should be considered potential sources of infection. Their status should be clarified through repeated testing.

Polymerase Chain Reaction (PCR) for FeLV Provirus

PCR is used to detect FeLV provirus (the viral DNA integrated into the cats' genome), while RT-PCR (in which a reverse transcription step is required first) detects RNA and thus, replicating virus. RT-PCR to detect RNA is not used for routine diagnostics and does not provide any further information as it is always positive when soluble FeLV antigen tests are positive. Provirus PCR is highly sensitive and necessary to detect regressive FeLV infection.

Tests for FeLV Antibodies

FeLV antibody tests, such as antibodies against FeLV transmembrane protein p15E, would be necessary to confirm abortive infection but are not yet widely available.[55]

Prevention

Control of FeLV is facilitated by its short survival (only minutes) outside the host. Transmission among cats usually requires direct contact and can be prevented at home, in veterinary clinics, and in animal shelters by simple segregation and effective disinfection. A nonadjuvanted recombinant FeLV vaccine and several injectable inactivated adjuvanted vaccines are commercially available. Studies of vaccine efficacy vary in methodology, making comparisons difficult.[56,57] Nonadjuvanted vaccines might be less likely to cause feline injection-site sarcoma formation.[58] FeLV vaccine-induced immunity has been shown to persist for at least 1 to 3 years.[59-61] Protection is not absolute and vaccination cannot be used as a substitute for testing to identify and isolate infected cats. While FeLV vaccination significantly reduces risk of progressive infection, it does not induce sterilizing immunity and does not prevent development of regressive infection. Cats can become positive for circulating proviral DNA subsequent to FeLV exposure.[13,18,62,63] Nonetheless, efficacious FeLV vaccines are valuable. Protection against progressive infection can prevent FeLV-associated diseases.[62,64] FeLV vaccines are considered noncore and are only recommended for cats at risk of exposure (e.g., cats permitted outdoors, cats residing with FeLV-infected cats, or cats living in multiple-cat environments) in countries where FeLV remains common.[65] Cats should be tested for infection before initial FeLV vaccination. Administration of FeLV vaccines to infected cats has no value and FeLV vaccines are not without risk (such as development of injection-site sarcoma).[7]

Management and Treatment

The FeLV status of all cats should be known. FeLV-infected cats should be confined indoors to contain the spread of the viruses and to protect affected cats from other infectious agents carried by other animals.[7] Specific management measures for multi-cat households with FeLV infection and for individual FeLV-infected cats should be considered (Box 223-1).[7,66,67] Vaccination programs to prevent common infectious diseases should be maintained. Cats infected with FeLV might not adequately respond to vaccination. It is important to protect those cats from exposure to sick cats or contaminated environments.[68] Although it is recommended that FeLV-infected cats be given inactivated and not modified-live virus (MLV) vaccines (when available), little evidence supports increased risk of adverse effects through MLV vaccines.[7]

Box 223-1

Management of Multi-Cat Households with FeLV-Infected Cats and of Individual Cats with Progressive FeLV Infection[7,64]

Management of Multi-Cat Households with FeLV-Infected Cats

- FeLV is mainly transmitted through social contact, but also through biting and fighting.
- If a progressively FeLV-infected cat lives in a household with otherwise FeLV antigen-negative cats, many of the other cats might already have been exposed and developed abortive, regressive, or progressive infections. Cats with regressive and abortive infections are likely immune to new infection.
- The risk of new infections arising in cats with pre-existing long-term exposure to FeLV-infected cats is low. If they eventually become antigen-positive, this is more likely caused by reactivation of a regressive FeLV infection than by transmission from the other cats in the household. However, transmission cannot be totally excluded, and thus the only 100% safe prevention is to separate infected and uninfected cats.
- If owners refuse to separate housemates, the uninfected cats should receive FeLV vaccination to enhance their natural level of immunity. However, owners should be informed that vaccination does not provide complete protection in these high exposure environments.

Management of Individual FeLV-Infected Cats

- Progressively FeLV-infected cats should be kept indoors to avoid spread to other cats and exposure of the cat to other infectious agents carried by other animals.
- "Routine vaccination programs" should be maintained in cats with progressive FeLV infection (see ch. 208). They might not be able to mount an adequate immune response to vaccines and protection might not be comparable to that in a healthy cat. Therefore, testing for the immune response (e.g., antibody measurement after feline panleukopenia virus vaccine) and protecting against exposure should be considered.
- Progressively FeLV-infected cats should have health care visits at the veterinarian at least semi-annually in order to promptly detect changes in the health status. A complete blood count should be performed every 6 months, and a biochemistry profile and urinalysis once a year.
- Intact male and female cats should be neutered to reduce stress associated with estrus and mating behavior and the desire to roam outside the house and interact aggressively.
- Surgery is generally well tolerated, but perioperative antibiotic administration should be used.
- Cats with progressive FeLV infection can be housed in the same ward as other hospitalized patients, but in individual cages. They should not be placed in a "contagious ward" with cats suffering from other infections.
- If progressively FeLV-infected cats are sick, prompt identification of the secondary illness is essential to allow early therapeutic intervention.
- Most cats with progressive FeLV infection respond as well as uninfected cats do to appropriate medications, although a longer and more aggressive course of therapy (e.g., antibiotics) might be necessary.
- Corticosteroids and other immune-suppressive as well as bone marrow-suppressive drugs should be avoided in progressively and regressively infected cats, if possible.

Prompt and accurate identification of FeLV-associated as well as secondary diseases is important, to allow early therapeutic intervention and a more successful outcome (Box 223-2). Many cats infected with retroviruses respond as well as their uninfected counterparts to appropriate symptomatic treatment and therapy of secondary infection. Antiviral drugs and drugs aimed at modulating the immune system are commonly used in FeLV-infected cats (E-Table 223-2). Unfortunately, few large controlled studies have been conducted in naturally infected cats and most of them have shown no effect of the used antiviral drugs or immunomodulators.[69-73]

Box 223-2

Suggested Treatment Recommendations for Cats with Progressive FeLV Infection[14,74]

If No Clinical Signs Are Present

- No treatment is indicated
- Cats should be kept strictly indoors

If Clinical Signs Are Present

- Always look for underlying diseases first (FeLV itself might not be responsible for the clinical signs, e.g., secondary infections could be present)
- Treat underlying diseases

Treatment of FeLV-Infected Cats with Lymphoma

- Use chemotherapeutic drug protocols (e.g., protocol that includes cyclophosphamide, vincristine, and prednisone; see ch. 344)
- Inform owners about the more guarded prognosis

Treatment of FeLV-Infected Cats with Anemia

- Give blood transfusions if anemia is severe (see ch. 130)
- Look for underlying diseases causing the anemia
- Treat underlying diseases
- If hemolytic anemia is present, treat for occult hemotropic *Mycoplasma* spp. infection with doxycycline (see ch. 219)
- If underlying diseases have been ruled out, consider glucocorticoids (because anemia in FeLV-infected cats can have an immune-mediated origin; see ch. 198)

Treatment of FeLV-Infected Cats with Neurologic Signs

- Look for underlying diseases causing the neurologic signs (e.g., lymphoma)
- Treat underlying diseases
- If no underlying disease is present (and the neurologic signs are assumed to be indeed caused by FeLV), treat with zidovudine (5 mg/kg PO q 12 h)

Treatment of FeLV-Infected Cat with Recurring Infections

- Treat recurring infections aggressively (e.g., long-term antibiotics)
- Consider treatment with feline interferon-omega (10^6 IU/kg SC q 24 h for 5 consecutive days)

E-TABLE 223-2

Antiviral Drugs and Immunomodulators for Progressively Feline Leukemia Virus-Infected Cats (Including Evidence-Based [EBM] Grades for Judgment of the Available Efficacy Data and Personal Opinion of the Authors)[64,66,74]

DRUG	EFFICACY *IN VITRO*	CONTROLLED STUDY *IN VIVO*	EFFICACY *IN VIVO*	PERSONAL OPINION	EBM LEVEL (1-4)
Nucleoside Analogue Reverse Transcriptase Inhibitors					
Zidovudine (AZT)	Yes[75]	Yes	No[72,76]	Not very effective	1
Stavudine (d4T)	n.d.	No	n.d.	Possibly effective, but no data in cats available	4
Didanosine (ddI)	Yes[75]	No	n.d.	Possibly effective, but no data in cats available	4
Zalcitabine (ddC)	Yes[75,77,78]	Yes	No[77,78]	Not very effective, but toxic	2
Lamivudine (3TC)	No	No	n.d.	Possibly effective, but also toxic	4
Nucleotide Analogue Reverse Transcriptase Inhibitors					
Adefovir (PMEA)	Yes[79]	Yes	No[70]	Poorly effective, but relatively toxic	2

Tenofovir (PMPA)	Yes[80]	No	n.d.	Possibly effective, but likely also relatively toxic	2
Non-Nucleoside Reverse Transcriptase Inhibitors					
Suramin	No	No	n.d.	Possibly effective, but too toxic	2
Nucleotide Synthesis Inhibitors					
Foscarnet (PFA)	Yes[81]	No	n.d.	Effective *in vitro*, but too toxic	4
Ribavirin	Yes[82]	No	n.d.	Possibly effective, but too toxic in cats	4
Receptor Homologues/Antagonists					
Plerixafor	n.d.	No	n.d.	Very likely ineffective	4
Integrase Inhibitors					
Raltegravir	Yes[83]	No	n.d.	Possibly effective	4
Interferons					
Human interferon-alpha (IFN-alpha)					
SC high-dose	Yes[84]	Yes	No[76]	Ineffective	1
PO low dose	Yes[84]	Yes	No[71]	Ineffective	1
Feline interferon-omega					
(IFN-omega)	Yes[85]	Yes	Yes[86]	Some effect (most likely more on secondary infections)	1
PO low dose	Yes[85]	No	n.d.	Potentially some effect (most likely more on secondary infections)	1
Other Cytokine Inducers					
Staphylococcus protein A (SPA)	n.d.	Yes	Yes[71]	Weakly effective	1
Propionibacterium acnes	n.d.	No	n.d.	Likely ineffective	3
Bacille Calmette-Guérin (BCG)	n.d.	Yes	No[87]	Ineffective	2
Serratia marcescens (S. marcescens)	n.d.	Yes	No[88]	Ineffective	2
PIND-AVI/PIND-ORF	n.d.	Yes	No[69,73]	Ineffective	1
Acemannan	n.d.	No	n.d.	Possibly weakly effective	3
Other Drugs with Immunomodulatory Activity					
Levamisole	n.d.	No	n.d.	Likely ineffective	3
Diethylcarbamazine citrate (DEC)	n.d.	Yes	No[89]	Ineffective	2
Lactoferrin	n.d.	No	n.d.	Possibly effective in cat with stomatitis	4

n.d., Not determined; *PIND-AVI*, Parapoxvirus avis; *PIND-ORF*, Parapoxvirus ovis.

EBM, Evidence-based medicine: EBM level 1 = confirmed by at least one placebo-controlled double-blind field study; EBM level 2 = shown in a controlled experimental study; EBM level 3 = supported by case series; EBM level 4 = only based on expert opinion.

CHAPTER 224

Coronavirus Infections (Canine and Feline), Including Feline Infectious Peritonitis

Katrin Hartmann

Client Information Sheet: Feline Coronavirus Infections

Coronaviruses (family Coronaviridae, order Nidovirales) are large, single-stranded RNA viruses that are responsible for enteric and/or respiratory diseases in mammals—including humans—and birds.[1,2] Coronaviruses are classified into 3 different antigenic groups. Group 1 contains, among others, the canine enteric coronavirus (CECoV) and the feline coronavirus (FCoV), while the canine respiratory coronavirus (CRCoV) belongs to group 2.[1,3] Coronaviruses mutate easily, and mutation can result in more virulent strains; this has been shown for CECoV and FCoV, resulting in fatal pantropic canine coronavirus (pantropic CCoV) infection or feline infectious peritonitis (FIP), respectively.

Canine Coronavirus Infection

In dogs, 2 different coronaviruses, CECoV and CRCoV, have been recognized.[4] In addition, a highly virulent CECoV strain (pantropic CCoV) was responsible for an outbreak of fatal systemic disease in puppies.[5]

Canine Enteric Coronavirus, Including Pantropic Coronavirus

CECoV first was isolated in 1971 in dogs with acute enteritis in a canine military unit in Germany,[6] and experimental administration of the isolated strain to young dogs reproduced the gastrointestinal (GI) signs.[7]

Epidemiology

Since then, several CECoV outbreaks have been reported worldwide, showing that CECoV can be an enteropathogen in dogs. However, the true importance of CECoV as a pathogen is unknown, since many clinically healthy dogs shed CECoV. Most likely, changes in virulence and tissue tropisms leading to disease outbreaks occur through genetic variations in structural and/or non-structural proteins.[8-14] Antibody and RNA prevalence studies have shown that CECoV is widespread in the dog population, primarily in kennels and shelters.[15-21]

Clinical Signs

It is unclear how often and why clinical signs appear, and differentiation of CECoV from other infectious causes of enteritis is difficult, since many healthy dogs shed CECoV. Therefore, concurrent presence of CECoV infection and diarrhea is not proof of causation.[22] Infection usually is restricted to the alimentary tract, with sudden onset of signs typical of GI involvement, including loss of appetite, vomiting, diarrhea, dehydration, and rarely death. Fatal disease can occur as a consequence of mixed infections, e.g., with canine parvovirus[23] or canine distemper virus.[24] CECoV can mutate to more virulent strains; severe outbreaks have been reported in the USA,[25] England,[26] Sweden,[27] and Australia.[28]

Although CECoV usually is restricted to the enteric system, mutations can result in systemic spread, leading to high mortality in puppies.[5,29] In 2005, a highly virulent variant (CB/05) was detected in Italy[5]; it evolved through genetic mutation (truncated form of the ORF3b product and point mutations in the spike protein) of CECoV, and was classified as "pantropic CCoV" because it had acquired the ability to spread to

other tissues.[13] In addition to GI signs, pantropic CCoV infection caused severe leukopenia, neurologic signs (ataxia, seizures), and death within 2 days. Experimental infection with strain CB/05 reproduced the severe disease.[30] At necropsy, lesions in lung, liver, and renal tissues also were found in affected dogs.[29]

Treatment and Prevention

Treatment is supportive and needs to resolve dehydration (see ch. 129), acidosis (see ch. 128), and hypovolemic shock (see ch. 127 and 159). Inactivated and modified live virus (MLV) vaccines available in the USA are considered safe, but they provide incomplete protection[26,31,32] and probably no protection against pantropic CCoV (see ch. 208).[1] Necessity of vaccination has been questioned because CECoV usually causes no or only mild clinical signs.

Canine Respiratory Coronavirus

In 2003, a canine respiratory coronavirus (CRCoV) was first identified in the respiratory tract of dogs housed in a rehoming kennel in England with a history of endemic respiratory disease.[3] CRCoV is very closely related to the bovine coronavirus (BCoV) (sequence homology 97.3%),[3] and it has been suggested that originally, transmission of the virus occurred from cattle to dogs.[33]

Epidemiology

Since its first description, CRCoV has been detected in many countries. Antibodies against CRCoV were found in the USA, Canada, England, Ireland, Italy Greece, New Zealand, Japan, and Korea in 12-59% of investigated dogs.[34-41] CRCoV RNA was detected in the lower respiratory tract of 1-27% dogs with respiratory disease in Canada, England, Italy, Germany, Japan, and Korea.[3,37,38,42-45]

Clinical Signs

CRCoV can be responsible for mild respiratory signs and it is one of the etiological agents of canine infectious respiratory disease (CIRD), together with *Bordetella bronchiseptica,* canine adenoviruses type 1 and type 2, canine parainfluenzavirus, canine herpesvirus, reoviruses, canine pneumovirus, and influenza viruses (see ch. 227).[4,44,46] However, the true role of CRCoV as primary single pathogen is not completely clear. In one study, CRCoV RNA was detected only in the respiratory tract of dogs with respiratory signs, but not in healthy dogs,[44] confirming its pathogenicity. In addition, replication in the respiratory epithelium can damage the mucociliary system,[4] and this can lead to a more severe clinical course of infections caused by other respiratory pathogens.

Treatment and Prevention

Symptomatic treatment usually leads to complete cure (see ch. 276). Antiviral treatment is not recommended.[47] A vaccine is not available.

Feline Coronavirus Infection and Feline Infectious Peritonitis

Feline coronavirus (FCoV) is extremely common in the cat population worldwide, especially in multi-cat environments. Presence of FCoV-specific antibodies in up to 90% of cattery cats and in up to 50% of those in single-cat households demonstrates the high frequency of exposure. FCoV is transmitted by the fecal-oral route between felids, but is not infectious for other species (including humans). FCoV usually does not cause clinical signs, and only rarely is considered to be responsible for transient and mild diarrhea with or without vomiting,[48] due to replication of FCoV in enterocytes.[49] Kittens infected with FCoV develop diarrhea more commonly than do adults, and the diarrhea rarely is accompanied by stunted growth. Occasionally, the virus can be responsible for severe, acute or chronic vomiting and/or diarrhea with weight loss, which can be unresponsive to treatment and continue for months.[50]

Sporadically, these harmless viruses can be the cause of FIP in individual cats. It has been estimated that about 5% of FCoV-infected cats develop FIP in a multi-cat environment.[51,52] FIP is a fatal, immune-mediated disease and it is the most common infectious cause of death of cats.[53-56] It also is a frequent reason for referral, with approximately 1 of every 200 new feline cases presented to U.S. veterinary teaching hospitals having

FIP.[56] There is increasing evidence that FIP develops after spontaneous mutations of the genome of nonpathogenic FCoV within infected cats.[11,57] These mutations allow for successful virus replication in macrophages,[58] which is regarded as a key event in the pathogenesis of FIP.[9,59] Many different genes, including the S, 7a, 7b, and 3c genes, have been discussed as sites for the mutations that are crucial for the pathotypic switch and changes in tissue tropism.[9,11,60-70] In contrast to previous studies, in which none of the sequence changes appeared to be associated consistently with the virulent FIP-causing variant, a recent study found nucleotide differences in two regions in close proximity in the S (spike) gene (nucleotide 23531 and nucleotide 23537) that resulted in amino acid variations in the putative fusion peptide. These two mutations were correlated with the FIP phenotype in >95% of cases.[71] Considering the importance of the coronavirus S protein fusion peptide in cell entry,[72] these findings could explain the alteration in viral tropism. It also was shown that substitutions in a furin cleavage site within the S protein of FCoV can be detected in cats with FIP, which likely are leading to a modulation of proteolytic cleavage, thereby enhancing virus uptake in macrophages.[73] It even has been suggested that not only a single mutation in one gene but a combination of mutations (such as one mutation in the spike gene and one mutation in the 3c gene) might be necessary for the change in virulence.[60]

If a cat fails to eliminate the cells infected with the mutated virus, the presence of the virus within macrophages initiates the ultimately fatal immune-mediated reaction that defines FIP. In this aberrant modulation of the immune system, overproduction of proinflammatory cytokines plays an important role, such as through activation of the p38 MAPK pathway that regulates production of tumor necrosis factor-alpha (TNF-alpha) and interleukin-1-beta.[74] Granulomatous lesions in the target organs also are caused by overproduction of cytokines by infected macrophages, including neutrophil survival factors (TNF-alpha, GM-CSF, G-CSF),[75] that lead to systemic activation of neutrophils (such as increased expression if the alpha-chain of macrophage-1 antigen [Mac-1]) causing them to extravasate and form granulomas.[76] In addition, cats with FIP have a severe suppression of natural killer cells and regulatory T cells, leading to a decreased capacity of the immune system to battle the virus and suppress immunopathologic functions.[77]

Granulomatous lesions can occur in the central nervous system, eyes, and parenchymatous organs (including the intestine, commonly at the ileocecal junction, appearing as masses in the abdominal cavity).[78,79] Vasculitis leads to fluid accumulation in body cavities, including the pleural and peritoneal spaces and even the pericardium.[80] In addition, some unusual manifestations have been described, such as a mediastinal cyst-like mass in the thorax,[81] skin fragility syndrome,[82] and other skin lesions (e.g., skin papules and nodules, pododermatitis),[83,84] orchitis[85] or priapism (with FCoV antigen immunohistochemically being detected in penile tissue).[86]

Diagnosis

Once the clinical disease FIP develops, it almost always leads to death within a few days or weeks, and currently there is no treatment with proven efficacy.[87,88] Thus, a definitive diagnosis is essential but often challenging. A weighted score system for the diagnosis of FIP, taking several parameters into account, including background of the cat, history, presence of clinical signs, laboratory changes, and level of antibody titers, has been suggested.[89,90] Although useful to prioritize differential diagnoses and helpful to select further tests, the score only assesses the likelihood of FIP and thus does not help to definitively confirm the diagnosis. At present, necropsy or immunostaining of FCoV antigen (immunohistochemistry) in tissue samples obtained by laparotomy are considered the gold standard for the diagnosis of FIP.[91-94] Thus, the definitive diagnosis can only be achieved with invasive laparotomy and biopsies of multiple organs, or might not be possible at all. A suggested diagnostic algorithm for FIP is provided in Figure 224-1.

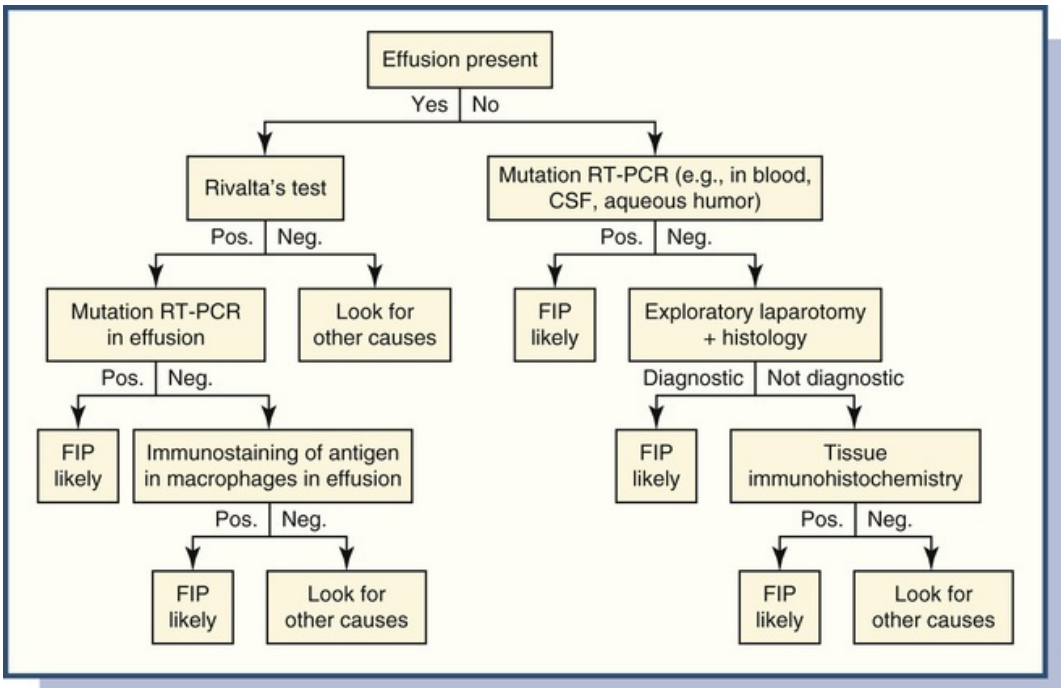

FIGURE 224-1 Algorithm for the diagnosis of feline infectious peritonitis (FIP) in a cat in which FIP is suspected. *PCR*, Polymerase chain reaction. *FIP*, Feline infectious peritonitis; *Neg.*, negative; *Pos.*, positive; *RT-PCR*, reverse transcriptase polymerase chain reaction.

Laboratory Values

Laboratory values often are altered in cats with FIP, but the changes are not pathognomonic. Lymphopenia often is present, but in combination with neutrophilia in sick cats, it commonly is part of a typical stress leukogram. A common finding in cats with FIP is an increase in total serum protein concentration caused by a rise in globulins, mainly gamma-globulins.[93,95-98] One mechanism leading to this massive antibody production is an overproduction of B cell differentiation/survival factors by virus-infected macrophages that promote B cell differentiation into plasma cells.[99] The hyperglobulinemia, together with the commonly-observed hypoalbuminemia, leads to a low albumin-to-globulin ratio. A low albumin-to-globulin ratio should raise the suspicion of FIP, but is never diagnostic by itself. Serum protein electrophoresis is not very helpful, because both polyclonal and monoclonal hypergammaglobulinemia can occur in cats with FIP, as they do in some tumors, such as multiple myeloma, and with other inflammatory conditions. Other laboratory parameters (liver enzymes, bilirubin, blood urea nitrogen, creatinine) can be elevated variably, depending on the degree and localization of organ damage. Acute phase proteins commonly are elevated, but this finding is not specific either.[100] Hyperbilirubinemia often is observed[93,101] and it can be caused by hepatic granulomatous inflammation. In addition, an increase in serum bilirubin concentration without evidence of hemolysis, primary liver disease, or extrahepatic cholestasis (hematocrit and alkaline phosphatase [ALP] and alanine aminotransferase [ALT] activities within the reference range and no sonographic bile duct changes) sometimes is present in cats with FIP and likely is caused by compromised bilirubin metabolism and excretion into the biliary system due to high levels of TNF-alpha that inhibit transmembrane transport (otherwise observed only in septic animals).[93,102]

Analysis of Effusion Fluid

Whenever effusion can be detected somewhere, the next diagnostic step always is to sample and analyze the fluid (see ch. 74 and 90), because tests on effusion have a much higher diagnostic value than tests performed on blood. In general, half of cats with body cavity effusion suffer from FIP.[103] Although effusions of clear yellow color and sticky consistency (Figure 224-2) often are considered "typical," the presence of this type of fluid alone is not diagnostic. Sometimes the fluid has a totally different appearance and, for example, cases of FIP with pure chylous effusion have been reported.[104] The effusion's protein content usually is high (>3.5 g/dL [>35 g/L]) and consistent with an exudate, whereas the cellular content is rather low (<5000 nucleated

cells/mcL) and resembles that of a modified transudate. Other diseases causing similar effusions include lymphoma, heart failure, cholangiohepatitis, and bacterial peritonitis or pleuritis. Cytologic evaluation of the effusion in cats with FIP usually shows a pyogranulomatous inflammation with a predominance of macrophages and neutrophils (Figure 224-3). Cytologic findings can appear similar in cats with bacterial serositis (although in these cases, cell counts usually are higher) or with lymphoma (although in these cases, malignant cells usually are present). A simple, inexpensive, and very robust method (fluid can be stored in the refrigerator for at least 3 weeks before performing the test) for evaluating the effusion,[105] the "Rivalta's test," can help to differentiate FIP from effusions of other origins (Box 224-1; Video 224-1).[93] Positivity (Figure 224-4) is caused by not only the high protein content, but also other components, such as high concentrations of fibrin and inflammatory mediators. The Rivalta's test had a sensitivity of 91.3% and a specificity of 65.5% in a recent study of 851 cats, with a high positive predictive value of almost 90% in cats <2 years old (due to the high prevalence of FIP in young cats).[106] Thus, a negative Rivalta's test makes FIP very unlikely; a positive Rivalta's test at least increases the likelihood of FIP, especially in a young cat. False-positive Rivalta's test results can occur in cats with bacterial serositis or lymphoma; those effusions, however, can usually be differentiated through cytologic evaluation and/or bacterial culture.

FIGURE 224-2 Yellow, clear, sticky effusion that is considered "typical" in a cat with feline infectious peritonitis obtained through ultrasound-guided abdominocentesis. (From Hartmann K: Feline infectious peritonitis. *Vet Clin North Am Small Anim Pract* 35:39-79, vi, 2005.)

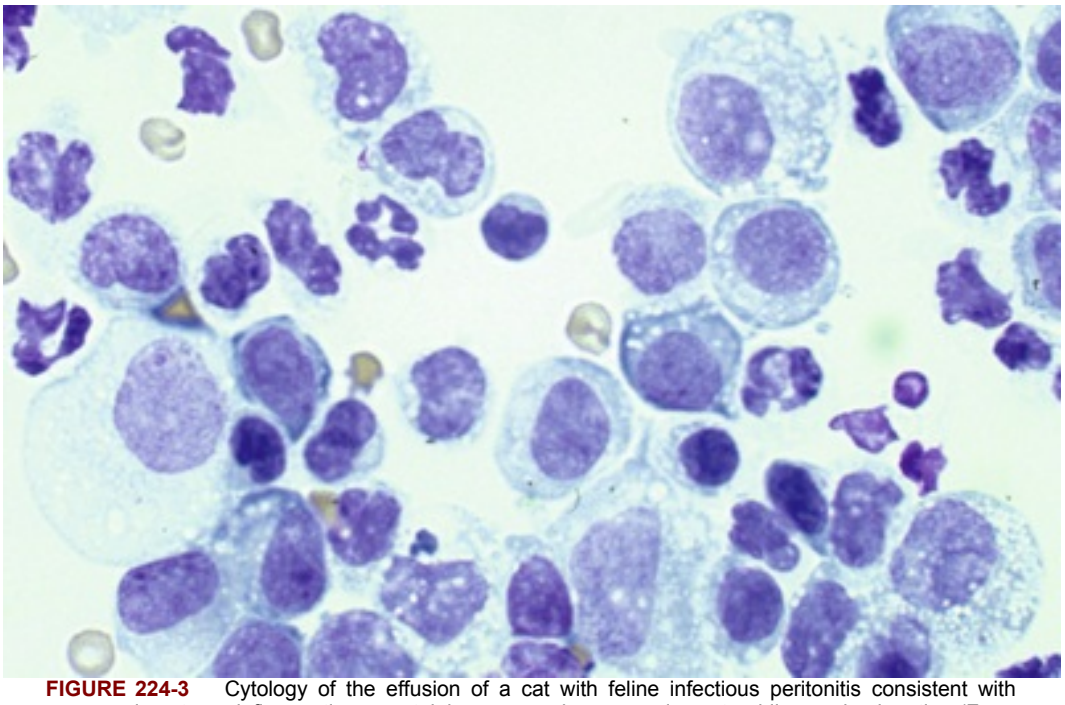

FIGURE 224-3 Cytology of the effusion of a cat with feline infectious peritonitis consistent with pyogranulomatous inflammation, containing macrophages and neutrophils predominantly. (From Hartmann K: Feline infectious peritonitis. *Vet Clin North Am Small Anim Pract* 35:39-79, vi, 2005.)

Box 224-1

Procedure and Interpretation of the Rivalta's Test

Rivalta's Test Standard Procedure

- A plastic test tube (volume 10 mL) is filled with 7 mL of distilled water
- 20 mcL (1 drop) of acetic acid (100%) is added
- The solution is thoroughly mixed
- 20 mcL (1 drop) of the effusion is layered on the surface of this solution
- The outcome of the drop is observed

Rivalta's Test Interpretation

- The Rivalta's test is defined as **positive**
  - If the drop stays attached to the surface
  - If the drop retains its shape and keeps a connection to the surface
  - If the drop slowly floats down to the bottom
  - If the drop does not stay in shape, but changes to an "upside-down jelly fish"
  - If the drop disperses in little cloudy pieces that can be observed falling down to the bottom of the tube
- The Rivalta's test is defined as **negative**
  - If the drop disappears and the solution remains clear
  - If clear or cloudy cords seen are falling down, which dissolve before reaching the bottom of the tube, but no drop or "upside-down jelly fish" is visible

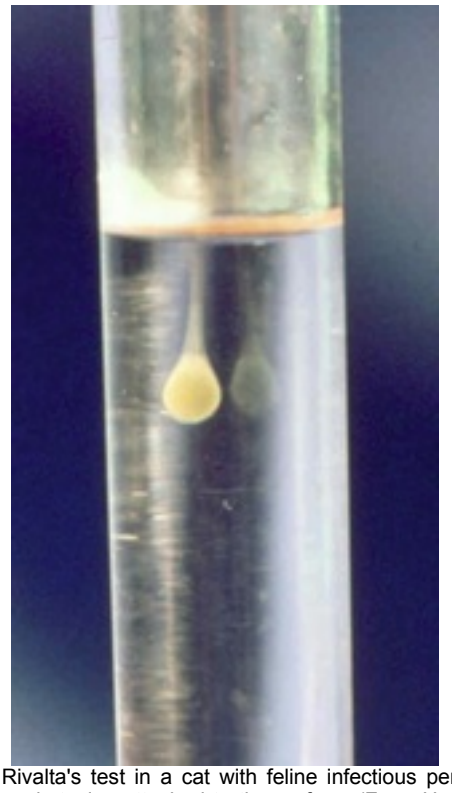

FIGURE 224-4 Positive Rivalta's test in a cat with feline infectious peritonitis, with a drop of the effusion retaining its shape and staying attached to the surface. (From Hartmann K: Feline infectious peritonitis. *Vet Clin North Am Small Anim Pract* 35:39-79, vi, 2005.)

Analysis of Cerebrospinal Fluid (CSF)

Analysis of cerebrospinal fluid (CSF) from cats with neurologic signs due to FIP can show elevated protein concentrations (50-350 mg/dL [500-3500 g/L] compared to a normal value of <25 mg/dL [<250 g/L]) and pleocytosis (100 to 10,000 nucleated cells/mcL) containing mainly neutrophils, lymphocytes, and macrophages (see ch. 115).[107,108] These are, however, relatively nonspecific findings. Some cats with neurologic signs caused by FIP have normal CSF results, and even if CSF changes indicate inflammation, they are not useful in differentiating FIP from other causes of inflammatory central nervous system disease.[108]

Antibody Titers

Antibody titers can be measured in blood, effusion, and CSF, but detection of antibodies in any of these fluids is not helpful in the diagnosis of FIP. Most cats with current or previous contact to FCoV, as well as vaccinated cats, have antibodies. Presence of antibodies in blood does not predict FIP and their absence does not exclude FIP, since in terminal FIP, titers often decrease,[109] and approximately 10% of cats with FIP have no antibodies because large amounts of virus in the cat's body bind to antibodies and render them undetectable, or antibodies are lost into the effusion when protein is extravasated due to vasculitis. The presence of antibodies in effusion is correlated with the presence of antibodies in blood,[110] and thus, antibody measurement in effusion also is not helpful.[111] Cats with neurologic signs due to FIP have had CSF antibody concentrations that were no different from those in cats with other neurologic diseases, indicating that measurement of antibodies in CSF also is not useful.[112] However, blood antibody testing still has a certain role in the management of FCoV in multi-cat households or catteries; for example, if all cats are known to be antibody-negative, then a FCoV-free colony can be maintained by admitting only new cats that are negative on antibody testing.[113]

Coronavirus-Specific Antibody-Antigen Complex Detection

Coronavirus-specific antibody-antigen complex detection can be performed in blood with a competitive ELISA. The rationale is that a diagnostic clue could be obtained if one looked for circulating complexes in

blood and effusions, but the usefulness of this test was shown to be limited.[93]

FCoV Antigen in Macrophages

FCoV antigen in macrophages can be detected using immunofluorescence staining or immunocytochemistry (in effusion macrophages) or immunohistochemistry (in tissue macrophages). Immunostaining cannot differentiate between the "harmless" FCoV and the mutated FIP-causing FCoV. However, only FIP-causing virus is considered able to replicate in the sufficiently large numbers in macrophages required to obtain positive staining (Figure 224-5), and replicating virus is associated with macrophages by immunohistochemistry.[119] In one study in which a large number of cats with confirmed FIP and controls with other (confirmed) diseases were investigated (n = 171), immunofluorescence staining of intracellular FCoV antigen in macrophages of the effusion had a positive predictive value of 100%, thus confirming the diagnosis of FIP. Unfortunately, the negative predictive value was not very high (57%), which mainly can be explained by low numbers of macrophages on effusion smears (even though cats have FIP), resulting in negative staining.[93] In another study, however, 2 cats with false-positive immunofluorescence staining were reported,[120] calling into question the credibility of the method as a confirmatory test. This was additionally shown in another study that used immunochemistry instead of immunofluorescence staining, with few false-positive control cats.[121] Recent studies have focused on the diagnostic utility of immunostaining of material other than effusion[121a] or aqueous humor,[121b] yielding similar results, such as false-positive results in cats with definitive other diseases. Immunohistochemistry is considered the gold standard in the diagnosis of FIP and has been proven to be 100% predictive if positive.[94,122] However, invasive methods (e.g., laparotomy or laparoscopy; see ch. 91) usually are necessary to obtain appropriate tissue samples. The diagnostic sensitivity between core biopsy (see ch. 89) and fine needle aspiration (FNA; see ch. 89 and 93) of liver and kidney tissue was compared in one study and the sensitivity of FNA was similar to that of core biopsy, with a higher sensitivity in the liver versus the kidney,[123] but the value of ultrasound-guided FNA to diagnose FIP as a routine method is limited.

Reverse Transcriptase Polymerase Chain Reaction (RT-PCR) Detecting FCoV or Detecting the Mutated Virus

Most RT-PCR (a reverse transcription of viral RNA to DNA has to be performed prior to amplification of DNA in order to detect RNA viruses) that are routinely used detect all FCoV because PCR primers do not discriminate between FIP-causing viruses and harmless enteric FCoV.[114] Several studies support the hypothesis that FCoV viremia occurs not only in cats with FIP but also in healthy carriers.[115,116] Thus, presence of FCoV viremia does not predict, nor does it predispose cats to, the development of FIP.[117] Therefore, the results of routine RT-PCR are not diagnostic for FIP. In addition, blood RT-PCR commonly is negative in cats with FIP due to the low viral load. However, while not useful in the diagnosis of FIP, RT-PCR used for detecting FCoV in fecal samples is sensitive and useful for documenting that a cat is shedding FCoV.[91] Identification of fecal shedding is an important step in management of cat populations when prevention of FCoV introduction or elimination of endemic infection is desired.

A RT-PCR that specifically detects nucleotide changes at positions 23531 and 23537 of the S gene,[71] and thus detects a virus with a crucial mutation in the spike gene that is considered the pathogenic pathotype,[72] is now commercially available. In one study, detection of one of the two mutations was 100% specific for FIP.[118] However, in a very recent study specificity was only 96.0% using this pathotype-specific PCR.[118a] In this study, a positive RT-PCR detecting one of the mutations also occurred in control cats with confirmed other diseases. It is unclear whether these were true false positives or whether early-stage FIP was detected in cats with separate diseases. Sensitivity of this test is high in effusion, but very low in blood, which is a problem because diagnosis of FIP in cats without effusion remains a challenge.[118a]

Treatment and Management

Virtually every cat with confirmed FIP dies from the disease. However, some cats can survive for several months and enjoy some quality of life with symptomatic treatment.

Prognosis

The prognosis for a cat with FIP is extremely poor. In a prospective study including 43 cats with FIP, the median survival time after definitive diagnosis was 8 days.[88] Some cats, however, live for several months; one cat has been documented that lived 200 days after a definitive diagnosis.[88] Some parameters can predict survival time: poor general condition, low platelet count, low lymphocyte count, high serum bilirubin concentration, and a large amount of effusion indicate a poor prognosis.[88] Seizures also have to be considered an unfavorable prognostic sign, since they occur significantly more frequently in animals with marked extension of the inflammatory lesions to the forebrain.[124]

Environmental Considerations

Often, the question arises as to whether it is dangerous to bring a cat (with confirmed FIP) back into a household with other cats. When a cat in a household develops FIP, other cats that have been in contact with the cat already have been exposed to FCoV, but the key question remains whether the mutated virus is transmitted from cat to cat. In general, this does not seem to be the case. Most studies have failed to detect mutated virus in secretions or excretions from cats with FIP.[125] A recent study showed that cats with FIP actually stopped shedding FCoV. Analysis of 27 cats with FCoV infection and 28 cats with FIP from the same households revealed that most cats that had developed FIP had no detectable intestinal FCoV and seemingly cleared the primary FCoV infection. In those with detectable intestinal FCoV, sequence analysis revealed that the virus was different and seemed to have been acquired by FCoV superinfection.[60] Therefore, if a cat with FIP starts to shed virus again, this is due to a new superinfection from other cats in the household and not the original virus of the cat. Mutated FCoV that was found in FIP-associated organ lesions was not found in the feces, except in 1 cat. In this cat, a single-residue deletion in the 3c protein was found in ascitic and intestinal virus. Likely, the presence of the virus in feces resulted from leakage of systemic virus into the intestine, e.g., in case of intestinal granuloma.[60] In one study, the genomic RNA sequence of a field FCoV strain isolated postmortem from the jejunum and the liver of a cat with FIP revealed 100% nucleotide identity between the enteric- (jejunum) and nonenteric- (liver) derived viral RNA sequences, a finding that demonstrates that FIP-causing virus could be shed under some circumstances.[126] However, even if the mutated virus is shed on very rare occasions, it still would not cause FIP in another cat because this virus would not be able to replicate in the intestine of another cat after transmission. Studies have demonstrated that feces of cats with FIP will not cause FIP in another cat.[63] On the basis of current knowledge, the appropriate advice seems to be that it is relatively safe to bring the cat with FIP back into the household to the cats that have already been in contact, as these cats will have a certain immunity to the FCoV strain endemic in the household. It is, however, not recommended to allow contact of the cat with FIP to any new, "naïve" cat.

Supportive Treatment

As FIP is an immune-mediated disease, supportive treatment is aimed at controlling the immune response to FCoV, and the most successful approach consists of high dosages of immune-suppressive and antiinflammatory drugs that slow down disease progression, such as prednisolone (2-4 mg/kg PO q 24 h). Although glucocorticoids have been used in nearly every published case, their effect never has been substantiated in controlled studies. If effusion is present, some cats benefit from daily centesis for removal of the fluid (see ch. 90 and 102), and injection of dexamethasone into the abdominal or thoracic cavity (1 mg/kg q 24 h until effusion is no longer produced). Cyclophosphamide (2-4 mg/kg PO 4 times/week), alone or in combination with glucocorticoid, sometimes is used but there are no data available on its efficacy. Cats should also be treated with broad-spectrum antibiotics and supportive therapy (e.g., fluids; see ch. 129) in addition to the immunosuppressive treatment. A thromboxane synthetase inhibitor (ozagrel hydrochloride) that inhibits platelet aggregation and cytokine release has been used in 2 cats with some improvement of clinical signs.[127] Propentofylline has been used because it appears to down-regulate proinflammatory cytokines, which in turn can reduce vasculitis. However, in a placebo-controlled, double-blind study in cats with confirmed FIP, there was no significant difference in survival time, quality of life, or any clinical or laboratory parameter in cats treated with this drug versus cats receiving placebo.[87]

Antiviral Chemotherapy and Immunomodulators

The search for an effective antiviral compound has not been very successful in the past (Table 224-1). There are some promising experimental approaches, including protease inhibitors,[127a] inhibition of the FCoV spike protein that binds to receptors on the host cell membrane and mediates fusion of the viral envelope with host cell membranes,[128,129] circular triple helix-forming oligonucleotide RNA targeting viral RNA,[130] or small interfering RNAs (siRNA) leading to RNA interference and thus inhibition of virus replication,[131] but these compounds are still in an investigational stage. Some drugs are effective *in vitro,* but too toxic for cats, such as ribavirin[132-134] or chloroquine.[135] Others only have been investigated *in vitro,* but *in vivo* efficacy is unknown, such as vidarabine,[136] which inhibits polymerases; nelfinavir, a protease inhibitor of human immunodeficiency virus; *Galanthus nivalis* agglutinin (GNA), a carbohydrate-binding agent that binds to FCoV-glycosylated envelope glycoproteins, thereby inhibiting viral attachment to the host cell[137]; or cyclosporine A, which binds to cellular cyclophilins, thereby inhibiting calcineurin, which is required by many viruses for replication.[138,139] For many of these drugs, evaluation of data is hampered by the lack of well-controlled clinical trials in which new treatments are compared against standard care or placebo, and the fact that the presence of FIP was not even confirmed before treatment was initiated, making an assessment of the outcome impossible.[140]

TABLE 224-1

Treatment Options (Including Antiviral Drugs and Immunomodulators) for Cats with Feline Infectious Peritonitis (Including Evidence-Based [EBM] Grades for Judgment of the Available Efficacy Data and Personal Opinion of the Author)[91,169,170]

DRUG	EFFICACY *IN VITRO*	CONTROLLED STUDY *IN VIVO*	EFFICACY *IN VIVO*	PERSONAL OPINION	EBM LEVEL (1-4)
Nucleoside Analogue RNA Synthesis Inhibitors					
Vidarabine (Ara-A)	Yes136	No	n.d.	Likely ineffective	4
Nucleotide Synthesis Inhibitors					
Ribavirin	Yes136	Yes	No133,134	Not effective and toxic132 if given systemically	2
Alkylating Agents Interfering with RNA					
Melphalan	n.d.	No	n.d.140,171	Likely ineffective	4
Protease Inhibitors					
Nelfinavir	Yes137	No	n.d.	Potentially effective	4

EBM, Evidence-based medicine: EBM level 1 = confirmed by at least one placebo-controlled double-blind field study. EBM level 2 = shown in a controlled experimental study. EBM level 3 = supported by case series. EBM level 4 = only based on expert opinion.

Interferons are used frequently in cats with FIP. Human interferon-alpha was effective against an FIP-causing FCoV strain *in vitro*, but in a placebo-controlled treatment study including 74 specific pathogen-free cats in which FIP was induced experimentally, neither the prophylactic nor the therapeutic administration of high dosages (10^4 or 10^6 IU/kg) of interferon-alpha, of feline interferon-beta (10^3 IU/kg), of the immunomodulator *Propionibacterium acnes* (0.4 mg/cat or 4 mg/cat), or of a combination of these agents significantly reduced mortality in treated versus untreated cats. However, in cats treated with 10^6 IU/kg interferon-alpha in combination with *Propionibacterium acnes*, the mean survival time was prolonged, but only by 3 weeks.[141] As an explanation of the limited efficacy of interferon-alpha, it has been suggested that ORF-7-encoded accessory protein 7a of FIP-causing strains can act as type-I interferon antagonists and counteract the interferon-alpha–induced antiviral response.[68] FCoV replication also is inhibited by feline interferon-omega *in vitro*,[142] which is licensed in some European countries and Japan. Promising results were obtained in one uncontrolled trial, but in the cats that were studied, FIP was not confirmed.[143] In a randomized, placebo-controlled, double-blind treatment trial in 37 cats with confirmed FIP, feline interferon-omega was not more effective than glucocorticoids alone.[88] Some older case reports suggest some effect through immunomodulator treatment, such as tylosin, promodulin, acemannan, or "paraimmunity inducers," but again FIP was not confirmed in these studies.[140,144-148]

A drug that has shown promise for immunomodulation is polyprenyl immunostimulant.[149] In a case series of three cats, polyprenyl immunostimulant was associated with prolonged survival in cats with FIP without effusion.[149] No placebo group was included for comparison; thus, definitive conclusions about the effectiveness of this drug cannot be drawn so far. The idea behind immunomodulator treatment is that these products might stimulate the immune response toward a cell-mediated response or to reduce an overactive Th2 response. An imbalance in T cell versus B cell response has been suggested to contribute to the development of FIP, although this hypothesis has been questioned recently.[119] A nonspecific stimulation of the immune system might in fact even be contraindicated, since the clinical signs develop and progress as a result of an immune-mediated response. Therefore, treatment with these drugs is not recommended as long as there is a lack of documented efficacy in well controlled studies.[140]

Prevention

Preventing FIP is extremely difficult. The only way to truly prevent the development of FIP is to prevent

infection with FCoV.

Management to Control FCoV in Infected Cats

Under natural circumstances, cats go outside to defecate and bury their feces, in which case FCoV usually remains infectious only for hours (or up to days in freezing conditions). However, domesticated cats have been introduced to littertrays in which FCoV can survive for several days and possibly up to 7 weeks in dried-up feces. Elimination of FCoV in multi-cat households is extremely difficult. Management recommendations for private households, breeding catteries, and shelters are summarized in Box 224-2.

Box 224-2

Management of Multi-Cat Households with FCoV-Infected Cats[102]

Management of Cats in Private Households with FCoV-Infected Cats

- In most households with >5 cats, FCoV is endemic. If FCoV is detected in a household, usually all cats are infected and many are shedding FCoV. Usually, most cats will have antibodies, as 95-100% of cats exposed to FCoV become infected and develop antibodies 2-3 weeks after exposure).
- A few cats might be "resistant" to FCoV infection. Some cats in FCoV-endemic multiple-cat households remain antibody-negative[91] (mechanism unknown). These cats should be used for breeding.
- Owners should be reassured that presence of antibodies is not necessarily associated with a poor prognosis. Most cats infected with FCoV will not develop FIP, and many cats in single-, 2-, or 3-cat households eventually clear the infection, and become antibody-negative months to years later.
- Owners should be advised that cats infected with FCoV have a better chance of eliminating FCoV if allowed to go outside, reducing reinfection with virus in their own feces.[50]

Management of Shelters with FCoV-Infected Cats

- "Normal" isolation procedures are ineffective for preventing transmission of FCoV because of the ease with which FCoV is transported on clothes, shoes, dust, and cats.
- Keeping previously uninfected cats together in a shelter leads to exponential increase of infection rates. In a study in which stray cats were tested at the time they were brought into local shelters (in which multiple cats were kept in one room) and at 1- to 2-week intervals thereafter, only a low number of cats had antibodies at the time of entering, but the percentage increased rapidly until virtually all cats in the shelters were infected with FCoV.[178]
- Prevention of occasional cases of FIP is extremely difficult in a shelter setting where FCoV prevalence is high and compounded by stress and co-infections. Cases usually are sporadic and unpredictable, and tend to cluster in litters of predisposed kittens.
- Comparison of shelters with different types of handling revealed a significant correlation between increases in number of handling events outside the cages and increases in the percentage of FCoV antibody-positive cats.
- Shelters should minimize crowding and length of stay, design facilities for easy sanitation, and optimize husbandry to minimize virus spread and stress levels.[91]
- The Advisory Board of Cat Diseases (ABCD) provides specific shelter guidelines that can help in the management of FCoV infection.[179]

Management of Breeding Catteries with FCoV-Infected Cats

- Ideally, breeding catteries should be free of FCoV. This, however, rarely is the reality.
- Catteries with <5 cats can spontaneously and naturally become FCoV-free, but in catteries with >10 cats, this is almost impossible as the virus will pass from one cat to another, maintaining the infection.[91]
- The most important tactic to eliminate FCoV from a cattery is to reduce the number of cats (especially kittens <12 months old).
- It is also important to keep potentially FCoV-contaminated surfaces clean, to minimize the environmental load of FCoV.
- Antibody testing and segregating cats are methods aimed at stopping exposure.[50,172] FCoV is excreted

by ≈1/3 of antibody-positive cats,[173] and every antibody-positive cat should be considered infectious. After 3-6 months, antibody titers can be retested to determine whether cats become negative.

- Alternatively, RT-PCR testing of fecal samples (4 samples, each 1 week apart) can be performed to detect chronic FCoV carriers shedding high virus loads.[174] In large, multi-cat environments, 40-60% of cats shed virus in feces at any given time.
- If a cat is persistently fecal RT-PCR-positive for >6 weeks, it should be eliminated from the cattery and placed in a single-cat environment.[91,175,176]
- An early weaning protocol for preventing FCoV infection in kittens from infected queens has been proposed. The queen is isolated for 2-3 weeks prior to parturition, the queen and kittens are strictly quarantined, and kittens are weaned early (4-6 weeks old). Rationale: it has been proposed that young kittens have mucosal immunity to the virus, and kittens of FCoV-shedding queens have been considered protected from infection by local maternal antibodies until they are 5-6 weeks old.[51] However, early weaning failed and viral infection of 2-week-old kittens was demonstrated in a study in Switzerland. In addition, early weaning might exact a social price on the kittens. Thus, this procedure should only be undertaken with careful consideration and consultation with the breeder.[91]
- If possible, maximizing heritable resistance to FIP is recommended. Genetic predisposition plays a role (not completely understood).[177] Full-sibling littermates of kittens with FIP have a higher likelihood of developing FIP. If a cat has ≥2 litters in which kittens develop FIP, that cat should not be bred again. Particular attention should be paid to pedigrees of tomcats where FIP is overrepresented.[91]

Vaccination

There have been many attempts to develop effective vaccines, but most have failed, mainly because of the so-called antibody-dependent enhancement (ADE). ADE is caused by enhancement of the infection of macrophages[150] and it describes a phenomenon whereby cats that develop antibodies after vaccination and are subsequently infected with FCoV will develop FIP faster and will die earlier than cats that are not vaccinated.[151-156] A vaccine available in the USA and several European countries contains a temperature-sensitive mutant of an FCoV strain that can replicate in the cool lining of the upper respiratory tract but not at higher internal body temperature.[157-160] This vaccine, administered intranasally, produces local immunity (IgA antibodies) at the site where FCoV enters the body (the oropharynx) and also induces cell-mediated immunity. Safety concerns always raised are whether the vaccine could cause FIP or produce ADE. Although some experimental trials using this vaccine have recorded ADE on challenge, field studies have demonstrated that this vaccine is safe. In neither of 2 extensive placebo-controlled double-blind field trials did cats develop FIP or ADE after vaccination.[161-163] There were a few immediate side-effects after vaccine application, such as sneezing, vomiting, or diarrhea, the incidences of which were not significantly different in the vaccinated group compared to the placebo group.[162] However, efficacy of this vaccine is questioned constantly. Experimental studies have published data on preventable fractions between 0%[164,165] and 50% to 75%[160,166] depending on the investigator. In a survey of 138 cats belonging to 15 cat breeders, in which virtually all of the cats had antibodies prior to vaccination, no difference was found in the development of FIP between the vaccinated group and the placebo group.[162] Thus, vaccination in FCoV-endemic environments or in households with known cases of FIP is not effective. In a placebo-controlled double-blind trial FCoV-naive cats before vaccination, a small but statistically significant reduction in the proportion of cats that developed FIP was noted.[167] As the vaccine is ineffective when cats have already had an encounter with FCoV, antibody testing might be beneficial before vaccination. One disadvantage is that cats develop antibodies after vaccination, making establishment and control of an FCoV-free household difficult. In conclusion, study results do not clearly identify whether vaccination has no effect versus a small effect in reducing the probability of FIP.[168] Although only marginally, if at all efficacious, the vaccine is at least safe.

CHAPTER 225

Canine and Feline Parvovirus Infection

Andrew Lambert Leisewitz

Client Information Sheet: Canine and Feline Parvovirus Infection

Etiology and Epidemiology

Members of the Parvovirus genus infect a wide range of mammalian hosts but do show host specificity. Canine parvovirus (CPV) and feline panleukopenia virus (FPV) are the two important parvoviruses of dogs and cats, respectively, and are classified according to the hosts from which they have been isolated. Both CPV and FPV are considered to be host range variants among the feline parvoviruses.[1] The genetic sequences of CPV and FPV differ by only around 2% and antigenically they are very similar.[2] The virion is a simple, small, non-enveloped, single-stranded DNA virus with a genome size of around 5000 base pairs. The capsid proteins are the key structures determining host specificity and antigenicity. The host range of these two viruses differs and is determined by fewer than 10 amino acid differences in the capsid.[3] The virus makes use of the transferrin receptor to gain entry to cells and polymorphisms in this receptor are responsible for host specificity.[4] FPV replicates in feline cells *in vitro* and *in vivo* but not in canine cell cultures. CPV replicates in feline and canine cells in culture and in dogs *in vivo.* FPV is able to replicate to a limited extent in dogs but without causing illness. It infects the dog thymus and bone marrow and hence is also unable to spread among dogs.[1] The first CPV discovered in 1967 was called the minute virus of canines (later called CPV-1).[5] It is clinically insignificant today.[6] CPV-2 was discovered in dogs in 1978 in the United States and it was responsible for a devastating global pandemic within months.[7] It is now well established worldwide and is probably the single most common infectious disease of dogs with a high morbidity and mortality. This virus has subsequently mutated into CPV-2a, CPV-2b and lately to CPV-2c, which was first identified in Italy in 2000[8,9] but is now reported worldwide. CPV-2a and CPV-2b are capable of infecting cats and causing a clinical illness indistinguishable from panleukopenia, although this is rare.[10,11]

The fecal-oral route is the traditionally understood means of transmission, but fomite transmission also is very efficient. Diseased dogs can shed the virus at very high titers (up to 10^9 tissue culture infective dose-50 [$TCID_{50}$] per gram of feces) in their stool.[12] In the author's hospital, the caseload is directly correlated with wind speeds and inversely with humidity.[13] There is also evidence for seasonality in CPV in Canada[14] and in FPV across North America that corresponds to a peak in the susceptible kitten population.[15] There is evidence that certain breeds are more susceptible to infection, with Rottweilers, American Pit Bull Terriers, Doberman Pinschers, English Springer Spaniels, and German Shepherds being at increased risk. The odds to develop CPV enteritis were higher in purebreds compared to mixed-breed puppies in one study.[16] There is no published evidence of breed susceptibility among cats. Because immunity is conferred by antibody, maternally derived titers mean that neonates are almost never affected. Approximately 90% of maternally derived antibody is from colostrum and it has a half-life of around 10 days.[17] Susceptibility increases as maternal immunity wanes at around 12-14 weeks of age. Vaccination is highly effective at protecting from infection. The age at which puppies and kittens are affected also means that periods during which there is an abundant supply of susceptible animals will increase disease incidence. Introduction of infected animals into shelter environments also can result in explosive outbreaks. Other factors that contribute to infection include intestinal parasites, overcrowding, and unsanitary and stressful environmental conditions. Both CPV and FPV are extremely stable in the environment, which makes indirect transmission important and environmental decontamination difficult. Care should be taken in veterinary clinics where unvaccinated or inadequately vaccinated puppies are likely to come into contact with contaminated surfaces. Dogs admitted

to hospital for treatment should be kept isolated from the rest of the hospital population. Recently, it been shown that flies also play an important role in the spread of the infection among dogs.[18]

Pathogenesis and Clinical Signs

CPV and FPV share a very similar pathogenesis and clinical presentation. The virus is unable to induce mitosis in the cells it infects and hence it relies on the rapidly multiplying cells of the body for its success. The virus thus shows a tropism for cells of the thymus, bone marrow, spleen, and crypt cells of the gut epithelium. Stress factors, in particular parasitic and other nonspecific factors such as weaning, can predispose dogs to infection by increasing mucosal cell activity.[19] FPV disease has been documented to be enhanced by feline leukemia virus (FeLV),[20] *Clostridium piliforme*,[21] and feline coronavirus.[22] Because a robust antibody response is very protective, parvoviral infections are almost exclusively a disease of animals under a year of age that are past the age at which maternally derived antibodies provide protection, or are unvaccinated or inadequately vaccinated. For both CPV and FPV, vaccination status plays a very important role in susceptibility.

Following oral infection, the virus disseminates to the regional lymph nodes of the pharynx and the tonsils. In an experimental study in dogs, fecal shedding was present from day 3 following oral infection, peaked on days 3 and 4, and was greatly reduced by day 7.[23] Shedding could well occur for a day or 2 before clinical signs are apparent. The incubation period of this disease varies from around 4 days (under experimental conditions) to the more typical 1 to 2 weeks usually seen under natural conditions. Following infection of lymphoid tissues of the upper gastrointestinal (GI) tract, including the tongue, a cell-free viremia ensues. Under experimental conditions, this lasts from day 1 to day 5 post-infection, with the first signs of serum antibodies developing on day 5 and peaking from day 7 onwards.[23] Thymic and lymphoid tissue infection leads to thymic atrophy, lymphoid depletion, lymphopenia, and immunosuppression. Viral antigen is detectable in the proliferative zone of the crypt epithelium of the intestinal tract from day 4. Very little antigen remains in either the lymphoid tissues or gut epithelium from day 7 onward. Subclinical infection probably is common, especially in older, immune-competent animals.

The earliest clinical signs include fever, depression, and a loss of appetite. This is followed by diarrhea and vomiting. This is true of CPV and most cases of FPV. The diarrhea initially is clinically characteristic of small bowel disease (see ch. 40). It may quickly become melenic and then frankly hemorrhagic, and take on the character of a mixed small and large bowel type diarrhea (Figure 225-1, *B*). These puppies carry a very characteristic fetid odor. The vomiting usually increases in frequency and can become very severe and frequent with little more than foam produced. Hematochezia can be present and ascarids also can be observed in the vomitus. In peracute FPV, young cats can die within 12 hours of showing depression, due to profound septic shock, dehydration, and hypothermia, and vomiting and diarrhea may be minimal or absent.

FIGURE 225-1 The typical clinical presentation of advanced parvovirus infection in a young German Shepherd Dog puppy. The dog is moribund **(A)** and in hypovolemic shock, with hemorrhagic diarrhea **(B)** and pale, dry mucous membranes **(C).**

Bone marrow infection can lead to bone marrow necrosis in both dogs and cats.[3] This leads to leukopenia and also can contribute to the anemia seen in some cases. In most cases of CPV and FPV, leukopenia is present by the time hemorrhagic diarrhea and vomiting are present. Thrombocytopenia, however, is not a feature of the disease.[24] An increased concentration of granulocyte-colony stimulating factor (G-CSF) has been documented in dogs with CPV and this is likely to be a response to the neutropenia.[25] The neutropenia also is partially due to an overwhelming demand in the gut. The immunosuppression associated with CPV does mean these dogs are very susceptible to acute secondary infections. The most common of these are bacterial bloodstream infections, which manifest clinically as endotoxic shock (see ch. 127 and 132); on recovery some puppies develop skin necrosis (Figure 225-2), bacterial polyarthritis, and discospondylitis (Figure 225-3) (R. Kirberger, personal communication). The immune-suppressed condition also means that barrier nursing practices should be strictly enforced (Figure 225-4). Puppies with other infectious diseases should not be kept within the same facility. The most important differential diagnosis for systemic CPV-like signs is canine distemper virus infection. Every effort must be made to exclude this highly contagious disease from being cared for in a facility that admits CPV-infected puppies or by the same caregivers.

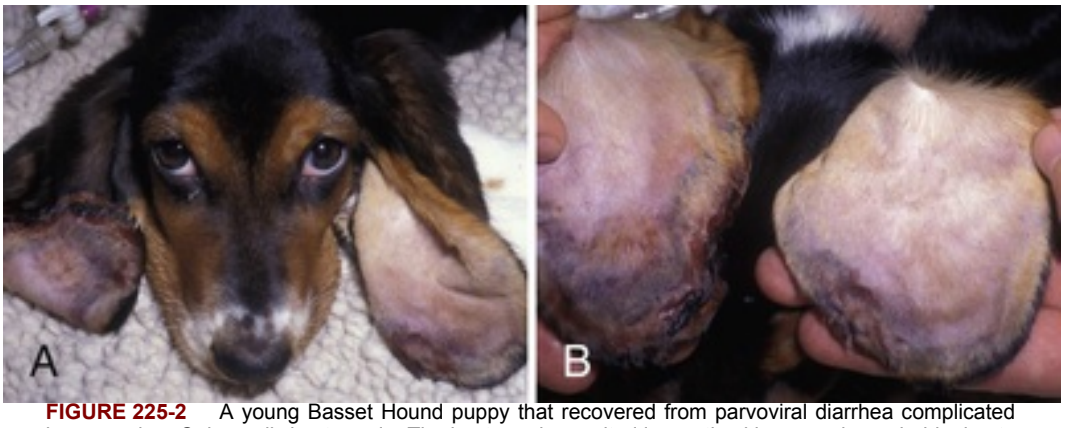

FIGURE 225-2 A young Basset Hound puppy that recovered from parvoviral diarrhea complicated by secondary *Salmonella* bacteremia. The bacteremia resulted in ear-tip skin necrosis, probably due to micro-embolization of the peripheral vasculature.

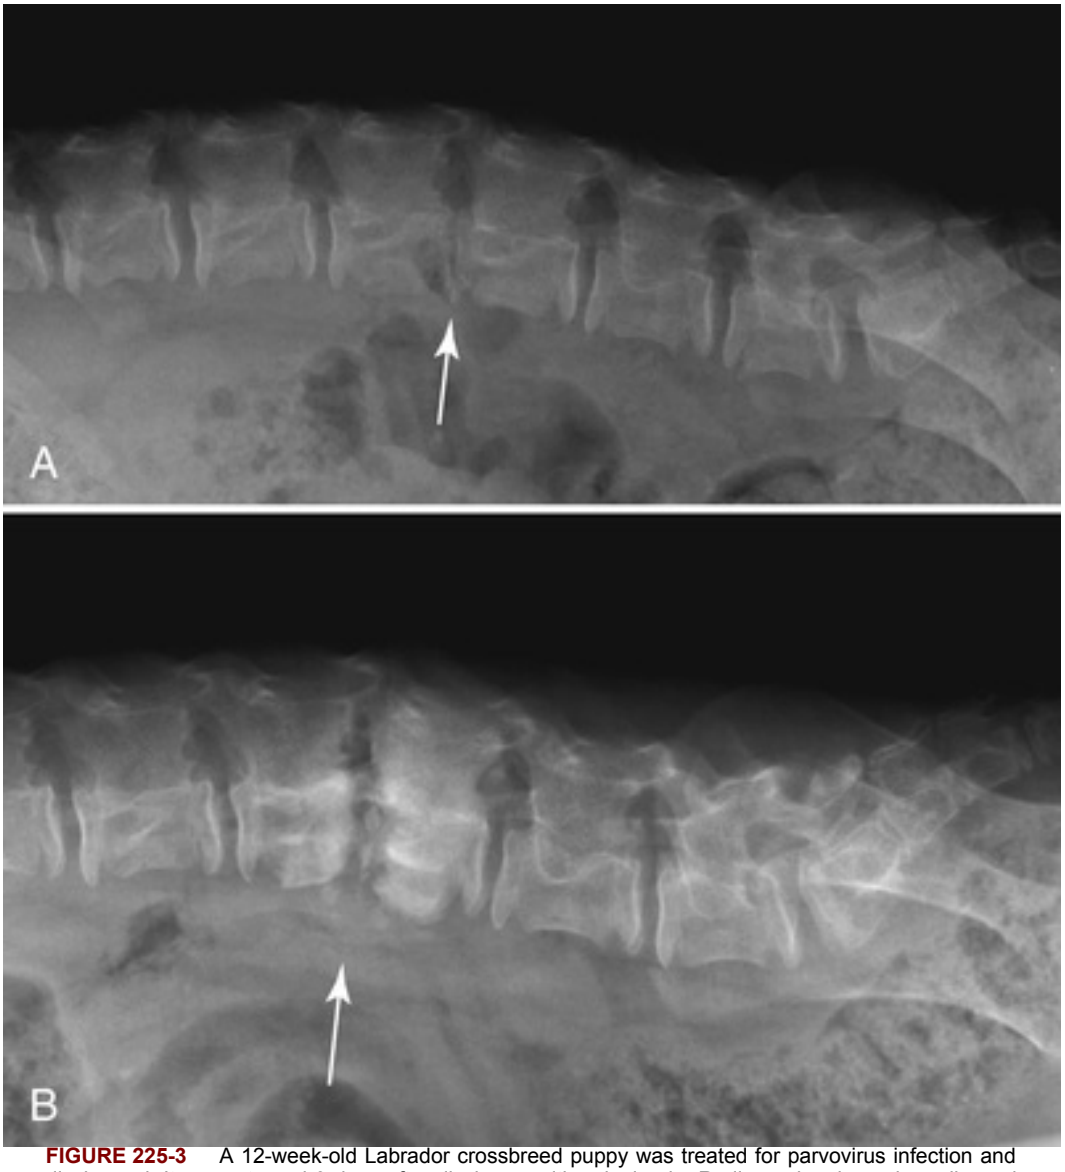

FIGURE 225-3 A 12-week-old Labrador crossbreed puppy was treated for parvovirus infection and discharged. It was returned 3 days after discharge with spinal pain. Radiographs showed a collapsed lumbar 4-5 disc space with mild subluxation **(A).** Follow-up radiographs up taken 2 weeks later showed findings typical of discospondylitis with subluxation (**B,** arrow) with a new lesion in a cervical space (not

shown). (Images courtesy R. Kirberger.)

FIGURE 225-4 The isolation ward of the Onderstepoort Veterinary Academic Hospital where dogs with parvovirus are treated. The highly contagious nature of the disease necessitates barrier nursing, as shown. The resistant nature of the virus requires that the facility be easily disinfected.

Viral infection of the gut leads to crypt necrosis and villous collapse; loss of the normal gut barrier function has serious consequences, as elements of the gut content can no longer be kept out of the bloodstream.[26,27] *Escherichia coli* was recovered from the lungs and liver of 90% of 98 CPV-infected puppies in one study.[28] Blood loss into the gut may be significant, resulting in melena, hematochezia, and anemia (which can be masked in dehydrated animals). Ascarid infestations can result in additional blood loss and are known to aggravate the disease. This comorbidity is common. Less common are concurrent giardiasis and coccidiosis.

Devastating fluid and electrolyte losses can be caused by vomiting and diarrhea. This leads to dehydration and electrolyte deficiencies, the most notable of which is hypokalemia. The dehydration would be classified as isotonic or hypotonic (due to hypertonic fluid loss) and it results in dry mucous membranes, increased skin turgor, increased capillary refill time, tachycardia, hypotension, collapse, and reduced urine production. The acid-base disturbances have been shown to be complex and heavily influenced by chloride, free water, and albumin. Severely affected animals tend to demonstrate hypochloremic alkalosis, whereas mildly affected puppies typically have a hyperchloremic acidosis. The strong ion model proposed by Stewart provides better insights into pathological mechanisms than does the traditional Henderson-Hasselbalch model.[29] Coagulation abnormalities also have been documented in a small study of 9 dogs with parvoviral infection. The study showed a high prevalence of clinical thrombosis or phlebitis and laboratory evidence of decreased antithrombin activity, prolonged activated partial thromboplastin time, increased maximum amplitude in the thromboelastogram, and increased fibrinogen concentrations. This cohort thus demonstrated hypercoagulability without disseminated intravascular coagulopathy.[24] Although this was a very small study, the older work that seemed to suggest the presence of disseminated intravascular coagulopathy should be questioned. Clinically obvious petechiation and hemorrhage from sites other than the gut are not a feature of CPV infections.

FPV is a well-known cause of cerebellar hypoplasia in kittens exposed to the virus either *in utero* or in the early neonatal period. The virus destroys Purkinje cells and granule precursor cells in the developing

cerebellum.[30] Affected kittens can show a wide range of disease, from very severe hydranencephaly, hydrocephalus, and porencephaly to milder cerebellar disease. Less seriously affected animals can make acceptable pets, as the disease is non-progressive. Clinical signs vary widely and can be multifocal depending on the areas of the brain affected and the degree to which they are affected. Seizure activity is possible with cerebral involvement.

Early in the CPV-2 disease pandemic, when dogs were not vaccinated and dams transferred no maternal antibodies to their pups, very young (<8 weeks of age) pups or pups *in utero* became infected and the clinical presentation was somewhat different to what it is today. Myocardial disease due to CPV now is very rare[31] although it does still occur in isolated unvaccinated populations.[32] Enteric signs were not always present with cardiac signs. A wide range of cardiac signs has been described, from peracute congestive failure to more chronic failure becoming evident only months after infection. It would appear, however, that CPV is not a common trigger for myocardial disease in dogs anymore.[33] Using molecular methods, FPV was identified by polymerase chain reaction (PCR) in 10 of 31 cats with cardiomyopathy but in none of the 17 controls in one study, suggesting a possible role of viral infection in the pathogenesis of feline cardiomyopathy.[34]

The ultimate cause of death in acute CPV and FPV infection is septicemia, endotoxemia, and shock (see Figure 225-1). It has been shown that endotoxin and the subsequent inflammatory cascade initiated by endotoxin are related to disease severity and outcome.[35,36] One study showed that 22% of the IV catheter tips used for fluid infusion were infected. Most of the organisms involved were Gram-negative, gut-associated bacteria.[37] Hypoglycemia is a common finding and this is likely due to the young age of most affected dogs, and the concomitant anorexia and the hypermetabolic state associated with endotoxic shock. The most likely cause of seizures in puppies with CPV infection is hypoglycemia (neuroglycopenia).

Diagnosis

The diagnosis of parvoviral disease is not problematic and is usually based on combining a cluster of findings that include the presentation of the typical signalment (young and un- or inadequately vaccinated), classic chief complaints of depression, anorexia, vomiting and diarrhea (which can be hemorrhagic) and the typical clinical findings of fever, dehydration, fluid-filled and gassy intestine on abdominal palpation, and leukopenia on peripheral blood smear. In many cases, no further diagnostic tests are performed and a legitimate presumptive diagnosis is made. The next step in diagnosis typically would involve the use of a fecal parvovirus antigen enzyme-linked immunosorbent assay (ELISA) test to confirm the clinical suspicion. These tests are used widely and will detect CPV 2a, b and c, but do have some problems with sensitivity.[38] It must be remembered that fecal viral shedding is transient and fecal antibodies can bind the virus, making it unavailable in the assay. Specificity, however, is not a problem with these tests. False positives can occur following vaccination due to the shedding of the vaccine virus for 4 to 8 days following vaccination with modified live CPV vaccines. A similar problem has been reported following FPV vaccines.[39] Serology seldom is used. ELISA assays that are semi-quantitative for anti–CPV-2 antibodies are more typically used for determining the need for vaccination rather than diagnosis. Fecal electron microscopy, although useful, also is seldom used as its availability is limited. Polymerase chain reaction also is well described but seldom used clinically. The diagnosis of FPV is based on finding the typical clinical evidence as seen in dogs, and the use of the same point-of-care fecal ELISA tests used for detecting CPV.[40,41] These tests suffer from the same problems in the detection of FPV as they do with CPV. A fecal flotation and wet-prep examination should be routine in all cases of suspected CPV or FPV to rule out concomitant parasitoses (see ch. 81).

Clinical Management

The level of care strongly affects outcome. There is no specific antiviral treatment available and hence supportive care is the mainstay of therapy. Outpatient-based treatment is not recommended as the standard of care, because in most cases owners are unable to maintain hydration orally. It might be necessary to provide subcutaneous or intraperitoneal fluids and oral antibiotics in some cases because of the financial constraints of some owners. Preliminary results of an outpatient-type protocol, consisting of intravenous fluid resuscitation followed by cefovecin (8 mg/kg SC once), maropitant (1 mg/kg SC q 24 h × 5 days) and SC fluids PRN, showed a survival rate rivaling that of inpatient treatment.[42] However, the prognosis could worsen when treatment relies on client involvement (compliance, home monitoring and treatment) if such involvement continues to be insufficient, as indicated by a history of inadequate basic preventive care like vaccination. Affected dogs and cats should be admitted to a facility that can provide isolation and barrier

nursing. The often small size of the patients and the intensive nature of the treatment and monitoring required necessitate a high level of care.

Intensive treatment with crystalloid fluids, synthetic and natural colloids, correction of hypoglycemia and any electrolyte disturbances, and a combination of antimicrobials, antiemetics, analgesics, enteral nutritional support, and anthelmintics, usually form the basis of the treatment plan. Fluid therapy to treat dehydration, re-establish effective circulating blood volume, and correct electrolyte and acid-base disturbances is the mainstay of managing more severely affected puppies (see ch. 129).[43] Fluid therapy in these patients can be complex, and careful attention should be paid to physical examination in addition to electrolyte and acid-base status.[44] The preferred route of administration is intravenous, but intraosseous administration, although rarely used, can be useful in patients that need rapid fluid administration when intravenous access is impossible (see ch. 77). All intravenous catheters should be replaced every 72 hours. The initial fluid of choice is a balanced electrolyte solution that is isotonic to blood (e.g., lactated Ringer's solution). The initial rate of fluid administration will depend on the condition of the patient. IV fluid boluses can be necessary in patients with hypovolemic shock (see ch. 127). Fluid deficits should be replaced as soon as possible (within 1 to 6 hours of presentation).[43] Once perfusion is restored, the intravenous fluid rate is reduced to a maintenance rate plus estimated ongoing losses. Hypokalemia is common and potassium chloride (KCl) should be added to the IV fluids until serum potassium concentrations have normalized (see ch. 68). Hypoglycemia also is common, and in severe cases, 25% dextrose should be given as a bolus to correct this (see ch. 61 and 303). Following this, the IV fluid infusion can be supplemented with 2.5-5% dextrose to maintain normoglycemia.

Hypoalbuminemia is common as a result of protein-losing enteropathy (see ch. 60 and 276). Colloid oncotic pressure could require support with a synthetic colloid such as hydroxyethyl starch if the serum albumin concentration should drop below 2 mg/dL (20 g/L) or if there is an obvious third space fluid loss. The role of blood products in the treatment of CPV is controversial. Patients suffering from anemia secondary to hemorrhagic diarrhea or concurrent endoparasitism should be transfused with packed red blood cells or whole blood (see ch. 130). Fresh frozen plasma (FFP) transfusion has been recommended in the treatment of CPV enteritis for its ability to provide oncotic components (albumin), immunoglobulin, and serum protease inhibitors, which can help to neutralize circulating virus and control the systemic inflammatory response associated with this disease.[45] However, FFP infusion has been shown to be a poor means of supporting colloid oncotic pressure, as very large volumes need to be infused to improve this measure significantly.[46]

Evidence supports the use of early enteral nutrition. In a randomized controlled trial, puppies receiving early enteral nutrition via a nasoesophageal tube (see Video 225-1 for placement technique; see also ch. 82), when compared with puppies that received nothing per os until vomiting ceased, showed earlier clinical improvement, significant weight gain, and improved gut barrier function, which could limit bacterial or endotoxin translocation.[26] Once vomiting has ceased, an oral deworming program should be initiated (see ch. 163).

The most commonly used antiemetic drugs for CPV enteritis are metoclopramide (0.2-0.4 mg/kg SC q 8 h or 1 mg/kg/day IV constant rate infusion [CRI]), prochlorperazine (0.1 mg/kg IV q 8-12 h), ondansetron (0.1-0.5 mg/kg IV q 12 h), or maropitant (1 mg/kg SC q 24 h × 5 days maximum). In cases of intractable vomiting, and when intestinal obstruction has been ruled out, combination therapy and continuous intravenous infusions of these drugs could be more effective than monotherapies or boluses. A retrospective study showed that in a high number of cases, antiemetics did not completely control vomiting, and puppies that received antiemetics generally required longer hospitalization. Although this study demonstrated an association between antiemetic use and prolonged hospitalization,[47] a cause-and-effect conclusion cannot be drawn, and antiemetics are definitely indicated in the management of this disease.

Treatment with intravenous, broad-spectrum, bactericidal antibiotics is warranted in puppies suffering from CPV enteritis, due both to the disruption of the intestinal barrier and to severe leukopenia. A combination of a beta-lactam antibiotic (e.g., ampicillin, 20 mg/kg IV q 8 h) or a beta-lactamase-resistant penicillin (e.g., amoxicillin/clavulanate, 20 mg/kg IV q 8 h) with an aminoglycoside (e.g., amikacin, 20 mg/kg IV, IM, or SC q 24 h once the dog has been rehydrated; used for a maximum of 5 days) will provide broad coverage. Metronidazole (15-20 mg/kg PO q 12 h for up to 10 days) is indicated in cases where motile protozoa are found on fecal wet preparation.

Despite the lack of canine-specific interferon products, several studies have shown recombinant interferons (IFNs) to significantly ameliorate severe enteritis caused by CPV and to reduce mortality.[48-50] In one multicenter, double-blind, placebo-controlled field trial that compared 43 IFN-omega treated dogs (2.5 million units/kg IV q 24 h × 3 consecutive days) with 49 placebo-treated dogs, there was a >4-fold reduction in

mortality in the treated group.[50] Another study using a recombinant feline IFN-omega preparation (1-5 million units IV q 24 h for the first 3 consecutive days) also showed a significant treatment benefit when compared to the placebo-treated group in both experimental and field trial conditions.[48]

Analgesia is an important component of case management in almost all cases, as the enteric pain can be severe; even in very depressed dogs, abdominal palpation can elicit immediate abdominal splinting due to pain. The most commonly used drugs include buprenorphine (e.g., 0.005-0.02 mg/kg IV q 8-12 h) and fentanyl (e.g., 2-5 mcg/kg/h IV CRI).

Several other adjunctive agents have been investigated, including recombinant human G-CSF (rhG-CSF) and recombinant bactericidal/permeability-increasing protein (rBPI21) but neither of these has demonstrated any benefit.[51,52] Oseltamivir, an antiviral drug that inhibits neuraminidase (NA), was recently investigated and also found to be of minimal benefit.[53]

Daily monitoring to allow treatment adjustments and assessment of progression is crucial. Clinical data (including a full physical examination) to specifically assess hydration, frequency of vomiting and defecation, abdominal palpation (to specifically palpate for intussusception), and levels of pain are standard care. Under normal circumstances, the following laboratory data should be monitored at least daily, and in some cases more frequently: hematocrit, total serum solids (or total serum protein and albumin), serum electrolytes (Na, K, Cl), and blood glucose.

Prognosis

Outcome varies greatly, with a survival rate of around 10% in untreated puppies to in excess of 90% with intensive treatment, and this is very much a function of what owners can afford.[54,55] The earlier in the disease course the animal presents for care and the sooner intensive treatment is initiated, the better the outcome. Various hematological variables have been negatively associated with prognosis, including leukopenia, lymphopenia, monocytopenia, and neutropenia.[16,56] The presence of a systemic inflammatory response syndrome at the time of admission also is a negative indicator.[16] Other factors that have been correlated with outcome include season of presentation,[55] pure breed,[14,54,57] body weight,[58] vomiting, hypercoagulability,[24] hypercortisolemia,[59] hypothyroxinemia,[60] hypoalbuminemia, elevated C-reactive protein,[61] increased tumor necrosis factor, hypocholesterolemia,[62] and hypocitrullinemia.[58]

Prevention

The cornerstone of protection is vaccination. Live attenuated and inactivated vaccines are widely available and are part of the core vaccination program for both dogs and cats (see ch. 208). Immunity is antibody-dependent and sterile. Immunity following the clinical disease is probably lifelong. It is unsafe to vaccinate pregnant animals with the live vaccine, as the fetuses could be affected negatively. Inactivated vaccines are not as quick at providing protection, which translates to a much longer period of susceptibility early in life. By far the most common cause for vaccine failure remains vaccine neutralization by maternally derived antibodies. Traditional vaccination programs start at 4 to 6 weeks, are boosted a month later and again a month after this (with the last and most effective vaccine occurring at 14 to 16 weeks of age). Where problems exist in breeding establishments, very early vaccination programs can be used in an attempt to reduce the window of vulnerability. It has been shown that a high-titer modified live virus vaccine can provide protection for pups vaccinated as early as 4 weeks old.[63] The frequency of boosting through life is contentious but it is generally accepted that a booster should be given at a year of age and then every 3 years thereafter.[64] The need for repeated vaccination through a dog's life has come under scrutiny and there is a growing tendency to assess the antibody titer against a viral pathogen before booster vaccinations are administered. One study has suggested that a CPV titer of ≥1:80 (measured by an on-site ELISA) was a practical way of separating protected from unprotected dogs admitted to a shelter.[65]

Some concern has been raised about the ability of available CPV-2 strain vaccines to protect against CPV-2c.[66] However, challenge studies using dogs vaccinated with CPV-2 have demonstrated good protection against CPV-2c.[67,68]

The highly contagious and very resistant nature of the virus make barrier nursing of infected animals and very stringent disinfection protocols (such as with 1:30 dilutions of hypochlorite bleach in tap water) crucial to preventing contagion. Because natural environments cannot be disinfected, only vaccinated animals should be allowed onto potentially contaminated surfaces.

CHAPTER 226

Rabies

Cathleen A. Hanlon

Client Information Sheet: Rabies

Overview

The word *rabies* may invoke keen attention, concern, or fear among veterinarians, pet owners, caregivers of domestic and wild animals, and the public. Rabies continues to have the highest mortality rate of any known infectious agent. In contrast to Ebola and Lassa fever, which have mortality rates as high as 50-90%, rabies is still virtually 100% fatal, despite reports of a recent human survivor and continuing attempts to treat infected individuals. The global burden of rabies continues to be associated with transmission among domestic dogs, mainly in Asia and Africa (Figure 226-1). The threat of exposure to humans and domestic animals in Europe and North America was significantly reduced several decades ago by eliminating dog-to-dog perpetuation of canine rabies virus variants. This was achieved through coordinated, methodical, population-based vaccination of dogs against rabies, as well as control of stray dog populations. In practicality, these techniques could be applied globally.

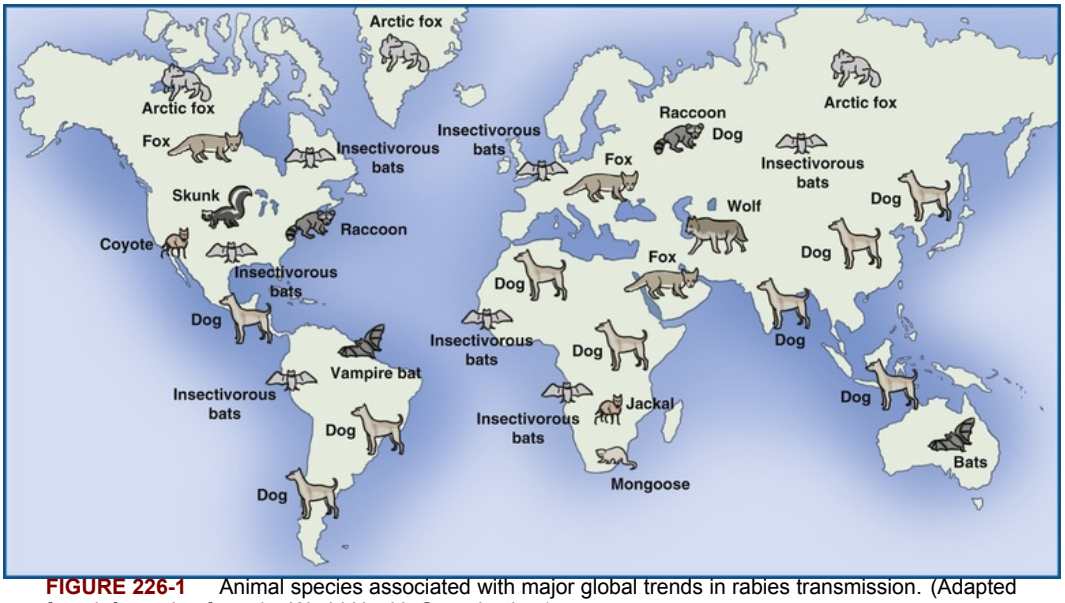

FIGURE 226-1 Animal species associated with major global trends in rabies transmission. (Adapted from information from the World Health Organization.)

Due to elimination of dog-to-dog transmission, the trend in animal and human rabies in North America has changed substantially in the last 50 years. The number of people infected with rabies decreased due to fewer exposures and better prophylactic biologics. At the same time, increase in rabies transmission among wildlife was detected. This increase was due, in part, to enhanced surveillance among other wildlife reservoir species, including skunks in the 1970s and 1980s, then bats, and also geographic expansion of the raccoon rabies virus variant. Substantial improvement in canine rabies control over the past two decades has occurred in Latin America. Overall, reports of animal rabies trends in North America have decreased from over 20,000 cases per

year a decade ago to the current level of approximately 10,000 per year. About 85% of those cases occur in the United States (Figure 226-2). These trends reflect the recent success in canine rabies control in Mexico and a decline in cases in Canada due to oral rabies vaccination of red foxes. By contrast, rabies represents a continuing enzootic disease in the United States and Canada caused by the geographic spread of raccoon rabies. Despite the historic extinction of canine rabies virus variants in most of North America, numerous rabies virus variants are found in various wildlife species and they constitute an ever-present risk of exposure (Figure 226-3). Those reported are a subset of all naturally occurring cases (Figure 226-4). Human and animal travel and contact with bats maintain the global risk of rabies.

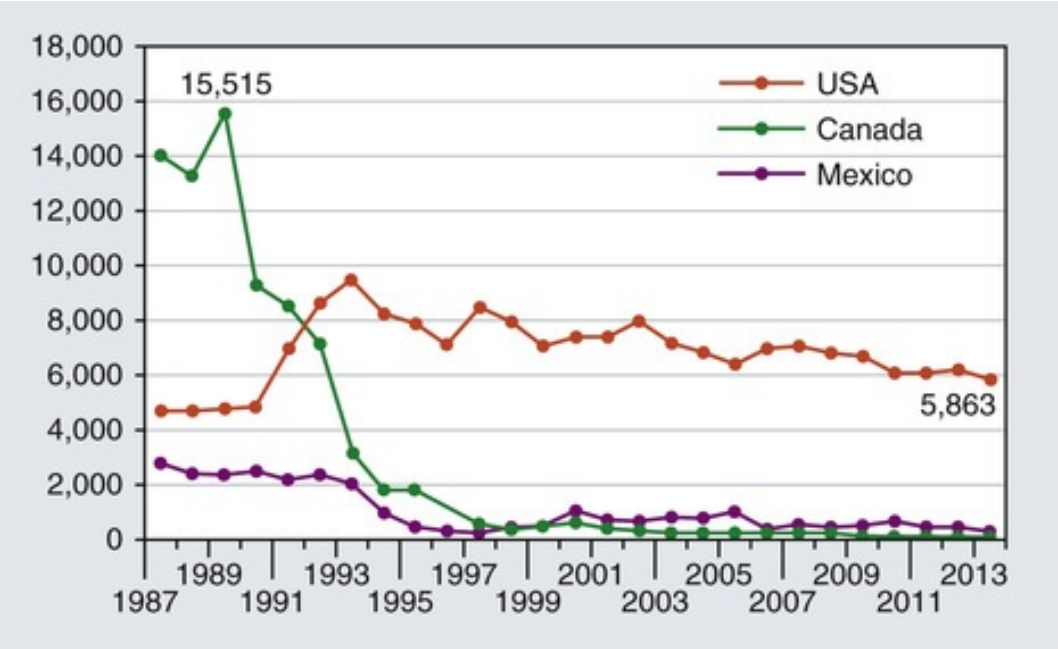

FIGURE 226-2 Animal rabies cases in North America by country, 1987-2013.

species. *CA,* California; *MX,* Mexico; *US,* United States.

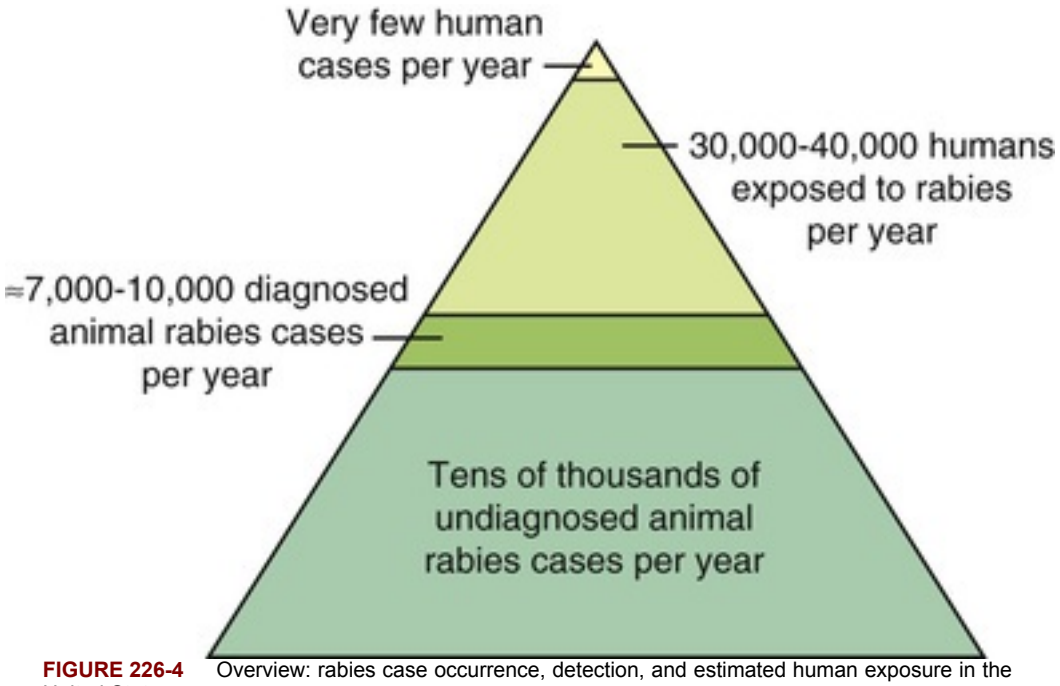

FIGURE 226-4 Overview: rabies case occurrence, detection, and estimated human exposure in the United States.

Cause and Epidemiology

The term *rabies* describes an acute fatal disease of the nervous system caused by viruses in the genus *Lyssavirus,* family Rhabdoviridae. The viruses are bullet-shaped and enveloped with a negative-sense, single-stranded genome. In addition to these rabies viruses, the *Lyssavirus* genus has six additional recognized members and four newly described members. The rabies-related Lyssaviruses are Lagos bat, Mokola, Duvenhage, European bat Lyssaviruses 1 and 2, Australian bat Lyssavirus and the Eurasia bat viruses: West Caucasian, Irkut, Aravan, and Khujand Lyssaviruses. The viruses are perpetuated in Chiroptera (bats) and Carnivora. Mammals are susceptible to rabies in varying degrees; the disease does not occur in amphibians, reptiles, birds, or invertebrates.

During 2013, 49 states and 4 other jurisdictions reported 5,865 cases of rabies in animals and 3 cases in humans to the Centers for Disease Control and Prevention (CDC). This was a 4.8% decrease from the 6,162 rabid animals and 1 human case reported in 2012. About 92% of the cases were in wildlife and 8% were in domestic animals. Relative contributions by the major animal groups were as follows: 1,898 raccoons (32.4%), 1,598 bats (27.2%), 1,447 skunks (24.7%), 344 foxes (5.9%), 247 cats (4.2%), 86 cattle (1.5%), and 89 dogs (1.5%). One human, from Maryland, was determined to have been infected via organ transplantation. Infection in the organ donor, a North Carolina resident, was retrospectively diagnosed. Both the donor and the recipient were infected with the raccoon rabies virus variant. A third human report, from Texas, involved a Guatemalan resident who was detained while crossing the US border. The infection was determined to be caused by a canine rabies virus variant that circulates in Central America. On a national level, the number of cases reported in 2013 had decreased from 2012 among cats, cattle, raccoons, bats, and skunks. The number increased for dogs and foxes. The United States remains free of dog-to-dog transmission of canine rabies virus variants. The 5% increase in the number of rabid dogs was likely due to infections from local wildlife sources.

The rabies viruses in North America are associated with wildlife and are perpetuated mainly through animal-to-animal transmission within a single reservoir species. The epizootiologic patterns of "spillover" to other species are strongly influenced by the ecology of the reservoir species and the co-occurrence of susceptible wild or domestic mammalian hosts. There are four major geographic areas within North America where rabies is transmitted primarily among skunks or raccoons. The raccoon rabies virus variant is found from Florida to Maine and into Ontario and New Brunswick, Canada, with extension westward to the

Appalachians and Ohio. Throughout the mid-western United States, there are two distinct skunk-associated viruses termed *North-Central* and *South-Central skunk rabies* virus variants. Another skunk rabies virus variant is found in southern California. The emergence and establishment of a rabies virus variant previously associated with Big Brown bats *(Eptesicus fuscus)* is transmitted among skunks in the Flagstaff area of Arizona. Rabies virus variants have been identified in Texas and southern Arizona gray foxes and a coyote/dog rabies virus variant from Mexico has been identified in Texas. A variant of rabies virus is found in Alaskan and Canadian arctic foxes and another variant identified in Puerto Rico mongooses (see Figure 226-3). Superimposed and extending beyond these geographically distinct sources are the numerous rabies virus variants found in various species of insectivorous bats.

In the United States, cats with rabies are seen 3 times more commonly than dogs (Figure 226-5).[1] Cats are less likely than dogs to be vaccinated against rabies, they are more likely to roam outdoors, and they are more likely to be outdoors at night. These factors contribute to increased likelihood of encounters with reservoir species—for example, with skunks, raccoons, or bats. Livestock occasionally develop rabies, which has potential public health impact if the animal was in contact with the public on farms, petting zoos, competitions, or through the sale of raw products. Exotic or native wildlife are at risk for exposure unless conscientiously avoided while considering extra-label use of animal rabies vaccines.

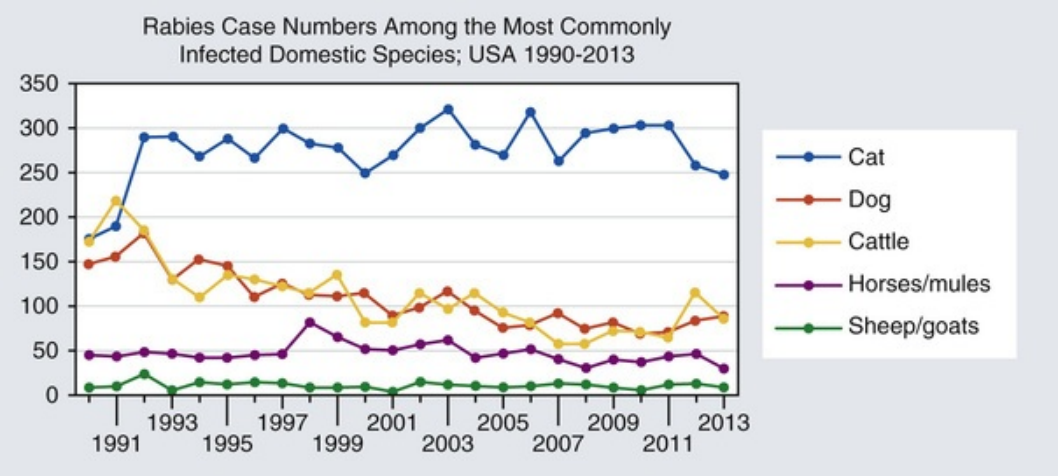

FIGURE 226-5 Rabies case numbers among the most commonly infected domestic species, United States, 1990-2013.

Exposure and Related Considerations

Natural Transmission and Vaccination Status

The predominant and natural route for rabies virus transmission is via bite wounds.[2] Rabies virus infection, in a reservoir host, causes unique behavioral changes that may favor transmission. For example, infection may cause an adult animal to sound like a juvenile, attracting other animals. In particular, those of the same species may be more likely to investigate the vocalization source, enhancing chance for bites and transmission. In one study, 13 of 264 rabid dogs (4.9%) and 22 of 840 rabid cats (2.6%) had histories of having received rabies vaccination. Of these, 2 dogs and 3 cats were classified as "currently vaccinated"; 1 dog and 5 cats had received 2 rabies vaccines in their lifetime. These results suggest that rabies is uncommon in vaccinated dogs and cats but can occur. Veterinarians should include rabies in the differential diagnosis for any dog or cat with clinical signs, regardless of vaccination history. Continued surveillance is imperative to document vaccination failure and to identify trends in vaccination failure.

Contact Transfer

Contact transfer of rabies via animate or inanimate objects has not been found to cause infection. Transmission of rabies was demonstrated experimentally when freshly collected saliva from an infected dog was "painted" on a wound of another dog that had been inflicted by investigators, more than 100 years ago.

Thus, contamination of an open wound with infectious saliva or tissue from a rabid animal is clearly an exposure to rabies. Inadvertent nosocomial transmission of rabies has occurred via corneal, organ, or vascular transplantation from people infected and dying with rabies without the condition being recognized until the recipients became ill and died. Infection via oral exposure or ingestion is not common. However, such a mode of transfer could occur if a predator with an oral wound (a site of viral entry) consumes any portion of a rabid animal. Virus is inactivated by stomach acidity.

Aerosolization

The natural history of rabies virus transmission does not rely upon aerosolization, although artificially created aerosols cause serious risk of infection. For example, two laboratory workers were infected after manipulating rabies virus–laden material and inadvertently forming an infectious aerosol. Conditions that allow aerosolization of rabies viruses are stringent and would be rare in nature. The greatest potential for this to take place is in humid, cool, small caves occupied by high densities of a natural reservoir species—for example, the Mexican free-tailed bat *(Tadarida brasiliensis).* These bats live in dense colonies. If active rabies infects even a small percentage of the several million bats in a colony, tremendous quantities of virus-laden droplet secretions descend from bats roosting on cave ceilings and walls. People entering such caves are exposed to rabies virus through bites, inhalation, contamination of mucous membranes, or open wounds. Therefore, appropriate precautions (immunization, clothing, respiratory, etc.) are vital.

Other Exposure-Related Considerations

For people, contact with infectious material on intact skin is not considered "an exposure to rabies." Thus, petting a rabid animal does not constitute an exposure to rabies.[2] The assessment of exposure risk from a contact encounter of a pet with a wild animal or other suspect- or proven-rabid animal may be difficult. Close contact of a pet or other animal with a suspect- or proven-rabid animal is, in most cases, considered a "potential exposure" by local or state public health professionals. The authority for determination of whether a domestic animal experienced a potential exposure to rabies varies by jurisdiction. Generally, a known bite from or direct contact with a potential or proven-rabid animal is considered an exposure to rabies. Other, less clear but still risky, scenarios include: (1) an animal returns from unsupervised activity with a wound compatible with a bite; (2) an animal returns from unsupervised activity smelling of skunk (especially in a skunk or raccoon rabies enzootic area); (3) sounds of animals fighting are overheard by people who suspect their pet was involved; and (4) a dead animal (especially a high-risk species such as a raccoon, skunk, or bat) is found in the vicinity of the pet. Even cats maintained indoors are at risk for exposure if a bat or other wild animal enters the home. Some "indoor" cats do roam outdoors on occasion. Pet owners should be encouraged to routinely examine their animal companions for wounds, especially following any unsupervised activity outdoors. Any wound should be assessed and treated by a veterinarian.

Rabies viruses are relatively fragile. Once saliva or contaminated tissue has dried, the material is no longer infectious. The envelope bilayer of virions is readily disrupted by commonly used disinfectants. If a currently vaccinated animal is potentially exposed to rabies, the Compendium of Animal Rabies Control indicates that a booster rabies vaccination should be administered as soon as possible and then the animal should be observed for 45 days (see Figure 226-7).[3] Observation periods may vary by locality and observation is imposed as a precaution. If a rabies exposure to a currently vaccinated animal is recognized in a timely manner and treated with local wound cleansing and a vaccine booster, the chance of vaccine failure is minimized. If a failure were to occur, clinical signs of rabies would have the highest likelihood of occurring within the 45-day observation period.

If an unvaccinated animal or one whose vaccination status is outdated is potentially exposed to rabies, euthanasia is recommended to prevent rabies. If an owner refuses, a quarantine of 6 months is imposed. It is extremely unlikely for rabies to manifest after this length of time. Quarantine conditions are determined by local or state authorities. An updated Compendium of Animal Rabies Control will likely include another option for managing dogs and cats outdated on rabies vaccination status: immediate wound cleansing, obtaining a blood sample, rabies booster administration, and collection of a second blood sample 5-7 days later (see Figure 226-7). The blood samples should be evaluated for neutralizing rabies antibodies. In a pilot study, a robust anamnestic response was observed in all animals, regardless of the time from previous vaccination.[4] Results to date are supportive. This option will help avert the unneeded euthanasia of many dogs and cats potentially exposed to rabies, while also protecting the public.

Clinical Signs

The initial clinical signs of rabies are often nonspecific and may include general lethargy, inappetence, diarrhea and/or vomiting. The clinical course is persistent and progressive, with daily, if not hourly, irreversible deterioration. Changes in behavior may be among the first clinical signs, consisting of episodic mild-to-dramatic changes. An animal may become more reclusive or attention-seeking. It may unpredictably and intermittently attack animate (humans or other animals), inanimate, or unseen objects (e.g., humans report hallucinatory episodes; animals may appear to be "snapping at flies"; see ch. 9). Rabies is neurotropic and may result in irritation or paresthesias at the site of initial infection, even if the wound has healed. A combination of increased volume of saliva and a decreased ability to swallow may cause profound contamination of the mouth, chin, and forelegs with potentially infectious saliva. Cranial nerve involvement may be focal and unilateral, such as anisocoria, facial paralysis, tongue paresis, or altered phonation. As the condition progresses, unpredictable episodes of biting may be invoked by auditory, visual, or tactile stimuli. Aggression may escalate to self-mutilation. In the final stages, most animals become profoundly moribund.

Pathogenesis

Once an animal potentially has been exposed to rabies, the probability of the animal becoming infected depends upon the individual host, host species, rabies virus variant, amount of virus, severity and route of exposure. Multiple deep bites to the head and face from a proven-rabid animal would be more likely to cause infection than a superficial wound in a distal extremity. Regardless, any potentially exposed rabies-naïve animal is at risk for developing the condition any time within a 6-month period following exposure. Virus is introduced into tissue via bites from the infected host (Figure 226-6). Only limited amounts of viral replication take place locally, however.

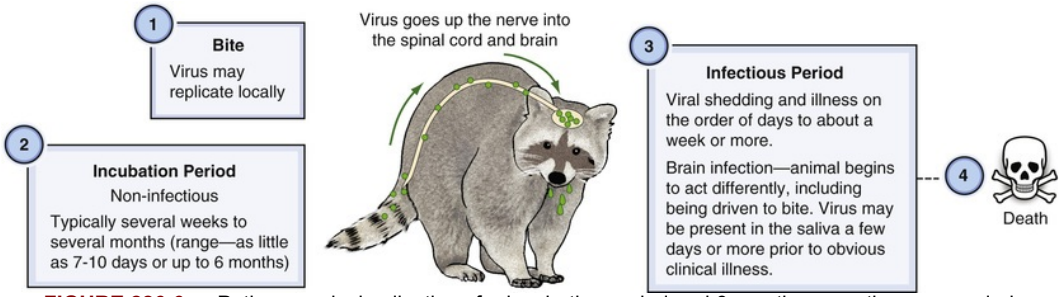

FIGURE 226-6 Pathogenesis: implications for incubation period and 6-month quarantine versus viral shedding and 10-day observation period.

At present, there is no reliable method to determine exposure or probability of infection. The virus is highly neurotropic; there is no period of viremia or of shedding via the urogenital or gastrointestinal tracts. Timing from infection of local neurons at the bite location to the time virus reaches the central nervous system (CNS) is not predictable. The incubation period is variable and is generally inversely related to virus dose and severity of exposure. Most infected animals become clinically "rabid" within weeks to a few months of exposure. Based on experimental and field data, a 6-month quarantine (or euthanasia to prevent the development of rabies) is imposed on exposed, unvaccinated (or outdated) domestic animals. This is the likely maximum incubation period. Once virus reaches the CNS, infection usually spreads quickly along multiple neuronal tracts to all major organ systems. Large numbers of virus are produced in the salivary glands, leading to virus in the saliva. The clinical period is on the order of days rather than weeks. Profound neuronal dysfunction occurs and, even with assisted preservation of an airway and ventilation, may manifest as autonomic instability and death.

Traditional pathogenesis studies have been conducted in dogs, cats, and ferrets. These studies provide the basis for a 10-day observation period (Figure 226-7). If a healthy dog, cat, or ferret bites or otherwise potentially exposes a person or animal to rabies, that animal, regardless of vaccination status, should simply be observed for 10 days. If the animal remains alive and well throughout the 10 days, there is little risk of rabies having been transmitted. If viral shedding and transmission had occurred during the bite, the biting animal would have signs of clinical rabies (sometimes including acute death) within the 10 days. If an animal develops clinical illness compatible with rabies (or dies or is euthanized) during the 10-day period, the body should be tested for rabies. This determines need for post-exposure prophylaxis for exposed people and

animals. If a bite takes place or if a person is exposed in another manner, risk of transmission is assessed on local transmission patterns, severity, and other related factors. Local and state public health authorities may allow extrapolation of data on which the 10-day observation is based, to domestic livestock and exotic hooved stock and impose a prolonged observation period of up to 30 days. If these animals remain well, the potentially exposed person does not need to undergo post-exposure prophylaxis. The animal may still develop clinical rabies in the future, but was not infectious at the time of biting or other exposure to the person.

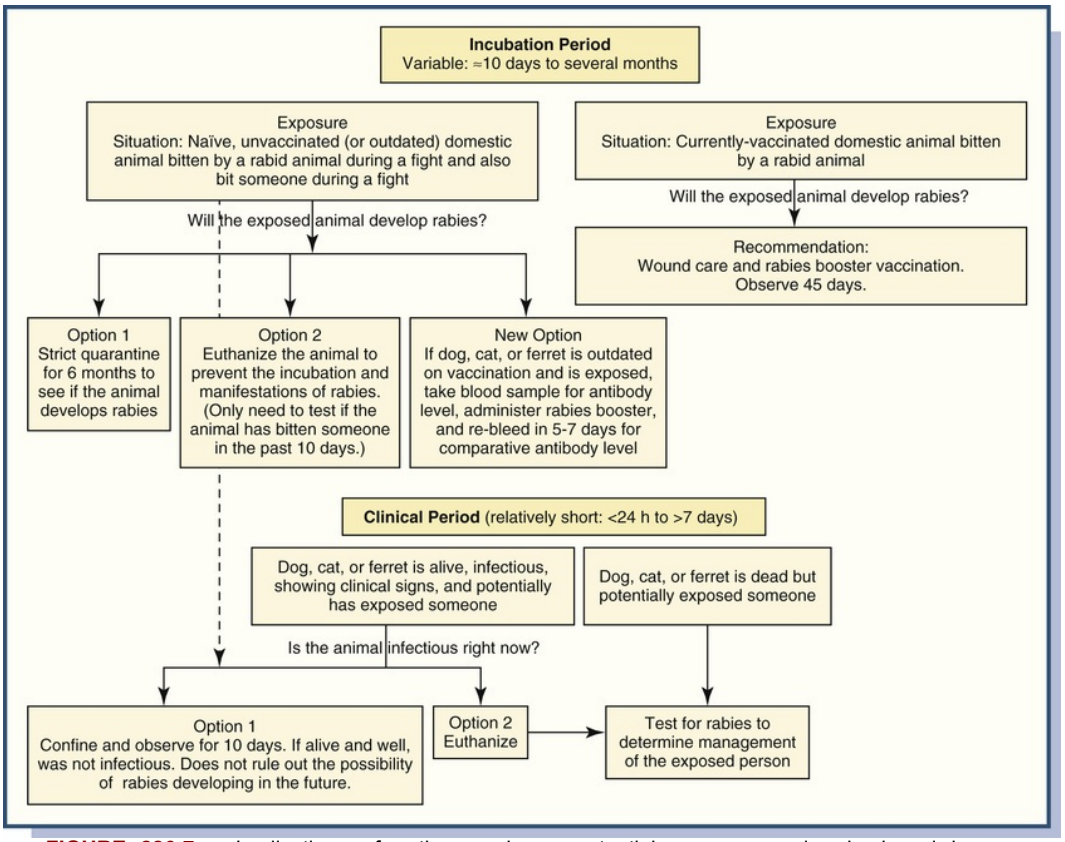

FIGURE 226-7 Implications of pathogenesis on potential exposure and animal and human management.

Diagnosis

The direct fluorescent antibody (dFA) test is the gold standard for rabies diagnosis. A definitive result is obtained through postmortem testing since a full cross-section of fresh brainstem and cerebellum is required by the National Standard Protocol for diagnosis of rabies.[2] Historically, rabies diagnosis was based on special silver-based staining (Seller's stain) to detect Negri bodies when applied to formalin-fixed brain tissue. Although specialized immunohistochemical tests for rabies may be performed at reference laboratories, the more sensitive gold standard dFA test requires fresh brain tissue. When laboratory testing for rabies is necessary, brain material fixed with formalin should be avoided as it delays definitive diagnosis. Delayed diagnosis is highly undesirable. It may lead to starting rabies post-exposure prophylaxis in a person with its expense and risk of adverse events, while waiting for a definitive answer.

Treatment

There is no medically recognized treatment for rabies. Once clinical signs are present, the disease is fatal. There are extremely rare exceptions.

Prevention

Pre-Exposure Vaccination and Exposure Management

The Compendium of Animal Rabies Control is updated and published annually.[3] It is the guiding document on animal rabies control in the United States. Pre-exposure vaccination of domestic animals, with booster vaccination if exposed, is an effective method of disease prevention. Although no vaccine is 100% effective, rabies vaccines are licensed only when a majority of vaccinated test group animals survived a lethal rabies virus challenge that killed the majority of the control (unvaccinated) group. The greatest risks for rabies in a vaccinated animal occurs: (1) when the vaccine coverage period has expired; (2) when the animal is young and has received only a single vaccination; (3) when a severe exposure has occurred; and (4) when the potential exposure is not recognized, no primary wound care is given, and no post-exposure booster vaccination is administered. Rabies is prevented in most exposed animals if currently vaccinated, if wound care consists of copious flushing to reduce probability of productive infection, and if a booster rabies vaccination is administered. As a precaution, the animal should also be confined and observed for as long as 45 days.

Prevention of rabies in wildlife is conceptually achievable through oral vaccination.[5] The greatest successes have been achieved in rabies control of red foxes in Europe and Canada. The practicality of oral vaccination depends upon: (1) the ease of orally vaccinating a particular species; (2) population densities; (3) ecologic characteristics (e.g., family groups with dominant animals interfere with vaccinating all equally); and (4) accessibility of the target population to efficient bait distribution methods and constraints near human population densities. Novel biologics are often required. Veterinarians may be consulted when domestic animals contact or consume baits distributed free-choice for oral wildlife vaccination. It is ideal for veterinarians to be familiar with wildlife vaccination projects and the associated biologics as they may pose a risk for infection and adverse events in uniquely susceptible humans and domestic animals.[6,7]

According to the Advisory Committee on Immunization Practices, pre-exposure rabies vaccination should be offered to persons at frequent or high-risk for potential rabies exposure, such as veterinarians and their staff, animal handlers, and some laboratory workers.[2] Pre-exposure vaccination also should be considered for persons whose activities bring them into frequent contact with rabies virus or potentially rabid bats, raccoons, skunks, cats, dogs, or other species at risk for having rabies. Persons in the frequent-risk group should have a serum sample tested for rabies virus neutralizing antibody every 2 years. If the titer is less than complete neutralization at a 1 : 5 serum dilution by the rapid fluorescent focus inhibition test, the person should receive a single booster dose of vaccine. If vaccinated persons are exposed to rabies, they are considered immunologically primed against rabies and simply require post-exposure prophylaxis (i.e., vaccination boosters on days 0 and 3).

Post-Exposure Management

Post-exposure rabies prophylaxis of rabies-naïve humans is practiced with essentially 100% success when administered promptly and appropriately. The practice consists of prompt wound cleansing, infiltration of rabies immune globulin of human (or equine) origin, and 5 IM doses of vaccine administered on days 0, 3, 7, 14, and 28. In theory, this approach could be applied to naïve, exposed animals and has been experimentally successful in dogs.[8] However, the global supply of human rabies biologics is limited. Insufficient vaccine supplies and their cost limits deployment of the ideal treatment approach. About 55,000 people are estimated to die each year from rabies, mainly in Asia and Africa. While these strategies could be used to prevent rabies in exposed domestic animals in the United States when owners may have neglected to have them vaccinated, it is far safer and less expensive to educate the public regarding the importance of pre-exposure vaccination of animals. This allows biologics to be available for human rabies prevention, especially in regions of the world with continuing human mortality.

Vaccination Requirements in Travel

Humans and animals may travel extensively, increasing risk of disease introduction. Despite extinction of dog-to-dog types of rabies viruses through enforcement of stray dog control measures and mandatory vaccination, risk of reintroducing related variants remains a real and compelling reason for continuing to require vaccination of domestic animals, especially dogs. Even though vaccination of an individual animal simplifies exposure management of endogenous wildlife rabies virus variants, required vaccination of the population provides a measure of biosecurity against potential introduction of exogenous canine rabies virus variants.

Recently, young dogs from Puerto Rico, Thailand, India, and Iraq have been moved to Massachusetts, California, Washington, Alaska, and New Jersey. These dogs, exposed to rabies prior to traveling, demonstrate the risk of moving an infectious disease from place to place.[9] Risk of disease translocation can be mitigated through carefully crafted requirements for animal identification, vaccination, serologic monitoring, and advanced planning for a risk-reducing waiting or quarantine period. The most critical component of risk mitigation is education of animal owners and other members of the public as to the importance of these requirements for the prevention of rabies in domestic animals and the prevention of human exposure to rabies from domestic pets and livestock.

Like many zoonoses and other emerging infections, rabies control and prevention requires the cooperation of animal control personnel, law enforcement, environmental conservation or natural resource agency personnel, veterinarians, diagnosticians, public health professionals, physicians, and others. Responsibilities start locally and on the state level. Rules and regulations pertinent to rabies control may exist under the purview of public health, agriculture, or, less commonly, wildlife agencies. With the majority of rabies cases now in a variety of wildlife species, animal control officers in some localities have been trained and authorized to manage a variety of domestic and wildlife species, not just dogs and cats. At present, a majority of the diagnostic, educational, epidemiologic, and rabies control and prevention responsibility is borne by public health agencies. Close coordination between multiple local, state, and federal entities is necessary for updating current regulations and being prepared for disease emergence or reintroduction, be it unintentional or intentional. This is done through the improvement and practice of comprehensive prevention and preparedness strategies. The need for an accessible, interactive, real-time, geographic information systems–based tool is critical for timely display of disease occurrence, planning of interactions, and assessment of disease prevention strategies. It will also be a powerful tool for spatiotemporal analysis of land-use features and their interaction with intensity and occurrence of rabies and other diseases and environmental conditions, as well. Diligent attention and dedicated effort will be required to maintain and indeed, even advance, emerging and zoonotic disease control, with rabies as a tangible "best-practices" template, beyond the major advances made in the last 50 years.

CHAPTER 227

Canine Infectious Respiratory Disease

Simon Lawrence Priestnall

Client Information Sheet: Kennel Cough

Background

Canine infectious respiratory disease (CIRD), also known as "kennel cough" or infectious tracheobronchitis, is a clinical syndrome of multifactorial etiology (see ch. 240-242). Several pathogens have been associated with the disease complex, with canine parainfluenza virus (CPIV), canine adenovirus type 2 (CAV-2) and canine herpesvirus 1 (CHV-1) traditionally considered the main viral causes, often in conjunction with or preceding *Bordetella bronchiseptica* infection.[1-3] Clinical signs such as coughing, nasal discharge and dyspnea are rarely associated with a single pathogen and more often attributed to multiple agents which act sequentially or synergistically to cause disease.

There are several multivalent vaccines which offer protection against these known pathogens (see ch. 208); however, outbreaks of respiratory disease occur in dogs despite routine vaccination, suggesting a role for other pathogens in CIRD.[4] Research into the causes of CIRD has revealed a number of additional pathogens, but it should be remembered that they are only part of a multifactorial process that also includes host factors (stress, immune status, previous exposure) and environmental conditions (overcrowding, poor ventilation) which all contribute to the clinical expression of CIRD.

Etiology and Epidemiology

Viruses

Canine Parainfluenza Virus (CPIV)

CPIV is an enveloped, single-stranded RNA virus in the *Paramyxoviridae* family. CPIV is the most commonly recognized viral pathogen associated with clinical CIRD. A recent study identified positive CPIV tests in almost 38% of dogs with acute respiratory signs. There has been almost no substantive published research on CPIV in the last few decades, despite its worldwide prevalence as a viral component of CIRD. This is particularly interesting as vaccination, both as part of a core vaccine and a specific "kennel cough" vaccine, is routinely performed, suggesting the virus is highly variable and/or current vaccines are not particularly effective.

Canine Adenovirus 2 (CAV-2)

CAV-2 is a non-enveloped double-stranded DNA virus in the *Adenoviridae* family that is genetically and antigenically related to CAV-1. Although there are some geographic variations in prevalence, CAV-2 is seldom isolated from dogs with CIRD in Europe, perhaps due to effective vaccination strategies. Only one CAV-2 PCR-positive dog was identified among 90 healthy controls.[5] This mirrors a previous longitudinal study within a rehoming kennel which failed to identify a single positive case of CAV-2 in any dog with CIRD.[6]

Canine Herpesvirus 1 (CHV-1)

CHV-1 is an enveloped, double-stranded DNA virus in the *Herpesviridae* family. Serology surveys have demonstrated higher viral prevalence in kenneled dogs than household dogs in Europe, but few studies have documented the prevalence in dogs in the United States. Although controversial and not clearly defined,

CHV may have a secondary role in CIRD, with activation of viral replication induced by more virulent respiratory pathogens. In one study, almost 13% of dogs with CIRD were positive by PCR for CHV; however, more recently the incidence of CHV as a respiratory pathogen seems to be greatly reduced, with no cases reported in some studies.[5,6]

Canine Distemper Virus (CDV)

CDV was once considered a component of the CIRD complex, but this multi-systemic morbillivirus is capable of causing fatal disease in its own right and is not grouped with the other viral causes of CIRD. Vaccination is widely practiced in much of the Western world (see ch. 208) and the incidence of the disease in dogs is reduced (see ch. 228).

Canine Respiratory Coronavirus (CRCoV)

CRCoV is a large, enveloped, single-stranded RNA virus in the *Betacoronavirus* genus of the *Coronaviridae* family. It is most closely related to bovine coronavirus (BCoV) and human coronavirus OC43.[7] CRCoV is serologically and genetically distinct from canine coronavirus (CCoV), an etiological agent of enteric disease, although pan-tropic CCoV strains have been identified.[8] The discovery of CRCoV in 2003 was prompted by the apparent lack of protection provided by commercially available vaccines to kenneled dogs who developed CIRD despite a rigorous vaccination regime.[9] A strong association was shown between exposure to CRCoV and the development of CIRD in dogs entering a kennel. Since the initial report, serological or PCR-based surveys have revealed CRCoV is the second most prevalent virus in CIRD, after CPIV. About 50-60% of dogs in North America and 20-40% of dogs in Europe have antibodies to CRCoV.[10,11] In one study, CRCoV was detected in almost 10% of dogs with acute CIRD.[5]

Canine Influenza Virus (CIV)

CIV was first detected in racing Greyhounds in Florida in 2004.[12] Genetically, this single-stranded RNA virus, part of the *Orthomyxoviridae* family, is most closely related to equine influenza virus H3N8, suggesting direct transmission from horses to dogs.[12-14] CIV is transmitted directly from dog to dog and antibodies are detected widely in dogs across the United States.[13,15] Seropositivity to CIV is as high as 50% in at-risk dog groups, those in multi-dog households or rehoming kennels, and can spread rapidly among immunologically naive animals regardless of age.[16] Evidence of infections and even antibodies to CIV are distinctly lacking outside North America.

Strictly speaking, CIV refers to infection with H3N8, but other influenza subtypes have been detected in dogs. In 2007, in South Korea, a number of outbreaks of respiratory disease in kenneled dogs was attributed to avian H3N2 influenza. Subsequently, a novel rearrangement between pandemic H1N1 and canine H3N2 in Korean dogs resulted in the novel and potentially more pathogenic H3N1 CIV.[17,18] Perhaps most worrisome is the recent demonstration that the low pathogenic avian influenza virus, H5N2, is capable of dog-to-dog transmission, causing mild clinical signs of respiratory disease and demonstrating that dogs can play a role in transmission and spread of influenza viruses.[19]

Canine Pneumovirus (CnPnV)

CnPnV is a single-stranded RNA virus in the *Paramyxoviridae* family, isolated from kenneled dogs in the northeastern United States with acute respiratory disease in 2010.[20,21] CnPnV is related to human and bovine respiratory syncytial virus, but shares closest homology with murine pneumovirus. Since its discovery, CnPnV has been detected in kenneled dogs in 8 US states and, recently, was identified as a cause of CIRD in the United Kingdom and Italy.[21-23] Extensive serological testing, surveillance surveys, and pathogenesis studies are needed to determine the prevalence of CnPnV globally, and to fully establish an association with clinical disease.

Bacteria

Bordetella Bronchiseptica

B. bronchiseptica, a Gram-negative, aerobic coccobacillus, is a known contributor to CIRD, but also is considered a normal inhabitant of canine upper respiratory tracts. Although capable of acting as a primary pathogen, the bacterium more commonly is recognized as a secondary pathogen, complicating otherwise

mild and often self-limiting viral infections. In one study, *B. bronchiseptica* was isolated from about 80% of dogs with acute respiratory disease, but also from about 45% of healthy dogs.[5] Most dogs with CIRD are co-infected with the bacterium and CPIV. Despite years of specific and widespread vaccination, co-infection with these two pathogens remains the principal cause of CIRD worldwide.

Mycoplasma Cynos

Mycoplasmas are members of the class Mollicutes, unique bacteria because they lack a cell wall and they are the smallest living organism capable of independent existence. *Mycoplasma cynos* was first isolated from the lungs of a dog with pneumonia in 1972.[24] Since then, limited data are available regarding prevalence, pathogenesis and nature of the immune response after *M. cynos* infection. Mycoplasmas are regularly isolated from both diseased and healthy dogs; however, *M. cynos* is the only mycoplasma significantly associated with respiratory disease.[25] *M. cynos* has been isolated from several dogs with CIRD, but its role in CIRD is not well understood.[26-29]

Streptococcus equi subsp. *Zooepidemicus*

S. zooepidemicus is a Gram-positive coccus and is a recognized cause of sporadic disease in dogs. *S. zooepidemicus* is a beta-hemolytic, Lancefield group C bacterium. It is distinct from group G bacteria such as *Streptococcus canis,* commonly isolated as commensal organisms from dogs. While there are occasional reports of the bacterium causing chronic nasal discharge and rhinitis, it is more frequently associated with acute hemorrhagic, fibrinosuppurative, sometimes fatal, bronchopneumonia in kenneled and racing dogs from a number of countries.[30-35] The prevalence of the bacterium in the canine respiratory tract and whether it is a true cause of CIRD, and/or a primary pathogen in its own right, remains to be determined.[36]

Pathogenesis

All the described respiratory viruses are transmitted by oronasal exposure through direct contact with virus-contaminated respiratory secretions and environmental fomites. Transmission can follow inhalation of aerosolized respiratory droplets generated by sneezing or coughing. CHV-1 is also transmitted in genital secretions and transplacentally. The incubation period ranges from 3 to 10 days, and virus shedding in respiratory secretions generally ceases within 10 days of primary infections, or in the case of CHV-1, reactivation of latent infection.[37,38] Transmission of the bacteria is less well characterized and while *Bordetella* and various mycoplasmas can be carried within the upper respiratory tract of healthy dogs, the role of carriers in *S. zooepidemicus* infections is far from clear.

In most dogs with CIRD, initial infection takes place in the ciliated epithelial cells (and sometimes goblet cells) of the upper respiratory tract and, for most uncomplicated viral infections, seldom spreads further than the nasal cavity, sinuses, trachea and perhaps bronchi. Detailed histopathological and functional studies of the effects of CIRD viruses on the canine respiratory tract have only been performed for CRCoV; however, it is expected that the other viruses result in similar changes. Viral replication causes loss of coordinated beating of cilia, followed by ciliostasis, and later loss of cilia.[39] In primary viral infections, dogs can be asymptomatic or have mild clinical disease consisting of rhinitis, sinusitis, tracheitis, and bronchitis, or a combination of these. CIV is an exception in that it also seems to result in a greater incidence of lower respiratory tract involvement and infected dogs develop necrotizing tracheitis, bronchitis and in some cases also bronchiolitis and pneumonia.[40]

In uncomplicated viral infections, ciliated cells are replaced from a reserve stem cell population. This process takes time and often the ciliated cells are replaced initially by goblet cells (hyperplasia) before the differentiation pathway allows production of ciliated epithelium. It is during this early phase of the viral infection that the main defense of the upper respiratory tract, the "mucociliary escalator," is rendered ineffective. This can allow secondary pathogens, principally bacteria, to invade and establish infection.

B. bronchiseptica produces a range of toxins to aid colonization and infection, such as tracheal cytotoxin that induces ciliostasis, and adenylate cyclase that inhibits neutrophil phagocytosis. Infection with CPIV or CRCoV creates an environment in which *Bordetella,* which may be carried harmlessly in the upper tract, colonizes and invades. In essence, it is a pathogenic synergy that has evolved unparalleled in veterinary medicine. *S. zooepidemicus* appears to act somewhat differently and, similar to CIV, is able to cause much more severe, acute or even peracute and rapidly progressive respiratory disease. It is likely that as yet unidentified exotoxins produced by the bacteria and the host's overly exuberant immune response to these toxins lead to

the often fatal disease which characterizes outbreaks involving this bacterium.

Clinical Presentation

The principal reason for veterinary consultation, and the dominant physical exam finding, typically is a cough that can be very loud, persistent, and usually has been noted for a few days (see ch. 26). The medical history classically includes a new exposure to other dogs, such as in a boarding kennel or dog park. Medications, whether by prescription or over-the-counter, usually have not produced any benefit. Appetite can be decreased slightly but anorexia of 24 hours' duration or longer is very uncommon except in patients showing other, more serious abnormalities to suggest systemic inflammation and/or complications such as pneumonia.

On presentation, affected dogs usually are bright, alert, and afebrile. Exceptions can include the more serious, systemic clinical syndromes described above for certain etiologies. Typically, the patient's respiratory effort and respiratory rate are normal. Pulmonary auscultation can reveal increased bronchovesicular sounds but wheezes and crackles are very uncommon. Tracheal sensitivity is a frequent finding, and a cough often can be elicited with mild tracheal palpation (Video 227-1) if it does not occur spontaneously during the exam. The intensity and sound of the cough often are much more severe (and of greater concern to the owner) than any other respiratory, or any systemic, effects of the disease. Likewise, ocular discharge is usually limited to a mild serous discharge if there is one at all. Mucopurulent discharges warrant further evaluation. Mucopurulent nasal discharge is not expected in uncomplicated cases; its presence suggests canine distemper infection (see ch. 228), secondary bacterial pneumonia (see ch. 242), or virulent disease with or without immunosuppression.

Coughing is usually not associated with significant phlegm or material produced at the end of tussive gagging. Occasionally, a small amount of white phlegm is produced. Increased expectoration suggests a deeper or more serious problem that could warrant further evaluation.

Diagnosis

The diagnostic evaluation of a dog suspected of having CIRD is adapted to the clinical severity of disease (Figure 227-1). In an otherwise healthy dog with a recent history of exposure to new dogs, and who manifests a cough and no other physical abnormalities, diagnostic tests beyond the physical exam can be deferred or excluded. Conversely, a febrile, inappetent, or lethargic patient, or a patient with concurrent illness that could predispose to immunoincompetence, or a patient with a cough of more than 1 week's duration, or a patient whose owner expresses concern beyond that which can be alleviated by the veterinarian's opinion, could benefit from orthogonal-view thoracic radiographs to rule out pneumonia, radiopaque foreign body, or other abnormalities. A complete blood count can be evaluated for a left shift and/or toxic changes to neutrophils, which would suggest systemic inflammation. A Baermann fecal examination (see ch. 81) is appropriate in geographic regions where lungworms are endemic. Advanced diagnostic testing to isolate the causative pathogen rarely is undertaken in mild cases without systemic signs. In patients with radiographic evidence of pneumonia, sampling for bacterial culture and sensitivity is warranted (see ch. 101, 240, and 242), ideally before the start of antibacterial therapy. Culture and sensitivity of nasal swab samples generally is unrewarding, due to contamination by nasal flora. Often, patients showing no other abnormalities beyond a cough are treated empirically without diagnostic testing, and the owner is instructed to return if the cough does not resolve after 7 days or at any time if additional clinical signs emerge.

Treatment

Therapeutic options likewise are selected based on the severity of the patient's signs. Cough that is distressing to the owner and/or the patient can be treated with antitussives (e.g., hydrocodone 0.25 mg/kg PO q 6-8 h PRN) if no other clinical signs are present. Over-the-counter antitussive agents or antihistamines can be

helpful in making the owner cognizant of the problem and occasionally alleviate some of the more racking efforts at coughing, perhaps via sedation. Antibacterial therapy is controversial because *Bordetella* and *Mycoplasma* often are present in healthy dogs; their roles as pathogens in a specific case, the need for their eradication, and their susceptibility profiles, often are unproven. Doxycycline (10 mg/kg PO q 12 h × 14-21 days in adults, 7-9 days in puppies to reduce risk of dental discoloration) has efficacy against both *Bordetella* and *Mycoplasma;* minocycline, amoxicillin-clavulanate, or trimethoprim-sulfa also have been used for *Bordetella,* whereas fluoroquinolones have been used for *Mycoplasma.* The usual precautions regarding antibiotics should be recognized and fluoroquinolone use in growing puppies is contraindicated (see ch. 169). Supportive care and monitoring are implemented if needed for dogs with pneumonia (see ch. 242) or other complications.

Prognosis and Transmission Control

The prognosis for most cases of CIRD is good: the cough typically resolves within 10 days and few or no permanent changes occur. Patients with systemic signs have a more guarded prognosis due to pathogens that are more virulent, immunoincompetence, and/or the effects of progressive systemic complications.

Contagion is a very substantial concern with CIRD, as organisms can be transmissible between dogs via aerosol or fomites. *Bordetella* shedding persists for up to 3 weeks after the resolution of cough, which justifies sequestration of affected dogs for this period after illness. Except in cases of canine distemper, permanent sequelae are uncommon, but as described above, immunity against future reinfection is limited because organisms can mutate rapidly. Vaccination prior to the occurrence of clinical signs is a cornerstone of prevention of transmission (see ch. 208).

It is strongly recommended that dogs with suspected infectious respiratory disease not be kenneled or taken to dog parks where other animals' health may be compromised. Likewise, if a dog is to be exposed to such facilities, twice yearly vaccinations are recommended. Vaccination for CIRD, where available, should be administered at least 7 days before the dog is taken to a boarding kennel for the dog to be properly immunized. It is important to recognize that these vaccines are not 100% effective in preventing CIRD but they may modify or lessen the severity of the disease should it develop.

CHAPTER 228

Canine Distemper and Other Canine Viral Infections

Thomas Wilhelm Vahlenkamp

Canine Distemper

Etiology and Epidemiology

Canine distemper is an acute to subacute systemic disease with high mortality rate in dogs and other carnivores worldwide. Affected dogs frequently develop neurologic manifestations. The causative agent, canine distemper virus (CDV), is an enveloped, single-stranded RNA virus belonging to the family Paramyxoviridae. CDV is capable of infecting a large variety of species including canids, mustelids (e.g., ferret, marten, mink, otter), and procyonids (e.g., raccoon) and large felids (e.g., lion, cheetah). Host range is defined by the viral surface hemagglutinin protein. There are six major lineages based on hemagglutinin genetic variability.[1] Each lineage contains biotypes or strains that differ in pathogenicity patterns affecting the type and/or extent of clinical signs. However, despite genetic variation, CDV isolates are serologically homogeneous. Due to the large reservoir in dogs and non-dog hosts allowing continuous exposure, especially for free-roaming dogs, CDV still is prevalent in many countries despite vaccination of dogs for more than 50 years. Although nowadays distemper is seen less commonly in veterinary practices, outbreaks occur frequently in shelter facilities. Several regional canine distemper epidemics have been documented in the past. Some of these were characterized by an unusually high morbidity and mortality, rapid spread over the country, and infections of several wild carnivore species. Molecular changes in the hemagglutinin gene are likely to be responsible for these biological features.[2]

Transmission

All ages and breeds are susceptible to CDV infection. CDV is transmitted by oronasal exposure to virus-contaminated respiratory secretions, vomitus, feces, urine, and environmental fomites. CDV also is spread efficiently by aerosols generated by coughing and sneezing, as well as aerosols of other excretions. The incubation period typically ranges from 1 to 3 weeks. Virus shedding starts within 7 to 10 days of exposure, coinciding with the hematogenous spread of the virus to epithelial and central nervous system (CNS) tissues irrespective of the severity of clinical signs. Virus is shed in all body excretions during the acute systemic disease. Dogs with subclinical infections also shed virus. Infected dogs can be contagious for up to 3 months, although shorter periods of shedding are more typical. To prevent viral transmission within a facility, infected dogs should be housed in isolation and cared for by staff adhering to strict biosecurity measures.

Pathogenesis

CDV causes systemic infection of epithelial tissues in many organ systems. Initially, the virus replicates locally in macrophages and monocytes in the tonsils, upper respiratory tract epithelium, and regional lymph nodes, reaching peak virion production by 2 to 4 days after inoculation.[3,4] The signaling lymphocyte activation molecule (SLAM, CD150) is the cellular receptor that is expressed on the surface of the cells of the immune system. Viremia occurs 4 to 6 days later, with systemic spread of virus to the stomach, small intestine, spleen and hepatic macrophages, bone marrow, and other lymphoid tissues. The widespread increase in virus production is associated with fever, lymphopenia caused by lymphocytic apoptosis, and immunosuppression. Further hematogenous spread of the virus is responsible for infection of epithelial cells in multiple organs, including the eyes, skin, and CNS. Virus shedding from the respiratory, gastrointestinal, and urogenital tracts coincides with epithelial infection. Virus persists for long periods of time in the uvea, uroepithelium, epidermis, and CNS.[1]

After 9 to 14 days, the clinical outcome of infection depends on the host's immune response. Viral infection in bone marrow and other lymphoid tissues can result in profound and protracted immunosuppression due to T-cell depletion and other undefined mechanisms.[1] In convalescing puppies, cell-mediated immunosuppression can persist after CDV infection for more than 10 weeks. Dogs with poor immune responses develop viral infection of several additional tissues, including skin and other glandular and epithelial organs. These animals generally exhibit severe clinical signs and are likely to die. Animals that do recover from the initial clinical signs maintain virus in tissues and are likely to develop clinical signs of CNS disease subsequently. In animals that mount an intermediate level of immune response, mild or clinically silent infection may develop, with virus persisting in the lungs, skin, or CNS (Figure 228-1). These animals can develop signs of CNS disease or can undergo complete recovery. Animals that mount strong immune responses are unlikely to develop signs of systemic infection but still can develop signs of CNS disease.

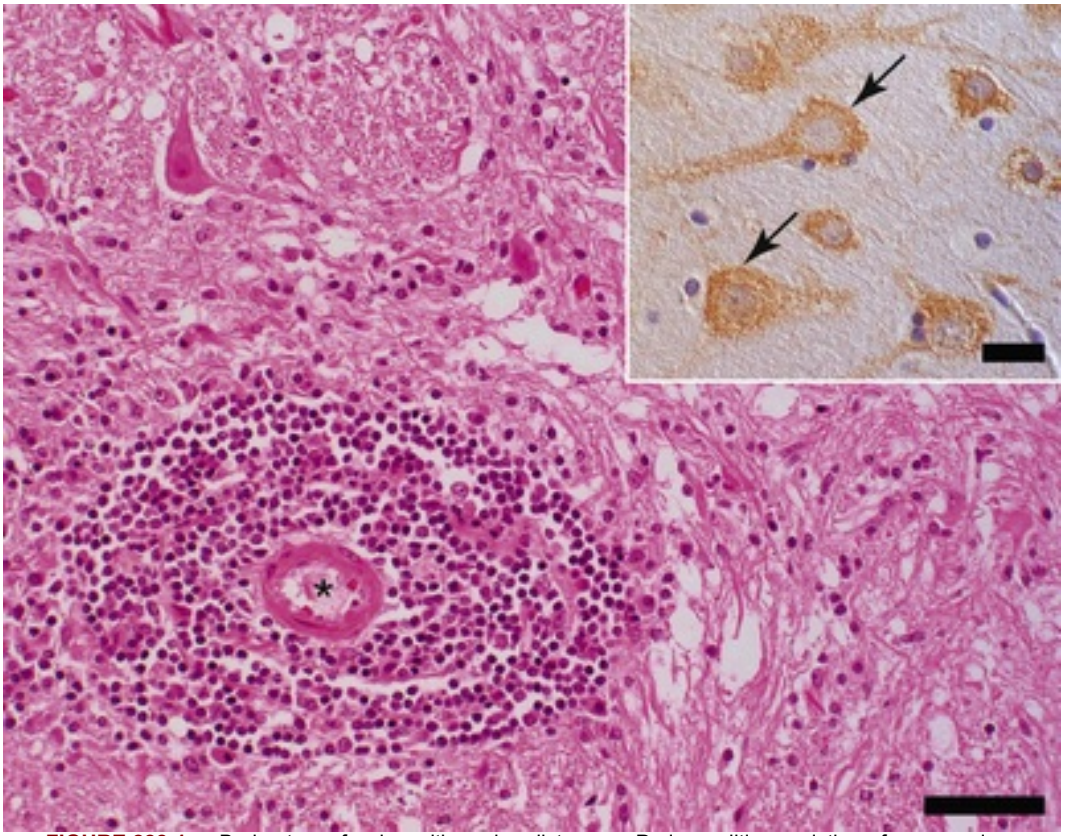

FIGURE 228-1 Brain stem of a dog with canine distemper. Perivasculitis consisting of mononuclear cells surrounding an arteriole (asterisk). Bar = 50 microns. Inset: Immunohistochemical demonstration of canine distemper virus antigen located in the cytoplasm of neurons (arrows). Bar = 20 microns. (Courtesy Dr. Denny Böttcher, Institute of Veterinary Pathology, University of Leipzig, Germany.)

Hematogenous spread of CDV into the CNS results in infection of choroid plexus epithelial cells, astrocytes, and neurons, which in general coincides with MHCII and proinflammatory cytokine upregulation. Dogs, especially the young or immune-suppressed, can develop acute demyelination attributed to direct viral injury in the absence of inflammatory reactions. Subacute to chronic CDV encephalitis appears to be a consequence of inflammatory responses to viral antigens in the CNS, with macrophage activation and release of cytotoxic mediators playing a role in destruction and demyelination of CNS cells.

Clinical Signs

The severity of the clinical course is a function of the animal's age, pathogenicity patterns for different viral strains, and immune responses.[1,3,4] Many dogs, particularly those that are older or have partial immunity, have asymptomatic infection or mild disease. Puppies are more likely to suffer from severe and protracted illness and have the highest mortality rate.

Within the first week of infection, systemic virus spread in lymphoid organs corresponds to a rise in body temperature and lymphopenia affecting both B- and T-cells. Affected dogs can be lethargic, anorexic, and dehydrated, and frequently develop conjunctivitis and respiratory signs. These include serous or mucopurulent oculonasal discharge and cough that progressively worsens if no adequate immune response develops. Viral infection of the lower respiratory tract results in pneumonia that might or might not be evident clinically but can be documented via radiographs. Viral pneumonia complicated by secondary bacterial infections can be life-threatening (see ch. 242). Infected dogs with mild clinical signs can be indistinguishable from those with other causes of kennel cough (see ch. 227). Depending on viral strain, affected dogs also can have vomiting and mucoid or hemorrhagic diarrhea from viral replication in epithelial cells of the gastrointestinal tract.

Viral infection of ocular tract epithelium can cause photophobia, anterior uveitis, and chorioretinitis. Recovered animals can have hyperreflective retinal lesions that develop from retinal atrophy and scarring, as well as keratoconjunctivitis sicca from scarring of the lacrimal glands. Optic neuritis can cause blindness or mydriasis; blindness also can result from serous retinal detachments. Production of large amounts of virus occurs in uroepithelium, including the kidneys and lower urinary tract, which can cause clinical signs associated with kidney and bladder dysfunction. Viral infection of the epidermis can result in a pustular rash and hyperkeratosis or "hardening" of the nasal planum and footpads. Infection of developing enamel buds in young puppies prior to eruption of the permanent dentition results in dental enamel hypoplasia. Some dogs, especially young large-breed dogs, are susceptible to metaphyseal osteosclerosis of long bones, which typically is not associated with lameness.

Neurologic signs can develop starting 1 to 3 weeks after recovery from systemic signs or can develop months later. Neurologic signs can develop in dogs that had no noticed evidence of systemic disease. Neurologic signs, whether acute or chronic, typically are progressive, and are the most significant factors affecting prognosis and recovery from infection. Curiously, certain features of clinical disease tend to correlate with the likelihood of developing neurologic disease. Dogs that develop pustular skin lesions are less likely to develop CNS disease, but hyperkeratosis of the nasal planum and digital footpads frequently is associated with the development of neurologic signs. Neurologic abnormalities can reflect lesions in any CNS site and include seizures, ataxia, hypermetria, paraparesis or tetraparesis, and severe cervical pain (see ch. 261 and 266). Myoclonus, either generalized or focal, is a common clinical sign and is strongly suggestive of CDV infection (see ch. 31). Hippocampal alterations can progress to the point of causing status epilepticus (see ch. 136). Puppies infected *in utero* or as neonates can develop CNS signs during the first 4 to 6 weeks of life. Abortion and neonatal death have been observed (see ch. 146 and 315).

Diagnosis

Due to the systemic infection and the variety of respiratory, gastrointestinal, and/or neurological signs, a firm diagnosis of CDV based solely on clinical signs can be difficult to achieve. Poor vaccination history might support a suspicion, but CDV also has been described in vaccinated dogs.[5,6] Intranuclear and intracytoplasmic viral inclusions can be seen in monocytes, lymphocytes, neutrophils, or erythrocytes during examination of a stained blood smear, but inclusions often disappear within 1 to 2 weeks after the onset of clinical signs. There are no pathognomonic laboratory abnormalities. Lymphopenia is the most consistent abnormality on the complete blood count. Biochemical profile abnormalities can include hypoalbuminemia and hypoglobulinemia. The cerebrospinal fluid (CSF) can have increased numbers of lymphocytes and monocytes and varying protein concentrations.[5] Dogs with respiratory disease can have interstitial or alveolar patterns on thoracic radiographs. Radiographs of long bones in lame animals can show metaphyseal lesions consistent with hypertrophic osteodystrophy. Animals with CDV-associated neurologic disease can be diagnostic challenges if there is no history or evidence of systemic signs. Abnormalities on magnetic resonance imaging (MRI) of the brains of dogs with acute CDV have been described and, though not specific, potentially could help support a diagnosis in dogs with few or no systemic signs.[7]

A definitive diagnosis of CDV hinges on the detection of viral antigen or nucleic acid in antemortem or postmortem samples, virus isolation, and serologic titers. Demonstration of viral antigen in cells on blood smears, smears from nasal, conjunctival, or pharyngeal swabs, or postmortem tissues by immunological methods such as fluorescent antibody or immunohistochemical testing confirms the diagnosis. CDV titers might not be sufficiently sensitive because they decrease beyond 3 weeks of infection.[3] Reverse-transcription–polymerase chain reaction (RT-PCR) assays are highly sensitive and specific for detection of CDV in clinical cases and can be performed on virtually any sample type, including conjunctival, nasal, and pharyngeal

swabs; whole blood; feces; urine; CSF; and postmortem tissues, particularly the urinary bladder.[8-10] However, CDV PCR assays offered by commercial laboratories do not discriminate between vaccine and field CDV strains in samples collected from dogs recently vaccinated with modified-live CDV. Duration of post-vaccine interference is variable but could be as long as 3 weeks.[10] An exception to vaccine interference with PCR testing is a recombinant canarypox-vectored CDV vaccine. Sequence analysis can discriminate between vaccine and CDV field strains.[11-13]

Serologic tests are widely available for documentation of CDV specific antibodies. However, due to profound immunosuppressive effects during acute CDV infections, the amount of antibody can be low or even remain below the detection limit for serological tests.[14] Immunofluorescent assays (IFA) are used for measuring immunoglobulin M (IgM) and IgG antibodies to CDV; detection of IgM antibodies, which can persist for 3 months, is supportive of CDV infection. The serum neutralization assay is considered the "gold standard" for quantifying total CDV antibodies. Diagnosis of recent active infection by this assay requires collection of paired acute and convalescent sera to determine seroconversion, defined as at least a fourfold increase in the antibody titer from the acute to the convalescent sample. Infection also is supported by demonstration of higher concentrations of CDV antibody in the CNS (see ch. 115) as compared with the serum, although not all animals will have CSF antibodies.[5]

Treatment

Treatment of dogs with CDV is largely supportive. Parenteral administration of fluids can be necessary in dogs with vomiting or severe diarrhea. Animals with secondary bacterial bronchopneumonia or other bacterial infections are candidates for antibiotics. In puppies, resolution of bronchopneumonia could require combinations of broad-spectrum bactericidal antibiotics administered for several weeks (see ch. 161). Seizure control with anticonvulsant drugs can be necessary (see ch. 35 and 260). Ribavirin inhibits CDV replication *in vitro,*[15] but its use has not been described in dogs. The prognosis for dogs with neurologic disease is considered guarded to poor.

Prevention

The key to CDV prevention is vaccination. CDV vaccines are considered a "core" vaccine that should be administered to all dogs (see ch. 208).[16] Maternal antibodies interfere with immunization and determine the proper time of vaccination of puppies. Transplacental uptake of maternal antibodies can range from 3-20% of the bitch's serum level. The predominant portion (approximately 80%) is absorbed in the pup's intestine from colostral antibodies mainly during the first day of life. Recommended vaccines contain high-titer, low-passage, modified-live CDV or a canarypox vector that contains CDV hemagglutinin and fusion genes. These vaccines are better able to effectively immunize dogs during the period of maternal antibody interference.[17] The canarypox-vectored CDV vaccine also is more likely to boost antibody titers in seropositive dogs compared to modified-live vaccines.[18] The duration of immunity following immunization with modified-live and recombinant vaccines is at least 3 years.[19-23] Current American Animal Hospital Association (AAHA) guidelines[16] recommend vaccinating dogs at 6 to 8 weeks of age, with repeat vaccinations performed every 3 to 4 weeks until 16 weeks of age. All dogs should receive a booster vaccine 1 year after completion of the initial series, followed by booster revaccination every 3 years. Immunization of dogs with modified-live CDV vaccine has been associated with post-vaccination complications, the most common of which is encephalitis, which can produce clinical signs of neurologic disease and variable neurological abnormalities 7 to 14 days after vaccination. However, onset of distemper-like disease shortly after vaccination is most likely due to infection with field strains of CDV prior to or at the time of vaccination, rather than disease due to reversion of modified-live vaccine strains to virulence.[1] CDV infection in previously-vaccinated dogs usually is associated with failure to induce immunity from improper vaccination schedules or improper storage of the vaccine.

In-clinic enzyme-linked immunosorbent assay (ELISA) kits can be used for measuring CDV antibodies.[24] Dogs that have recovered from CDV infection are considered immune to reinfection for long periods, most likely lifelong. Establishment of protective immunity can be determined by testing post-vaccination serum for protective neutralizing antibody titers, as serum titers correlate well with level of protection. A titer of ≥32 has been considered protective, which can vary between individual dogs and laboratory methods applied.

Besides immunization, isolation of CDV-diseased dogs appears to be the most important measure in

controlling disease spread. As an enveloped virus, CDV does not survive for long periods in the environment outside the host. The virus is susceptible to ultraviolet light, heat, and drying. Survival times are longer at colder temperatures. At near-freezing temperatures (0° C to 4° C), CDV can survive in the environment for weeks. The virus is susceptible to inactivation with a number of disinfectants such as phenolic (0.75%) or quaternary ammonium (0.3%) compounds. Routine disinfection procedures are usually effective in destroying CDV in a kennel or hospital.

Canine Herpesvirus

Etiology and Epidemiology

Canine herpesvirus (CHV) is an enveloped, double-stranded DNA virus belonging to the family Herpesviridae. The host range is restricted to domestic and wild canids. Herpesviruses have very large genomes encoding many structural and non-structural proteins involved in viral replication and modulation of the host's immune response. CHV is genetically related to other herpesviruses known in cats and horses.[25,26] CHV has a worldwide distribution. Serologic surveys in Europe have demonstrated a higher viral prevalence in kenneled dogs than in household dogs, but few studies have documented the prevalence in dogs in the United States. Although controversial and not clearly defined, CHV is considered part of a complex of pathogens causing the canine infectious respiratory disease complex (CIRD) or "kennel cough" (see ch. 227). The virus has been isolated repeatedly from dogs with respiratory disease and was found to replicate in the respiratory tract of dogs. However, clinical signs were not seen after experimental exposure. CHV might have a secondary role, with activation of viral replication induced by infection with more virulent respiratory pathogens.

Transmission

The virus is transmitted by oronasal contact with infectious respiratory or genital secretions and transplacental transmission also can occur. The source of infected material can be body excretions from young puppies, respiratory secretions from infected older dogs, or vaginal secretions from infected bitches. The incubation period for primary infection is 6 to 10 days. Virus shedding occurs for 7 to 10 days after primary infection or reactivation of latent infection.[25,26] In newborn pups, infection spreads rapidly and all puppies in an infected litter usually die. Spread of infection among older dogs appears to be slower and, even in close contact, not all dogs become infected. Fetuses can be infected *in utero* during primary infection of the pregnant bitch.

Pathogenesis

Transplacental infection during primary infection of dogs results in fetal resorption, abortion, stillbirths, or birth of weak puppies that die within days. Immunity following primary infection protects future litters. Infection of naïve puppies younger than 2 weeks old causes fatal generalized necrotizing and hemorrhagic disease. Neonatal puppies are infected by oronasal contact with the dam's infectious birth canal secretions with actively replicating virus, or via grooming by the dam. CHV first replicates in the epithelial cells of the oropharynx and tonsils. Virus subsequently enters macrophages, which allows spread to other tissues hematogenously, including the lymph nodes, spleen, adrenal glands, kidneys, lungs, liver, and CNS. The lower body temperature of neonates, in conjunction with a limited capacity to mount a febrile response, facilitates systemic spread of the virus.

Infection of older pups and adults is confined to the respiratory, ocular, or genital tract without systemic spread. Most infections are subclinical or can present as mild and self-limiting respiratory, ocular, or genital disease. Following a short replication period, CHV establishes latent infection in neurons of the trigeminal and lumbosacral ganglia, lymphocytes in the retropharyngeal lymph nodes and tonsils, and epithelial cells in the parotid salivary gland.[25,26] Reactivation of viral replication can be provoked by stress or immunosuppressive disease/therapy.

Clinical Signs

The incubation period appears to be 4 to 6 days. Bitches remain overtly healthy and milk production continues unchanged. The disease course in puppies is rapid. Infected neonatal puppies exhibit persistent crying, anorexia, signs of abdominal pain, dyspnea, and petechial hemorrhages. Most puppies in affected

litters die between 1 and 4 weeks postpartum, 24 to 48 hours after onset of clinical signs. Petechial hemorrhages in the liver, kidneys, and lungs are typical lesions observed on necropsy. Older puppies develop mild signs of respiratory disease (rhinitis, pharyngitis) with spontaneous recovery, but latent infections can emerge later as a cause of neurologic disease, with signs of ataxia, blindness, or central vestibular disease being most common. Puppies with maternal antibodies are readily infected by CHV. The infection, however, remains localized and there is no systemic clinical disease. Infection in adult dogs usually remains subclinical, but some dogs have rhinitis, pharyngitis, vaginal or preputial hyperemia, hyperplasia of vaginal mucosal lymphoid follicles, and sometimes submucosal hemorrhages. Corneal ulceration has been reported in adult dogs during natural infection with CHV,[27] while conjunctivitis occurred in experimentally infected dogs.[28] The clinical significance of CHV infections in ocular diseases is not defined, but CHV should be considered a potential cause of conjunctivitis or corneal disease after more common causes have been excluded.

Diagnosis

The diagnosis is made by observation of clinical signs in puppies of susceptible age in conjunction with necropsy lesions. Viral inclusion bodies can be observed in cells surrounding areas of necrosis and hemorrhage. A definitive diagnosis of CHV infection centers on demonstration of virus, viral antigen, or nucleic acids by PCR, electron microscopy, or immunohistochemical techniques. PCR assays also can be performed on ocular, nasal, pharyngeal, vaginal, or preputial swabs collected from older puppies and adults. Serologic testing for neutralizing antibodies confirms exposure but not necessarily active infection.

Treatment

Treatment is supportive but often ineffective at preventing neonatal losses. Injection of immune sera pooled from bitches that have had recent losses of litters might help reduce mortality during outbreaks. Keeping puppies warm and hydrated can lessen mortality in affected litters, primarily by limiting the spread of infection among uninvolved puppies.

Prevention

CHV is poorly immunogenic. Maternal antibody levels usually are low, but they suffice to protect puppies from disease (but not always from infection) for the first 2 weeks of life. Infection of older puppies usually remains subclinical. In individual kennels, CHV often is self-limiting. Dams that have lost litters to CHV infection subsequently have healthy litters; therefore, artificial insemination or caesarean sections are not considered useful approaches to limit the spread of infection. Disease outbreaks with CHV can be restricted by reducing contact with infected dogs. Currently, no vaccine is available in the United States. In Europe, a subunit vaccine licensed for pregnant dogs provides protective immunity to newborn puppies.

CHV is not stable in the environment and is inactivated by most common disinfectants such as quaternary ammonium products.

Canine Adenovirus Type 1

Etiology and Epidemiology

Canine adenovirus type 1 (CAV-1), a non-enveloped double-stranded DNA virus belonging to the family Adenoviridae, is the cause of infectious canine hepatitis (ICH). CAV-1 is closely related genetically and antigenically to CAV-2. In addition to the domestic dog, red foxes, wolves, and coyotes seem to be most sensitive. In foxes, the disease is manifested primarily as encephalitis and it does not spread as readily among wild foxes as among dogs, probably because of differences in social behavior. Gray foxes and raccoons are less susceptible and probably—like many of other members of the Canidae family—become infected but do not develop clinical signs of disease. The incidence of ICH in dogs in the United States and Europe has decreased with vaccination, although sporadic cases are identified, particularly in unvaccinated or improperly vaccinated puppies imported from countries where the disease is more prevalent.

Transmission

Infection occurs after oronasal exposure to virus-contaminated body secretions and excretions and environmental fomites. Unlike canine distemper virus, CAV-1 is not airborne. The incubation period is 4 to 9

days.[25] Virus shedding occurs during acute infection in all body secretions (saliva, respiratory) and excretions (feces, urine) and is shed in the urine of dogs that have recovered from clinical disease for up to 6 to 9 months.[25] Infected urine therefore seems to be the most important source of virus transmission.

Pathogenesis

CAV-1 causes systemic infection, with a tropism for endothelial cells, epithelial cells, and hepatocytes.[25] After exposure, CAV-1 replicates in lymphoid tissue of the tonsils and regional lymph nodes. Viremia follows 3 to 4 days post-infection, leading to infection of other tissues. Direct cytopathic effects of the virus in the liver, eyes, and kidney contribute to early clinical signs, which can become apparent in naïve dogs 4 to 9 days after exposure. Hemorrhages, which can be seen in many tissues, are the result of vascular damage after viral replication in endothelial cells. The extent of hepatic necrosis (Figure 228-2) is a function of the level of antiviral antibody present at the time of infection: animals with minimal antibody exhibit extensive necrosis that often is fatal; those with high levels of antibody exhibit minimal clinical signs; and those with intermediate antibody levels are susceptible to persistent hepatic inflammation.[25] Clinical signs of corneal edema and anterior uveitis ("blue eye") initially develop as a consequence of the inflammation following infection of corneal endothelial cells and the deposition of immune complexes (hypersensitivity reaction type III) as the antibody response to the virus increases.

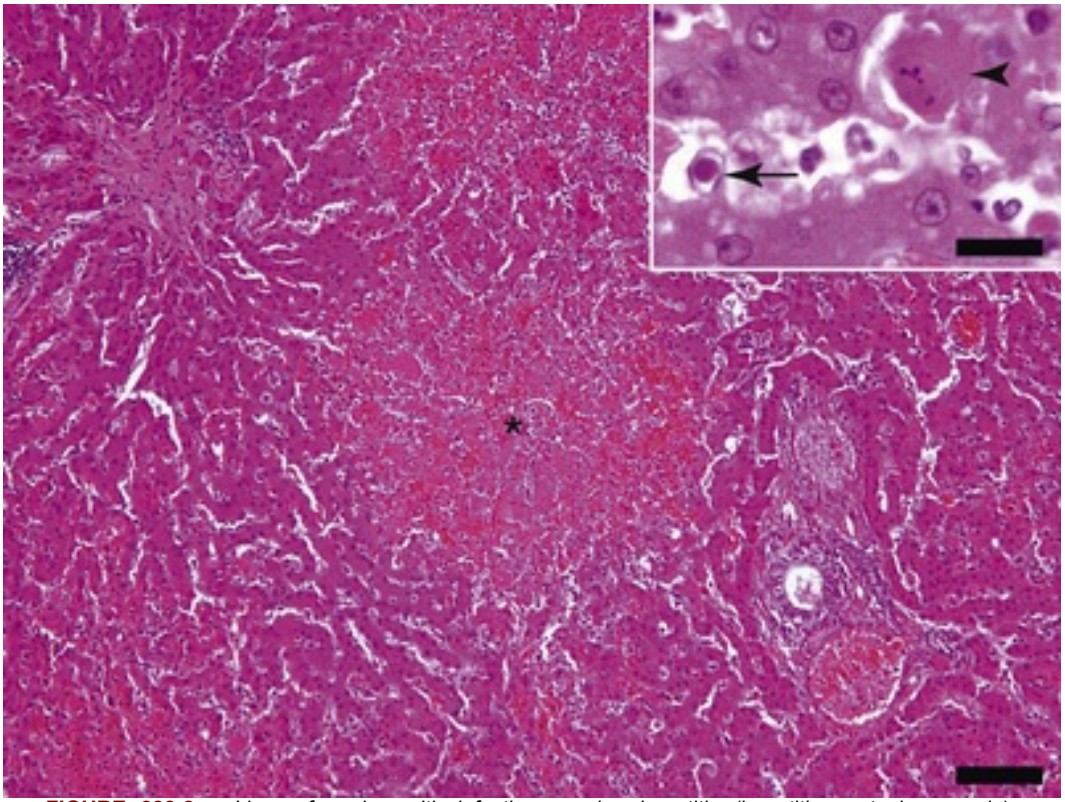

FIGURE 228-2 Liver of a dog with infectious canine hepatitis (hepatitis contagiosa canis). Centrilobular acute hepatic necrosis and hemorrhages (asterisk). Bar = 100 microns. Inset: Intranuclear viral inclusion (arrow) within a hepatocyte. A necrotic hepatocyte is indicated by the arrowhead. Bar = 20 microns. (Courtesy Dr. S. Schöniger, Institute of Veterinary Pathology, University of Leipzig, Germany.)

Clinical Signs

Dogs of all ages are susceptible to CAV-1 infection and disease; however, most dogs are infected early in life. Initial clinical signs include fever, depression, and lethargy. Later, development of signs of abdominal discomfort, mucous membrane pallor, and inflammation of the tonsils and pharynx with tonsillar and cervical lymph node enlargement occur. Leukopenia develops and persists until the febrile period is over.

Abdominal fluid and hepatomegaly can be detected in some dogs. Laryngitis, tracheitis, pneumonia, coughing, vomiting, and diarrhea occur in some. In severe cases, petechial and ecchymotic hemorrhages and epistaxis can develop from coagulation abnormalities secondary to hepatic dysfunction and disseminated intravascular coagulation (DIC; see ch. 197). Icterus is uncommon despite the presence of hepatic necrosis. Neurologic signs can be seen as a consequence of hepatic encephalopathy or CNS infection; serum bile acid or plasma ammonia concentrations, if elevated, would support hepatic encephalopathy as a cause of neurologic signs (see ch. 283). Dogs with severe disease can die within hours of showing clinical signs, whereas dogs with less severe disease can exhibit clinical improvement 5 to 7 days after onset of clinical signs. Anterior uveitis and glomerulonephritis from deposition of immune complexes can occur within a month of recovery.

Diagnosis

The diagnosis of ICH usually is based on finding evidence of acute hepatic disease in a dog with a poor vaccination history. No specific laboratory abnormalities are pathognomonic for CAV-1 infection.[25] There can be leukopenia or leukocytosis depending on whether the patient is seen early or later in the course of disease, respectively. Thrombocytopenia is possible and could contribute to bleeding disorders in the setting of DIC or abnormal platelet function. Increases in serum alanine aminotransferase (ALT) and alkaline phosphate (ALP) activities are expected, but the magnitude of activity will depend on the extent of hepatic necrosis and the timing of sample collection. Prolongations of activated partial thromboplastin time (aPTT) and prothrombin time (PT) are common as a result of decreased hepatic synthesis of coagulation factors, DIC, or both. Proteinuria also is expected as a sequel to renal injury during viremia or immune complex injury later in the course of disease.

Definitive diagnosis of CAV-1 infection can be established by PCR performed on secretions or excretions; ocular, nasal, and pharyngeal swabs; and tissues.[25] PCR assays are sensitive and can differentiate CAV-1 from CAV-2. Serologic titers and tissue staining by immunofluorescent antibody and immunohistochemistry cannot distinguish between CAV-1 and CAV-2.[25] Intranuclear inclusion bodies observed during cytologic or histologic examination of tissue, particularly the liver, can be strongly supportive of the diagnosis.[25]

Treatment

Therapy is directed at provision of supportive care and management of clinical signs and complications. Intravenous fluid therapy to replace losses from vomiting or diarrhea is important (see ch. 129), as is administration of blood products to manage the complications of hemorrhage and DIC (see ch. 130 and 197). In patients with neurologic signs from hepatic encephalopathy, administration of lactulose via enema (or orally if the patient is not vomiting) can help reduce circulating concentrations of encephalotoxins (see ch. 281 and 284).

Prevention

Vaccination is the foundation of prevention of CAV-1 infection. Vaccines for CAV-1 are considered a "core" vaccine that should be administered to all dogs (see ch. 208).[16] Vaccination of dogs and induction of active immunity has controlled CAV-1 in the canine population very effectively. Therefore, the disease rarely is seen today. Most commonly used vaccines for CAV-1 use modified-live CAV-2 isolates that, through the production of cross-reactive antibodies, will elicit a protective immune response without the complications, such as corneal edema, associated with vaccines using CAV-1 isolates. The duration of immunity following immunization with modified-live and recombinant vaccines is at least 3 years.[19-23] Current AAHA guidelines[16] recommend vaccinating dogs at 6 to 8 weeks of age, with repeat vaccinations performed every 3 to 4 weeks until 16 weeks old. All dogs should receive a booster vaccine 1 year after completion of the initial series, followed by booster revaccination every 3 years.

The virus is relatively hardy, surviving in the environment for days to months. The virus is resistant to most disinfectants except some quaternary ammonium compounds, bleach (1 : 32 dilution in tap water), potassium peroxymonosulfate, and hydrogen peroxide products.

Canine Adenovirus Type 2

Etiology and Epidemiology

Canine adenovirus type 2 (CAV-2) is a non-enveloped double-stranded DNA virus belonging to the family Adenoviridae. CAV-2 is genetically and antigenically related to CAV-1. CAV-1 and CAV-2 share the same host range. CAV-2 together with canine parainfluenza virus (CPiV), an enveloped single-stranded RNA virus belonging to the family Paramyxoviridae, are part of a complex of pathogens causing CIRD or "kennel cough" (see ch. 227). High-density, high-turnover populations in kennels, pet stores, or shelters are at risk for infection.

Despite the same host range and serologic cross-reactivity between CAV-1 and CAV-2, the tissue tropism of the two viruses is entirely different. Vascular endothelial cells as well as hepatic and renal parenchymal cells are the main targets of CAV-1, whereas the respiratory tract epithelial cells and, to a limited degree, intestinal epithelial cells, are targets of CAV-2.

Vaccines for CAV-2 are recommended for dogs at risk for exposure in shelters, boarding/training kennels, pet stores, and breeding kennels.[16] However, CAV-2 is included in parenteral "core" vaccines containing CDV and canine parvovirus, with CAV-2 providing cross-protective immunity to CAV-1 (see ch. 208). Therefore, when using these combination or multivalent vaccines, the frequency of vaccination against CAV-2 follows the schedule recommended for the "core" components, including booster vaccination every 3 years following the initial immunization series.[16] For dogs at risk for exposure, intranasal vaccines containing modified-live CAV-2 can be given as early as 3 weeks of age, with repeat administration 2 to 4 weeks later, and every 6 to 12 months thereafter.[16] Additional information regarding CAV-2 is presented in ch. 227.

Canine Papillomavirus

Etiology and Epidemiology

Papillomaviruses are non-enveloped double-stranded DNA viruses belonging to the family Papillomaviridae. Different papillomaviruses have been described in dogs. Canine oral papillomavirus (COPV-1) is the most familiar. Oral papillomas typically occur in dogs younger than 2 years of age. Although benign and usually self-limiting, oral papillomas can cause serious inconvenience by interfering with mastication. Other incompletely classified papillomaviruses in dogs cause ocular and cutaneous papillomas. Ocular papillomas occur in dogs 6 months to 4 years of age, and cutaneous papillomas, including those causing lesions on footpads and interdigital spaces of the feet of adult and immunosuppressed dogs, occur in older dogs.[29,30]

Transmission

Papillomaviruses are highly species- and tissue-specific, contagious, and transmitted by direct or indirect contact. Through small wounds in the skin or mucosal surfaces, papillomaviruses get access to the basal cell layer where infection and virus replication occurs. Papillomas typically develop 1 to 2 months after infection.

Pathogenesis

Papillomaviruses cause benign mucocutaneous proliferations (warts) of epithelial origin. The viruses primarily infect cells in the basal layer of the epithelium of the oral cavity, penis, vulva, conjunctiva, and skin, and it is likely that different papillomaviruses account for differences in lesion distribution.[31] Once infected, basal cells increase mitotic activity to produce the characteristic warts (Figure 228-3). Infectious virus particles are synthesized finally in the differentiated cells of the cornified layers of the skin or mucosal surfaces. Lesions usually regress spontaneously, but regression can vary from weeks to years.

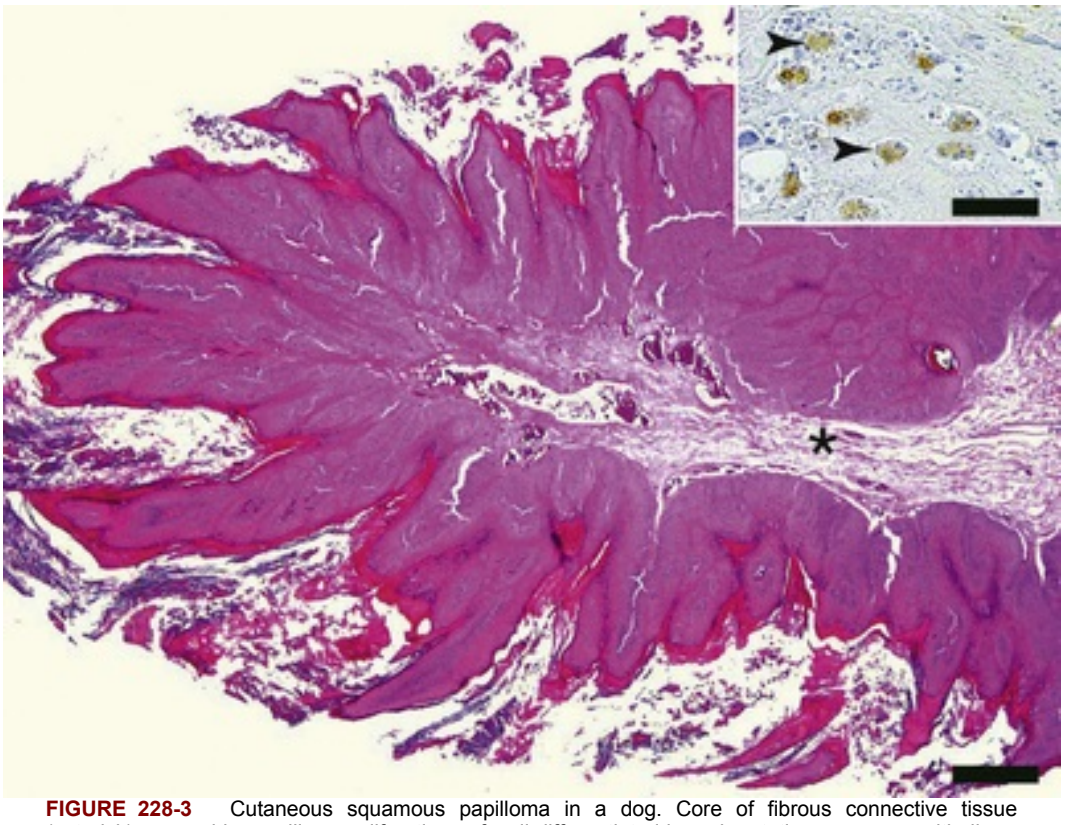

FIGURE 228-3 Cutaneous squamous papilloma in a dog. Core of fibrous connective tissue (asterisk) covered by papillary proliferations of well differentiated hyperkeratotic squamous epithelium. Bar = 200 microns. Inset: Immunohistochemical demonstration of intranuclear papillomavirus antigen (arrowheads). Bar = 20 microns. (Courtesy Dr. S. Schöniger, Institute of Veterinary Pathology, University of Leipzig, Germany.)

Clinical Signs

The primary clinical sign of COPV infection is the appearance of one, a few, or even dozens of smooth, fingerlike raised lesions measuring a few mm height and diameter (papillomas) in the oral cavity or on other epithelial sites (see ch. 218). Papillomas typically regress within 4 to 8 weeks (and occasionally longer) when cell-mediated immune responses cause T-cell infiltration into the warts.[32] Humoral immune responses, although capable of preventing infection, do not seem to play a role in regression of lesions. Although lesions can become quite extensive, especially in the oral cavity, the functional impact of papillomas to the affected animal is usually minimal unless warts develop in locations that lead to dysphagia or respiratory obstruction.

In contrast to COPV, additional incompletely classified papillomaviruses cause ocular and cutaneous papillomas. A papillomavirus designated as *Canis familiaris* papillomavirus type 2 (CfPV-2) has been described more frequently on the footpads or in the interdigital spaces of the paws and has not been incriminated as a cause of oral warts.[29,33,34] The lesions associated with this virus have been more endophytic (inward growing) than exophytic (outward growing) and have persisted for much longer periods of time. In addition, CfPV-2 has been associated with the development of squamous cell carcinomas (SCC) in immunosuppressed dogs. It is quite likely that early initial reports of SCC in mucosal and cutaneous sites associated with a novel papillomavirus reflect associations with CfPV-2.[35,36] This virus might also play a role in the development of pigmented cutaneous papillomatosis.[37]

Diagnosis

Diagnosis of COPV usually is based on the observation of characteristic lesions and is supported by histopathologic evaluation of biopsied lesions. Immunohistochemistry, electron microscopy, and PCR can be used for virus detection.

Treatment

Because COPV-related disease usually regresses spontaneously in the majority of dogs, treatment is not necessary unless warts compromise eating or respiration. In such cases, warts can be removed by surgical excision, cryosurgery, or electrosurgery. Refractory cases could benefit from autogenous vaccination, in which the superficial parts of warts containing complete virus particles are removed for making a crude vaccine that is then injected into the same dog.[32] Etretinate, a retinoid, has been used to treat viral-associated pigmented plaques.[30] The optimal treatment for lesions of the digit pads and other sites associated with CfPV-2 has not been established, but surgical resection and histopathologic examination are reasonable considerations, particularly to evaluate for the presence of malignant changes.

Prevention

No preventive vaccine is available for dogs. Dogs that have recovered from COPV generally are immune to reinfection. Some dogs, presumably those that are older or immunosuppressed, can be susceptible to repeated bouts of clinical disease. These viruses are relatively stable in the environment.

Canine Rotavirus

Etiology and Epidemiology

Canine rotavirus enteritis most often is caused by group A rotaviruses belonging to the family Reoviridae, which are non-enveloped, double-stranded RNA viruses. Group C rotaviruses, which are found more commonly in pigs and other species, also have been documented in diarrheic dogs.[38,39] Compared with other enteric viruses, clinical disease caused by canine rotavirus appears to be less common.[40-42] Nevertheless, rotavirus antigens were detectable in fecal samples in about 7% of young dogs with diarrhea in one study.[43] Canine rotavirus infections cause subclinical or mild gastroenteritis in puppies younger than 3 months old. Severe fatal enteritis has been reported in puppies younger than 2 weeks old. Investigations showed a high seroprevalence (60-80%) to group A rotavirus in adult dogs. Rotaviruses are generally considered species-specific, but genetic sequence analyses suggest interspecies transmission events between animals including dogs and humans.[43-45] A canine-like rotavirus isolate was associated with enteritis in a child.[44]

Transmission

Infection usually occurs via oronasal exposure to virus-contaminated feces or fomites. Virus shedding can start within 2 days of infection and continue for 7 to 10 days. However, animals that have recovered from diarrhea occasionally can shed virus for prolonged periods of time.

Pathogenesis

After exposure, rotavirus infects epithelial cells of the villus tip of the jejunum and ileum from the luminal side of the gastrointestinal tract. Loss of villous epithelial cells ensues, with development of villous atrophy. Virus is shed early as infected, necrotic epithelial cells are sloughed from the villus.

Clinical Signs

Anorexia, vomiting, and mild diarrhea, which occasionally can be bloody, are the typical clinical signs of rotaviral gastroenteritis. Without secondary infections, recovery is expected in most animals within 5 to 7 days of onset of clinical signs.

Diagnosis

Commercially-available tests are available to detect group A rotaviral antigens but are not employed commonly in small animal practice. Other methods to obtain a definitive diagnosis include demonstration of virus in feces by electron microscopy or RT-PCR. Sequence analysis can resolve the genotype (G- and P-) of the rotavirus involved.

Treatment

Therapy of rotaviral gastroenteritis is supportive care, with attention to maintenance of hydration status in puppies with anorexia and vomiting (see ch. 39, 40, 129, and 276).

Prevention

There is no vaccine currently available for prevention of rotaviral infection in dogs. Rotaviruses are durable in the environment and require disinfectants such as bleach, potassium peroxymonosulfate, or accelerated hydrogen peroxide products for complete inactivation.

Pseudorabies Virus

Etiology and Epidemiology

Pseudorabies is an uncommon but fatal disease of dogs caused by an enveloped, double-stranded DNA virus in the alpha-herpesvirus family. Affected dogs usually have a history of having been in contact with pigs, the primary virus reservoir that causes this disease colloquially referred to as "mad itch."

Transmission

Most cases in dogs are believed to result from ingestion of infected raw pork. The incubation period is 3 to 6 days. Despite the presence of an envelope, pseudorabies virus is relatively stable in the environment.

Pathogenesis

After ingestion, the virus enters nerve endings in the mucosa and spreads to the brain along nerve axons. Inflammation and functional abnormalities in brain cells result in clinical signs.

Clinical Signs

Signs of neurologic dysfunction are common features of the disease.[46] Neurologic abnormalities can be variable and have included ataxia, abnormal pupillary light responses, restlessness, trismus, and cervical rigidity. Ptyalism, tachypnea, and hyperpnea are common. Intense pruritus of the head and neck area can lead to self-induced excoriation. In some dogs, vomiting and diarrhea predominate. The clinical course of pseudorabies infection in dogs is usually swift, with most dogs dying within 48 hours after onset of neurologic signs.

Diagnosis

The diagnosis is suspected based on history of exposure to pigs or pork products, and clinical signs. A definitive diagnosis can be established by virus detection based on immunofluorescent antibody or PCR testing of brain and tonsillar tissue.

Treatment

Treatment is supportive, but most affected dogs succumb to the disease irrespective of treatment.

Prevention

There is no approved pseudorabies vaccine for dogs, so prevention relies on limiting exposure of dogs to pigs and preventing ingestion of raw pork products.

West Nile Virus

West Nile virus (WNV) is an enveloped, single-stranded RNA virus belonging to the family Flaviviridae. WNV is found worldwide and is maintained in natural settings via transmission from infected to naïve birds via mosquitoes.[47] Mosquitoes are able to transmit the virus to dogs.[48-50] Epidemiologic studies have demonstrated that, in endemic areas, higher seropositive rates can be found in dogs than in people, suggesting the potential for the dog as a sentinel species.[51]

Experimental infection has shown that dogs are able to develop viremia, which generally is of low

magnitude and of short duration.[48-50] Despite dogs' being able to support viremia, clinical disease in naturally-exposed or experimentally infected dogs is uncommon, even when dogs are pretreated with high dosages of glucocorticoids.[48-50] Signs of CNS disease, reflecting meningoencephalitis, and fever have been observed most consistently in naturally infected dogs; multisystemic disease also has been reported.[52-55] Reports in dogs suggest that the organs most likely to have virus are the brain, kidney, and heart.[52-55] The factors that determine the outcome of infection, and the pathogenic events underlying clinical signs in affected dogs, are unknown. Definitive diagnosis requires demonstration of viral antigen or nucleic acid in infected tissues; one report[52] of viral antigen present in renal cellular casts and other renal tubular debris raises the possibility that urine-based tests could be diagnostically useful. There are no specific treatments beyond supportive therapy. Experimental vaccination of dogs has prevented viremia after challenge,[49] but there is no approved vaccine to prevent infection in dogs and the value of vaccinating species in which disease manifestations are uncommon is uncertain.

Bornavirus

Bornavirus (BV) is an enveloped, single-stranded RNA virus belonging to the family Bornaviridae. BV causes a fatal disease of the CNS in horses and other animals. Clinical disease in dogs appears to be relatively uncommon, and seropositivity in the absence of clinical signs appears possible.[56] The pathogenesis of the disease in dogs is unknown, but clinical signs in dogs have included tremors, salivation, mydriasis, and circling.[57,58] The infection is suspected based on the histopathologic observation of non-suppurative encephalomyelitis predominantly in the gray matter of the brain. Demonstration of viral RNA by *in situ* hybridization or PCR-based assays has provided a definitive diagnosis.

Circovirus

Circoviruses are non-enveloped, single-stranded DNA viruses with a circular genome. They belong to the family Circoviridae. Recently a canine circovirus (DogCV) was described in dogs with vasculitis, granulomatous lymphadenitis and/or hemorrhagic diarrhea in the United States and Europe.[59-61] DogCV has been detected in animals with different clinical signs. The virus was detected by PCR in fecal samples from 19/168 dogs (11.3%) with diarrhea and 14/204 healthy dogs (6.9%), and in the blood of 19/409 dogs (3.3%) with thrombocytopenia and neutropenia, fever of unknown origin, or past tick bite. Co-infections with other canine pathogens were detected in 13/19 DogCV-positive dogs with diarrhea (68%).[60] DogCV also was detected in an outbreak of acute gastroenteritis in a litter of Dachshunds. The animals were 5 to 6 months of age and had completed the first year vaccination protocol against CPV, CDV, CAdVs and *Leptospira* spp.[61] Clinical signs in the dogs were severe, with hemorrhagic diarrhea, vomiting, and death of 2 animals after one week of illness. The other dogs recovered completely within 12 to 15 days after the onset of clinical signs.[61] There are no specific treatments beyond supportive therapy. Despite these reports, currently it is unknown whether DogCV really contributes to clinical disease, as experimental infections to reproduce the observed clinical signs have not yet been performed in dogs. The detection of DogCV in tissues or excretions of infected dogs can be done using published PCR protocols.

CHAPTER 229

Feline Upper Respiratory Infections

Maria Manuel Afonso, Rosalind M. Gaskell, Alan Radford

Client Information Sheet: Feline Upper Respiratory Infections

Overview

Feline viral respiratory disease is most commonly seen where cats are grouped together, such as in breeding and boarding catteries, and in rescue shelters. The two main causes of viral respiratory disease in cats are feline herpesvirus (FeHV-1) (feline rhinotracheitis virus) and feline calicivirus (FCV). FeHV-1 generally induces a more severe disease than FCV, but FCV appears to be more common. Bacterial pathogens such as *Bordetella bronchiseptica, Chlamydia felis,* and possibly *Mycoplasma felis,* are also involved in infectious respiratory and ocular disease in cats. Other viruses implicated albeit rarely in the syndrome include feline reovirus and cowpox virus (see ch. 230).

Recently, there has been a resurgence in interest in influenza biology in cats, largely driven by the demonstration that cats are susceptible to highly pathogenic and zoonotic avian influenza H5N1; although likely to be very rare in most settings, this is a rapidly changing area and so an update is included at the end of this chapter.[1]

Causative Agents

FeHV-1 is an alpha herpesvirus affecting both domestic cats and other members of the *Felidae.* Only one serotype of the virus exists, and genetically, all isolates are similar. The virus contains double-stranded DNA and is enveloped, making it relatively labile.

FCV is a small non-enveloped RNA virus. Although FCV is quite variable, it is generally considered that there is only one genotype and one serotype of the virus.[2-4] There is some evidence of two genetic clusters/genotypes in Japan, although the international significance of this remains uncertain.[5,6] Most strains of FCV are closely related enough antigenically to induce some degree of cross-protection and this has been utilized in developing vaccines. FCV affects both domestic cats, and some nondomestic *Felidae.* Interestingly, FCV-like viruses have also been isolated from dogs; however, their clinical significance in both dogs and cats is uncertain.[7,8] In addition, epidemiologic evidence of a possible association between dogs and FCV infection in cats is conflicting.[9,10]

B. bronchiseptica is a Gram-negative coccobacillus, and is considered to be a primary as well as a secondary pathogen of domestic cats. It is also a significant if seemingly infrequent zoonosis of immunocompromised people,[11] and can be transmitted between animal species.[12,13]

C. felis is an obligate intracellular Gram-negative rod-shaped coccoid bacterium.[14] A possible association between rare cases of conjunctivitis in humans and *C. felis* has been reported, though such cases are difficult to substantiate without genetic typing.[15]

M. felis is a small prokaryote lacking a cell wall. It belongs to the class Mollicutes. Several studies suggest that mycoplasmas are more common in cats with respiratory and/or ocular disease (conjunctivitis) than those without. Although their role as a primary pathogen in upper respiratory and conjunctival infection is still unclear, there is some evidence that they may be a primary pathogen in some cases of lower respiratory tract disease in cats.[16]

Clinical Signs

FeHV-1 causes upper respiratory tract (URT) disease (Figure 229-1), with oculonasal discharges, conjunctivitis, sneezing, and sometimes hypersalivation and coughing (Video 229-1).[17] Occasionally, more severe signs including pneumonia and generalized disease may be seen, particularly in young or debilitated animals. Viral replication can also lead to osteolytic changes in the turbinate bones that are believed to predispose some cats to develop more chronic rhinitis. Abortion occurs rarely, and is probably due to severe systemic disease and not to the virus itself. The role of FeHV-1 in conjunctivitis and, in some cases, ulcerative keratitis, has long been known. However, improved viral detection using polymerase chain reaction (PCR) has led to increasing recognition of this role in the acute disease as well as in more chronic ocular lesions such as stromal keratitis.[17-19] The role of FeHV-1 in other ocular conditions such as eosinophilic keratitis, corneal sequestration, and uveitis is less clear.[17,18,20] Skin ulcers and an ulcerative facial and nasal dermatitis characterized by eosinophilic infiltration have also been described.[17,21,22]

FIGURE 229-1 Cat with severe nasal, ocular and oral discharge caused by feline upper respiratory viral infection. (Courtesy Bryan Langlois, DVM.)

In FCV infection, considerable strain diversity may lead to some variation in clinical signs. The most characteristic sign is oral ulceration, typically on the tongue, but lesions may also occur elsewhere in the mouth or on the skin. Classic URT disease signs, such as sneezing, ocular and nasal discharges and conjunctivitis, also commonly occur, but these are generally milder than those seen with FeHV-1. With some strains of FCV, lameness and pyrexia may be a feature, with or without respiratory/oral disease; other strains may induce an interstitial pneumonia with infection of alveolar macrophages,[23] and some appear apathogenic.[24] In addition, FCV infection is associated with chronic stomatitis, although its precise role in the condition is not clear and other factors are likely to be involved.[4,25]

More recently, hypervirulent strains (virulent systemic FCV; VS-FCV) have emerged across North America and in several European countries. In addition to URT disease, affected cats show to varying degrees pyrexia,

cutaneous edema, ulcerative dermatitis, anorexia, and jaundice, with a high mortality rate.[26-31] Adult cats are frequently affected more severely than kittens, and in the field, disease is seen in both vaccinated and unvaccinated individuals. Each outbreak appears to be caused by a distinct strain; so far none of these VS-FCVs appears to have become widely established in the population.[32]

Experimental studies confirm that *B. bronchiseptica* can be a primary pathogen of cats, inducing mild clinical signs consisting of fever, coughing, sneezing, oculonasal discharge and submandibular lymphadenopathy.[33,34] In addition to the above, field infection may also lead to more severe disease, usually in younger kittens, including pneumonia with dyspnea, cyanosis and death.[35,36] It is likely that factors such as overcrowding and poor hygiene may lead to higher challenge doses and more severe disease.

Infection with *C. felis* is generally associated with both acute and chronic conjunctivitis, though upper and lower respiratory signs may sometimes also be seen.[15] Cases that start in one eye can rapidly progress to become bilateral.[14] Affected eyes can be markedly painful with profound conjunctival hyperemia, chemosis, blepharospasm, and watery followed by mucoid or mucopurulent ocular discharges. In some cases adhesions of the conjunctiva may develop although keratitis and corneal ulcers, and other systemic illness, are not common and this can help differentiate *C. felis* from FeHV-1. Whilst it is best considered an ocular pathogen and not a respiratory pathogen, it is mentioned here as part of the differential for FCV and FeHV-1, both of which can cause ocular as well as respiratory disease.

Diagnosis

Diagnosis of FeHV-1 and FCV infection has classically been confirmed by virus isolation in cell culture from oropharyngeal or conjunctival swabs, although immunofluorescence has also been used, particularly for FeHV-1. In many laboratories, PCR is used for diagnosis of FeHV-1, because it is significantly more sensitive than traditional methods, especially in the chronic stages of the disease.[17,37] Such PCRs also allow an estimate of viral quantity, thereby allowing some laboratories to stage disease and predict whether FeHV-1 is likely to be the cause of any acute signs, or a more chronic infection. A comparison of PCR tests available does show considerable differences in sensitivity between the published assays.[38]

For FCV, reverse-transcriptase PCR (RT-PCR) is also used, but in some cases may be less sensitive than isolation largely because of the variability between strains and the difficulty of finding suitably cross-reactive primers. Veterinarians relying on RT-PCR tests should discuss this with their laboratory. In addition to diagnosis, RT-PCR followed by sequencing is useful for differentiating between FCV strains in investigating the epidemiology of infection and disease, and in particular, can help pinpoint where an individual cat became infected from.[39-41] Unfortunately, despite some effort, there are no reliable molecular markers to predict from a given strain's sequence the type of clinical signs it may produce.[4,30,32] Such a test would be particularly valuable to confirm if an FCV isolate obtained from a cat with signs of VS-FCV was truly the cause of the signs, or just a coincidental infection with a more typical FCV strain. In order to identify cases of VS-FCV it is advisable to both demonstrate FCV infection, and to confirm antigen in what are otherwise considered unusual sites such as the liver.[26] Interpretation of test results for either FeHV-1 or FCV can be problematic. A positive result can support a clinical diagnosis but may also indicate a shedding carrier. In countries where intranasal vaccines are available, a positive result may also indicate recent vaccination.

Diagnosis of *B. bronchiseptica* can be by isolation or PCR.[35] As with FCV and FeHV-1, recovered cats can continue to shed the organism, so care must be taken when interpreting a positive result. The demonstration of *B. bronchiseptica* in samples obtained by bronchoalveolar lavage from cats with lower respiratory signs is considered to be diagnostic.

A PCR is the preferred method of diagnosing acute *C. felis* infection.[42]

Because of the high prevalence of FCV, FeHV-1, *B. bronchiseptica* and *C. felis*, serology is generally not useful for diagnosing clinical infection. It can help determine how widespread previous infection is in a group of cats, and may help shelters manage housing cats in the face of an outbreak by rapidly identifying those most at risk because of immune naivety. Although serologic tests are gaining some traction in dogs as a pre-vaccination check to help identify those that most need vaccination, their use in cats is generally not recommended.[43,44] High *C. felis* antibody titers may also be used to imply a role for *C. felis* in rarer cases of chronic ocular disease.[14]

Treatment

Primary treatment involves supportive therapy. Care should always be taken when using antimicrobials in order to minimize the risk of resistance—the use of antimicrobials should therefore be reserved for the more severe cases where bacterial infection is clearly evident, and best follows local or national guidelines (see ch. 161). For general treatment of severe cases a broad spectrum antimicrobial may be indicated (e.g., potentiated amoxicillin)[45]; other drugs should be restricted to those cases where resistance testing indicates their use. Tetracyclines are generally indicated if *B. bronchiseptica*[46] or *C. felis*[42] is involved; in the youngest kittens, potentiated amoxicillin may be preferred to avoid potential side-effects.[15] For *C. felis*, treatment should be continued for two weeks after resolution of clinical signs to reduce the likelihood of recrudescence.

Although several topical and systemic antivirals and other putative treatments have been investigated for use against FeHV-1, none of these is widely used except in cases of ocular disease.[37] Some anti-herpes viral drugs used in human medicine, such as acyclovir, are not sufficiently active against FeHV-1 or are too toxic for systemic use in cats,[17,47] although famciclovir may show some efficacy (see ch. 162).[48,49] Others such as trifluridine have been used topically with some success in cats with ocular herpesvirus lesions, and even acyclovir may have some effect when applied frequently.[17,50,51]

The value of recombinant interferon in cats with viral respiratory or ocular disease is uncertain, although its use may reduce FCV shedding (see also ch. 224).[25,51-54] Similarly, robust evidence that orally administered L-lysine ameliorates the signs of FeHV-1 infection is lacking, and any effect may require lysine supplementation before infection, or be limited to reducing shedding.[37,55,56] In some countries, passively acquired antibodies are available, and may shorten the duration of clinical signs.[57]

Epidemiology

Both FCV and FeHV-1 are primarily transmitted by direct contact between cats, although indirect transmission may also occur in the short term through contact with infectious discharges. Feline calicivirus may also be shed in urine[58] and feces of cats[59] and fleas,[60] although these routes are not thought to be of major significance. Aerosols are also not a major route of transmission because tidal volumes are believed to be too low, although sneezed macrodroplets may transmit infection over a distance of 1 to 2 meters (see Video 229-1).

Acutely infected cats are clearly an important source of virus, but infection also commonly occurs from clinically recovered carrier cats. For FeHV-1, it is generally believed that all cats recovering from acute infection develop a lifelong latent infection. In such cats, the virus persists in a latent or quiescent form largely in trigeminal ganglia, though other tissues may also be involved.[17,61] During this latent phase, infectious virus is generally not detectable from oronasal secretions. Periodically, particularly after a stressful event, virus reactivates in such carriers and they can then infect other animals. Stresses that may induce virus shedding include a change of housing (including going into a cattery), kittening and lactation, and corticosteroid treatment. Some cats may show clinical signs during a reactivation episode, which can be a useful indicator that they are likely to be infectious.

The FCV carrier state is defined as a cat shedding virus for more than 30 days after infection. In a minority of cats, the FCV carrier state appears to be lifelong.[4] However, most carriers appear to eliminate virus at some point, but remain susceptible to reinfection. During the carrier phase, FCV carriers shed virus more or less continuously and are therefore always infectious to other cats. The virus persists in the tonsils and other oropharyngeal tissues. FCV carriers appear to be common, with approximately 10% of cats in the general population shedding FCV, rising to almost 100% in some more densely populated environments such as rescue shelters and larger colonies.[10,41,62-66] From studies of endemically infected colonies, it appears that only a minority of carrier cats are true persistent shedders; the majority are undergoing cycles of reinfection from other cats in the environment.[41]

Prevention and Control

Prevention and control may be achieved through a combination of vaccination and management. Both modified live virus (MLV) vaccines and inactivated adjuvanted vaccines are marketed for parenteral injection against FeHV-1 and FCV (see ch. 208). More recently, a non-adjuvanted inactivated FCV and modified live FeHV-1 vaccine has become available in some countries. Modified live intranasal vaccines are also available in some countries but are not widely used. Several recombinant vaccines have also been created, including FeHV-1 deletion mutants, baculovirus constructs, a myxoma FCV recombinant, and an FCV DNA vaccine,

but none is licensed.

Both MLV and inactivated FeHV-1 and FCV vaccines are reasonably effective at protecting against disease, but none protects against infection or the development of the carrier state.[4,17,67] For FCV, various strains are used in commercial vaccines, such as FCV-F9 or FCV-255 in isolation, or two strains such as FCV-431 and FCV-G1.[68] Most seem to be reasonably cross-reactive against the majority of recent FCV isolates when assessed *in vitro,*[66,69] and there are some publications that point to their continued ability to induce heterologous cross-protection following challenge.[30,70] Partial efficacy has also been reported with some vaccines against some VS-FCV strains.[24,27,30] In the United States, one vaccine is available that has incorporated a single strain of VS-FCV. However, since each outbreak is caused by a different strain, the broad applicability of this approach remains to be proven in the field.

Parenteral MLV vaccines are generally safe, but disease may occasionally occur following their use. This may be due to inadvertent oronasal exposure to the vaccine that may occur if the vaccine virus has leaked onto the skin surface and the cat, or an in-contact cat, licks the injection site.[39,62,67,71] Inactivated vaccines may therefore be safer in disease-free colonies. However, most inactivated vaccines are adjuvanted, and this can sometimes cause local or systemic reactions. Very rarely, sarcomas may develop at the site of injection of both vaccines and non-vaccines (feline injection site sarcomas [FISS; see ch. 346]). To date there is little evidence to suggest one type of vaccine is safer than another.[44]

Intranasal MLV vaccines induce better protection but often at the expense of slight side-effects, such as transient sneezing and occasionally other signs.[72] They are, however, useful for rapid onset of protection.

Historically, vaccination schedules were entirely the remit of vaccine companies, with frequency of vaccination largely driven by duration of immunity studies needed for licensing. Now there is a growing number of guidelines to inform clinicians, namely the American Association of Feline Practitioners (AAFP) Feline Vaccine Advisory Panel Report,[44] the World Small Animal Veterinary Association (WSAVA) Vaccination guidelines[43] and the European Advisory Board on Cat Diseases guidelines.[25,37] These are in general recommending less frequent vaccination driven by a growing understanding of the duration of immunity of feline vaccines, and also by a better understanding of the potential side-effects of vaccination.

Primary vaccination in young kittens is generally at 8 to 9 weeks of age with a second dose at 12 weeks. Some guideline groups recommend repeated vaccinations every 3 to 4 weeks, from as early as six weeks, until 16 weeks of age[43,44]; others recommend this only where the kittens concerned are believed to be at a heightened risk due to vaccine interference by high levels of maternally derived antibodies (MDA).[25,37]

All cats should receive a booster within one year of this primary course. Thereafter, annual revaccination has traditionally taken place. However, there is now a growing consensus towards revaccination every 3 years, apart from cats living in or going into high-risk situations where more frequent vaccination may still be considered.

Live attenuated *B. bronchiseptica* intranasal vaccines are available for cats.[73] For *C. felis,* both inactivated and MLV vaccines are available as part of multivalent preparations. Guideline groups recommend these as non-core, to be used in situations where the pathogen is known or strongly suspected.[14,35,43,44]

Management measures are aimed at preventing spread of viruses within a cattery, through both direct and indirect contact between cats. Upper respiratory infections can be particularly problematic in rescue shelters where many animals of uncertain history are brought together.[41,74,75] Many cats can be shedding pathogens when they arrive, and there is often a significant increase in the proportion shedding in the days following admittance.[76,77] In boarding catteries and rescue shelters, cats should be individually housed with solid partitions between pens and good hygiene and disinfection procedures employed. FCV can persist in the environment for up to several weeks, compared to a day or so for FeHV-1, and is less susceptible to some disinfectants.[4,17] However, a diluted hypochlorite/detergent mixture should be effective for both viruses. In breeding colonies, young kittens are most at risk as they lose their MDA. Overcrowding should be avoided and cats kept as stress-free as possible. Ideally, queens should kitten in isolation and/or early weaning of kittens or earlier vaccination schedules implemented if required. Such measures have been described in detail elsewhere.[78]

Influenza in Cats

In areas in Asia where H5N1 infection is endemic in poultry, localized outbreaks of H5N1 with high mortality have been described in various felids including domestic cats, tigers and leopards.[79-82] Infection was

considered to be by ingestion of contaminated poultry meat, but horizontal transmission may also have occurred. Occasional asymptomatic infections have also been seen in domestic cats in Europe, where there was close contact with infected aquatic birds.[83]

Experimental studies have shown that cats can become infected both through contact with infected cats and by consuming infected poultry.[80,84] Infected cats developed a severe respiratory disease with a high mortality. Virus has been detected in feces and in oropharyngeal swabs from infected animals.[84,85] Influenza H5N1 should be considered in cats in contact with birds where highly pathogenic H5N1 is currently circulating.

More recently, population and experimental studies have shown that cats are susceptible to a wide range of influenza viruses including H1N1, H3N2, H3N8, H5N2 and H9N2 and in some cases developing clinical signs.[86-91] It seems likely that as further studies are undertaken, the range of influenza viruses cats are shown to be susceptible to will only grow.

It is now increasingly clear that cats can be infected with zoonotic influenza viruses, but there is no clear evidence of cats infecting humans: the vast majority of human risk is either from infected humans or direct from avian species. Heterologous vaccination of cats has been shown to protect against lethal infection of cats with H5N1, and reduce shedding, leading some to suggest vaccines may have a role in reducing risk of onward transmission from cats.[82]

CHAPTER 230

Other Feline Viral Infections

Maria Manuel Afonso, Rosalind M. Gaskell, Alan Radford

There are several viruses that infect cats. Some of these, such as panleukopenia (parvo) virus (see ch. 225), the respiratory viruses (see ch. 229), and the retroviruses (see ch. 222 and 223, and see Table 230-1) are significant pathogens of cats and both the viruses and the diseases they cause have been well characterized. Others such as cowpox virus and Hantavirus are essentially pathogens of other animal species and only occasionally infect cats. Although possible new feline viruses continue to emerge (e.g., kobuvirus infection), in comparison with humans and some other species the list of known cat viruses is not very long. This almost certainly reflects the relatively limited amount of investment there has been in feline virology, but it may also be a reflection of the fact that cats evolved to live mainly singly, and not in groups, which can restrict virus transmission. Thus, in order for viral pathogens to survive in the cat population, they may have had to develop techniques such as long-term persistence within the host (e.g., feline respiratory viruses: feline herpesvirus and feline calicivirus) or outside the host (e.g., feline panleukopenia virus). However, many cats are now kept in large groups in catteries and shelters, and this increased population density may encourage rapid transmission and evolution of viruses leading to potentially more virulent or emerging diseases.[1,2]

TABLE 230-1

Recognized Virus Infections of Cats

VIRUSES	DISEASES
Upper Respiratory Tract (URT) Viruses (see ch. 229)	
Feline herpesvirus type 1 (FeHV-1)	URT disease; sometimes ocular and skin lesions
Feline calicivirus (FCV)	URT and oral disease; sometimes lameness
Feline reovirus	Conjunctivitis/respiratory lesions/diarrhea, experimentally; no evidence important in the field
Enteric Viruses	
Feline parvovirus (FPV; see ch. 225)	Enteritis and panleukopenia; cerebellar hypoplasia; fetal death
Feline coronavirus (see ch. 224)	Mild enteritis (FECoV); feline infectious peritonitis (FIP)
Feline rotavirus	Mild diarrhea; disease uncommon
Feline astrovirus	Persistent watery diarrhea; disease uncommon
Feline torovirus	Putative torovirus detected in cats; possible association with protruding nictitating membrane and diarrhea syndrome in cats
Kobuvirus	Recently identified in cats and possible association with diarrhea
Retroviruses	
Feline leukemia virus (FeLV)	See ch. 223
Feline immunodeficiency	See ch. 222

virus (FIV)	
Feline foamy virus (FFV)	Previously feline syncytium-forming virus; no definite disease association
Miscellaneous Virus Infections of Cats	
Cowpox virus	Sporadic disease in cats; mainly skin lesions; cowpox virus endemic in small wild rodents
Hantavirus	Endemic disease in rodents; serologic evidence of infection in cats; zoonotic (but cats are unlikely source)
Rabies virus	See ch. 226
Aujeszky's disease virus/pseudorabies virus (see also ch. 228)	Herpesvirus infection in pigs/swine; cats occasional host; disease signs are severe behavioral changes, pruritus, paralysis, coma, and death
Canine distemper virus (CDV; see ch. 228)	Evidence from field serology and experimental studies indicate that cats can be infected subclinically; however, severe disease with neurologic signs seen in large felids.
Feline morbillivirus	Recently identified in urine and blood of cats. Some, yet to be proven, association with renal disease.
Paramyxoviruses: Hendra and Nipah viruses	Fatal zoonotic respiratory disease of horses in Australia (Hendra virus) and pigs in Malaysia (Nipah virus); endemic in certain species of fruit bats; cats can be infected experimentally with both viruses
Paramyxovirus: unclassified	Report of demyelinating lesions in central nervous system of cats
Avian influenza virus	Cats are susceptible to a range of influenza viruses, most notably H5N1. This virus can replicate in cats after experimental inoculation leading to severe respiratory disease, and some evidence of cat-cat transmission; feline infection may occur occasionally in the field during avian influenza outbreaks.
Borna disease virus (BDV; see also ch. 228)	Rare but fatal neurologic disease that occasionally occurs in cats
Arthropod-borne viral infections	Cats in some parts of the world may become infected with several arthropod-borne diseases; usually asymptomatic, occasionally cause encephalitis

In addition, newer technological approaches such as metagenomics[3] are identifying an increasing number of viruses in the cat population which may revolutionize our understanding of cat viral diseases.[4,5]

Borna Disease Virus (Feline Staggering Disease)

Borna disease (BD) is a rare but fatal neurologic disease caused by a negative-stranded RNA virus, Borna disease virus (BDV; see also ch. 228). The disease occurs predominantly in horses and sheep. A number of other species may also be affected, and increasing evidence indicates that cats are also susceptible (see ch. 270).[6,7] The disease in cats has been reported mainly in Europe but also occurs in other parts of the world, including Japan.[8] The true global distribution remains somewhat uncertain as some early reports remain controversial.[9] Affected cats show motor dysfunction and behavioral changes including an unsteady "staggering" gait and a progressive hindlimb stiff ataxia. Other signs may include fever, depression, anorexia, constipation, with absent or decreased postural reactions and menace responses on examination.[10]

Diagnosis is challenging. Whilst the clinical signs are not pathognomonic, other neurological signs such as generalized seizures, compulsive walking, facial paralysis or vestibular signs are generally not a feature of BDV infection, and if present, can help rule out BDV as a likely cause. In addition, BDV specific antibodies and/or BDV-RNA can be detected in the serum of a high proportion (≈89%) of patients, much higher than in unaffected cats (≈16%), and may therefore aid in the clinical diagnosis of affected cats.[11] The disease is generally progressive, and despite supportive treatment, affected cats die or are euthanized. The virus persists in the central nervous system of both experimentally and naturally infected cats.[10]

At necropsy, there is a characteristic nonsuppurative meningoencephalomyelitis, mainly in the gray matter of the cortex, brainstem, and spinal cord. In some cases, infection is present in cats with no neurologic disease. It has been suggested that BDV or a related virus may be involved in psychiatric disorders in humans.[10]

Poxvirus Infection

Cats are susceptible to cowpox virus, a member of the Orthopoxvirus family.[12-14] Occasional cases of parapoxvirus infection in cats have also been reported.[15] Cowpox virus is found only in Eurasia, and the reservoir hosts are small wild mammals such as voles and wood mice. In North America, orthopoxvirus infections affecting the skin of cats are extremely rare, but a case of raccoonpox has been reported in a Canadian cat.[16]

Cowpox is mostly seen in rural cats that hunt rodents, and most cases are seen in summer and autumn, when opportunities for contact with the reservoir hosts are highest. Cat-to-cat transmission only rarely occurs and generally causes only subclinical infection.

The disease typically starts with a single primary lesion, generally on the head, neck, or forelimb, which may be ulcerated or crusting and can become secondarily infected. Although some cats may only have a primary lesion, in many cases widespread secondary skin lesions also develop after 1 to 3 weeks. These appear as randomly distributed, small epidermal nodules that increase in size over a few days to well-circumscribed ulcers about 1 cm in diameter. These gradually become scabbed and heal over a period of 4 to 5 weeks and most animals recover uneventfully. Occasionally, especially in immunosuppressed cats, systemic illness including pneumonia may develop.[17] Exotic felids (e.g., cheetahs) are particularly susceptible, and a rapidly fatal pneumonia often develops.

Diagnosis is most likely to be by polymerase chain reaction (PCR) of skin crusts material, although virus culture, electron microscopy (EM) and serology may also still be used.[13,18] Characteristic histopathologic lesions include the presence of intracytoplasmic, eosinophilic inclusion bodies, and if necessary, viral antigen can be confirmed by immunostaining.

Treatment includes broad-spectrum antibiotics to control secondary bacterial infection and general supportive therapy with fluids where necessary (see ch. 129). Glucocorticoids are contraindicated as they can predispose to the development of secondary lesions, more severe disease, or both.

Cowpox is zoonotic and cases of suspected cat-human transmission may occasionally occur, resulting in localized lesions and sometimes, severe systemic illness in infected people, particularly those who are immunosuppressed.[13,19,20] There is some suggestion that discontinuation of human smallpox vaccination is leading to an increase in the susceptibility of the human population.[21] However, the risk of cat-human transmission remains small if basic hygiene precautions are taken, with the majority of human infections likely to come from indirect or direct contact with infected rodents.[22-24]

Feline Foamy Virus (Feline Syncytium-Forming Virus) Infection

Feline foamy virus (FFV) is a member of the foamy virus group (spumaviruses) in the retrovirus family. Spumaviruses have been isolated from many species, but they generally do not appear to be pathogenic. Their main importance lies not in clinical medicine but as potential contaminants in research and vaccine production, and more recently, as possible viral vectors in recombinant vaccine technology.

FFV infection is very common in cats, with seroprevalences of up to 90%, depending on the population tested.[25,26] Infected cats harbor virus indefinitely; therefore, being seropositive equates with infection. As well as horizontal transmission, FFV can in some cases be transmitted vertically from infected queens to kittens.

The virus has been isolated from both clinically healthy cats and cats with a variety of diseases, although no clinical signs have been seen experimentally, at least for the 6 months post-infection that were studied.[27] However, in the same study, a mild glomerulonephritis and moderate interstitial pneumonia were observed in infected cats, although there were no contemporaneous controls available for comparison. As such, FFV remains an enigma, a virus in search of a disease. It remains possible that FFV may predispose to disease in conjunction with other agents, or particular major histocompatibility types, such has been suggested for FFV in feline progressive polyarthritis syndrome.[28] However, it is also entirely possible that infection is asymptomatic.

Astrovirus Infection

Astroviruses have been detected in a number of species including cats, and in humans are a common cause of gastroenteritis. These viruses have been detected in the feces of both kittens and cats with and without diarrhea.[4,5,29]

Diarrhea associated with astrovirus infection has been described as persistent (4 to 14 days) and watery and

may be accompanied by vomiting, pyrexia, and depression. Mild diarrhea was reproduced experimentally.[30] How commonly such disease occurs in the field is not clear. A recent study in Korean hospitalized cats found that 19% and 15% of diarrheic and normal feces, respectively, were positive for astroviruses, but the difference was not statistically significant.[31] A limited serologic study has reported that fewer than 10% of cats in the United Kingdom have antibodies, although this may be an underestimate as only one serotype was examined.[29]

Serologic cross-reactivity has been reported between feline astrovirus and human sera, although whether this represents zoonotic transmission or more likely antigenic cross-reactivity between distinct viruses is not known. Astroviruses show genetic diversity and a propensity for recombination, and sequence data suggest an evolutionary link between pig, human, and feline astroviruses.[32,33] However, these are thought to be historical associations[5] and there is no evidence of ongoing human-animal transmission.

Feline Reovirus Infection

Reoviruses have been isolated from both healthy and diseased cats with a variety of signs. Serologic surveys suggest infection is widespread, although the clinical importance of reovirus infection in cats is unknown.[34] Three serotypes of the virus exist. Experimental inoculation of kittens with serotype 3 induced predominantly conjunctivitis, photophobia, and serous ocular discharges; type 2 induced mild diarrhea, and newborn kittens inoculated with type 1 nursed poorly and died 2 days later with respiratory lesions identified at necropsy.[34-36] Little evidence suggests that these conditions occur in the field.

Rotavirus Infection

Rotaviruses are a major cause of enteritis in humans and in many animal species such as cattle and pigs. Typically, rotavirus infections occur in neonatal animals, although older animals may also be affected.

In cats, rotavirus infection is widespread, with up to 100% of cats seropositive depending on the population sampled.[29,37] Molecular studies have found prevalence of 3-13% in fecal samples from various populations, with a higher prevalence of infection in summer.[38] Recently, highly divergent strains of rotavirus have also been found in cats.[5] Clinical disease appears to be uncommon and diarrhea, when it occurs, tends to be mild and of only short duration.[29,39,40] Diagnosis of rotavirus infection may be carried out from fecal samples by EM, polyacrylamide gel electrophoresis of viral RNA, or by PCR.[29] Because of serologic differences between strains, enzyme-linked immunosorbent assays (ELISAs) developed for diagnosis of human rotavirus infections may not necessarily detect all feline rotaviruses.[29]

Cross-species transmission is known to occur with rotaviruses experimentally, though to what extent this happens under natural conditions is not known. Several recent reports have shown close phylogenetic relationships between some feline and some human rotavirus strains,[29,38,41] with additional evidence for recombination,[42] leading to the suggestion that cross-infection between cats and humans may sometimes occur.

Hantavirus Infection

Hantaviruses are enzootic worldwide in wild and laboratory rodents and are zoonotic.[43,44] Strains vary in their pathogenicity to humans. Disease syndromes seen in man include hemorrhagic fever with renal syndrome in Asia and Hantavirus pulmonary syndrome in North America. Only mild or subclinical disease is seen with most European strains.[45]

Hantavirus antibody has been detected in up to 16.9% of cats from a variety of backgrounds including pet cats in the United Kingdom, mainland Europe and North America.[46-48] In addition, virus has been isolated from a cat in China. Seroprevalence is higher in cats that roam, or are allowed outdoors, and a recent study has shown a significantly higher prevalence in cats from more densely forested areas in Belgium, consistent with the ecological variations of Hantavirus risks in humans.[49] However, the clinical significance of Hantavirus infection in cats is not known. Hantaviruses are an important zoonosis. Most humans are believed to be infected by inhaling dust after disturbing infected rodent habitats. There is little evidence to suggest that cats are a likely source of human infection, although an increased risk of human infection associated with cat ownership has been reported in China.[50,51]

Torovirus Infection

Toroviruses are a group of viruses similar to coronaviruses, but with a characteristic rod or doughnut-shaped core. They have been detected in a number of species, including cattle (Breda virus), horses (Berne virus), and humans, and tend to be associated with enteritis. There is some evidence for a torovirus of cats, which may be associated with protruding nictitating membrane and diarrhea syndrome.[36] Others have been unable to substantiate this.[52]

Kobuvirus Infection

The Kobuvirus genus represents an emerging potential pathogen of the Picornaviridae. Human aichivirus was the first described member and was found in humans with oyster-associated gastroenteritis. Other members of the kobuvirus genus have been associated with enteric infections in pigs, cattle, sheep, wild boars, bats, rodents and dogs. A recent serosurvey indicated that cats might be susceptible to kobuvirus infection.[53] Subsequently molecular studies have identified kobuviruses by reverse transcription PCR (RT-PCR) in 13-14% of fecal samples of cats with diarrhea in South Korea[54] and Italy, but not in normal feces.[55] Genetic analysis of a feline kobuvirus has shown it belongs to a group of aichiviruses which include mouse and canine kobuvirus.[54,56]

Morbillivirus Infection

Feline morbillivirus belongs to the Paramyxoviridae family and was first identified in Asia.[57-59] The virus may be associated with tubulointerstitial nephritis, although concrete evidence is still lacking.

CHAPTER 231

Cryptococcosis

Joseph Taboada

Client Information Sheet: Cryptococcosis

Cryptococcosis is an opportunistic systemic fungal infection of worldwide significance that usually initially infects the nasal cavity, paranasal tissues, or lungs. It can then disseminate, most commonly to the skin, eyes, or central nervous system (CNS). Disease occurs in a wide variety of mammalian species. Among domestic animals, it occurs most commonly in the cat, in which it is the most common of the systemic mycoses.[1] Unlike the other systemic mycoses, cryptococcosis does not follow strict geographic boundaries but is most common in the southeastern and southwestern United States, southern California, the western part of British Columbia, and the east coast of Australia.

Cryptococcosis is caused primarily by *Cryptococcus neoformans* and *Cryptococcus gattii,* saprophytic, round, basidiomycetous yeasts separated on the basis of numerous differences such as geographical distribution, ecological niches, epidemiology, pathobiology, clinical presentation, and molecular characters.[2] The genus *Cryptococcus* includes over 37 species, of which only a few have been implicated in causing clinical disease. *C. neoformans* (serotypes A, D, and AD) most commonly causes disease and is environmentally associated with pigeon droppings or other avian habitats. In people, infection with *C. neoformans* is most often associated with immunosuppression but the organism appears to be a primary pathogen of immunocompetent cats and dogs.[3] *C. gattii* (serotypes B and C) is a second species capable of causing disease that is generally seen to be restricted to the tropics and subtropics and is associated with bark and leaf litter of certain eucalyptus trees. Recently molecular typing techniques have been used to identify genotypes of cryptococcal organisms that cause disease. Eight major molecular types have been identified based on polymerase chain reaction (PCR) fingerprinting and other molecular techniques. *Cryptococcus neoformans* is now classified as VNI and VNII (which belong to serotype A), VNIII (serotype AD), and VNIV (serotype D), while *C. gattii* is classified as VGI and VGII (which belong to serotype B), VGIII, and VGIV (serotypes B or C).[2] Different molecular types have been correlated with geographic regions as well as with differences in *in vitro* drug susceptibility.[4]

Outbreaks of *C. gattii* have been noted in cats and dogs as well as humans residing in or traveling to the coastal Douglas fir biogeoclimatic zone of Vancouver Island in British Columbia, with recent spread of the species along the northwestern coast of the United States.[5-9] Molecular typing has been used to determine that the *C. gattii* species responsible for the outbreak in the Pacific Northwest was most likely of Australian or South American origin.

Cryptococcus is considered infectious as a desiccated yeast cell or basidiospore in the environment that enters the body primarily through the respiratory tract, where it infects nasal, paranasal, or lung tissue before disseminating more widely with a predilection for the CNS. In infected tissue, and often when cultured, the organism is a variable-sized yeast (3.5 to 7 microns) with a large heteropolysaccharide capsule (1 to 30 microns). Both species have been shown to cause disease in cats, dogs, and humans. *C. neoformans* is a more important cause of disease in situations of immunocompromise, while *C. gattii* often causes disease in patients with normal immune function.

The pigeon and other avian species are thought to be the most important vectors of *C. neoformans.* The *Cryptococcus* organism can be found in high numbers in pigeon roosts, barn lofts, haymows, and along cupolas and cornices where pigeons often sit. In the desiccated state, the *Cryptococcus* organism may be no larger than 1 micron and may survive up to 2 years.

Pathophysiology

Cryptococcosis is not a contagious disease. Infection occurs most commonly via inhalation of yeast from the environment. Debris and droppings in and around avian habitats, especially pigeon habitats, contain the largest numbers of *Cryptococcus* organisms. Most yeasts are probably too large to be inhaled into the lungs and settle out in the nasal cavity or nasopharynx, where they can produce disease or result in animals becoming asymptomatic carriers of the organism.[5,6,9] In one study, cryptococcal organisms could be cultured from nasal washings in 14% of asymptomatic dogs and 7% of asymptomatic cats.[7] The small, desiccated forms of the yeast are also infective and can be inhaled into the small airways and alveoli, leading to pulmonary disease but pulmonary disease is seen in less than 10% of dogs and cats. After inhalation into the nasal cavity, paranasal sinuses, or lungs, a cell-mediated immune response results in granuloma formation. Dissemination can occur by either direct extension or hematogenous spread. Direct extension from the nasal cavity through the cribriform plate to the CNS or to the paranasal soft tissues and skin is common. Although dissemination can be to any organ system, the skin, eyes, and CNS are most often affected.

Lesions consist of either granulomatous inflammation with few organisms or gelatinous masses of organisms with little inflammation. The large capsule surrounding the cryptococcal organism contributes to pathogenicity by inhibiting phagocytosis, plasma cell function, and leukocyte migration. As with the other systemic mycoses, the immune response determines the severity of clinical disease. Antibodies are readily produced by the humoral immune system but are not considered protective. Recovery, therefore, is dependent on cell-mediated immunity. Most human cases of cryptococcosis are associated with immune suppression, especially lymphoreticular neoplasia and HIV/AIDS. While immune suppression may play an important role in some veterinary species, especially with *C. neoformans* infection, *Cryptococcus* spp. are often a primary pathogen of immunocompetent cats and dogs. An association with feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) infections in cats has been reported, and chronic glucocorticoid use has been implicated as a predisposing factor in both cats and dogs.[10-13] The picture is complicated by the fact that infectious diseases such as cryptococcosis may cause changes in the immune system, making it difficult to determine if the immune system compromise is a cause or an effect of the disease process.[14]

Clinical Signs

Cats are more commonly affected by cryptococcosis than are dogs.[9,15] No apparent sex or age predilection exists in cats, but one large case series from southeastern Australia identified Siamese, Birman, and Ragdoll cats as being significantly overrepresented.[16] Clinical findings are usually related to upper respiratory, nasopharyngeal, cutaneous, ocular, or CNS involvement.[17] Unlike in other systemic mycoses, the lungs are not commonly clinically affected. Nonspecific signs such as depression and anorexia are common in chronic cases, but fever is uncommon. Upper respiratory signs associated with nasal cavity involvement are the most common clinical signs in cats, seen in 50% to 80% of affected cats. In these cats, sneezing and snuffling are common, and unilateral or bilateral mucopurulent nasal discharge with or without blood is typically seen. Proliferative soft tissue masses or ulcerative lesions within the nasal cavity, on the nasal planum, or over the bridge of the nose are seen in approximately 70% of cases with upper respiratory involvement (Figure 231-1).

FIGURE 231-1 Nasal cryptococcosis in a cat. (Courtesy Dr. Carol Foil.)

Oral ulcerations are occasionally noted but are not common. Nasopharyngeal mass lesions causing snoring, stertor, and inspiratory dyspnea are occasionally noted.[13] The skin or subcutaneous tissues are affected in approximately 40% to 50% of infected cats. Primary lesions include papules or nodules that may ulcerate and drain. Multiple lesions are typical, and regional lymphadenopathy is common. Hematogenous spread from the respiratory system may result in lameness secondary to osteomyelitis, renal failure secondary to renal disease, and generalized lymphadenopathy.

The eyes are affected in 20% to 25% of infected cats, especially those with CNS involvement (see ch. 11). Granulomatous chorioretinitis with or without exudative retinal detachment is the most common ocular manifestation and can lead to panophthalmitis. Less often, optic neuritis can be seen, resulting in blindness. Anterior uveitis is not as common as posterior segment disease.

CNS involvement is reported in approximately 20% of affected cats. This may be an underrepresentation of the actual number of cases with nervous system involvement.[13] The forebrain is most commonly affected, because invasion through the cribriform plate is thought to be common. Signs may include depression, behavior changes, seizures, circling, ataxia, blindness, head pressing, cranial nerve deficits, and paresis. Nasopharyngeal granulomas may occlude the auditory tube resulting in otitis media/interna and resultant peripheral vestibular signs.[18] Cats with concurrent FeLV or FIV infection tend to be more severely affected and may be more likely to develop neurologic or ophthalmic signs.

Canine cryptococcosis is typically seen in dogs younger than 4 years of age. No apparent sex predilection exists, and American Cocker Spaniels, Labrador Retrievers, Great Danes, and Doberman Pinschers appear to be overrepresented. In dogs, clinical findings associated with CNS involvement are most common, with other clinical findings most often related to upper respiratory, ocular, or cutaneous involvement.[17,19,20] As in cats, depression and anorexia are common but fever is not. CNS involvement is reported in approximately 50% to 80% of affected dogs. The brain is affected in most of these dogs.[20,21] The spinal cord may be affected along with the brain, and rarely the spinal cord alone is affected, causing signs consistent with either meningitis or an extradural compressive lesion.[22-24] Signs of nervous system involvement may include mental depression, vestibular syndrome, ataxia, cranial nerve deficits (especially cranial nerves V, VII, and VIII), seizures, paresis, blindness, hypermetria, and cervical pain. In dogs with CNS signs, other systems are usually affected as well, reflecting multisystemic dissemination.

The upper respiratory system or paranasal tissues are affected in approximately 50% of dogs with cryptococcosis (Figure 231-2).[19] The caudal nasal cavity and frontal sinuses are affected more often than is the rostral nasal cavity. Signs may include upper airway stridor, nasal discharge and sneezing, epistaxis, or firm swellings over the bridge of the nose.

FIGURE 231-2 Periocular swelling in a female Siberian Husky, caused by cryptococcal infection.

The eyes or periorbital tissues are affected in approximately 20% to 40% of affected dogs. Granulomatous chorioretinitis with or without exudative retinal detachment is the most common ocular manifestation and can lead to panophthalmitis. In addition to chorioretinitis, fundic examination may reveal retinal hemorrhage or retinal scarring (see ch. 11). Optic neuritis may be noted as a cause of blindness. As with the other systemic mycoses, anterior uveitis is less common than posterior segment disease.

The skin is affected in approximately 10% to 20% of dogs with cryptococcosis. Subcutaneous nodules with ulcerative draining lesions, often on the head, feet, nail beds, and mucous membranes of the mouth, occur most commonly. Proliferative lesions in the ear canals may result from cryptococcal otitis externa. Direct extension from the ears to the CNS may occur.

Abdominal or gastrointestinal involvement, either alone or with multisystemic involvement is occasionally reported.[25-27] Multiorgan dissemination is more common in dogs than in cats. Disease may be subclinical or may result in clinical signs referable to the organ systems affected. In one study, *C. neoformans* was the most likely isolated species in dogs, while *C. gattii* was the most often isolated species in cats.[9]

Diagnosis

Hematology and clinical chemistries are often normal in animals with cryptococcosis. Mild nonregenerative anemia and mature neutrophilia or neutrophilia with a mild left shift may be seen. Because the nervous system is so commonly affected, cerebrospinal fluid (CSF) tap for culture, cytology, and antigen determination should be considered (see ch. 115). CSF commonly yields increased opening pressure, increased protein, and mixed mononuclear and neutrophilic pleocytosis. Organisms are visualized in the CSF in approximately 90% of dogs with CNS cryptococcosis.[15,22] Because opening pressures are often high and may result in shifting of CNS tissue during CSF collection, CSF tap is only recommended if diagnosis cannot be made by less invasive means. Organisms can be visualized on cytology of other affected tissues between 50% and 70% of the time. Organisms are found on cytology more often from cats than from dogs.[9]

Nodular infiltrates, an interstitial pattern, pleural effusion, and tracheobronchial lymphadenopathy are occasionally seen on thoracic radiographs. Nasal radiographs and computed tomography may demonstrate increased soft tissue opacity and soft tissue and fluid opacification of the nasal cavity or frontal sinus, contrast-enhancing mass lesions of the nasal planum, and lysis of the nasal bones or cribriform plate. Brain

magnetic resonance imaging (MRI) findings in cats with CNS involvement include single or multifocal contrast-enhancing mass lesions (cryptococcomas) that tend to be hyperintense on T2-weighted (T2W) images and hypointense on T1W images. In some cats, lesions appear fluid-filled on T2W images but with more T1W intensity than expected for acellular fluid. The lesions may have surrounding T2 hyperintensity, consistent with edema.[15,28]

Organism identification allows for definitive diagnosis and can usually be made cytologically or histologically. Cytology from affected tissue is the quickest and easiest means of identifying cryptococcal organisms. Nasal swabs, exudate from cutaneous lesions, aspirates of masses, subretinal or vitreal aspirates, and CSF often reveal organisms. Organisms are apparent in approximately 50% to 75% of cases. The large capsule makes identification easy (Figure 231-3). Gram's stain is useful in looking for cryptococcal organisms, because the cells retain the crystal violet and the capsule stains lightly red with the safranin. If India ink is used, the organism and capsule appear unstained and silhouetted against the black background (Figure 231-4). Care must be taken in interpreting India ink preparations, as lymphocytes, fat droplets, and aggregated ink particles may be confused with the organism. Budding is occasionally noted. The thin wall and the large capsule differentiate *Cryptococcus* from *Blastomyces*.

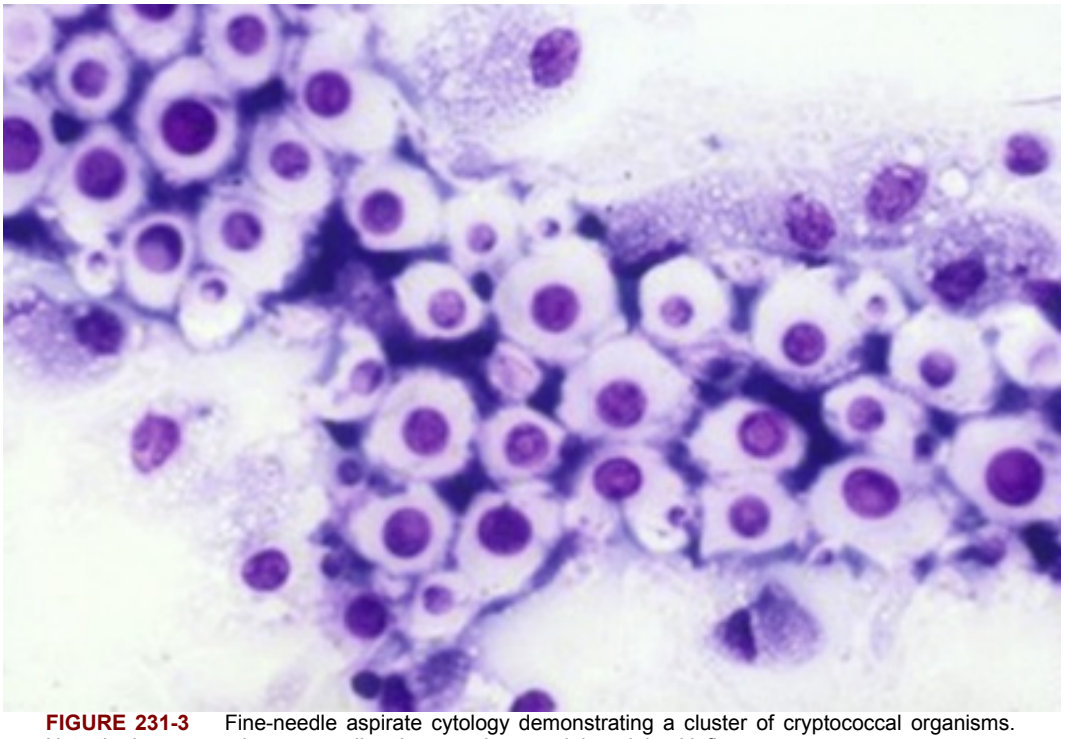

FIGURE 231-3 Fine-needle aspirate cytology demonstrating a cluster of cryptococcal organisms. Note the large capsules surrounding the organisms and the minimal inflammatory response.

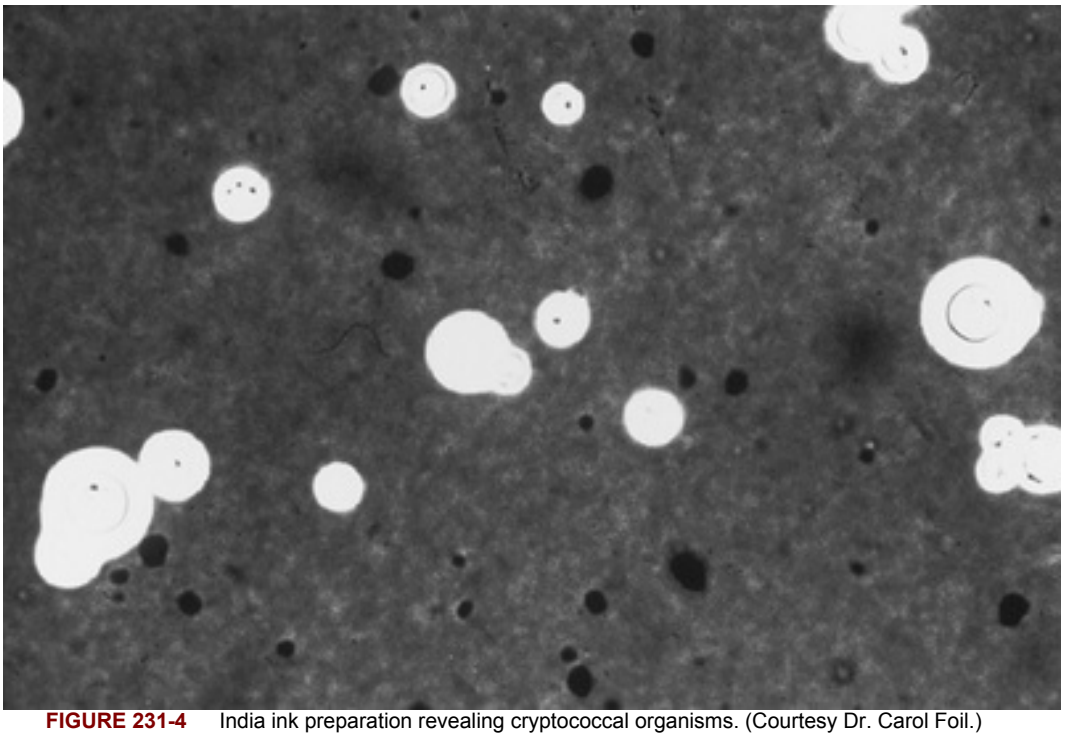

FIGURE 231-4 India ink preparation revealing cryptococcal organisms. (Courtesy Dr. Carol Foil.)

Histopathology should be used if cytology fails to identify organisms. Nodular to diffuse granulomatous lesions or areas of degeneration with little inflammation are seen in infected tissue. Yeastlike organisms are usually numerous. Special stains such as periodic acid–Schiff (PAS), Gridley's fungal, and Grocott's Methenamine Silver or Gomori methenamine silver (GMS) stain are best at demonstrating organisms. Mucicarmine stains best demonstrate the capsule.

Cryptococcal organisms grow readily when cultured. The organism can be cultured from infected tissue, exudate, CSF, urine, joint fluid, and blood if large enough samples are submitted. Yeastlike growth occurs in 2 days to 6 weeks on Sabouraud's dextrose agar. Hyphae rarely grow, even at 37° C. Care must be taken in interpreting positive cultures from the nasal cavity, because 14% of asymptomatic random-source dogs and 7% of asymptomatic random-source cats were culture-positive in one study.[5,6,10] Animals in the previously mentioned study were all negative on serum latex agglutination tests and did not have macroscopic or microscopic findings supportive of cryptococcal infection.

Serology is useful as an inexpensive and noninvasive diagnostic test and should be performed early in the diagnostic evaluation when cryptococcosis is suspected. Antibody titers are not useful diagnostically, because most infected animals do not mount a humoral immune response.[22] Commercially available latex agglutination assays for cryptococcal capsular antigen are both sensitive and specific tests that can be used on serum, urine, or CSF. CSF is the best sample to use in animals with neurologic signs, and serum is the best sample to use in animals with upper respiratory, cutaneous, or systemic signs but without neurologic signs. Most cases are positive with titers between 1 : 10 and 1 : 100,000. The median titer in infected cats in one study was 1 : 1000.[22] False-negative antigen titers are rare but may occasionally be seen in localized disease or if the organism fails to produce a capsule. False-positive antigen titers are uncommon and are usually related to technique or interfering substances such as rheumatoid factor (RF). Pretreatment of serum samples with pronase, a proteolytic enzyme, reduces the number of false-positive test results by eliminating nonspecific interference with macroglobulins, such as rheumatoid factors, as well as other unknown factors.[29] The latex agglutination antigen titer tends to correlate well with the extent of disease but does not correlate well with prognosis.[30] It may be used to evaluate the treatment progress and in determining how long to maintain an animal on antifungals.

Treatment

Cryptococcosis is a challenging disease to treat in cats and dogs and it typically requires protracted therapy and long-term follow-up. Few case-control or cohort studies with extensive treatment information are

available, but treatment evidence has recently been reviewed by the European Advisory Board on Cat Diseases.[31] While amphotericin B is the most effective treatment, azole monotherapy with either fluconazole or itraconazole is effective in many cases with and without CNS involvement.

Amphotericin B is the most effective drug *in vitro* against cryptococcal isolates and is generally recommended in infected people. Both itraconazole and fluconazole have proven to be equally efficacious to amphotericin B in treating CNS cryptococcosis in people, but the length of treatment can be quite long and the azole antifungals are generally recommended for consolidation therapy and for maintenance therapy after a course of amphotericin B has been given. Amphotericin B appears to be very effective in treating cryptococcosis in dogs and cats, but less information is available comparing it to using azole antifungals. Amphotericin B may be the treatment of choice in severely affected animals with CNS or systemic involvement but single agent azole antifungal therapy has been successful. Amphotericin B is synergistic with flucytosine. Flucytosine can be used at a dosage of 11.4 to 22.7 mg/lb (25 to 50 mg/kg) orally four times a day and has been used in dogs and cats. The combination of amphotericin B and flucytosine may be especially useful for treating CNS infections in cats. Cryptococcal organisms may rapidly develop resistance to flucytosine, so it has limited efficacy as a sole treatment agent. The dosage of flucytosine should be adjusted downward in animals with concurrent renal failure. Toxicosis from flucytosine includes ulcerative drug eruptions on the skin (especially on the face) and mucocutaneous junctions, enterocolitis, leukopenia, and thrombocytopenia that are especially prominent in dogs. Amphotericin B has also been effective when combined with azole antifungal agents.

Subcutaneously administered amphotericin B alone or in combination with azole antifungals or flucytosine has been used to successfully treat both feline and canine cryptococcosis.[3,32] Amphotericin B (0.22 to 0.36 mg/lb; 0.5 to 0.8 mg/kg) is diluted in 0.45% saline containing 2.5% dextrose (400 mL for cats, 500 mL for dogs <20 kg, 1000 mL for dogs >20 kg) and administered subcutaneously two to three times per week. This protocol may allow larger cumulative doses of amphotericin B to be given with reduced toxicosis. Concentrations greater than 20 mg/L of amphotericin B resulted in local irritation and sterile abscess formation; therefore, more concentrated formulations of amphotericin B should not be used subcutaneously.

The azole antifungals have expanded the treatment options available and are central to successful treatment either as sole agents or in consolidation therapy following amphotericin B–containing protocols. There was no significant difference in outcome between cats treated with amphotericin B–containing protocols and those treated with fluconazole or itraconazole.[3] Fluconazole (50 mg/cat PO q 12 h; 2.2 mg/lb [5 mg/kg] PO q 12 to 24 h for dogs) is very effective and is the treatment of choice for cryptococcosis in cats and probably dogs with mild to moderately severe disease. Fluconazole is considered the maintenance treatment of choice for human patients with or without HIV/AIDS diagnosed with cryptococcal meningoencephalitis.[33] However, recent work in murine models and in people with treatment failures has suggested that fluconazole monotherapy may not be an appropriate treatment, at least for meningoencephalitis.[4] Itraconazole (4.5 mg/lb [10 mg/kg] PO daily) is effective in cats and dogs but appears to require longer treatment times than fluconazole does. In one uncontrolled study evaluating long-term follow-up in cats and dogs with cryptococcosis, cats that were cured required median treatment times of 4 months for fluconazole and 9 months for itraconazole.[3] Controlled trials in people have revealed the two drugs to be equally efficacious but itraconazole monotherapy is considered more appropriate than fluconazole monotherapy for meningoencephalitis caused by azole-resistant molecular genotypes. Ketoconazole (4.5 to 13.6 mg/lb [10 to 30 mg/kg] PO q 12 h) is variably effective as a sole treatment agent but is ineffective in cases with CNS involvement. Terbinafine (4.5 mg/lb [10 mg/kg] PO q 24 h) can be used in combination with azole antifungals or in cases where azole antifungal resistance is suspected.

Resolution of clinical signs is the best means of patient monitoring, but the resolution of clinical signs is insufficient evidence that the infection has been eradicated, as improvement occurs well before all viable fungus has been cleared from host tissues. Serially monitoring latex agglutination antigen titers can significantly augment the clinician's clinical observations, but recurrence can occur despite a marked reduction in the serum antigen titer and even after the sterilization of the CSF in CNS infections.[12,30]

Rechecks should be performed at least monthly while dogs or cats are being treated with azole antifungals and should include a chemistry panel to evaluate liver enzymes and a latex agglutination antigen titer. Sequential titers should differ by two or more dilutions before they are considered significantly different. A decline of twofold to fourfold per month during the initial few months of antifungal therapy generally corresponds to an adequate clinical response. Ideally, treatment should be continued until the titer is negative or for at least 2 months beyond resolution of clinical signs. In some animals, detectable cryptococcal polysaccharide antigen persists in the circulation long after the infection has been successfully treated. This is

thought to be caused by continued elimination of unviable organisms and capsular material from infected tissues and macrophages. Most of these animals have low titers. High residual titers may indicate insufficient therapy and thus persistence of viable organisms.[12] One recommendation is to continue antifungal drug treatment to a titer of less than 1.[30] In cases in which there has been a 32-fold decrease and resolution of clinical signs, treatment may be discontinued; however, titers should be reevaluated periodically to ensure that they continue to decline or at least remain stable. Animals should be reevaluated at least 3 and 6 months after discontinuing treatment to assess for relapse. Negative antigen titers are occasionally seen in animals with localized disease, so they do not always indicate clinical cure.

Dogs or cats with cutaneous or subcutaneous granulomas may require surgical excision of the granulomas to effectively clear the organisms. Latex agglutination titers may not decrease until granulomas have been surgically excised and organisms within the granulomas may serve as a nidus for relapse. Because resolution may occur without surgery in some cases, it is recommended to first treat medically and to monitor the size of granulomas before deciding on a surgical option.

The prognosis is good for cats with extraneural disease, and it is guarded for dogs with any form of the disease and for cats with CNS involvement. About 75% of cats and 50% of dogs have been noted to respond successfully to treatment. Cats responding completely to treatment appear to have about a 15% to 20% relapse rate.[3] Cats with FIV do not appear to be less likely to respond nor does the species of *Cryptococcus* appear to significantly influence prognosis.[28]

CHAPTER 232

Coccidioidomycosis

Jane E. Sykes

Client Information Sheet: Coccidioidomycosis (Valley Fever)

Etiology and Epidemiology

Coccidioidomycosis is a disease caused by soil-borne fungi belonging to the genus *Coccidioides.* In the environment, *Coccidioides* exist as a mycelium and in tissues as *spherules.* A mycelium is a chain of barrel-shaped arthroconidia (or arthrospores). The arthroconidia remain in the soil for long periods, ultimately fragment apart, are subsequently aerosolized and are inhaled by animal hosts. This in turn can lead to a localized pulmonary disease *(pulmonary coccidioidomycosis)* or a serious multisystemic disease *(disseminated coccidioidomycosis)* if there is an inadequate immune response.

In the soil, *Coccidioides* spp. are distributed in regions characterized by semi-arid to arid soils, low elevations above sea level and hot summers. *Coccidioides* spp. are found in the southwestern and western USA, eastern Washington state, Mexico, and parts of Central and South America. In the USA, highly endemic regions include the south-central valley of California ("valley fever") and Arizona, especially the greater Tucson and Phoenix areas.[1] Infections have also been reported in non-endemic areas in dogs and humans that have a history of travel to endemic regions. Two species of *Coccidioides* have been identified, *C. posadasii* and *C. immitis,* that appear to cause similar clinical manifestations with similar antifungal drug susceptibilities.[2] The geographic range of *C. immitis* is limited to the central valley of California, whereas *C. posadasii* is found elsewhere.[3]

Infection of animals and humans often follows a cycle of moist conditions, a dry period, then soil disruption, such as may occur with heavy rainfall, earthquakes, dust storms, prolonged droughts, or construction.[4-6] Dogs of any breed, age, or sex may be affected, although young adult dogs are at greatest risk.[7-9] Weimaraners, Dalmatians, Hungarian Vizslas, Norfolk Terriers, and Greyhounds appear to be predisposed.[9] Risk factors for infection in dogs from Arizona included being housed outdoors during the day, roaming an area > 1 acre, and walking in the desert.[10] Among dogs seen at the University of California, risk factors were digging behavior (which increased risk 6.7-fold) and a history of travel to or residence in the central valley of California or Arizona (which increased risk 4.4-fold).[9] Latent infections can occur in dogs and reactivate following treatment of other conditions with glucocorticoids or chemotherapeutic agents. Relapse can also occur with immunosuppressive drug treatment in dogs that have previously recovered from coccidioidomycosis. Coccidioidomycosis occurs in cats, but is rare.[11]

Pathogenesis and Clinical Features

Following inhalation, arthroconidia are phagocytosed by alveolar macrophages and then enlarge into a spherule (8 to 100 microns in diameter; Figure 232-1). Hundreds of endospores (3 to 5 microns in diameter) develop within each spherule and are released when the mature spherule ruptures. This is associated with a pyogranulomatous to granulomatous inflammatory response. Surviving endospores then enlarge into new spherules. In hosts unable to mount an effective immune response, endospores disseminate to lymph nodes in the respiratory tract and elsewhere. Inoculation coccidioidomycosis with a focal cutaneous lesion has been described rarely.[12] Most infections in endemic areas are subclinical.[13] Development of clinical signs often follows a subacute to chronic course, with mild systemic signs such as intermittent fever (range, 103 to 106° F [39.4-41.1° C], but typically low-grade), lethargy, inappetence, and weight loss.[7,14] Many dogs otherwise

appear healthy with only brief periods of inappetence.[7] Signs may be present for months to years before dogs are brought to a veterinarian.[8] Signs of respiratory tract involvement include a harsh cough, increased respiratory effort, tachypnea and/or exercise intolerance.[8,14] Rarely, diffuse fungal pneumonia follows a fulminant course.

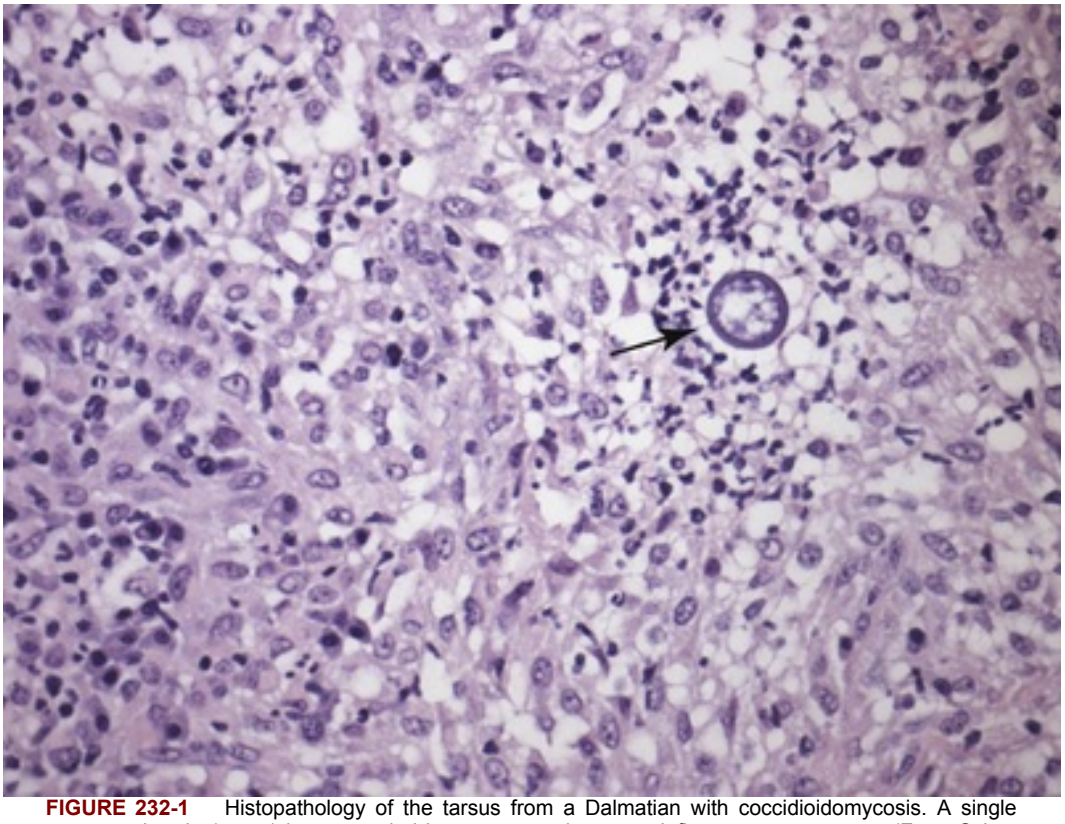

FIGURE 232-1 Histopathology of the tarsus from a Dalmatian with coccidioidomycosis. A single mature spherule (arrow) is surrounded by a pyogranulomatous inflammatory response. (From Sykes JE: *Canine and feline infectious diseases*, St Louis, 2014, Saunders.)

Sites of dissemination include bone, the central nervous system (CNS), skin, peripheral lymph nodes, and the pericardium.[8,15] Less commonly, joints, eyes, testes, gastrointestinal tract, prostate, liver, spleen, and urinary systems are affected.[7] Sometimes dissemination to only one site is detected. Evidence of past or current pulmonary involvement may be absent.[7] Bone involvement may be manifest as nonspecific pain, lameness, and/or one or more firm swellings associated with the appendicular or axial skeleton. Dogs with skin involvement may have ulcerated skin lesions that drain serosanguineous fluid, or subcutaneous mass lesions.[7] Neurologic signs resulting from fungal meningoencephalitis include obtundation, blindness, nystagmus, absent menace reflex, ataxia, postural reaction deficits, pacing, circling, cervical pain, tetraparesis, and seizures (see ch. 261).[8,16,17] Ocular manifestations include chorioretinitis, uveitis, and endophthalmitis (see ch. 11).[8,18,19] Liver or gastrointestinal tract infection can lead to gastrointestinal signs.[7] Pericarditis may lead to signs of right-sided heart failure, with development of ascites and pleural effusion (see ch. 254).[7] More than 50% of 48 cats with coccidioidomycosis had skin lesions.[11] Respiratory signs were present in 25% of affected cats, and lameness, ocular abnormalities, and neurologic signs in less than 20% of cats.

Diagnosis (Figure 232-2)

History, Physical Examination, Laboratory Results

Early diagnosis of coccidioidomycosis requires a high index of suspicion based on consistent clinical findings and a history of travel to or residence in an endemic region. Digging behavior or exposure to soil disturbance should increase suspicion. The diagnosis is usually confirmed with cytologic examination of aspirates or body

fluids, serologic tests that detect antibodies to *Coccidioides* spp., histology of biopsy specimens, or fungal culture.

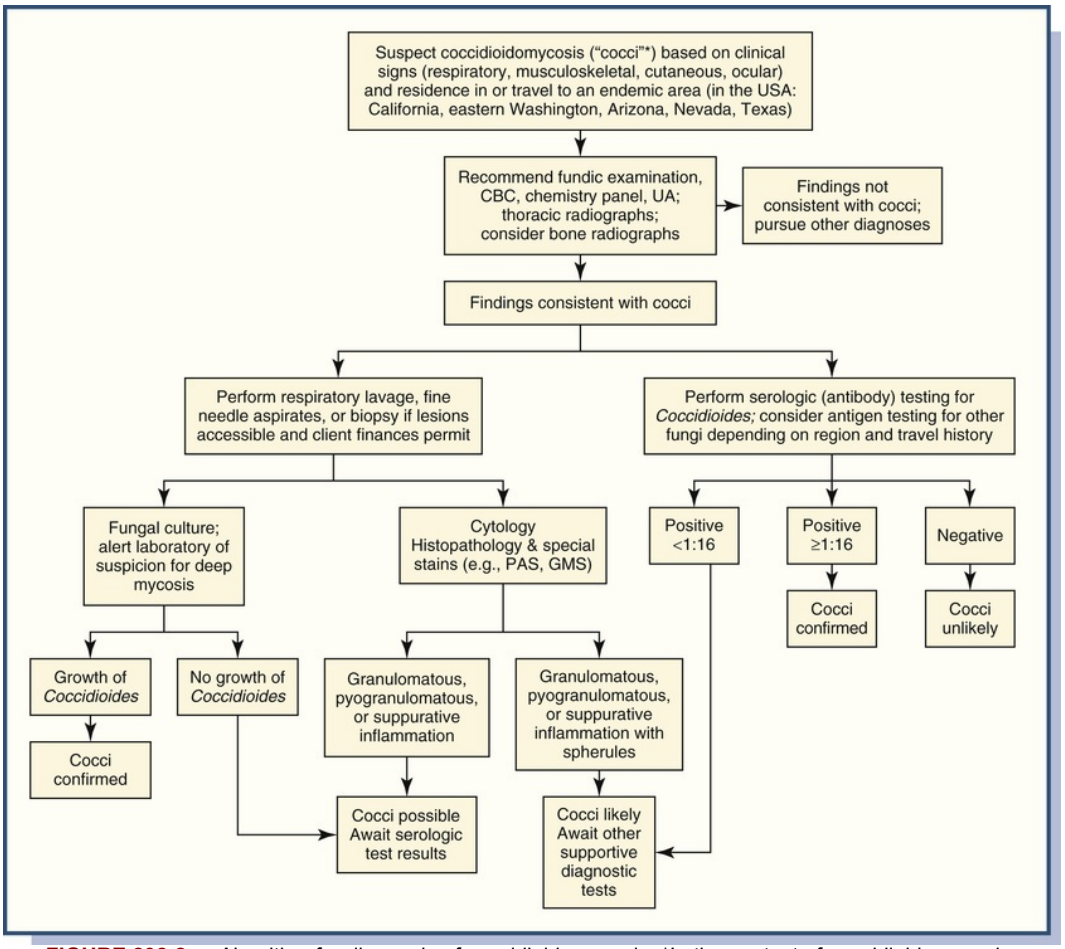

FIGURE 232-2 Algorithm for diagnosis of coccidioidomycosis. *In the context of coccidioidomycosis, "cocci" is pronounced "coxy." *GMS,* Gomori's methenamine silver; *PAS,* periodic acid-Schiff.

Laboratory testing of most affected dogs reveals mild non-regenerative anemia, mild neutrophilia, and hypoalbuminemia.[8,20] About half of affected dogs and cats are hyperglobulinemic.[8,11] Proteinuria has been detected in 60% of dogs, and can be severe (urine protein to creatinine ratios as high as 9.5, reference range < 0.5).[21] Some dogs have renal pathology consistent with immune-complex glomerulonephritis at necropsy and fewer had pyogranulomatous nephritis with intralesional spherules.[21] Cerebrospinal fluid (CSF) analysis (see ch. 115) in dogs with CNS involvement can reveal an increase in protein concentration (generally < 300 mg/dL; reference range < 25 mg/dL), and increases in nucleated cell counts (usually < 50 cells/mcL; reference range < 2 cells/mcL).[8] The differential cell count may show mixed or neutrophilic pleocytosis.

The most common radiographic finding in dogs with pulmonary coccidioidomycosis is hilar lymphadenomegaly (Figure 232-3).[8] Most dogs with hilar lymphadenopathy have mild to moderate pulmonary interstitial infiltrates. Nodular interstitial, interstitial-alveolar, bronchointerstitial infiltrates, and/or sternal lymphadenomegaly may also be present.[8,14] Dogs with pericarditis may have cardiomegaly and pleural effusion, with hepatomegaly and decreased abdominal detail.[20] Thoracic computed tomography (CT) findings include contrast-enhancing miliary nodular pulmonary lesions; single or multifocal masses; tracheobronchial, sternal, or mediastinal lymphadenopathy; focal regions of alveolar or peribronchial infiltrates; lobar consolidation; pleural or mediastinal thickening and rarely pleural effusion. Radiographs of affected bones reveal local periosteal proliferation as well as osteolysis and soft-tissue swelling (Figure 232-4).[7,11] Echocardiography in dogs with pericarditis may reveal thickening and mass lesions of the pericardium, pericardial and pleural effusion, and evidence of cardiac tamponade (see ch. 104 and 254).[20] Magnetic

resonance imaging (MRI) of the brain in dogs with CNS coccidioidomycosis may show focal hyperintense lesions within the brain on T2-weighted images. These are typically isointense on T1-weighted images and they enhance with contrast. Other findings include ventricular dilation and/or evidence of meningeal enhancement.

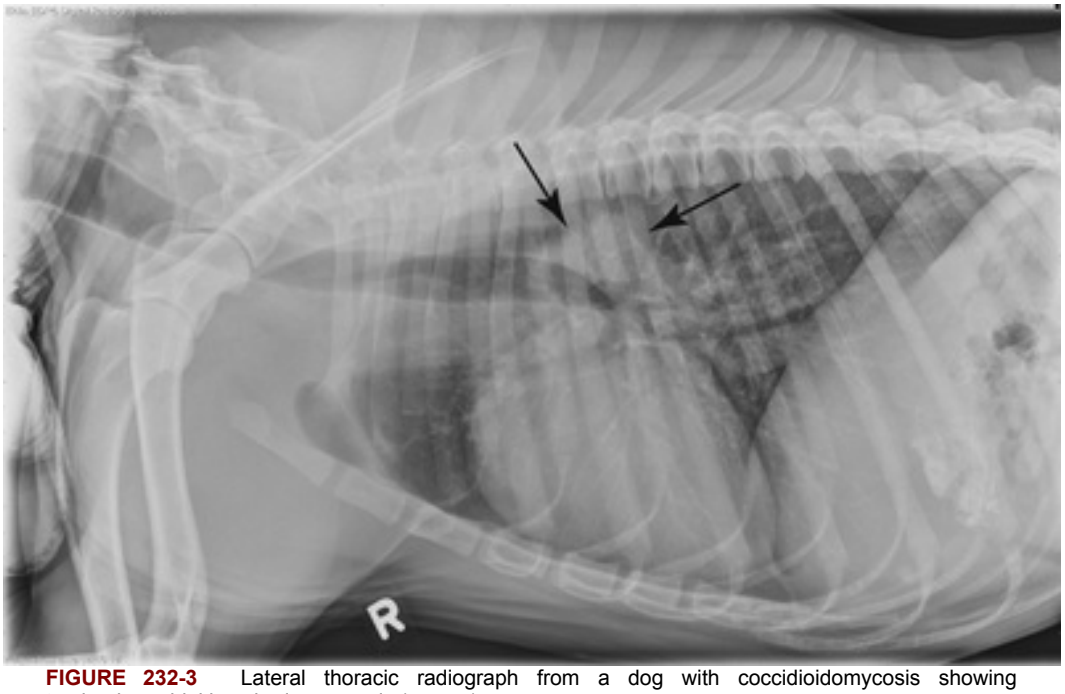

FIGURE 232-3 Lateral thoracic radiograph from a dog with coccidioidomycosis showing tracheobronchial lymphadenomegaly (arrows).

FIGURE 232-4 Osteomyelitis caused by *Coccidioides* spp. in a Shih Tzu Dog. There is a predominantly lytic lesion of the left ilium (arrow).

Cytologic examination of tissue aspirates (see ch. 86, 87, 89, and 93) or respiratory lavage specimens (see ch. 101) usually reveals granulomatous or pyogranulomatous inflammation. Uncommonly, spherules are visualized as deeply basophilic structures 8 to 70 microns in diameter (Figure 232-5).

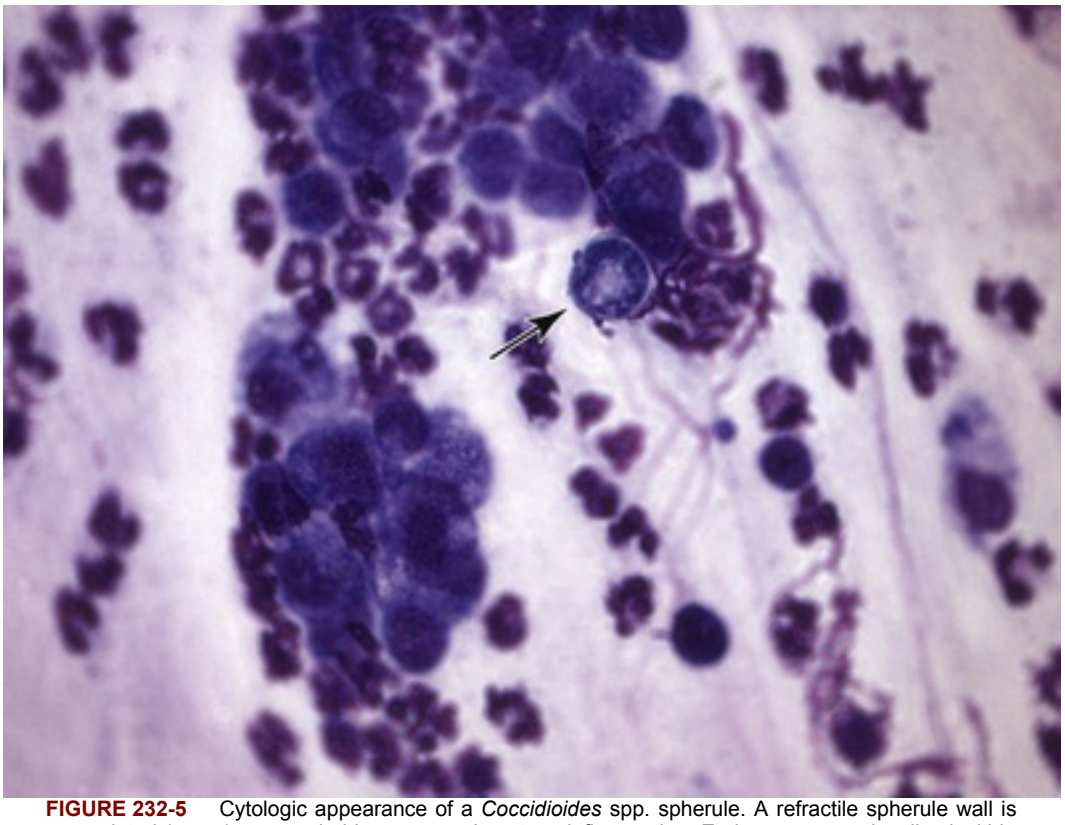

FIGURE 232-5 Cytologic appearance of a *Coccidioides* spp. spherule. A refractile spherule wall is appreciated (arrow) surrounded by pyogranulomatous inflammation. Endospores are visualized within the spherule as granular material.

Microbiological Tests

Serologic assays that detect antibodies to *Coccidioides* spp. are important diagnostic aides because cytology and histology are not sensitive for detection of this condition. Most laboratories screen specimens with qualitative gel immunodiffusion assays for IgG or IgM antibodies. Detection of IgM (tube precipitin) or IgG (complement fixating) antibodies is reported, depending on the antigen preparation used. In dogs, IgM is detectable within 2 to 5 weeks of infection, and IgG appears after 8 to 12 weeks.[15] Quantification of an IgG antibody response can then be performed with quantitative immunodiffusion.[13] False negative results are quite rare in dogs with coccidioidomycosis from California but have been described in dogs from Arizona.[8,20,22,23] Antibody titers typically range from 1 : 2 to 1 : 256; with a median of 1 : 32 in one study.[8] Dogs with active infection may have titers as low as 1 : 2, and healthy dogs in hyperendemic areas in Arizona have had titers as high as 1 : 16.[13] Positive titers of 1 : 16 or lower should always be interpreted in the context of clinicopathologic abnormalities. In hyperendemic areas, additional tests should be employed for diagnosis confirmation. A serologic assay that detects *Coccidioides* antigen in urine has unacceptably low sensitivity (≤20%) and is not recommended.[24] *Coccidioides* spp. can be isolated from clinical specimens on routine fungal media. Culture of *Coccidioides* spp. is a laboratory health hazard and should only be performed in suitably equipped locations. The laboratory should be warned of the suspicion for a dimorphic fungal infection.

Treatment and Prognosis

Treatment generally consists of a combination of prolonged antifungal drug therapy, supportive care, and in some cases, surgery. Animals with pulmonary coccidioidomycosis may respond well to monotherapy with fluconazole (5-10 mg/kg PO q 12 h) or itraconazole (5 mg/kg PO q 24 h). Itraconazole is preferred for animals with bone involvement and may be effective in dogs that fail to respond to treatment with fluconazole. Treatment with deoxycholate amphotericin B or lipid-complexed amphotericin B is recommended either alone or in combination with an azole antifungal for dogs with refractory or disseminated disease. The reader is referred to ch. 162 and 233 for dosing protocols for amphotericin B. Voriconazole and posaconazole have

been used to treat refractory coccidioidomycosis in people.[1] Voriconazole could be considered for treatment of refractory meningoencephalitis in dogs due to its excellent CNS penetration, if client finances permit its use.

Dogs with persistent osteomyelitis may require amputation for infection control. Enucleation may be required in dogs with endophthalmitis. *Coccidioides* pericarditis has been successfully managed after subtotal pericardiectomy, epicardial excision, and antifungal drug therapy. Perioperative mortality rate was reported as 24%.[20] Other treatments that may be required for dogs with severe pulmonary coccidioidomycosis include oxygen supplementation (see ch. 131), drainage of thoracic effusions (see ch. 100 and 102), nutritional support (see ch. 82 and 189), anti-inflammatory drugs (see ch. 164) and IV fluid therapy (see ch. 129). Concurrent treatment with glucocorticoids and anti-seizure medications may be necessary in dogs with CNS coccidioidomycosis (see ch. 35 and 261). Topical prednisolone acetate solution and anti-glaucoma agents may be required for dogs with ocular lesions.

Treatment duration ranges from 6 months to many years. In some dogs, life-long treatment is needed. IgG titers decrease with successful treatment, which should be continued until lesions resolve and the titer is 1 : 2 or lower. Dogs with localized pulmonary infection have the best prognosis.

Public Health Aspects

Coccidioidomycosis is a serious infection in people. Individuals involved in construction, agriculture, and excavation are at high risk in endemic areas.[1] African American and Filipino patients, as well as patients with acquired immunodeficiency syndrome (AIDS) and women in the third trimester of pregnancy, are at risk for disseminated disease, which occurs in approximately 0.5% of infected humans.

Dogs have been used as a sentinel for human exposure to environmental sources of *Coccidioides* spp.[25] Direct transmission as a result of contact between infected pets and humans has not been reported. However, inoculation coccidioidomycosis may follow bites from animals with disseminated infections or after injury with a contaminated instrument. If accidental inoculation occurs, people should seek immediate medical attention. Prolonged fluconazole prophylaxis is generally recommended with monitoring of *Coccidioides* serology and liver function tests. Necropsies should be performed without delay with suitable protective clothing, and the carcasses of animals that die from coccidioidomycosis should immediately be incinerated, because conversion of the organism to a mycelial form can occur after death. For the same reason, burial is not recommended because of the potential for contamination of the environment. Prophylaxis is also indicated after accidental laboratory exposure.[26]

CHAPTER 233

Blastomycosis and Histoplasmosis

Andrea Dedeaux, Joseph Taboada

Client Information Sheets:
Blastomycosis
Histoplasmosis

Blastomycosis

Blastomycosis is a systemic fungal infection that usually originates in the lungs and then disseminates. In endemic areas, blastomycosis usually occurs as a sporadic event, but outbreaks are occasionally observed in both dogs and people.[1-4] Epidemiologically, outbreaks can often be traced back to a common point source in the environment from which infective spores had been aerosolized for a limited period of time.

The dimorphic fungus *Blastomyces dermatitidis* is the causative agent of blastomycosis. In infected tissue or when cultured at 37° C, the organism is a thick-walled yeast that reproduces by budding. Most often, organisms in tissue have a single bud, attached to the mother cell by a broad base. When cultured at 25° C, mold colonies grow slowly and contain branching, septate 1- to 2-micron mycelia.

Disease occurrence is reported primarily in a geographically restricted distribution that follows the Mississippi, Ohio, Missouri, Tennessee, and St. Lawrence Rivers, the southern Great Lakes, the southern Mid-Atlantic states, northern California, Pacific Northwest, and the Canadian provinces of Alberta, Manitoba, Ontario, Quebec, and southern Saskatchewan (Figure 233-1).[4,5] Within these geographic regions, infections are generally limited to smaller geographic pockets, with most affected animals living within a quarter of a mile of water.[2,6,7]

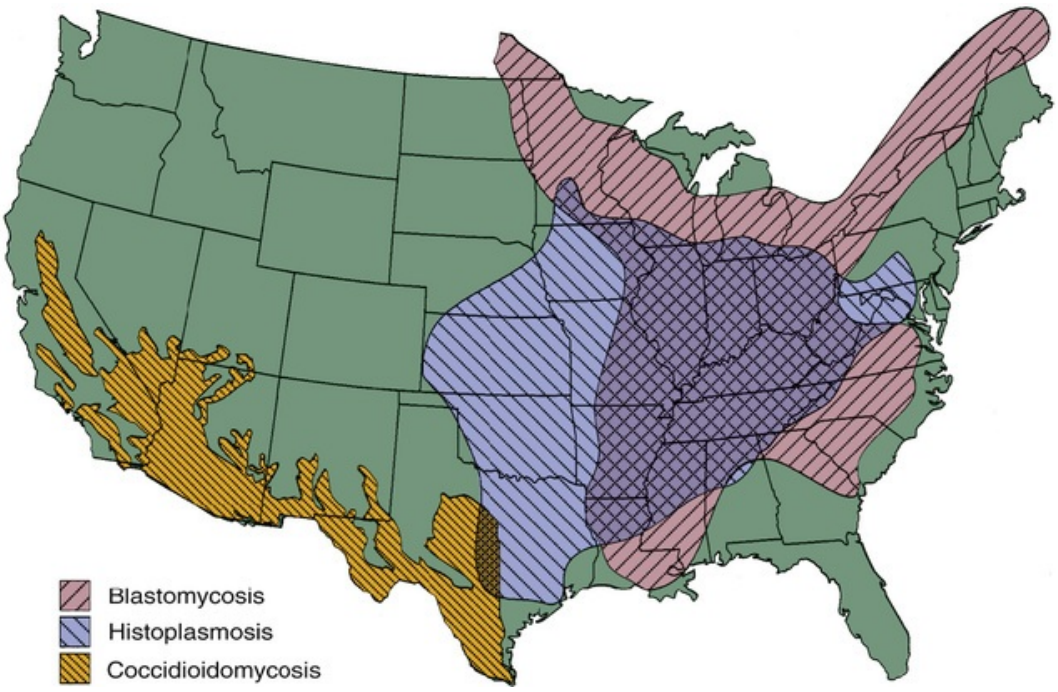

FIGURE 233-1 Areas in North America where blastomycosis, histoplasmosis, and coccidioidomycosis are endemic.

Pathophysiology

Blastomycosis is not a contagious disease. It follows contact with the organism in the environment. Infection usually occurs via the respiratory route after the host inhales infective conidiophores. Rarely, subcutaneous disease may be seen after direct inoculation.[8] The incubation period varies from 5 to 12 weeks. Rain, dew, fog, or mist may play a critical role in liberating conidiophores. In addition, activities that disrupt the soil such as digging or construction may play a role in spore aerosolization. After inhalation, conidia are phagocytized by alveolar macrophages and transform from the mycelial phase to the yeast phase. The yeast stimulates local cell-mediated immunity, which results in a marked suppurative to pyogranulomatous inflammatory response. In some cases, the cell-mediated immune response controls infection locally; in others, phagocytized yeasts are transported into the pulmonary interstitium, where they gain access to both lymphatic and vascular systems. Hematogenous and lymphatic dissemination then results in multisystemic pyogranulomatous disease. Although dissemination can be to any organ system, the lymph nodes, eyes, skin, bones, subcutaneous tissues, and prostate are organs commonly affected in dogs[6,9,10]; skin, subcutaneous tissues, eyes, central nervous system (CNS), and lymph nodes are most commonly affected in cats.[11,12]

The immune response determines the severity of clinical disease. Recovery from infection is dependent on cell-mediated immunity. An adequate immune response may result in mild respiratory disease that resolves spontaneously. If dissemination has occurred, disease may be obvious in other organ systems, even without apparent pulmonary involvement.

Clinical Signs

Bluetick Coonhounds, Treeing Walker Coonhounds, Pointers, Weimaraners and retrievers have the highest risk of infection.[4,5,13] Males are affected more commonly, and although any age dog can be affected, those in the 2- to 4-year age group have the highest incidence of disease. Exposure to possible environmental sources of infection, close proximity to water, and the likelihood of being housed in outdoor kennels probably explain the breed association.

Nonspecific signs such as anorexia, depression, weight loss, cachexia, and fever are common. Approximately 40% of dogs are febrile. Pulmonary signs are seen in 65% to 85% of affected dogs, ranging from mild respiratory distress when exercised to severe dyspnea at rest. Hypoxemia resulting in cyanosis has a negative prognostic significance.[10] A dry, hacking cough is common. Enlarged perihilar lymph nodes compressing primary bronchi, as well as infiltrative bronchointerstitial and alveolar disease, contribute to the cough. Pleural effusion, pleuritic pain, chylothorax, solid granulomatous masses, and pulmonary thromboembolism are uncommonly reported complications of blastomycosis.

Diffuse lymphadenopathy is seen in about 40% to 60% of dogs with blastomycosis. Cutaneous signs are reported in about 30% to 50% of affected dogs and are also commonly noted in affected cats. The reported prevalence of skin disease is likely underestimated as lesions are small and easily can be overlooked. Single or multiple papules, nodules, or plaques that can ulcerate and drain a serosanguineous to purulent exudate characterize typical skin lesions. The nodular lesions are often quite small in dogs, but large abscesses occasionally occur, especially in cats. Paronychia is common in dogs, so the feet and nail beds should be closely examined.

Ocular involvement is noted in 20% to 50% of cases, with approximately 50% of affected dogs having bilateral involvement. Posterior segment disease usually occurs initially. Optic neuritis may signify more diffuse CNS involvement and a poorer prognosis. Anterior segment disease is usually secondary to the posterior segment involvement. It may be characterized by conjunctivitis, keratitis, iridocyclitis, and eventually anterior uveitis and endophthalmitis. Secondary glaucoma is common. Dogs that are blind at the time of initial diagnosis rarely regain vision.

Lameness caused by fungal osteomyelitis or painful paronychia is noted in about 25% of dogs with blastomycosis, and fungal osteomyelitis is noted in about 10% to 15% of dogs with blastomycosis. The pain and swelling are usually noted over epiphyseal regions below the elbow or stifle. Single lesions are more common than multiple.[14]

Mycotic mastitis or fungal prostatitis or orchitis is seen in approximately 5% to 10% of affected dogs.[15]

Testicular infection with blastomycosis without evidence of disseminated disease has been reported.[16]

Neurologic signs, often associated with diffuse or multifocal disease, are seen in less than 5% of dogs but are more common in cats (Figure 233-2); however, brain involvement may be present without neurologic signs, making the prevalence of CNS infection greater than expected.[17] Computed tomography (CT) or magnetic resonance imaging (MRI) should be considered in any dogs and particularly cats diagnosed with blastomycosis, even if obvious neurologic signs are not apparent. Other potential sites of infection include heart, pericardium, cranial mediastinum, liver, spleen, kidney, and nasal cavity.[18-20]

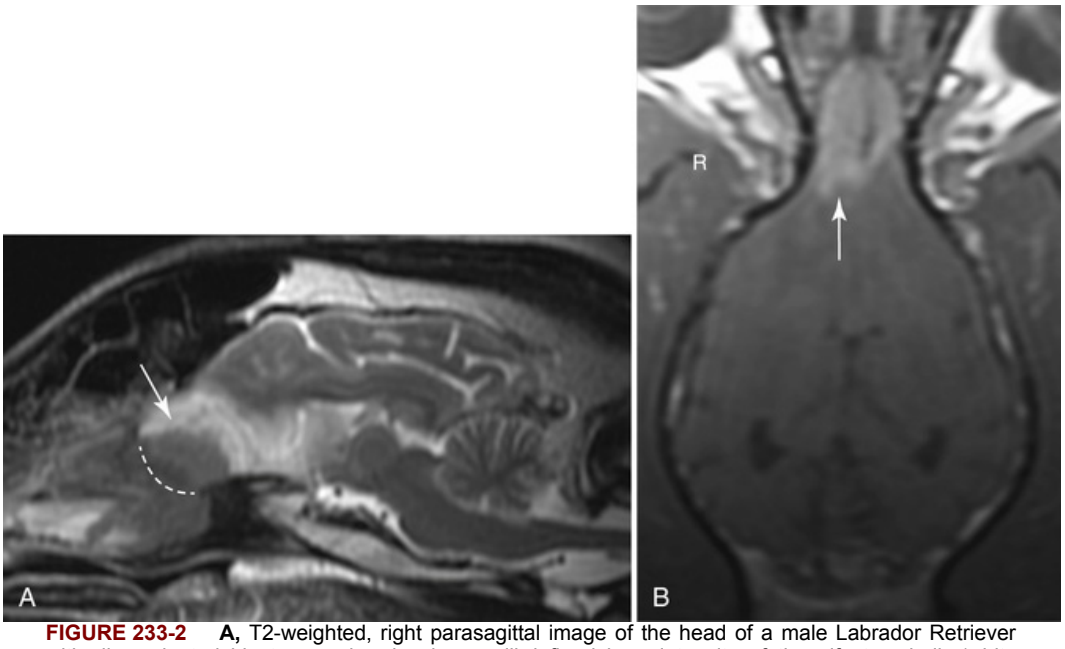

FIGURE 233-2 **A,** T2-weighted, right parasagittal image of the head of a male Labrador Retriever with disseminated blastomycosis, showing an ill-defined hyperintensity of the olfactory bulb (white arrow) extending from the cribriform plate (dotted line) to the level of the sella turcica and involving the right frontal lobe. **B,** T1-weighted, post-contrast enhanced coronal image of the head showing enhancement of the right olfactory bulb (arrow), cribriform plate, ethmoid turbinate with extension to the left olfactory bulb. (Courtesy Dr. Lorrie Gaschen.)

Feline blastomycosis is less common than canine blastomycosis.[5,11,12,21-23] Most of the clinical signs observed in dogs are also noted in cats. The main differences are that large abscesses are more common in cats than in dogs, and neurologic involvement is often noted.

Diagnosis

Blastomycosis is usually fairly easy to diagnose because of the large numbers of characteristic yeasts found within lesions, especially within infected skin, eyes, and lymph nodes.[6,22,24,25] Complete blood count (CBC) results are often normal. A mild nonregenerative anemia and mature neutrophilia or neutrophilia with mild left shift may be seen.[26] Chemistry results are often unremarkable, although hypoalbuminemia is the most consistent abnormality. Mild hypercalcemia is noted in up to 10% of cases.[27] Severe hypercalcemia requiring treatment is occasionally seen. Excessive production of 1,25-dihydroxy-vitamin-D has been reported in a cat. Ionized hypercalcemia resolved with antifungal treatment.[23] Hypercoagulability is also a sequela of *B. dermatitidis* infection.[26]

Thoracic radiographs reveal an interstitial pattern in about 70% of canine cases. Although a nodular interstitial pattern is classically observed (41% of cases), diffuse interstitial (24%) and bronchointerstitial (5%) patterns may also be prominent findings (Figures 233-3 to 233-5). An alveolar or mixed interstitial-alveolar pattern is observed in about 20% of dogs, and tracheobronchial lymphadenopathy is noted in about 30%. Radiographic patterns mimicking other diseases are not as common. Pleural effusion and pneumothorax are rarely observed.[28] Osteolytic bone lesions may be noted on the ends of long bones of distal limbs (Figure 233-6). The forelimbs are affected more commonly than the rear limbs, with most limb lesions being distal to the

elbow or the stifle. Periosteal proliferation and soft-tissue swelling are noted in about 50% of lesions.

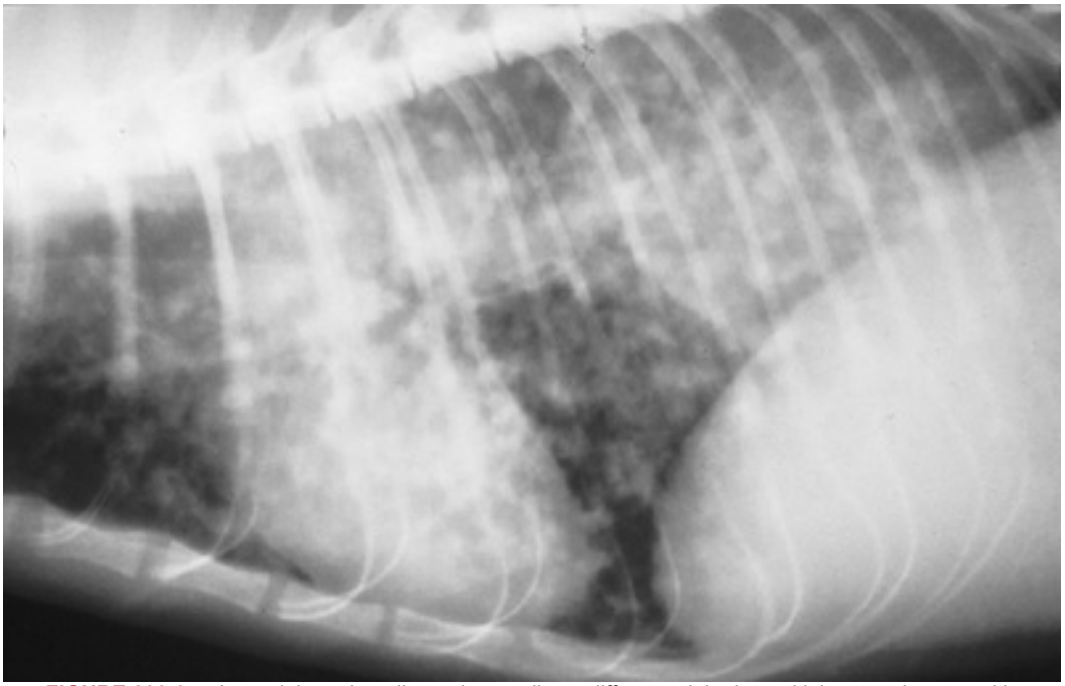

FIGURE 233-3 Lateral thoracic radiograph revealing a diffuse nodular interstitial pattern in a cat with blastomycosis.

FIGURE 233-4 Consolidation of the right cranial lung lobe in a cat with blastomycosis. Consolidating and abscessing lesions are often seen in cats with systemic fungal infections.

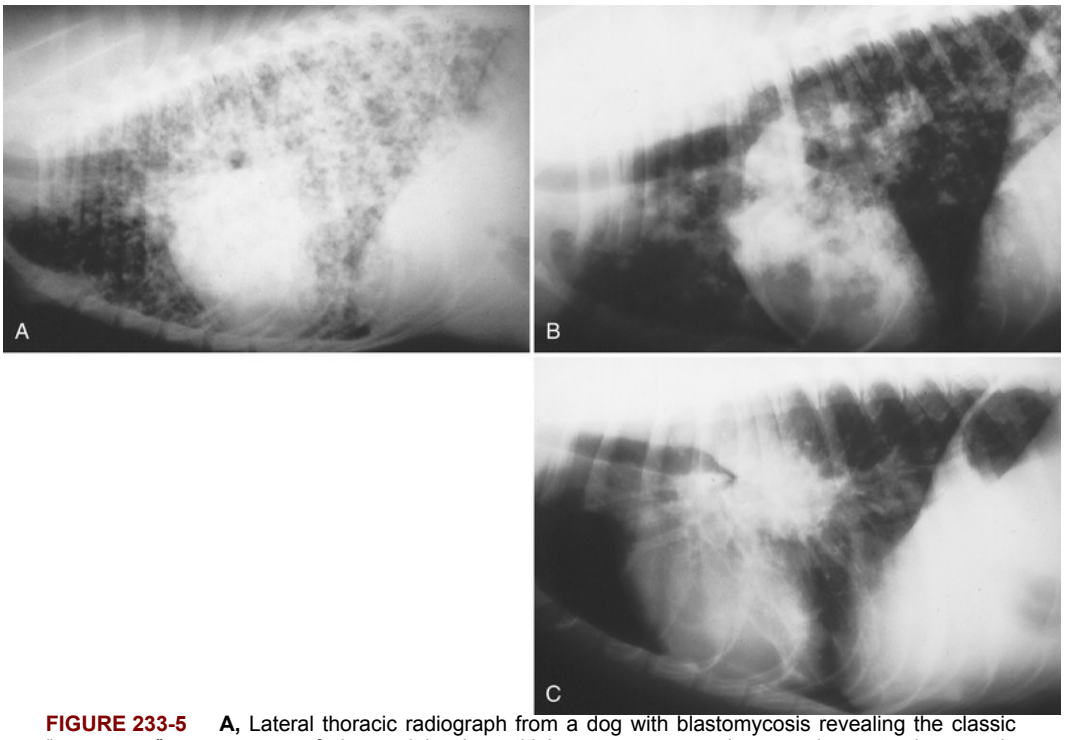

FIGURE 233-5 **A,** Lateral thoracic radiograph from a dog with blastomycosis revealing the classic "snowstorm" appearance of the nodular interstitial pattern commonly seen in systemic mycotic infections. **B,** Lateral thoracic radiograph from a dog with blastomycosis showing multiple large, ill-defined nodules and a bronchointerstitial pattern. **C,** Lateral thoracic radiograph from a dog with blastomycosis showing perihilar lymphadenopathy and a patchy interstitial pattern. Perihilar lymphadenopathy is common in systemic fungal infections, especially histoplasmosis and coccidioidomycosis.

Cross-sectional imaging has become an important tool in evaluating patients for potential CNS involvement. On magnetic resonance imaging (MRI), CNS lesions are often characterized as broad-based, extra-axial intracranial lesions that commonly occur in the frontal lobe with meningeal enhancement and perilesional edema present. These lesions appear hypo- to isointense on T1, hyperintense on T2, and enhance after contrast administration. Most dogs with evidence of CNS infection also have disseminated disease, although primary CNS blastomycosis has been reported.[29] Lesions may occur secondary to hematogenous spread or as a result of extension of disease from the nasal cavity, sinuses, and orbit and into the calvarium.[17,29,30] Instead of a mass-like lesion, some affected animals only demonstrate evidence of inflammation and ventriculomegaly on MRI and CT.[31,32] Cerebrospinal fluid (CSF) analysis (see ch. 115) often reveals neutrophilic pleocytosis and increased protein concentration. Organisms may not be identified on cytological examination of CSF.[29]

Definitive diagnosis is made by organism identification. This can be done by cytology or histology. Cytology from affected tissue typically reveals pyogranulomatous or suppurative inflammation, often with thick-walled yeasts (8 to 12 microns in diameter, with 0.5- to 0.75-micron-thick walls) that bud to form daughter cells from a broad base (Figure 233-7).[24,33] Skin lesions yield organisms about 80% of the time and are the easiest and most useful site for cytologic diagnosis (see ch. 86). Vitreal aspirates yield organisms from almost all affected eyes, and lymph node aspirates yield organisms approximately 60% of the time (see ch. 95). Bone and lung aspirates, transtracheal wash cytology, and bronchoalveolar lavage each yield organisms less often (see ch. 101).[6,34] Urinalysis or prostatic wash cytology rarely reveals organisms (see ch. 111).[33] Rarely, organisms may appear on fecal examination (see ch. 81).[35] Care must be taken when handling samples that may contain yeast cells. Direct inoculation of organisms from needle-stick injury may result in

localized cutaneous disease.[8]

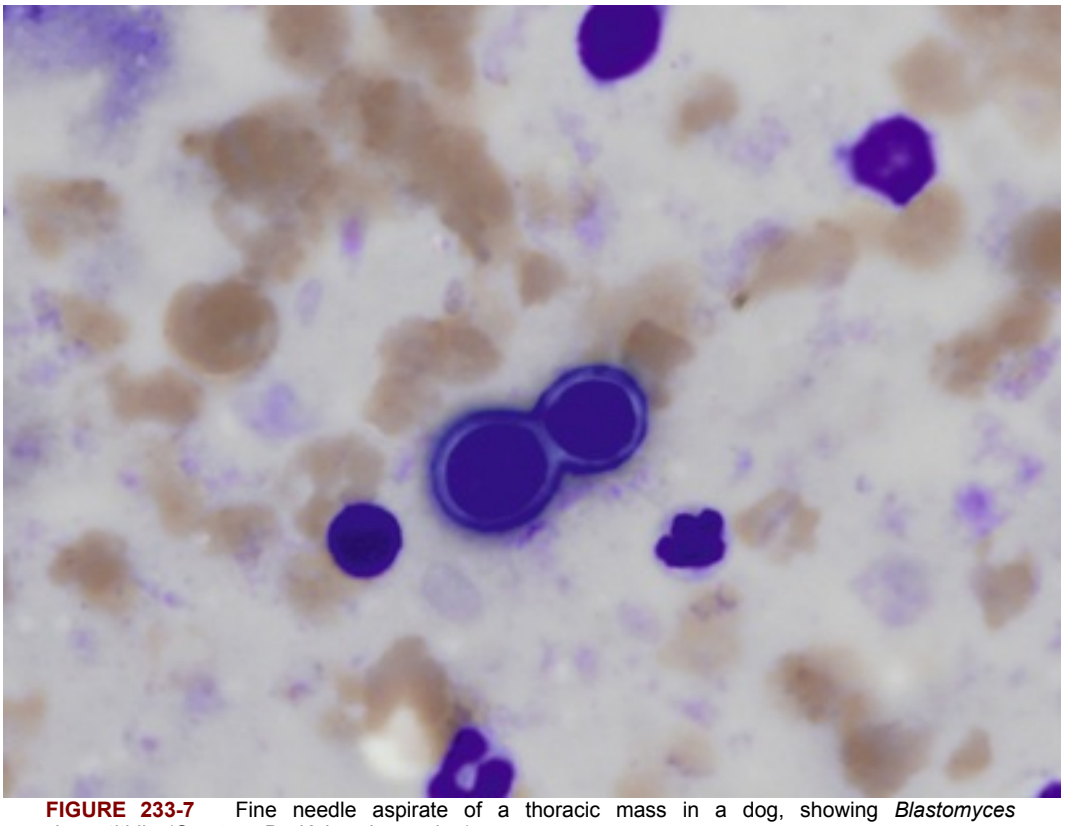

FIGURE 233-7 Fine needle aspirate of a thoracic mass in a dog, showing *Blastomyces dermatitidis*. (Courtesy Dr. Kelsey Legendre.)

Histopathology is generally characterized by purulent to pyogranulomatous inflammation, with broad-based organisms usually being apparent. Special stains such as periodic acid–Schiff (PAS), Gridley's fungal, and Gomori's methenamine silver (GMS) stain are best for demonstrating organisms. Polymerase chain reaction (PCR) has recently been used to identify organisms in tissue.[36]

Culture is not needed for definitive identification in clinical cases. Culturing the organism from the environment is rarely achieved. Culture of blastomycosis presents a significant health risk to diagnostic laboratory personnel if specimens are not handled properly.[37]

A *Blastomyces* antigen enzyme immunoassay (EIA) has been used in both serum and urine to detect cell wall galactomannan that is immunologically indistinguishable in histoplasmosis and blastomycosis.[38] Antigen testing was sensitive in a group of dogs with blastomycosis. Testing urine yielded a higher sensitivity when compared to testing serum. The antigen test shows cross-reactivity with histoplasmosis, and other fungal diseases. Therefore, the test is useful in supporting a diagnosis of fungal disease but is not effective in making a definitive diagnosis of a specific fungal infection. Antigen concentrations correlate with severity of disease and will decrease with successful treatment, making the test useful in following response to therapy and as a predictor of relapse.

Serology assessing for the presence of antibodies against *Blastomyces* is generally considered to have low sensitivity and specificity. In one recent study, serology was positive in only 50% of dogs with confirmed blastomycosis.[33] Antibody titers, most commonly measured via agar gel immunodiffusion (AGID), have not proven useful in following response to therapy and are not more sensitive than antigen testing.

Treatment

All dogs and cats with blastomycosis should be treated. Itraconazole is presently considered the treatment of choice, except in cases of moderate to severe hypoxemia or CNS infection, when amphotericin B should still be considered the drug of first choice (see ch. 162).[10] Clinical cures can be expected in 70% to 75% of treated

cases. Treatment failure is most likely in dogs that are hypoxemic or have three or more organ systems affected. In cats, treatment failure has been associated with latent CNS involvement. The dosage of itraconazole that has proven effective is 5 mg/kg orally once a day or divided twice a day. The drug should be continued for 2 to 3 months or until active disease is not apparent. Response to itraconazole treatment is minimal during the initial 1 to 2 weeks. A loading dose of 10 mg/kg daily for the first 3 days of treatment may minimize this lag time. Recurrence occurs in approximately 20% of treated dogs from months to years after treatment has been discontinued.[6,10] Cats require a higher dosage of itraconazole: 10 mg/kg once a day or divided twice a day, and longer courses of treatment as compared to dogs.

Fluconazole is generally considered to be less effective in treating blastomycosis compared to itraconazole. Relapse rates may be higher.[39] However, fluconazole treatment may be more cost-effective than itraconazole or newer azole antifungal drugs. Longer duration therapy using fluconazole has proven effective in treating blastomycosis, making it often the first choice drug. Because fluconazole is excreted in the urine and crosses the blood-brain, blood-ocular, and blood-prostatic barriers well, it may be a more appropriate treatment choice for urinary tract, prostatic, and CNS infections.[39]

Adverse effects of the azole antifungal agents are similar across the class. Ketoconazole is the least tolerated, and fluconazole appears to be the best. Dosage-related gastrointestinal (GI) side-effects (anorexia and vomiting) are most common, especially in cats. When these occur, dividing the dose into two treatments or reducing the dosage may be of benefit. Liver enzymes should be monitored in animals being treated with azole antifungals. Asymptomatic increases in transaminase concentrations are seen in about half of animals treated with itraconazole and about 20% of dogs treated with fluconazole but do not warrant a change in therapy unless the patient is experiencing concurrent anorexia, vomiting, depression, or abdominal pain.[39] Enzyme concentrations often return to normal over time without intervention. Symptomatic hepatotoxicosis is occasionally seen with itraconazole use, but is unusual after fluconazole administration. Cutaneous reactions secondary to vasculitis (Figure 233-8) are seen in approximately 7% of dogs receiving itraconazole at a dosage of 10 mg/kg and usually resolve after drug discontinuation.[10]

FIGURE 233-8 **A,** Lesion on the prepuce of a Dachshund being treated for blastomycosis with itraconazole. The lesion is caused by an itraconazole-induced cutaneous vasculitis. **B,** Paronychial lesion caused by an itraconazole-induced cutaneous vasculitis in a Doberman Pinscher.

Amphotericin B is often used in combination with itraconazole or fluconazole for severely affected, hypoxemic animals or animals with CNS involvement. ABLC (Abelcet), a lipid-complexed formulation of amphotericin B is recommended due to reduced toxicity.[40] A dose of 2 to 3 mg/kg IV every other day to a total dose of 24 to 27 mg/kg has been recommended for dogs with blastomycosis.

The deoxycholate formulation, although much less expensive, carries a higher risk of toxicosis. The dosage is 0.5 mg/kg for dogs, 0.25 mg/kg for cats, intravenously every other day to a total dose of 4 mg/kg when used in combination with azole antifungal drugs. A higher dosage of 0.5 to 1 mg/kg to a total dose of 8 mg/kg is recommended in dogs if amphotericin B is the sole treatment agent. Amphotericin B should be discontinued if the dog or cat becomes azotemic (blood urea nitrogen [BUN] ≥50 mg/dL, creatinine ≥3 mg/dL). The efficacy of amphotericin B when combined with fluconazole or itraconazole is equal to that seen with itraconazole alone, but side-effects are much more likely.

Ancillary therapy in hypoxemic animals should include oxygen (see ch. 131), bronchodilators, and possibly antibiotics. Anterior uveitis and secondary glaucoma should be treated appropriately (see ch. 11). Oral

glucocorticoids may result in an increased probability of retaining vision in dogs with ocular involvement without significantly reducing prognosis for systemic involvement.[41] They also may improve survival in dogs with dyspnea resulting from airway edema and severe inflammation following initiation of treatment.

Resolution of clinical signs is the best means of patient monitoring. Monthly rechecks, consisting of physical and fundic examinations, as well as thoracic radiographs and chemistry panels, should be performed as long as the patient is receiving antifungal therapy. Treatment should be continued for 1 month beyond resolution of clinical signs, and animals should be re-evaluated 3 and 6 months after discontinuing therapy to assess for relapse. Antigenuria should become negative or decrease below 1 ng/mL with successful therapy. Increasing urine antigen concentration may suggest relapse.[38,42] Serology is not useful in monitoring response to therapy or evaluating for relapse.

Dogs that die are usually those with severe respiratory disease and hypoxemia. Dogs that live through the first 10 days of therapy generally do well. Hypoxemia and the involvement of three or more body systems are poor prognostic factors.[10] Relapse occurs in 15% to 20% of treated dogs. It usually occurs in the first 6 months after treatment but can occur after a year or more. Relapses should be treated as new infections and are no less likely to respond.

Public Health Significance

Blastomycosis is not likely to be transmitted from animal to animal or from animal to person. Localized *Blastomyces* infections have occurred after needle-stick injuries when obtaining fine needle aspirates from infected lesions, and laboratory workers can potentially be infected from fungal cultures. Outbreaks in which both people and dogs are affected are due to exposure to a common environmental source rather than to zoonosis.

Histoplasmosis

Histoplasmosis is a systemic fungal infection that usually originates in the lungs and potentially the GI tract, then disseminates to the lymphatics, liver, spleen, bone marrow, eyes, and other organs. A wide variety of mammalian species can be affected, and cats may be more susceptible to infection than dogs. As with most systemic fungal diseases, animals younger than 4 years old are at an increased risk, but any age can be affected.

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum*. In infected tissue, the organism is a yeast. In the environment, *H. capsulatum* is a soil saprophyte endemic throughout most of the temperate and subtropical regions of the world. Most cases of histoplasmosis in North America occur in the upper midwestern area of the United States and south central Canada, with the geographic distribution following the Mississippi, Ohio, and Missouri Rivers (see Figure 233-1).

Pathophysiology

Histoplasmosis is not a contagious disease. Infection is via inhalation or ingestion of infective conidia from the environment. The respiratory system is likely the primary route of infection in cats, humans, and dogs, but the GI system may also be an important route in the dog.

After inhalation or ingestion, conidia transform from the mycelial phase to the yeast phase and are phagocytized by cells of the macrophage monocyte system, where they grow as facultative intracellular organisms. Hematogenous and lymphatic dissemination results in multisystemic disease. Dissemination can be to any organ system, resulting in a granulomatous inflammatory response. The lungs, GI system, lymph nodes, liver, spleen, bone marrow, eyes, and adrenal glands are common organs affected in dogs; lungs, liver, lymph nodes, eyes, and bone marrow are most commonly affected in cats. The incubation period is 12 to 16 days in dogs and humans.

The cell-mediated immune response determines the severity of clinical disease, with subclinical infection probably being common. Most cases of infection are sporadic events, but point-source outbreaks of disease are occasionally reported in both dogs and humans. Epidemiologically, these outbreaks are usually associated with exposure to areas heavily contaminated with *Histoplasma* organisms such as chicken coops, bat habitats, or starling roosts. While histoplasmosis has been reported in strictly indoor-only cats, the source of exposure may have been houseplants or unfinished basements.[43]

Clinical Signs

Feline histoplasmosis occurs most commonly in cats younger than 4 years of age. No breed or sex predilection exists. Disease in cats is usually insidious in onset and nonspecific. Depression, anorexia, fever, pale mucous membranes, and weight loss are common. Pulmonary involvement, as evidenced by dyspnea, tachypnea, or abnormal lung sounds, is seen in less than 50% of affected cats. Cough is uncommon. Hepatomegaly, splenomegaly, or lymphadenopathy is noted in about a third of affected cats. Ocular involvement may result in abnormal retinal pigment proliferation, retinal edema, granulomatous chorioretinitis, anterior uveitis, panophthalmitis, or optic neuritis (see ch. 11). Retinal detachment and secondary glaucoma are less common than in animals affected with blastomycosis. Fungal osteomyelitis may cause lameness in one or more limbs. Cutaneous lesions consisting of multiple small nodules that may ulcerate and drain or crust over are noted less commonly than in animals affected with blastomycosis. GI signs other than anorexia are uncommon in cats with histoplasmosis when compared to dogs. Oral and lingual ulceration has been reported as an unusual manifestation. Icterus is occasionally seen in cats with hepatic involvement. Primary cutaneous infection as well as skin fragility secondary to histoplasmosis infection of the skin have been reported in cats.[44,45] In a retrospective study of 22 cats with histoplasmosis, disseminated disease was found in the majority of cases (15/22) with primary GI disease and primary pulmonary disease occurring in 3/22 and 4/22 cases respectively.[46]

Canine histoplasmosis is most commonly seen in dogs younger than 4 years of age. Male dogs are affected 1.2 times as frequently as female dogs, and Pointers, Weimaraners, and Brittany Spaniels may be overrepresented. The clinical findings are related to the route of infection and the extent of systemic dissemination. Clinically inapparent infection is probably common after inhalation of organisms. In those dogs showing clinical signs, findings vary greatly, but GI signs are most common. Both small and large bowel diarrhea may be seen, as well as protein-losing enteropathy, depending on the portion of the GI tract affected.

Nonspecific clinical signs such as fever, anorexia, depression, and severe weight loss are common and may be caused by elaboration of inflammatory mediators such as tumor necrosis factor (TNF) and interleukin-1 (IL-1). Abnormal lung sounds with or without coughing, tachypnea, or dyspnea are seen in less than 50% of affected dogs. Pleural effusion is seen in rare cases and may contribute to respiratory signs.[47] Splenomegaly, hepatomegaly, and lymphadenopathy are occasionally seen.

Diagnosis

Normocytic-normochromic nonregenerative anemia, the most common CBC abnormality, likely has a multifactorial cause in these patients, with chronic inflammation, GI blood loss, and bone marrow infection playing a role in severity.[43,46] Neutrophilia and monocytosis are often seen, but leukocyte counts are variable. Neutropenia or pancytopenia is noted in a minority of affected animals, especially in cats. Fungemia is rare in dogs and cats. *Histoplasma* organisms are only occasionally seen in monocytes or neutrophils and rarely in eosinophils. Thrombocytopenia due to increased use or platelet destruction is seen in as many as one half of affected dogs and one third of affected cats. Hypoalbuminemia is the most consistent chemistry abnormality.[43,46] Increases in serum alanine aminotransferase (ALT), serum aspartate aminotransferase (AST), alkaline phosphatase, and total bilirubin may indicate hepatic involvement. Hypercalcemia is more common in cats than in dogs.[48] It should be noted that hypoalbuminemia may mask subtle hypercalcemia. In a retrospective review of 22 cats with histoplasmosis, 42% had hypocalcemia on serum chemistry panel; all hypocalcemic cats were also hypoalbuminemic.[46] Cats are usually retrovirus-negative. Urinalysis is unremarkable in most cases.[46] *Histoplasma capsulatum* can lead to vasculitis and disseminated intravascular coagulopathy.[49]

Thoracic radiographs often reveal a diffuse interstitial or linear interstitial pattern that tends to coalesce to a nodular interstitial pattern (Figure 233-9).[43] Alveolar infiltrates are rarely reported. Hilar lymphadenopathy is common in dogs but unusual in cats. Calcified pulmonary infiltrates or hilar lymph nodes may indicate inactive disease in dogs. Lytic bone lesions, periosteal new bone formation, and subperiosteal bone proliferation are rarely noted. Bones of the distal appendicular skeleton, especially carpal and tarsal bones, are affected most commonly. Cats are more commonly affected with osseous lesions than are dogs.

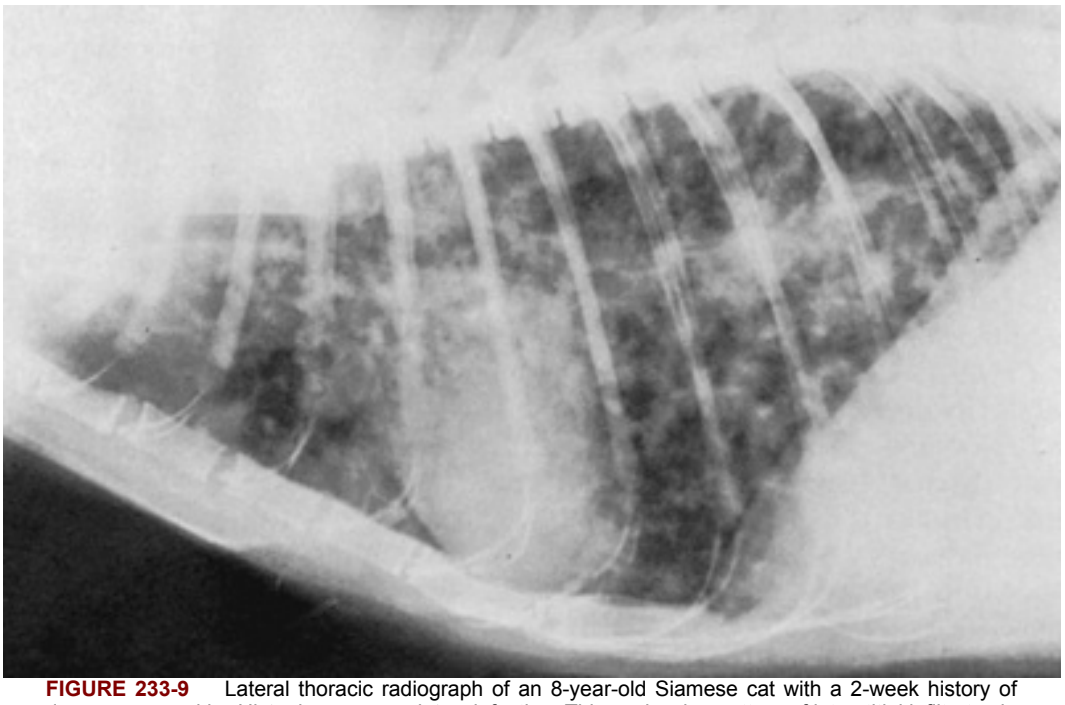

FIGURE 233-9 Lateral thoracic radiograph of an 8-year-old Siamese cat with a 2-week history of dyspnea caused by *Histoplasma capsulatum* infection. This coalescing pattern of interstitial infiltrates is commonly seen in cats with pulmonary histoplasmosis.

Abdominal ultrasonographic examination (see ch. 88) may reveal hepatomegaly, changes in hepatic or splenic echo texture, abdominal lymphadenomegaly, peritoneal effusion, renomegaly, and adrenomegaly.[43,46] The discovery of an enlarged and hypoechoic spleen on ultrasound should increase suspicion for splenic involvement.[50]

Organism identification is required for definitive diagnosis. The most common means of organism identification is cytology. Cytology from affected tissue reveals pyogranulomatous inflammation, often with numerous small, round to oval intracellular yeast cells (2 to 4 micron in diameter) characterized by a basophilic center and a light halo caused by shrinkage of the cell away from the cell wall during fixation (Figure 233-10).

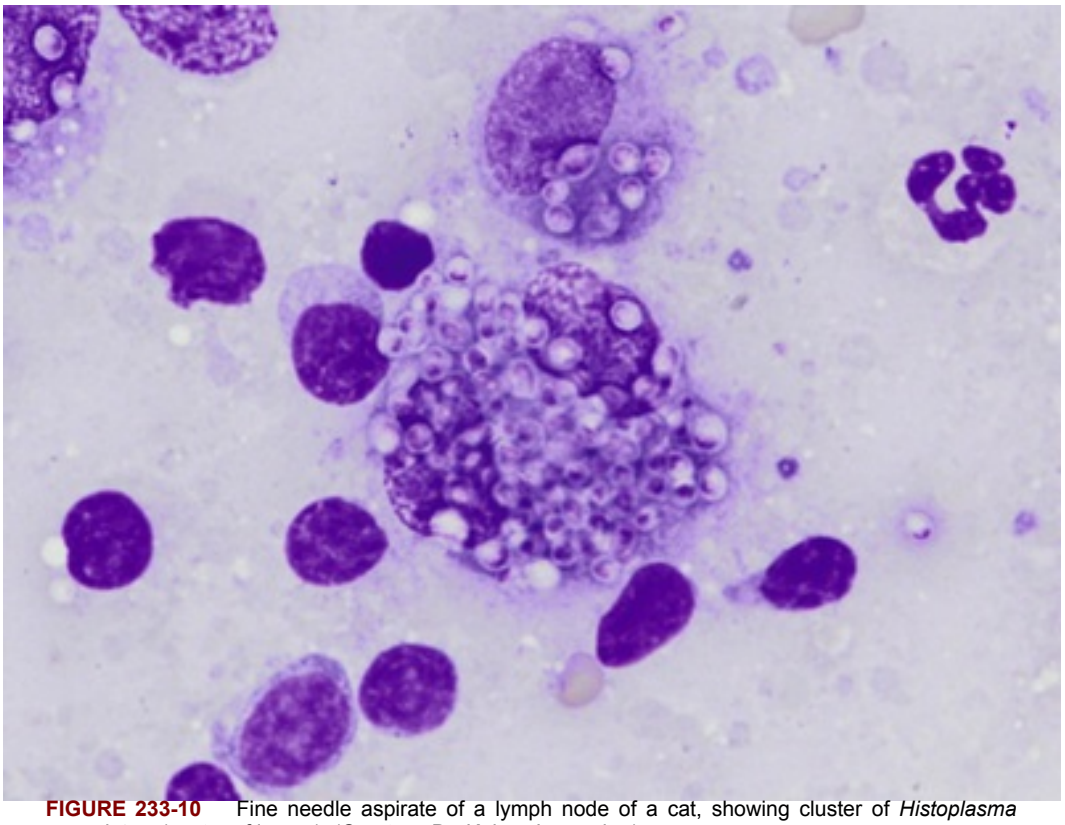

FIGURE 233-10 Fine needle aspirate of a lymph node of a cat, showing cluster of *Histoplasma capsulatum* (center of image). (Courtesy Dr. Kelsey Legendre.)

Although multiple *Histoplasma* organisms are usually found within phagocytic cells of the mononuclear phagocyte system, a small number of the organisms can be released from cells during slide preparation and may be seen free on the slides stained with a Wright-Giemsa-type stain. Samples for cytology should be collected from tissue with apparent abnormalities. In the cat, aspiration cytology from bone marrow, spleen, or lymph nodes or cytology from tracheal wash or bronchoalveolar lavage is most likely to yield organisms. In the dog, cytology from rectal scrapings or biopsies and aspiration cytology from bone marrow (see ch. 92), liver (see ch. 89), lymph nodes (see ch. 95), spleen, or tracheal wash or bronchoalveolar lavage (see ch. 101) are most likely to yield organisms. Buffy coat smears, cytology of pleural or peritoneal effusions, aspirates of lytic bone lesions, and aspirates or impression smears of nodular skin lesions (see ch. 86 and 87) may also yield organisms (see ch. 74).

Pyogranulomatous lesions with multiple intracellular organisms within macrophages are usually apparent. Histoplasmosis should be considered when granulomatous hepatitis or other granulomatous or pyogranulomatous disease is seen on biopsy.[51] The yeast does not stain well with routine hematoxylin-eosin (H&E) stains, so special stains such as PAS, Gridley's fungal, and GMS stain are often used to demonstrate organisms. In rare cases, hyphae may be seen admixed with yeast forms in histopathology samples.[52]

Fungal culture from affected tissue can be used for diagnosis but is rarely needed in clinical cases. The cultured organism has pathogenic potential, which precludes culture attempts in a practice setting.

Antibody detection is presently an ineffective method of diagnosis, as both false-positive and false-negative results are common. A galactomannan antigen is released from the cell wall during active infection and can be detected in the urine or serum. Antigenemia and antigenuria may be demonstrated using a *Blastomyces* antigen EIA for cell-wall galactomannan. A positive test is not specific for histoplasmosis but is indicative of systemic mycoses and may allow for an early diagnosis and treatment.[37] Antigen concentrations decline during treatment and increase with relapse. In the author's experience, use of EIA in urine may have a limited sensitivity in cases of localized infection, such as pulmonary histoplasmosis, as is the case in humans.[53] Hence, a negative titer should be followed by additional diagnostics, such as airway sampling, if disease is thought to be confined to the respiratory system (see ch. 101). PCR has been used to identify *Histoplasma capsulatum* from feline tissues in several case reports.[45,54]

Treatment

Pulmonary histoplasmosis may have a self-limiting clinical course, but antifungal treatment is still recommended because there is significant potential for chronic dissemination. Dogs or cats with disseminated histoplasmosis usually die without treatment. Treatment protocols are similar to those described for blastomycosis, although they have not been as well studied. Longer treatment times are probably needed in most cases, but this is highly variable.

Itraconazole 10 mg/kg PO once a day or divided twice a day is considered the treatment of choice for feline histoplasmosis. At least 2 to 4 months of therapy is required. Few studies have evaluated the efficacy of itraconazole treatment, but in one study all eight of eight treated cats were cured, while in another study only half of cats were ever discharged from the hospital.[46,48] The addition of amphotericin B to ketoconazole treatment regimens may improve efficacy, especially in severely affected cats. Fluconazole, posaconazole, voriconazole, and isavuconazole, new generation azoles, are likely effective but have not been well studied (see ch. 162).[55] Fluconazole therapy appears to have similar relapse and mortality rates compared to treatment with itraconazole in cats with histoplasmosis.[43] Fluconazole is less effective than itraconazole in treating people with histoplasmosis and posaconazole is often used in patients who cannot tolerate itraconazole and fail fluconazole treatment. Voriconazole is used in patients with CNS disease but CNS involvement is not as common as it is in blastomycosis. Similar observations have not been made in dogs and cats.

In dogs with histoplasmosis, ketoconazole has been described as the treatment of choice with amphotericin B being added to the protocol in fulminant cases; however, few studies have evaluated treatments for histoplasmosis in dogs, and ketoconazole studies were performed before newer azole antifungals were readily available. Itraconazole is the treatment of choice for histoplasmosis in people. Itraconazole and fluconazole are safer and may result in better efficacy than ketoconazole in dogs as well. Ancillary respiratory therapy may include oxygen (see ch. 131) and bronchodilators in hypoxemic animals and antibiotics in dogs with secondary bacterial pneumonia, although this is uncommon in dogs with systemic mycoses.[28] Corticosteroids have been recommended for treating dogs with airway obstruction secondary to hilar lymphadenopathy caused by histoplasmosis.[56]

Resolution of clinical signs is the best means of patient monitoring. Rechecks should be performed monthly during treatment and should include physical and ocular examinations, thoracic radiographs, and a chemistry panel in animals receiving azole antifungals. Urine antigen concentrations should be monitored every 3 months. Treatment should be continued for 1 month beyond resolution of clinical signs, and animals should be re-evaluated 3 and 6 months after discontinuing therapy to assess for relapse. Urine antigen tests will decline with successful treatment and increase with relapse, making repeated assessment of urine antigen concentration an appropriate method of following therapy. Serology is not useful in monitoring response to therapy or evaluating for relapse.

The prognosis is good for dogs with only pulmonary signs, but dogs with GI disease or severe dissemination have a guarded prognosis. The prognosis is fair to good for cats treated with itraconazole, although long-term therapy may be required. Severely debilitated cats have a guarded prognosis. Survival of cats with histoplasmosis varies from 55-66% with median survival times between 19-28.9 months.[43,46]

CHAPTER 234

Aspergillosis—Canine

Frédéric Billen, Dominique Peeters

Client Information Sheet: Canine Aspergillosis

Background

Aspergillus species are saprophytic and ubiquitous filamentous fungi involved in environmental recycling that may also act as opportunistic pathogens. Their small size (2-3 microns) enables them to remain airborne and penetrate the respiratory tract.[1] Most humans inhale several hundred conidia daily.[2] The respiratory defense system (mucociliary escalator, cell-mediated immunity and soluble mediators) eliminates these pathogens, preventing colonization within the respiratory system. However, change in any component of the defense system may lead to development of infection.[3] In dogs, two forms of *Aspergillus* infection are reported: *sinonasal aspergillosis* (SNA), in which the infection is restricted to the nasal cavities and the frontal sinuses, and *systemic aspergillosis*, in which the infection spreads deeper in the body.[4]

Sinonasal Aspergillosis (SNA)

Etiology

Fungal rhinosinusitis is one of the most common causes of chronic nasal discharge in dogs (see ch. 27).[5-7] The disease is most often caused by *A. fumigatus*, while *A. niger, A. nidulans, A. flavus, A. tubingensis* and *A. uvarum* or *Penicillium* spp. have occasionally been reported.[4,8] On rare occasions, other mycotic agents such as *Cryptococcus neoformans* or *Scedosporium apiospermum* may affect the nasal cavities of dogs (see ch. 231).[9,10]

Pathogenesis

The reason for *A. fumigatus* causing disease in only a small proportion of exposed dogs remains unclear. In rare cases only, a predisposing factor such as nasal foreign body, facial trauma, nasal tumor, or an impacted tooth is present.[11,12] Typically, affected dogs are not systemically immunocompromised, fungal infections are restricted to the nose and/or frontal sinuses, and there is no fungal invasion of respiratory mucosa.[13] Therefore, local nasal mucosal immune dysfunction is suspected to be involved in the pathogenesis of the disease. In affected dogs, there seems to be disequilibrium in the balance between pro-inflammatory (Th1 immunity) and anti-inflammatory (Th17 immunity and possibly T regulatory cells) signals that could perpetuate infection and its associated inflammatory response.[14] A defect in Toll-like receptor (TLR) expression or function might constitute the primary dysfunction leading to *Aspergillus* infection in these dogs.[15,16] SNA is characterized by severe nasal turbinate destruction, likely due to the inflammatory response and dermonecrolytic fungal toxins.[13] Severely affected dogs have bony destruction that may allow inflammation to extend into perisinusal and periorbital soft tissues and/or into the brain.[17]

Signalment and Clinical Findings

SNA affects primarily young to middle-aged dogs from large mesaticephalic and dolichocephalic breeds.[18] Sneezing, reverse sneezing, unilateral (bilateral later in the course of the disease) epistaxis, and muco- or sanguinopurulent nasal discharge may be present weeks to months prior to examination. Nasal planum depigmentation and ulceration (Figure 234-1), normal or even increased ipsilateral nasal airflow, facial

discomfort, lethargy and decreased appetite are common clinical findings that will usually not be present with other causes of nasal discharge in dogs. Rarely, inflammation extension into the forebrain due to cribriform plate destruction may result in dullness or even seizures.[12]

FIGURE 234-1 Depigmentation and ulceration of the nasal planum of a dog with bilateral (L > R) sinonasal aspergillosis.

Diagnosis

Overview

Even when SNA is highly suspected based on signalment and a typical clinical presentation, fungal infection must be confirmed prior to therapy. No test is 100% accurate and a combination of diagnostic procedures is required.[12] These include observation of destructive, "cavitating" changes of the nasal cavity by diagnostic imaging or rhinoscopy, and the demonstration of a fungal etiology with endoscopic visualization of fungal plaques, cytology, histology, fungal culture and/or serology.

Imaging

Diagnostic imaging studies should be performed prior to rhinoscopy because resultant hemorrhage may obscure subtle lesions and induce imaging abnormalities.[19] Several studies have demonstrated the higher sensitivity of computed tomography (CT) and magnetic resonance imaging (MRI), as compared to radiography, for the diagnosis of sinonasal diseases in dogs.[20-22] CT is particularly superior to radiography for defining the extent of the sinonasal lesions, detecting cortical bone lesions and in assessing integrity of the cribriform plate (see ch. 238).[19,23] The latter may be essential when choosing a therapeutic plan.[24] The most common CT findings in SNA are (1) moderate to severe cavitary destruction of the turbinates with presence of variable amount of abnormal soft tissue (secretions and/or fungus) in the sinus and/or nasal cavities (Figure 234-2), (2) non-specific thickening of the mucosa adjacent to the inner surface of bones of the frontal sinus, maxillary recess and nasal cavity, and (3) thickened reactive bone.[17] There is no clear advantage of using MRI versus CT in the diagnosis of canine SNA.[19]

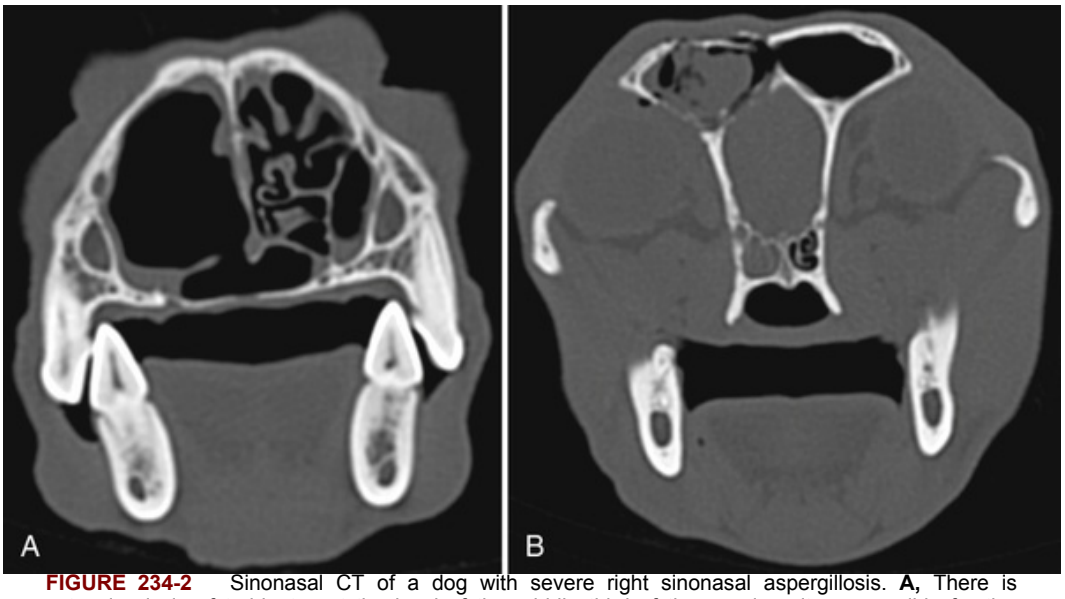

FIGURE 234-2 Sinonasal CT of a dog with severe right sinonasal aspergillosis. **A,** There is extensive lysis of turbinates at the level of the middle third of the nasal cavity responsible for the "cavitary-like" appearance. **B,** There is soft tissue attenuating material with a fragmented gas pattern present into the right frontal sinus. There is severe destruction of right frontal bone that involves the wall between the frontal sinus and cranial cavity, between the frontal sinus and orbit, and dorsally leaving a communication with the subcutaneous tissues.

Endoscopy

Endoscopic examination of the sinonasal cavities is the only procedure that may allow diagnosis (fungal plaques visualization and/or target sampling) and treatment (debridement ± foreign body retrieval, and infusion catheters placement) of the infection during one general anesthetic (see ch. 96).[11,12,25-27] Typical rhinoscopic findings include moderate to severe destruction of the turbinates, resulting in a typical cavity-like appearance, roughening of the mucosa, presence of intranasal (sanguino-) mucopurulent secretions and fungal colonies (Video 234-1). In some cases, nasal septum destruction and bilateral disease may be observed.[19,28] Fungal colonies typically appear as white or greenish fuzzy plaques adherent to the nasal or sinusal mucosa.[29] In some cases, fungal colonies may not be present in the nasal cavities, and frontal sinus access is required for the diagnosis of SNA (Figure 234-3). In one study, sinus trephination with sinuscopy was necessary to confirm the diagnosis of SNA in 17% of dogs with CT lesions suggestive of the disease.[11]

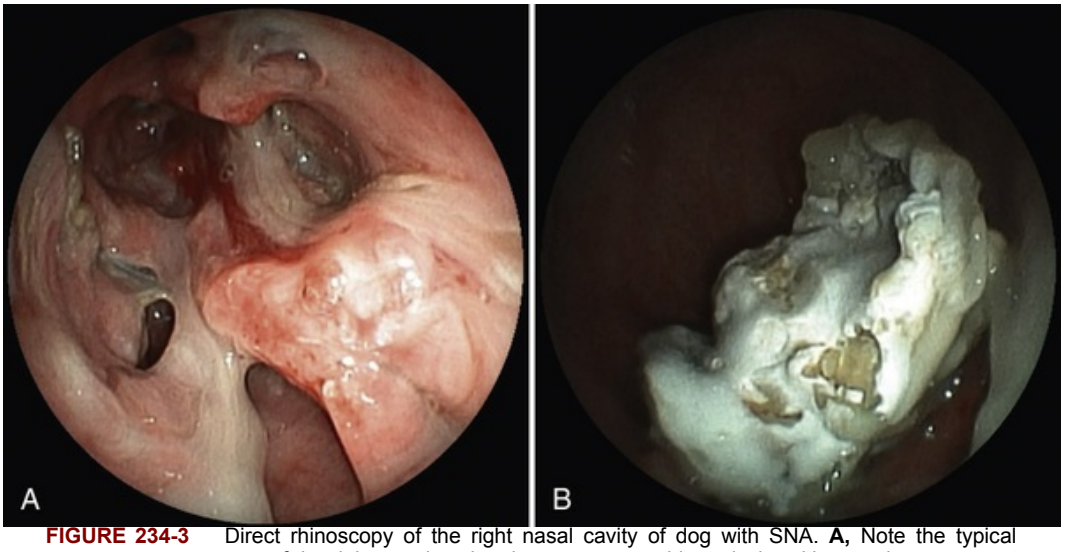

FIGURE 234-3 Direct rhinoscopy of the right nasal cavity of dog with SNA. **A,** Note the typical cavernous appearance of the right nasal cavity, due to severe turbinate lysis, with a moderate amount

of sanguino-mucopurulent secretions. **B,** Fungal granuloma was present only in the right frontal sinus.

Rhinoscopy is usually performed with a 0° or 30° viewing angle rigid endoscope, but a flexible small endoscope should be used whenever possible to facilitate entry into the frontal sinus in some dogs (see ch. 238).[19] This is generally feasible in medium- to large-breed dogs with moderate to severe turbinate destruction. The major limitations of endoscopy are its inability to evaluate bony structures and, especially, the integrity of the cribriform plate. For this reason, endoscopy and CT are considered complementary diagnostic procedures.[19,29]

Cytology

Cytology may be used to confirm the diagnosis of SNA (see ch. 93). The sensitivity of this technique depends on the sampling method. Direct smears from nasal exudate and blind endonasal swabs detected fungal hyphae in only 13% and 20% of the cases, respectively, while brushing of suspected lesions under endoscopic guidance and squash preparation of biopsies of suspected lesions detected fungal hyphae in 93% and 100% of cases, respectively.[25] As with cytology, sensitivity of histology for detection of fungal hyphae is highly dependent on the biopsy specimen. It usually requires sampling fungal plaques rather than adjacent mucosa or erroneously identified plaque-like exudate or necrotic debris.[13,30,31]

Culture

Recent data demonstrated fungal cultures to be 100% specific for diagnosis of SNA in dogs with nasal discharge.[26,32] Suboptimal laboratory methodology and inability to obtain appropriate nasal specimens most likely contributed to earlier low sensitivities. A recent study has shown that increasing the incubation temperature from room temperature to 37° C not only enhanced the sensitivity of fungal culture but also shortened time until fungal growth. The type of nasal sample obtained is of major importance. Sensitivity is the highest when fungal plaques are sampled (88%) followed by mucosal biopsies (75%). Blind endonasal swab samples are completely unreliable (19%) for diagnosing SNA.[26]

Serology

Tests detecting serum *Aspergillus*-specific antibodies use commercially available, standardized, highly purified *Aspergillus* antigen solutions. However, only a few studies have evaluated the diagnostic value of these standardized solutions in canine SNA. The agar-gel double immunodiffusion is a highly specific (98 to 100%) but poorly sensitive (57 to 76.5%) diagnostic method, while enzyme-linked immunosorbent assay (ELISA) yields a higher sensitivity (88.2%) with equal specificity (96.8%).[30,32,33] Because of its overall moderate sensitivity, serology is not considered a good screening test for SNA in dogs suffering from chronic nasal discharge. Serum galactomannan antigen (a cell wall component released during fungal growth) and quantitative whole blood or nasal tissue fungal DNA detection are not reliable for diagnosis of canine SNA.[33,34]

Treatment

Overview

Effective treatment of SNA remains challenging despite various available therapeutic options, including orally administered systemic therapy, topical application of antifungal solutions and more invasive surgical procedures (Table 234-1).

TABLE 234-1

Summary of First and Overall Treatment Success Rates of Studies Reporting the Use of Moderate/Non-Invasive Topical Treatment Techniques in Dogs with Sinonasal Aspergillosis

TREATMENT PROCEDURE	NUMBER OF DOGS	FIRST TREATMENT SUCCESS: RANGE (MEAN)	OVERALL TREATMENT SUCCESS: RANGE (MEAN)
(A) Infusion—1% clotrimazole—sinus catheters—temporary	84	54.1-76.9%	83.7-86.9%

trephination18,43,51		(63.8%)	(84.9%)
(B) Infusion—1% clotrimazole or enilconazole—nasal catheters—blindly placed18,23,28,30,43,48,50	208	40-76% (56.1%)	89.5-98% (94.3%)
(C) Infusion—2% enilconazole—nasal & sinus catheters—endoscopically placed28,48	19	58.3-85.7% (68.4%)	83.3-100% (89.5%)
(D) Infusion—2% enilconazole + 1% bifonazole cream depot—nasal & sinus catheters—endoscopically placed26,*	25	60%	96%
(E) Flush & cream depot—1% clotrimazole—temporary trephination18,45,53	48	58-86% (68.7%)	86-100% (94.8 %)
Total dogs from all studies listed above	384	40-86% (60.2%)	83.3-100% (91.9%)

*Billen et al, unpublished data.

Adapted from Sharman MJ, Mansfield CS: Sinonasal aspergillosis in dogs: a review. *J Small Anim Pract* 53:434-444, 2012.

Antifungal Drugs

Antifungal drugs that are used for treating SNA belong to the azole group: the second-generation imidazoles (ketoconazole, clotrimazole, enilconazole) and the more potent third-generation triazoles (itraconazole, fluconazole).[35] Through interaction with the fungal cytochrome P450 system, their primary mechanism of action is blocking synthesis of ergosterol, a key component of fungal cytoplasmic membranes. Many azoles also interact with mammalian P450 isoenzymes responsible for side-effects (hepatotoxicosis, anorexia, vomiting) and some drug interactions.[36] Triazole drugs are more specific in targeting fungal cytochrome P450 with fewer side-effects.[37] Because of poor to moderate efficacy, need for long-term administration (2-3 months), side-effects and cost, oral systemic therapy is not recommended as single therapy for SNA.[12,18] The use of topical antifungal administration is the most widely used method of therapy.[18] However, systemic therapy may still be indicated as part of the treatment regimen in cases of extra-nasal extension of the disease.[38]

Topical Drug Choices

Topical therapy mainly includes use of enilconazole and clotrimazole because of their poor solubility (see Table 234-1). To avoid severe local side-effects, only polyethylene glycol-based clotrimazole solutions should be used for intranasal infusion.[39,40] Enilconazole has the advantage of being less toxic, less irritating, and is active in the vapor phase over a distance of up to 1 cm.[24,41]

Debridement and Infusion Therapy

Various procedures have been developed to administer antifungal agents topically. The recommended mode of administration uses meticulous debridement of sinonasal cavities (see Video 234-1) followed by 1-hour infusion of 1% clotrimazole or 1-2% enilconazole through blindly placed catheters into each nasal cavity or through an endoscopically placed catheter into the nasal cavity and affected sinus.[28,42,43] This procedure has the advantage of being noninvasive and has now replaced the older technique necessitating implantation of the infusion catheters into the sinus and nasal cavities via temporary sinus trephination (see Table 234-1).[43,44]

Temporary Trephination and Infusion (+Debridement)

As topical infusion techniques require long-lasting anesthesia (mean: 2 h), a shorter but more invasive technique requiring temporary trephination of the frontal sinuses has been developed. This method consists of a 5 minute 1% clotrimazole flush followed by a depot of 1% clotrimazole cream (10-20 g) in the frontal sinuses (see Table 234-1).[45] Viscosity of the cream provides greater retention time in the frontal sinus than the solutions used during infusion procedures, thereby increasing drug contact time with fungal elements despite a shorter anesthesic. The average duration of anesthesia is reported to be reduced to 30 minutes. Another method combines endoscopic debridement, 1-hour 2% enilconazole infusion and the depot of 1% bifonazole cream in the affected frontal sinus through an endoscopically placed catheter (see Table 234-1).[27]

Infusion Complications

Leakage of antifungal drugs at the level of the trephination holes or around the infusion catheters is common and usually without adverse effect.[28,38] Perforation of the cribriform plate, in contrast, could allow leakage of antifungal solutions into the cerebral cavity, inducing meningoencephalitis and cortical signs that can include seizures, altered mental status, or even death. Infusions have been administered to a few dogs with a damaged cribriform plate without complication.[28,30,31,38,43] Development of mucosal blebs and/or scar tissue formation after enilconazole infusion has been reported but does not appear to have clinical relevance apart from occasional obstruction of the nasal-frontal opening.[12,28] Rarely, a nasal tumor has developed after intranasal enilconazole or clotrimazole infusion/depot.[12,46,47]

Treatment Response

Assessing response to treatment remains difficult because if clinical signs disappear 1-2 weeks after therapy, this is not predictive of long-term cure.[30,43,48] Serial serum *Aspergillus*-specific antibody titers cannot be used to assess response to treatment because they tend to decline quite slowly. Positive results may persist for several years in dogs that remain free of disease.[49] Assessment of the response to therapy with CT has not been evaluated, but the "cavernous" nasal cavity and hyperostosis of surrounding bone will persist. Thus, it seems unlikely that repeating CT after treatment will be able to differentiate cure from persistent disease. The only way to correctly assess therapeutic efficacy is endoscopic reexamination of the sinonasal cavities within 1 month after treatment. The sinuses must be reexamined either by nasal passage of a flexible endoscope via the nasal-frontal opening or observation through the previously placed trephine hole.[28,30,50] Absence of any fungal colony within the sinonasal cavities is in favor of cure (Video 234-2).

Treatment success rates of most studies reporting topical therapy are summarized in Table 234-1.[18,27,28,30,43,45,48,50-53] Despite methods for determining "cure" not being standardized, interpretations can be made from such studies with large numbers of dogs. The mean overall first treatment success rate is 60% (40 to 86%). Multiple treatments are usually required (most often 2) to definitively resolve the infection. The mean global treatment efficacy is 92% (83 to 100%). Treatment success seems to be associated with a younger age.[18] Chronicity of clinical signs, bilateral disease and adjunctive oral systemic antifungal therapy are reported to be associated with first treatment failure, but worse disease at time of diagnosis might account for this observation.[18] In some cases with only focal disease and very mild turbinate destruction, access to the infected part of the sinonasal cavity may be difficult, resulting in insufficient debridement and poor outcome.[31]

Reasons for treatment failure are likely to be multifactorial. The ability to effectively debride fungal plaques is probably a major factor contributing to treatment efficacy.[18,31] As high concentrations of antifungal agents are achieved locally with topical treatments, antifungal resistance is unlikely to be clinically significant for canine SNA.[31]

Surgical Treatment

Several surgical techniques have been described. They consist of rhinotomy, extensive debridement, and then topical application of povidone-iodine 10% "paint," povidone-iodine impregnated dressings, or enilconazole 2% soak. All procedures result in favorable outcomes.[54,55] Surgery can be quite destructive and should be used only in dogs with fungal lesions that cannot be otherwise debrided, in patients with cribriform plate damage, or refractory cases. Care must be taken to cause as little damage as possible to nasal mucosa and turbinectomy should be avoided.[38] Finally, bone flap replacement after rhinotomy is not recommended.[55]

Long-Term Outcome

Long-term outcomes after "successful" topical therapy have been investigated in few studies. One study reported follow-up periods of 5 to 64 months in which episodic or permanent mild to moderate nasal discharge and/or sneezing was seen in 52% of dogs.[48] In another study, follow-up ranged from 1.5 to 108 months with only 11% of dogs remaining completely free of clinical signs, while the others showed occasional sneezing and/or nasal discharge. Extensive and irreversible turbinate destruction probably predisposes to chronic lymphoplasmacytic rhinosinusitis and/or secondary bacterial infections. Some dogs were indeed successfully treated with local glucocorticoids or antimicrobials, respectively.[18,48,50] Recurrence of SNA has

been noted 2 months to 4 years after successful treatment.[30,43,48,50,56] Because of the very short time between cure and diagnosis of the new infection in some cases, persistent fungal infection could have been missed during follow-up reexamination and reinfection cannot definitively be excluded.

Systemic Aspergillosis

Systemic or disseminated aspergillosis usually involves multiple organs (such as intervertebral discs, bones, lungs, kidneys, eyes, lymph nodes, brain, gastrointestinal tract) without history of nasal infection. *Aspergillus* spp. are thought to gain entry via the respiratory tract with subsequent hematogenous spread.[57,58] The disease is most often caused by *A. terreus* or *A. deflectus*, but other *Aspergillus* species have also been reported.[57,59-61] Systemic aspergillosis has been mostly reported in young to middle age German Shepherd Dogs in which dysfunction in the mucosal innate immunity is suspected. Immunosuppressive drugs or disease are usually not identified in affected dogs.[57]

The clinical signs associated with systemic aspergillosis are chronic, non-specific and related to organ involvement. Spinal pain ± paraparesis, bone pain, anorexia, weight loss, lethargy, muscle wasting, and fever are the most common signs. Lung and ocular involvement are also frequently reported.[57,58] Pulmonary cavitary lesions, without evidence of further dissemination, have been reported in German Shepherd Dogs with chronic cough and hemoptysis.[62,63]

Diagnostic imaging findings are nonspecific and vary greatly with organ involvement.[57,63] Culture of *Aspergillus* spp. from a suspected lesion (lymph node, lung, intervertebral disc) or fluid (urine, bronchoalveolar lavage) together with visualization of hyphae on cytological or histological examination are considered the gold standards for diagnosis of canine systemic aspergillosis.[57,64] Detection of galactomannan antigens is a promising diagnostic tool with sensitivity and specificity higher than 85% in serum or urine.[64]

The prognosis for recovery is poor despite aggressive antifungal therapy and supportive care. In a series of 30 cases, 17 dogs were euthanized within 1 week and 3 were discharged without treatment.[57] Amphotericin B, ketoconazole, itraconazole, fluconazole, or voriconazole have all been reported but comparisons of their efficacy have not been reported. In some dogs, lifelong azole therapy is required.[58] Surgical excision of fungal granulomas may be helpful, if feasible.[63]

CHAPTER 235

Aspergillosis—Feline

Vanessa R. Barrs

Client Information Sheet: Aspergillosis—Feline

Upper Respiratory Tract Aspergillosis (URTA)

Aspergillosis can be divided into invasive and non-invasive syndromes based on histopathological evidence of tissue penetration and invasion by fungal hyphae.[1] In cats there are two forms of URTA: sino-nasal aspergillosis (SNA) and sino-orbital aspergillosis (SOA). SNA is typically non-invasive and characterized by superficial mucosal fungal plaques[2-4] whereas SOA, which comprises two-thirds of all reported cases of URTA, is invasive.[5] Feline URTA occurs worldwide, with cases reported in Australia,[5-11] the United States,[2-4,12-17] the United Kingdom,[9,18] mainland Europe[4,11,19-21] and Japan.[22,23]

Etiology

Aspergillus species found in soil cause feline URTA (Table 235-1).[5,9-11,22-24] The majority are from two species complexes in section *Fumigati:* the *A. fumigatus* complex and the *A. viridinutans* complex (Figure 235-1). Cryptic species within these complexes, so-called because they are indistinguishable from each other and from *A. fumigatus* sensu stricto using standard morphological features, are associated with invasive disease and have high levels of innate antifungal resistance compared to *A. fumigatus.* Molecular techniques are required for their definitive identification. Two cryptic species in the *Aspergillus viridinutans* complex, *A. felis* and *A. udagawae,* are the most frequent isolates in SOA. The two most common causes of SNA, *A. fumigatus* and *A. niger,* have not been associated with SOA, at least not where definitive molecular identification of the pathogen has been performed (see Table 235-1).[5,9,14,16,20,21]

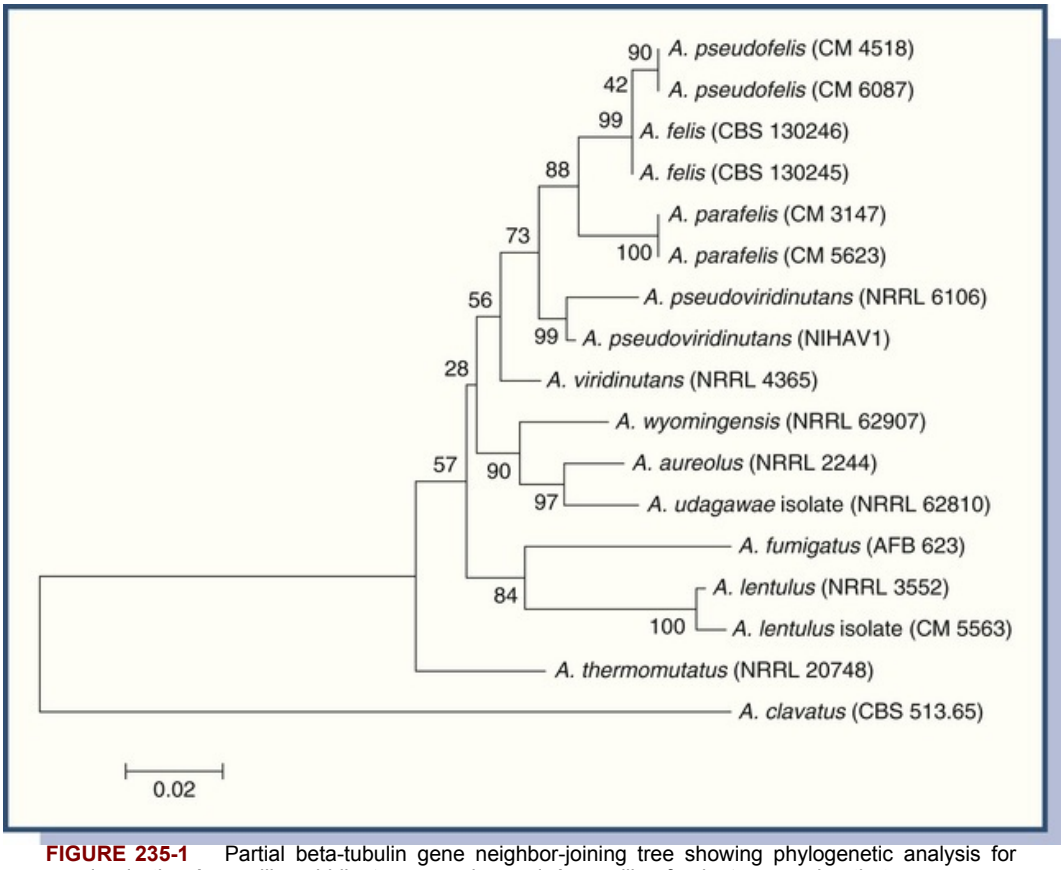

FIGURE 235-1 Partial beta-tubulin gene neighbor-joining tree showing phylogenetic analysis for species in the *Aspergillus viridinutans* complex and *Aspergillus fumigatus* complex that cause upper respiratory tract aspergillosis in cats. Drawn to scale with branch lengths expressed in units of the number of changes over the whole nucleotide sequence. (From Barrs VR, Beatty JA: Upper respiratory tract aspergillosis. In August JR, editor: *Consultations in feline internal medicine,* vol 6, St Louis, 2010, Saunders, pp 36-52.)

Pathogenesis

The nasal cavity is the portal of entry for *Aspergillus* conidia in both forms of URTA. Colonization of sinonasal mucosa occurs when immune defenses are inadequate. The route of extension to involve the orbit in SOA is via direct naso-orbital communication following bone lysis.[5,10,20,21] The propensity for cryptic species to cause invasive disease may be due, in part, to fungal virulence factors. *A. felis* is more virulent than *A. fumigatus* in bioassays using mice or *Galleria mellonella* larvae.[25] Most cats with URTA do not have identifiable systemic immunodeficiency and test negative for feline immunodeficiency virus (FIV) and feline leukemia virus (FeLV), although diabetes mellitus, a risk factor for aspergillosis in humans, has been reported in several affected cats.[2,7,26] Brachycephalic pure-breed cats of Persian lineage including Persians, Himalayans, Exotic Shorthair, British Shorthair, Scottish Shorthair and Ragdolls are overrepresented and account for over a third of all cases.[11] The basis for this predisposition for URTA is unknown. An immunogenetic disorder is possible, but has not been investigated. Brachycephalic skull conformation may also be a risk factor for fungal

colonization from impaired mucociliary clearance and mucosal edema with turbulent air-flow.[4] A role has also been proposed for viral upper respiratory infection and recurrent antibiotic therapy.[4,5,18] Feline URTA occurs occasionally in association with local damage to the sino-nasal mucosal barrier from facial trauma, nasal neoplasia and nasal foreign bodies.[24]

Clinical Signs

Infection can occur at any age (reported range 1 to 15 years, median 6.5 years) and there is no sex predisposition. Clinical signs in SNA include sneezing, serous to mucopurulent nasal discharge (unilateral or bilateral), stertor and mandibular lymphadenopathy. Less common signs are epistaxis, fever and a discharging sinus or mass involving the nasal or frontal bones. Cats with SOA are usually presented for signs associated with an invasive unilateral orbital granuloma (Box 235-1, Figures 235-2 and 235-3). In severe, chronic infections, bilateral orbital involvement can occur.[5,6,20] Nasal signs are absent in 40% of SOA cases at presentation, although the medical history usually reveals signs in the preceding 6 months.[5] Orbital granulomas can invade paranasal soft tissues, extending ventrally into the oral cavity and into the brain (Figures 235-2 and 235-4). In advanced disease, blindness due to optic nerve or optic chiasm involvement[5,20] and neurological signs including seizures, head tilt, circling, ataxia, facial muscle fasciculation and hyperesthesia have been reported (see ch. 259).[5,14,21]

Box 235-1

Common Clinical Signs at Presentation in Sino-Orbital Aspergillosis

- Exophthalmos with dorsolateral deviation of the globe
- Conjunctival hyperemia
- Third eyelid prolapse
- Exposure keratitis
- Oral mass or ulcer in the pterygopalatine fossa
- Paranasal soft tissue swelling
- Mandibular lymphadenopathy

FIGURE 235-2 Unilateral exophthalmos with prolapse of the third eyelid (OD) in two cats with sino-orbital aspergillosis with **(A)** dorsolateral deviation of the globe; **(B)** conjunctival hyperemia and edema and severe corneal ulceration. (From Barrs VR, Beatty JA: Upper respiratory tract aspergillosis. In August JR, editor: *Consultations in feline internal medicine,* vol 6, St Louis, 2010, Saunders, pp 36-52.)

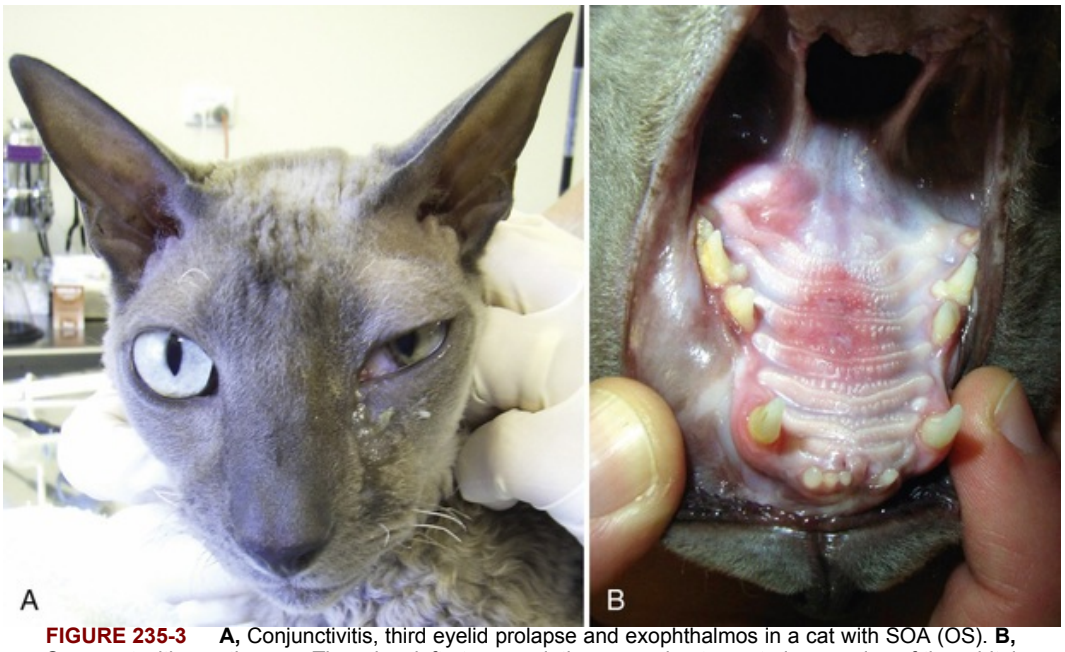

FIGURE 235-3 **A,** Conjunctivitis, third eyelid prolapse and exophthalmos in a cat with SOA (OS). **B,** Same cat with mouth open. There is a left pterygopalatine mass due to ventral expansion of the orbital mass, and ulceration of the hard palate. (From Barrs VR, Beatty JA: Upper respiratory tract aspergillosis. In August JR, editor: *Consultations in feline internal medicine,* vol 6, St Louis, 2010, Saunders, pp 36-52.)

FIGURE 235-4 Exophthalmos and third-eyelid prolapse (OD) and paranasal soft tissue swelling of the nasal bridge and maxillary soft tissues in a cat with sino-orbital aspergillosis. (From Barrs VR, Beatty JA: Upper respiratory tract aspergillosis. In August JR, editor: *Consultations in feline internal medicine,* vol 6, St Louis, 2010, Saunders, pp 36-52.)

Diagnosis

Differential diagnoses for SNA and SOA are listed in Box 235-2. Definitive diagnosis is based on detection of fungal hyphae on cytological or histological examination of tissue biopsies or sino-nasal fungal plaques. Fungal species identification should always be attempted.

Box 235-2

Differential Diagnoses of Nasal Signs in Cats with SNA or SOA and of Orbital Mass Lesions in Cats with SOA

Differential Diagnoses of Nasal Signs

Neoplasia (lymphoma, carcinomas, other)
Inflammatory (CRS, nasal polyps, NP polyp or stenosis)
Infectious
  Viral (FHV-1, FCV)
  Mycotic rhinitis (cryptococcosis, aspergillosis, sporotrichosis, phaeohyphomycoses, zygomycosis, other)
  Bacterial (*Bordetella, Mycoplasma, Chlamydia felis,* Actinomycetes)
Foreign body
Congenital (choanal atresia, palatine defects)
Dental disease (tooth root abscess, oronasal fistula)

Differential Diagnoses of Orbital Mass Lesions

Neoplasia (lymphoma, carcinomas, sarcomas, other)
Infectious
  Bacterial abscess/granuloma (odontogenic, penetrating bite wound, hematogenous)
  Mycotic granuloma (as for nasal signs)
  Pythiosis
Inflammatory

Hematological and serum biochemical changes are non-specific. Peripheral eosinophilia is uncommon. Mild to severe hyperglobulinemia was present in over half of cases of SOA in one study.[5] Detection of serum galactomannan, a fungal cell wall antigen, has low sensitivity and specificity for diagnosis, and is not recommended for routine testing.[27] Serological detection of anti-*Aspergillus* immunoglobulin G (IgG) by a customized enzyme-linked immunosorbent assay (ELISA) and a commercial agar gel double immunodiffusion assay (AGID) were evaluated in cats with URTA.[11] Diagnostically useful cross-reactivity of anti-*Aspergillus* IgG from cats with infections caused by *A. fumigatus* and cryptic species (including *A. felis* and *A. udagawae*), with a commercial antigen derived from fungal elements of *A. fumigatus, A. flavus* and *A. niger* was demonstrated using both assays. The sensitivity of the AGID was 43% and specificity was 100%. In contrast, the IgG ELISA had high sensitivity (95%) and specificity (92%) demonstrating that IgG detection by ELISA is a useful screening test for URTA in cats with clinical signs. Positive results should be corroborated with other diagnostic tests such as computed tomography/magnetic resonance imaging (CT/MRI) findings, rhinosinuscopy, cytology, histology and fungal culture.

CT findings in feline SNA are more variable than in canine SNA and mimic those of nasal neoplasia and chronic rhinosinusitis.[10,13] CT findings in SOA must be differentiated from invasive nasal neoplasia, and include nasal cavity involvement and an expansile ventromedial orbital mass with heterogeneous contrast enhancement (Figure 235-5). MRI is recommended for cats with concurrent central nervous system (CNS) signs. Orbital masses on MRI are T1- and T2-hyperintense and show heterogeneous contrast enhancement.[14,21,26] Rhinoliths or sinoliths are occasionally detected in SNA or SOA.[4,10]

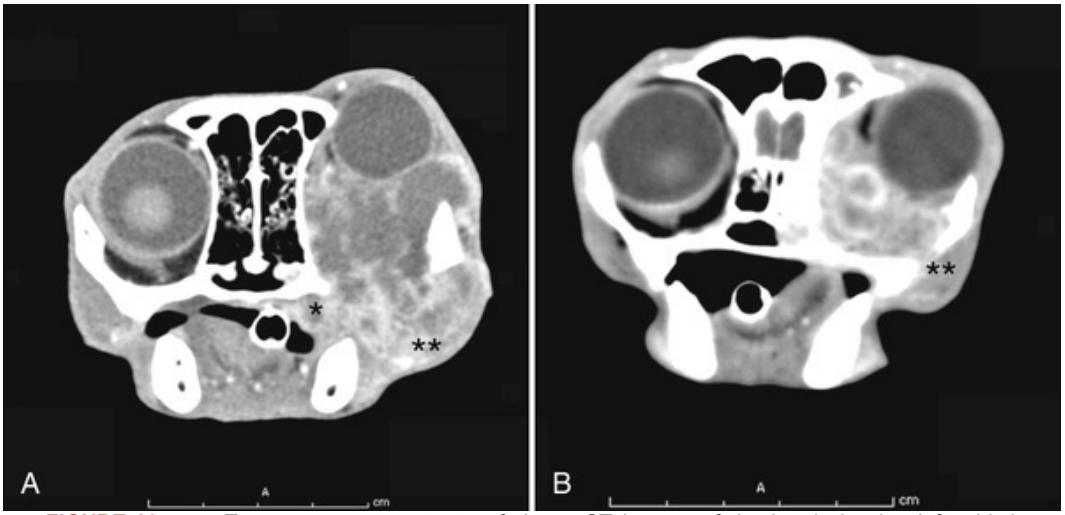

FIGURE 235-5 Transverse post-contrast soft-tissue CT images of the head showing left orbital masses in two cats with SOA and *A. felis* infection. There is heterogeneous contrast enhancement, with central coalescing hypoattenuating foci and peripheral rim enhancement. There is compression and dorsal displacement of the globe **(A** and **B),** and extension into the oral cavity **(A)** (asterisk), nasopharynx **(B),** and adjacent paranasal maxillary soft tissues (**A** and **B**) (double asterisks). (From Barrs VR, Beatty JA, Dhand NK, et al: Computed tomographic features of feline sino-nasal and sino-orbital aspergillosis. *Vet J* 201:215-222, 2014.)

Fungal plaques adherent to the nasal mucosa may be visualized on endoscopic examination in SNA[2] (Figure 235-6, *A*). In cats with invasive infections, mass lesions of variable appearance may be present within the nasal cavity, choanae or nasopharynx (Figure 235-6, *B*). Biopsies of orbital masses can be obtained with CT guidance or via the oral cavity where there is pterygopalatine invasion. Fungal pathogens can be readily cultured from tissue biopsies or fungal plaques using commercial culture media at 37° C.[5] Demonstration of growth at 50° C of a suspected *A. fumigatus* isolate with consistent morphology is adequate for identification since cryptic species are unable to grow at this temperature.[25,28] Antifungal susceptibility testing of isolates other than *A. fumigatus* is recommended.

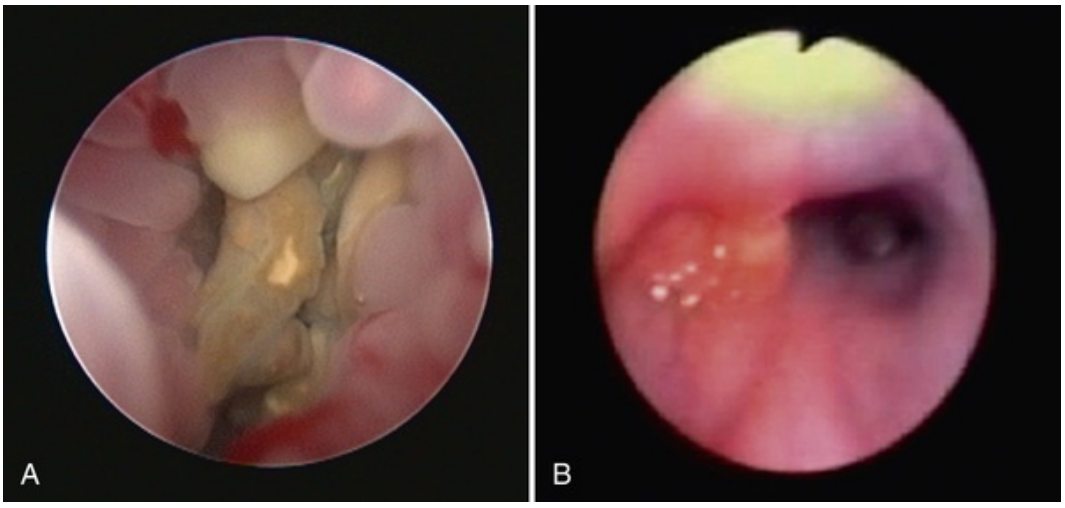

FIGURE 235-6 **A,** Rhinoscopic visualization of fungal plaques adherent to the nasal mucosa in a cat with sino-nasal aspergillosis caused by *A. fumigatus.* **B,** Choanal mass in a cat with SOA caused by *A. felis.* (**A,** Courtesy Dr. Elise Robertson, Feline VetReferrals, Brighton, UK.)

For molecular identification of cryptic species, fungal DNA is extracted from fungal culture material or, in culture negative cases, from frozen biopsies.[9,22] Comparative sequence analysis of the internal transcribed spacer (ITS) region of the ribosomal DNA gene complex (a multicopy gene common to all fungi), coupled with at least one additional gene region enables accurate identification to subgenus and species level, respectively.[25,29,30] Formalin-fixed paraffin-embedded tissues are less useful for polymerase chain reaction (PCR) due to low sensitivity of fungal DNA extraction.[31]

Histological changes in SNA include severe inflammatory rhinitis with lymphoplasmacytic or mixed-cell inflammatory infiltrates, necrosis, and mats of fungal hyphae on mucosal surfaces or in luminal exudates.[2-5] Cats with SOA have invasive granulomatous mycotic rhinitis[5,9] and orbital granulomas comprised of multifocal areas of coagulative necrosis with centralized fungal hyphae and peripheral zones of inflammatory cells.

Treatment

Non-invasive SNA due to *A. fumigatus* and *A. niger* is treated similarly to SNA in dogs (see ch. 234), although some cases have resolved with systemic triazole therapy alone.[3-5] Meticulous sino-nasal fungal plaque debridement and lavage is an important aspect of therapy and may require sinus trephination.[2-5] Intranasal 1% clotrimazole or 1-2% enilconazole solutions in polyethylene glycol were tolerated in cats where cribriform plate integrity was demonstrated.[2,5] Intranasal antifungal azole cream preparations used for treating canine SNA are not recommended in cats, because of the greater potential for airway obstruction from reluctance to mouth-breathe or brachycephalic conformation. Repeat debridement of fungal plaques and multiple intranasal azole infusions may be required to resolve infection. For cryptic species infections, or where *Aspergillus* species identity has not been confirmed, or where there is histological evidence of hyphal invasion of the sinus or nasal epithelium, additional treatment with oral itraconazole or posaconazole is recommended. Treatment should be continued until there is resolution of clinical, CT and endoscopic signs of active disease. The prognosis for feline SNA is favorable, although months of treatment may be required and only small numbers of treatment outcomes have been reported. Signs resolved in 11 of 14 cases where follow-up was available.[2-5,18]

Optimal treatment protocols for SOA have not been identified. *In vitro* resistance to azoles including itraconazole, posaconazole and voriconazole has been reported among some cryptic species isolates.[9,25,32] For susceptible isolates, based on treatment responses in individual cases, oral posaconazole or itraconazole given as monotherapy or combined with amphotericin-B or terbinafine is recommended.[5,14,16,23] Caspofungin was efficacious in one cat with SOA that failed treatment with amphotericin-B and posaconazole.[5] Anorexia and severe adverse neurological effects (hind limb paraplegia and blindness) can occur with oral voriconazole administration in cats[5,14,15] and further pharmacological studies are needed before its use can be recommended. Administration of systemic antifungals for 6 months or longer may be necessary and re-infection or relapse can occur. Surgical debridement of large granulomas by orbital exenteration has not been demonstrated to confer a treatment advantage over medical therapy alone. SOA carries a poor prognosis overall.

Disseminated Invasive Aspergillosis

Disseminated invasive aspergillosis (IA) is uncommon in cats.[33-37] Focal forms of IA affecting lung, gastrointestinal tract or urinary bladder have been described.[34,38-43] Molecular confirmation of *Aspergillus* species identified in disseminated IA has not been reported. There is no sex or breed predisposition. Disease has been most commonly reported in cats less than 2 years of age with systemic immunodeficiency from feline panleukopenia virus infection. Other cases have had concurrent FeLV infection or feline infectious peritonitis.

CHAPTER 236

Miscellaneous Fungal Infections

Amy M. Grooters

Infections caused by miscellaneous fungal organisms include sporotrichosis; candidiasis; pythiosis, lagenidiosis, and paralagenidiosis (caused by pseudofungal pathogens in the class Oomycetes); zygomycosis; and a myriad of opportunistic fungi that uncommonly cause disease in dogs and cats, more often affecting those being treated with immunosuppressant medications.

Sporotrichosis

Sporotrichosis is a chronic granulomatous disease of worldwide significance caused by dimorphic saprophytic fungi in the *Sporothrix schenckii* species complex. The organism lives as a mycelium in the soil or when cultured at room temperature, and as a yeast in tissues at body temperature. The mycelia are thin, finely branched, and septate. They produce clusters of conidia, which are the infective stage. The yeast form exists in infected tissue and is characterized as pleomorphic round, oval, or cigar-shaped cells that measure 2 by 3 microns to 3 by 10 microns (Figure 236-1).

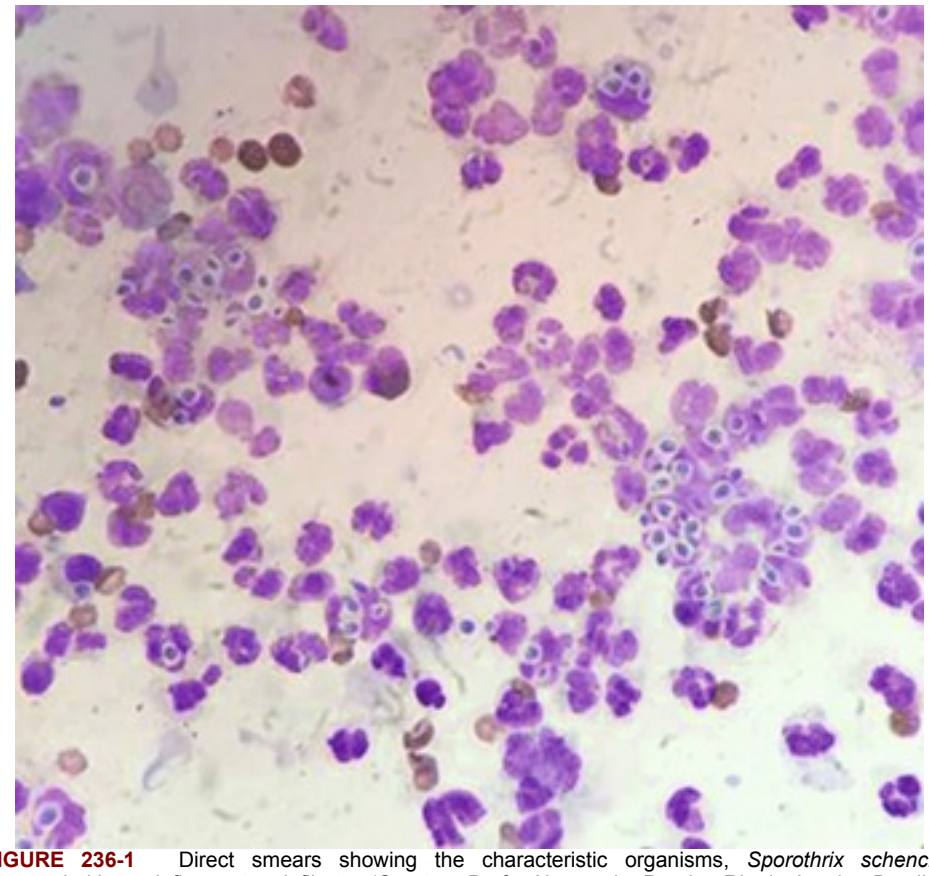

FIGURE 236-1 Direct smears showing the characteristic organisms, *Sporothrix schenckii,* surrounded by an inflammatory infiltrate. (Courtesy Profa. Alessandra Pereira, Rio de Janeiro, Brasil.)

The yeast morphology is fairly characteristic, and a diagnosis can usually be made from a cytologic

preparation. Both dogs and cats can be infected, but dogs are only rarely infected and typically have only cutaneous or subcutaneous disease. Cats are infected much more frequently and often have systemic dissemination.

Pathophysiology

Infection with *S. schenckii* in dogs and cats usually occurs after trauma that results in inoculation of infective conidia. Yeast from cutaneous lesions can be infective and are a potential source of zoonotic infection via contamination of wounds or via scratches or bites. The skin is the primary organ system affected. Traditionally it has been accepted that dissemination is via lymphatics from cutaneous sites and that this is common in cats and less common in dogs. However, an epidemic of *Sporothrix* infections in Rio de Janeiro, Brazil, studied between 1998 and 2012 allowed large numbers of cases to be evaluated and brought into question this traditionally accepted theory relative to infection and dissemination.[1-8] In a study that included 759 humans, 64 dogs, and 1503 cats with sporotrichosis, approximately 85% of dogs and humans were reported to have had contact with cats with sporotrichosis, with over half reporting cat bites or scratches.[1,3] People who were the care givers of infected cats were 4 times more likely to become infected than others in the same household. These observations support the importance of zoonotic transmission, especially in urban environments in which numbers of susceptible cats are high. In a separate study, 34% of 49 cats with sporotrichosis were fungemic, an observation that would appear to support a hematogenous role in dissemination.[4] Immune suppression has been reported to predispose to infection and increase the likelihood of dissemination. However, cats with feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) infection did not appear to be more likely to have disseminated disease in cases from Rio de Janeiro.

Sporotrichosis occurs in three primary forms: (1) cutaneous, (2) cutaneolymphatic, and (3) disseminated disease. In the dog, the infection is usually cutaneous or cutaneolymphatic. Disseminated disease is rare and usually follows immunosuppression with corticosteroids. All three forms appear to be common in the cat, with dissemination seen in more than 50% of feline cases. The nasal cavity and lungs are commonly affected, raising speculation that the respiratory tract may be an important site of entry, similar to other systemic mycoses. Cutaneous lesions in cats are characterized by large numbers of yeasts, making zoonotic transmission more likely from cats than from dogs.

Clinical Signs

Most affected cats are younger than 4 years of age, and males are affected approximately twice as often as females. Young hunting dogs may be predisposed. Multiple subcutaneous or dermal nodular lesions that occur most commonly on the head, neck, trunk, and distal limbs characterize the cutaneous form of the disease. The tail base may also be involved in cats. The nodules typically ulcerate, drain a purulent exudate, and crust over (Figure 236-2). They are often mistaken for bacterial bite wound abscesses or cellulitis. Lesions on the distal limbs commonly result in regional lymphadenitis, which is manifested as linear ulcerating lesions and regional lymphadenopathy. Lesions in cats may be associated with extensive areas of necrosis. Otitis externa has been reported.

FIGURE 236-2 **A,** Skin lesion of sporotrichosis, showing an alopecic, erythematous, moist, proliferative area of skin over this cat's elbow and triceps region. **B,** Nasal lesion of sporotrichosis, showing swelling and ulceration of the rostral aspect of the nose in a cat. (Courtesy Profa. Alessandra Pereira, Rio de Janeiro, Brasil.)

Dissemination may occur and be subclinical or may result in overt systemic disease. Cats with multiple lesions and those with evidence of systemic illness such as respiratory signs or weight loss are more likely to have dissemination. Nasal and oral cavities, lung, liver, lymph nodes, spleen, eyes, bones, muscles, and central nervous system (CNS) may all be affected.[1,6,7]

Diagnosis

Cytology from skin lesions is the most common means of diagnosis. Lesions from cats typically contain large numbers of organisms, making cytology and histopathology sensitive tools for diagnosis,[9] although there are exceptions.[10] In contrast, lesions from dogs usually contain very few organisms. The organisms may be seen intracellularly within macrophages or neutrophils or may be present extracellularly. Culture and molecular techniques can be used to make a definitive diagnosis.

Material for culture should include exudate from deep within a draining tract and tissue samples from biopsy specimens. Nasal and oral swabs may result in positive cultures in cats with systemic infection, especially if nasal signs are prominent. Blood cultures are also commonly positive in cats with disseminated disease. Cultured organisms pose a serious threat to persons working in the laboratory, so the laboratory should be notified whenever a sample is submitted from a dog or cat with suspected sporotrichosis. Histopathology reveals pyogranulomatous inflammation. Numerous organisms are commonly seen in lesions from cats, even when stained with hematoxylin and eosin (H&E). Fungal stains may aid in identifying the organisms.

Therapy

Historically, sporotrichosis was most often treated with potassium iodide, ketoconazole, or combinations of the two. Approximately 55% of treated cats in the literature responded to one or both of these drugs. Fluconazole may also be effective. Currently, however, itraconazole (10 mg/kg PO q 24 h) is the treatment of choice, and is especially valuable in cats because of the species' tendency to develop adverse effects when treated with potassium iodide or ketoconazole.[6,11] Therapy should be administered for at least 30 days beyond resolution of clinical signs, with a minimum of 4-6 months. Response to itraconazole in cutaneous and cutaneolymphatic cases is generally good. Based on observations from the epidemic in Rio de Janeiro, systemically affected animals may also respond well. Recurrence after discontinuation of treatment is not uncommon. Cryosurgery has been used successfully as adjunctive therapy in a small number of cats.[12]

Public Health Significance

Canine sporotrichosis appears to be of minimal zoonotic potential, but feline sporotrichosis is a significant zoonotic disease. Veterinarians and veterinary assistants are at the highest risk of infection, but owners who care for infected cats are likely at increased risk as well. Care should be taken to limit contact with exudate and lesions from infected cats. Gloves should always be worn when handling cats suspected of having sporotrichosis, and owners should be advised of the possibility of infection and the need for strict hygiene. After any contact, gloves should be removed carefully and disposed of, and hands, wrists, and arms should be washed thoroughly with either chlorhexidine or povidone-iodine scrub.

Candidiasis

Candida spp. are normal inhabitants of the GI, genitourinary, and upper respiratory systems. Overgrowth of these organisms may result from prolonged broad-spectrum antibiotic use, structural changes in local tissues (such as urethrostomy or urogenital neoplasia), or immunosuppression associated with corticosteroid therapy or systemic disorders such as diabetes mellitus or hyperadrenocorticism.[13,14] Animals with prolonged neutropenia are especially predisposed to infection. Common sites for *Candida* overgrowth include wounds, the oropharynx, the urinary tract, and the gastrointestinal (GI) tract. Infections may be localized, or dissemination may occur hematogenously, resulting in microabscesses at multiple sites.

Localized candidiasis is usually characterized as a non-healing ulcer covered by a whitish-gray plaque in

the oral cavity, ears, GI tract, or on the genitourinary mucosa. Chronic moist, exudative lesions may occur on the skin or at the nail beds. *Candida* urinary tract infections are most often diagnosed incidentally during the evaluation of patients with concurrent urinary or systemic disease (such as diabetes mellitus), and typically do not cause lower urinary tract signs unless accompanied by concurrent lower urinary tract disease.[14]

Treatment of localized candidiasis should include identification and correction of any identifiable predisposing factors, if possible, and this alone may allow spontaneous resolution of *Candida* infections in some cases.[14] Primary therapies for skin lesions include topical azoles and pH-modifying agents, combined with systemic itraconazole or fluconazole if lesions are severe (see ch. 162). For urinary tract infections, systemic fluconazole is likely the treatment of choice because it is mainly eliminated unchanged in the urine. In addition, intravesicular clotrimazole has been used successfully in a dog and a cat with urinary candidiasis, both of which were diabetic.[15,16] It should be noted that when underlying predisposing factors cannot be corrected, prolonged azole therapy may not clear *Candida* infections, and may result in azole resistance.[14] It should also be noted that some *Candida* species (such as *C. krusei* and *C. glabrata*) are likely to be inherently azole-resistant, so identification of organisms to species level and susceptibility testing may be important to guide therapy.

Disseminated candidiasis is typified by fever and the acute appearance of multiple raised erythematous skin lesions in dogs. Pain is often caused by myositis and osteomyelitis, and other signs are referable to the systems affected. Cats are less likely to have multiple skin lesions. The complete blood count (CBC) in systemically affected animals is often characterized by leukopenia and thrombocytopenia. Renal involvement is common, and yeast may be found in the urine, especially in cats. Itraconazole and amphotericin B lipid complex are considered the treatments of choice, but few reports of successful treatment are available.

Pythiosis

Pythiosis is a devastating and often fatal cause of chronic GI or cutaneous disease in dogs and cats. It is caused by *Pythium insidiosum,* an aquatic pathogen in the class Oomycetes in the Kingdom Stramenopila (Chromista). Oomycetes differ from true fungi in that ergosterol is not a principal sterol in the oomycete cell membrane. In the United States, pythiosis is encountered most often in the Gulf Coast states, but has been recognized in animals living as far north as New Jersey, Virginia, Kentucky, Wisconsin, and southern Illinois/Indiana, and as far west as Arizona, California, Oklahoma, and Kansas. Globally, pythiosis is most often encountered in Southeast Asia, eastern coastal Australia, and South America. Pythiosis, lagenidiosis, paralagenidiosis, and zygomycosis often are difficult to distinguish from one another because they share similar clinical and histologic features, including pyogranulomatous and eosinophilic inflammation associated with broad, poorly septate hyphae. However, differentiating among them is clinically important because prognosis and response to therapy differ.

Pathophysiology

The infective form of *P. insidiosum* is thought to be the motile biflagellate zoospore, which is released into aquatic environments and likely causes infection by encysting in damaged skin or GI mucosa. Many dogs with pythiosis have a history of recurrent exposure to warm freshwater habitats. However, some cases are observed in suburban housedogs with no history of access to lakes or ponds. Affected animals are typically immunocompetent and otherwise healthy.

Clinical Findings

In dogs, pythiosis most often affects young, large-breed dogs and is especially common in outdoor working breeds such as Labrador Retrievers. Infected dogs are presented to the veterinarian more often in the fall, winter, and early spring than in the summer months. Pythiosis is uncommon in cats; when it does occur, animals less than a year of age are often affected.

Cutaneous pythiosis in dogs typically causes non-healing wounds and invasive masses that contain ulcerated nodules and draining tracts, most often involving the extremities, tail head, ventral neck, or perineum.[17,18] Cats with pythiosis may have nasopharyngeal lesions, invasive subcutaneous masses in the inguinal, tail head, or periorbital regions, or they may have draining nodular lesions or ulcerated plaque-like lesions on the extremities, sometimes centered on the digits or footpad.[18,19]

GI pythiosis in dogs is characterized by severe segmental transmural thickening of the stomach, small

intestine, colon, rectum, or (rarely) the esophagus or pharyngeal region (Figure 236-3).[17,20] Mesenteric lymphadenopathy is common and is occasionally observed without accompanying GI tract lesions. The gastric outflow area, duodenum, and ileocolic junction are the most frequently affected portions of the GI tract. Involvement of the mesenteric root may cause severe enlargement of mesenteric lymph nodes, which are often embedded in a single, large, firm granulomatous mass in the mid-abdomen. Extension of disease into mesenteric vessels may result in bowel ischemia, infarction, perforation, or acute hemoabdomen. Focal intestinal lesions caused by pythiosis were described in two cats that were both treated successfully with surgical resection.[21]

FIGURE 236-3 Cross-section of a segmental colonic lesion resected from a 3-year-old female Doberman with gastrointestinal (GI) pythiosis. The reader should note the thickening of the submucosa and narrowing of the colonic lumen.

Clinical signs associated with GI pythiosis include weight loss, vomiting, diarrhea, and hematochezia. Physical examination often reveals a thin body condition and palpable abdominal mass. Signs of systemic illness are not typically present unless intestinal obstruction, infarction, or perforation occurs. Laboratory abnormalities that may be associated with pythiosis include eosinophilia, anemia, and hyperglobulinemia. In dogs with GI pythiosis, abdominal radiographs usually reveal an abdominal mass, thickened segment of the GI tract, or partial bowel obstruction. Ultrasonography typically demonstrates severe segmental thickening of the GI tract and mesenteric lymphadenopathy.

Diagnosis

Histologically, pythiosis is characterized by eosinophilic pyogranulomatous inflammation. Although *P. insidiosum* hyphae are difficult to visualize on H&E-stained sections, they are easily identified in sections stained with Gomori methenamine silver (GMS) as broad (mean, 4 microns; range, 2 to 7 microns), rarely

septate, occasionally branching structures. Because inflammation in GI pythiosis centers on the submucosal and muscular layers rather than mucosa and lamina propria, the diagnosis may be missed on endoscopic biopsies that fail to reach deeper tissues. Therefore, pythiosis should be considered when endoscopic biopsies reveal eosinophilic or pyogranulomatous inflammation without identification of a causative agent.

Isolation of *P. insidiosum* from infected tissues is not difficult when appropriate sample handling and culture techniques are used. For best results, unrefrigerated tissue samples should be wrapped in a saline-moistened gauze sponge and shipped at ambient temperature to arrive within 24 hours at a laboratory with experience culturing oomycetes. Identification of *P. insidiosum* should be based on morphologic features; growth at 37° C; production of motile, reniform, biflagellate zoospores; and specific polymerase chain reaction (PCR) amplification or ribosomal RNA gene sequencing. Although the production of zoospores is an important supporting feature for the identification of pathogenic oomycetes, it is not specific for *P. insidiosum.*

An enzyme-linked immunosorbent assay (ELISA) for the detection of anti–*P. insidiosum* antibodies in dogs and cats has been found to be highly sensitive and specific for the diagnosis of pythiosis.[22] In addition to providing a means for early, noninvasive diagnosis, this assay also appears to be useful for monitoring response to therapy. Immunohistochemical techniques have previously been used to confirm the diagnosis of pythiosis. However, the specificity of these antibodies has not always been well established.

Therapy

Aggressive surgical resection is the treatment of choice for pythiosis. When cutaneous lesions are limited to a single distal extremity and there is no regional lymphadenopathy, amputation is recommended. In animals with GI pythiosis, segmental lesions should be resected with 5-cm margins if possible. Because enlarged mesenteric lymph nodes are usually reactive rather than infected, they should be biopsied but do not need to be resected. Unfortunately, many dogs with GI pythiosis are not presented until late in the course of disease, when complete excision is not possible. Local postoperative recurrence of pythiosis is common, especially when wide surgical margins could not be obtained, and can occur either at the site of resection or in regional lymph nodes. For this reason, medical therapy with a combination of itraconazole (10 mg/kg PO q 24 h) and terbinafine (5 to 10 mg/kg PO q 24 h) is recommended when the surgeon is not confident that a minimum 5-cm margin was achieved. To monitor for recurrence, ELISA serology should be performed prior to and 2 to 3 months after surgery. In animals that have had a complete surgical resection and go on to have no recurrence of disease, serum antibody levels usually drop 50% or more within 3 months of surgery,[22] allowing medical therapy to be discontinued.

In general, pythiosis does not respond well to medical therapy, likely because ergosterol (the target for most currently available antifungal drugs) is generally lacking in the oomycete cell membrane. Despite this fact, clinical and serologic cures occur in some patients treated with a combination of itraconazole (10 mg/kg PO q 24 h) and terbinafine (10 mg/kg PO q 24 h). Dogs with non-resectable GI pythiosis are often treated with anti-inflammatory dosages of corticosteroids in an effort to palliate clinical signs and to decrease vomiting so that oral antifungal medication can be administered. Prednisone (1 mg/kg PO q 24 h) routinely causes improvement in clinical signs in the short term. Surprisingly, the author has observed complete and long-term resolution of GI lesions in a small number of dogs treated with prednisone alone. Although this is certainly not recommended as a primary treatment for animals with resectable lesions, it is a reasonable option in animals with non-resectable GI lesions, especially when financial concerns preclude the use of antifungal medication.

Lagenidiosis and Paralagenidiosis

Like *Pythium insidiosum,* species in the genera *Lagenidium* and *Paralagenidium* are members of the class Oomycetes, with most described as parasites of algae, fungi, nematodes, crustaceans, and insect larvae. The best-studied species, *Lagenidium giganteum,* is a mosquito larval pathogen previously approved for use as a biocontrol agent for mosquito populations. In the late 1990s, two novel oomycete pathogens that appeared to be members of the genus *Lagenidium* were recognized in dogs as causes of cutaneous lesions that resemble those associated with pythiosis. More recently, multigene phylogenetic analyses have allowed formal names to be published for these pathogens.[23] The first pathogen, which causes severe and often fatal progressive cutaneous disease, lymphadenopathy, pulmonary nodules, and great vessel invasion,[24] has been formally described as *Lagenidium giganteum* forma *caninum* because of its close phylogenetic relationship with *Lagenidium giganteum.* The second pathogen causes more slowly progressive disease that is limited to skin and subcutaneous tissues. Although it shares many antigenic and morphologic similarities with *L. giganteum* f.

caninum and other *Lagenidium* species, recent phylogenetic analyses support placement of the second novel pathogen in the new genus *Paralagenidium,* with the species name *Paralagenidium karlingii.*[23]

Clinical Findings

The epidemiologic and clinicopathologic features of lagenidiosis and paralagenidiosis are similar in many respects to those previously associated with cutaneous pythiosis. Infected animals are typically young to middle-aged dogs living in the southeastern United States. Although most have been from Florida or Louisiana, cases have been identified as far west as Texas and as far north as Maryland and southern Indiana. Many infected dogs have had frequent exposure to lakes or ponds.

Dogs with lagenidiosis are typically presented for progressive solitary or multifocal cutaneous or subcutaneous lesions involving the extremities, mammary region, perineum, or trunk.[24] Grossly, these lesions appear as firm dermal or subcutaneous nodules or as ulcerated, thickened areas with areas of necrosis and numerous draining tracts (Figure 236-4). Similar to the clinical course associated with cutaneous pythiosis, skin lesions in dogs with lagenidiosis tend to be progressive, locally invasive, and poorly responsive to medical therapy. Regional lymphadenopathy is often present and may occur in the absence of obvious cutaneous lesions. Unlike dogs with cutaneous pythiosis, these dogs typically have occult lesions in the thorax or abdomen, including involvement of the great vessels, sublumbar and/or inguinal lymph nodes, lung, pulmonary hilus, and cranial mediastinum. Animals with great vessel or sublumbar lymph node involvement typically have cutaneous or subcutaneous lesions on the hind limbs and often develop hind limb edema (see ch. 18). Sudden death caused by great vessel rupture and associated hemoabdomen may occur in these patients.

FIGURE 236-4 Ulcerative dermatitis caused by *Lagenidium giganteum* forma *caninum* infection in a 2-year-old female Border Collie presented for progressive skin lesions and generalized lymphadenopathy. This dog had similar lesions on all four limbs. Note the large eschar distal to the ulcerative lesion.

In dogs with paralagenidiosis, skin lesions are characterized by solitary or multifocal dermal nodules or thickening (sometimes without alopecia) or an ulcerative dermatopathy that may become extensive but rarely invades beyond cutaneous and subcutaneous tissues. Lesions in the chest, abdomen, and regional lymph nodes have not been identified, and the clinical course appears to be chronic and slowly progressive, with some patients having lesions that expand slowly or are somewhat stable for years.

Diagnosis

The histologic features of lagenidiosis and paralagenidiosis are similar to those associated with pythiosis and zygomycosis and are characterized by pyogranulomatous and eosinophilic inflammation associated with broad, irregularly branching, sparsely septate hyphae. In contrast to *P. insidiosum, Lagenidium giganteum* f. *caninum* and *Paralagenidium karlingii* hyphae are often visible on H&E-stained sections, and may be surrounded by a thin eosinophilic sleeve. On GMS-stained sections, numerous broad, thick-walled, irregularly septate hyphae are easily recognized. *Lagenidium giganteum* f. *caninum* hyphae typically demonstrate a great deal of variability in size but in general are much larger than *P. insidiosum,* ranging from 7 to 25 microns in diameter, with an average of 12 microns. *Paralagenidium karlingii* hyphae are closer in size to *P. insidiosum,* with a mean diameter of 7.5 microns.

An ELISA for quantitation of anti–*L. giganteum* f. *caninum* antibodies has recently been described as a sensitive but non-specific serologic test for the identification of *L. giganteum* f. *caninum*–infected, and to a

lesser degree, *Paralagenidium karlingii*–infected dogs.[25] Because of extensive cross-reactivity with anti–*P. insidiosum* and anti–*Paralagenidium karlingii* antibodies, positive ELISA results are often observed in dogs with pythiosis or paralagenidiosis in addition to those with lagenidiosis. In addition, some dogs with non-fungal dermatopathies have also had false positive results. Because of these limitations, definitive diagnosis of *Lagenidium giganteum* f. *caninum* and *Paralagenidium karlingii* infections should be based on culture followed by ribosomal RNA gene sequencing.

Treatment

Aggressive surgical resection of infected tissues is the treatment of choice for both lagenidiosis and paralagenidiosis. In animals with lesions limited to a single distal extremity, amputation is recommended. Because dogs with lagenidiosis often have occult systemic lesions, radiographic imaging of the chest and abdomen and sonographic imaging of the abdomen is recommended to determine the extent of disease prior to attempting surgical resection of cutaneous lesions. Unfortunately, many of these patients have non-resectable disease in regional lymph nodes or distant sites by the time the initial diagnosis is made. Because response to medical therapy is poor, dogs with lagenidiosis typically have a grave prognosis.

In contrast, for dogs with paralagenidiosis, surgery that achieves 3- to 5-cm margins is often curative. Although medical therapy for paralagenidiosis is usually ineffective, a combination of itraconazole (10 mg/kg PO q 24 h) and terbinafine (10 mg/kg PO q 24 h) along with repeated aggressive surgical resection was effective in resolving *Paralagenidium karlingii* infection in one dog with recurrent multifocal cutaneous lesions.

Zygomycosis

The term *zygomycosis* refers to infections caused by fungi in the class Zygomycetes, including the genera *Basidiobolus* and *Conidiobolus* in the order Entomophthorales, and the genera *Rhizopus, Absidia, Mucor, Saksenaea,* and others in the order Mucorales. Although infections caused by the Mucorales have not been well documented in small animals, the Entomophthorales typically cause chronic localized infections characterized by pyogranulomatous and eosinophilic inflammation in subcutaneous tissue, upper respiratory tract, or retrobulbar space. As *Basidiobolus* and *Conidiobolus* species are saprophytes found in soil and decaying organic matter, cutaneous infection likely occurs by direct implantation of spores via minor trauma or insect bites. Infection may also result from inhalation or ingestion of spores. Affected animals are typically immunocompetent, but pneumonia caused by *Conidiobolus* spp. has been reported in a single canine patient receiving immunosuppressive therapy.[26]

Clinical Findings

In mammals, conidiobolomycosis occurs most often as a nasopharyngeal infection with or without local dissemination into tissues of the face, retropharyngeal region, or retrobulbar region. Clinical manifestations may include nasal or facial swelling or deformity, nasal discharge, ulceration of the nasal planum or hard palate, exophthalmos, chemosis, ocular discharge, and sometimes skin lesions.[27] *Conidiobolus* infection has also been described in a single dog as a cause of multifocal nodular draining subcutaneous lesions and regional lymphadenopathy[28] and as a cause of pneumonia in a dog that was receiving chemotherapy.[26]

Basidiobolomycosis is a rare cause of ulcerative draining skin lesions in dogs and has also been reported in a single case as a cause of respiratory disease.[29] Disseminated *Basidiobolus* spp. infection involving the GI tract and other abdominal organs has also been described.[30]

In cats, confirmed cases of zygomycosis are rare, limited to single reports of cats infected with fungi in the order *Mucorales. Rhizomucor* was associated with duodenal perforation in a 7-month-old cat,[31] and *Cokeromyces recurvatus* was isolated from peritoneal fluid in a 16-year-old cat following jejunal perforation caused by lymphoma.[32] In addition, a subcutaneous mass caused by *Mucor* infection on the dorsum of the nose of a 14-year-old cat was treated successfully with posaconazole.[33]

Diagnosis

The histologic features of zygomycosis are similar to those associated with pythiosis, lagenidiosis, and paralagenidiosis. On GMS-stained sections, hyphae appear broad, thin-walled, and occasionally septate. The histologic hallmark of entomophthoromycosis is the presence of a wide eosinophilic sleeve surrounding the

hyphae. In general, hyphal diameter tends to be significantly larger for *Basidiobolus* spp. (mean, 9 microns; range, 5 to 20 microns) and *Conidiobolus* spp. (mean, 8 microns; range, 5 to 13 microns) than for *P. insidiosum* (mean, 4 microns; range, 2 to 7 microns).

The diagnosis of zygomycosis is based on isolation of the pathogen from infected tissues. Identification of zygomycetes in the laboratory is based on morphologic characteristics of asexual reproductive structures (conidia) and sexual reproductive structures (zygospores).

Treatment

Attempted therapy has only been described in a few patients with confirmed zygomycosis. Although anecdotal information and a small number of cases in the literature suggest that cutaneous entomophthoromycosis may be less aggressive than pythiosis or lagenidiosis, progression of cutaneous lesions and sometimes even dissemination despite treatment have also been described. Perhaps the most appropriate current recommendation for the treatment of entomophthoromycosis is aggressive surgical resection of infected tissues whenever possible, followed by itraconazole therapy for a minimum of 3 months. If resection is not possible, therapy with itraconazole, posaconazole, or amphotericin B lipid complex should be recommended. For nasopharyngeal conidiobolomycosis, the author's current recommendation is to treat with itraconazole (10 mg/kg PO q 24 h) for at least 6-12 months (see ch. 162). Because recurrence is common after discontinuation of medical therapy, a prolonged course of antifungal medication is essential.

Opportunistic Fungal Infections

Opportunistic fungi are those with low inherent virulence that most often cause infection only when normal host barriers or resistance mechanisms are compromised. They comprise a large number of genera and species with names that are often unfamiliar to veterinary clinicians, and traditionally have caused disease only sporadically. Over the past 10 years, the frequency with which opportunistic fungal infections are encountered in small animal patients has increased substantially with the use of multi-agent immunosuppressive therapy (especially with cyclosporine) to treat immune-mediated disease in dogs (see ch. 165).

Unlike the more easily recognized endemic fungal pathogens (for which a diagnosis can usually be made by visualizing unique morphologic features in cytologic or histologic samples), opportunistic fungi can only be identified to genus and species level by culture or molecular methods. However, they can be assigned to categories based on their morphologic features in tissue, such as pigmentation, hyphal diameter, organism distribution, and frequency of septation. These categories include **phaeohyphomycosis** (pigmented hyphal or yeast forms), **hyalohyphomycosis** (non-pigmented hyphal forms), and **eumycotic mycetoma** (fibrosing granuloma with black or white tissue grains comprised of aggregates of pigmented or non-pigmented fungi, respectively).

Although definitive identification of a pathogen based on culture is ideal, categorization of opportunistic mycoses is often adequate for choosing initial therapies and predicting clinical course and prognosis. It should be noted that many opportunistic fungi are common contaminants found on skin, nasal mucosa, and other non-sterile sites. Therefore, culture or PCR-based identification of a potential opportunistic fungus from a skin sample, nasal swab, or exudate should not be considered evidence of fungal infection unless there is supportive histologic or cytologic evidence of tissue invasion by a morphologically compatible organism.

Phaeohyphomycosis

The term *phaeohyphomycosis* refers to cutaneous, subcutaneous, cerebral, or disseminated infections caused by pigmented (dematiaceous) fungi that contain melanin in their cell walls. Infection usually results from traumatic implantation. Fungal genera that have been identified as agents of phaeohyphomycosis in veterinary patients include *Alternaria, Bipolaris, Cladophialophora, Curvularia, Exophiala, Fonsecaea, Moniliella,* and *Phialophora,* among others. The most common clinical presentations in immunocompetent small animals are cutaneous distal extremity, nasal, and pinnal lesions in cats.[34-40] The most common presentation in immunocompromised small animals is multifocal cutaneous lesions in dogs being treated with multi-agent immunosuppressive therapy.[41-43] In general, patients are presented with cutaneous nodules or a visible nasal mass. Infected tissues may appear grossly pigmented. Histologically, fungi that cause phaeohyphomycosis appear as dark-walled, irregularly septate hyphae or as yeast-like cells. The presence of melanin in the walls of lightly pigmented hyphae can be confirmed by the examination of unstained sections, by lowering the

microscope condenser during examination, or by utilization of a Fontana-Masson stain for melanin.

Lesions associated with phaeohyphomycosis tend to be locally invasive. Dissemination is not common in immunocompetent patients, but does occur in patients receiving immunosuppressive therapy. Because pigmented fungi are often poorly responsive to medical therapy, aggressive surgical resection is the treatment of choice for phaeohyphomycosis when lesions are solitary. It is important to obtain wide margins at the time of the initial surgery because post-operative recurrence is common. Digit amputation is usually indicated for lesions involving the distal phalanx. Although phaeohyphomycosis has traditionally been difficult to treat medically (in part because melanin is a virulence factor), in this author's experience, cutaneous phaeohyphomycosis that occurs in dogs receiving immunosuppressive therapy can be resolved in many cases with itraconazole (10 mg/kg PO q 24 h; see ch. 162) administered for at least 6 months if the immunosuppressive therapy can be tapered quickly (see ch. 165). Discontinuation of cyclosporine in these patients appears to be essential for achieving a good outcome. In cats with non-resectable phaeohyphomycosis, long-term therapy is essential. Recurrence of lesions after discontinuing medical therapy is very common. This author most often treats these patients with itraconazole or posaconazole administered for 12 months or longer.

Hyalohyphomycosis

The term *hyalohyphomycosis* refers to infections caused by fungi that are non-pigmented (hyaline) in tissue. Genera that have been described as agents of hyalohyphomycosis in veterinary patients include *Fusarium, Acremonium, Paecilomyces, Pseudallescheria, Sagenomella, Phialosimplex,* and *Scedosporium,* among others. By convention, infections caused by *Aspergillus* and *Penicillium* species are not included in the term *hyalohyphomycosis* because aspergillosis and penicilliosis can usually be identified as such based on their clinicopathologic features.

In general, hyalohyphomycosis is less frequently encountered in small animal patients than is phaeohyphomycosis. Dogs are much more often infected than cats, with affected animals presented with lesions ranging from local disease confined to the skin, nasal mucosa, or cornea, to disseminated disease.[44-50] Traditionally, the disseminated form has been most common. Therefore, animals that present with cutaneous lesions and no overt signs of systemic disease should still be evaluated for occult lesions in the chest and abdomen. However, in this author's experience, immunosuppressed patients that develop cutaneous hyalohyphomycosis may not have lesions at other sites, whereas immunocompetent patients that develop hyalohyphomycosis most often do have disseminated disease, or at least disease that is not confined to the skin.

Treatment of hyalohyphomycosis has traditionally been unrewarding because most patients have had disseminated disease. However, hyalohyphomycosis that develops while an animal is receiving immunosuppressive therapy seems to respond better to medical therapy (assuming that immunosuppressive therapy can be quickly tapered) than would have been expected based on previous experience with hyalohyphomycosis in immunocompetent patients, especially if the detectable lesions are confined to the skin. The prognosis should still be considered guarded, and aggressive antifungal therapy should be pursued. For treatment of hyalohyphomycosis, this author most often uses itraconazole (10 mg/kg PO q 24 h) administered for at least 6-12 months. Other options include amphotericin B lipid complex, voriconazole, or posaconazole (see ch. 162). Unfortunately, recurrence of clinical signs often occurs during the course of initial treatment.

Mycetoma

The term *mycetoma* refers to localized mycotic or actinomycotic infections characterized by the presence of colonies or aggregates of organisms that form "grains" in tissue. Eumycotic mycetomas are caused by soil fungi, with lesions developing from traumatic implantation of organisms into tissue. Tissue grains associated with eumycotic mycetomas are characteristically pigmented (black grain mycetoma) or hyaline (white grain mycetoma), depending on the type of fungal organism involved.

Black grain mycetomas are often caused by *Curvularia* species, and are typically manifested as chronic non-healing wounds or cutaneous nodules that develop on the extremities weeks to months after a traumatic incident. Draining tracts are common, and black grains may be present in the exudate. White grain mycetomas, usually caused by *Pseudallescheria boydii* or *Acremonium* species, typically occur as body wall and/or intra-abdominal granulomas that develop subsequent to contamination following surgical wound contamination or dehiscence. Lesions may not be evident until months or even a year or more after the

surgical event. Affected animals may be presented with a draining mass on the body wall, or may develop clinical signs of peritonitis. The treatment of choice for eumycotic mycetoma is aggressive surgical excision of infected tissues, including amputation if clinically indicated. Response to medical therapy is routinely poor. Dissemination of eumycotic mycetoma beyond local tissues is rare, but local extension of disease within the abdomen may be extensive.

Otitis Externa

Introduction

Otitis is considered to be one of the most frequent causes of consultations in small animal practice. Although often considered part of dermatology, it should instead be emphasized that otitis is often a consequence of an underlying disease, and the investigation and management of ear disease should therefore be viewed by the veterinarian as needing a full diagnostic approach.[1]

Definitions

Otitis is "any inflammation of the ear canal," whatever the cause or clinical presentation. Depending on the history and clinical signs observed, it is useful to differentiate some entities depending on the time of onset of clinical signs, the rate of relapse, and/or the clinical presentation, because the clinical approach and therapy will vary.[1] Specifically, *erythematous otitis* is characterized by inflammation of the ear canal without secretion (Figure 237-1): *erythemato-ceruminous otitis* involves inflammation of the ear canal and presence of an abundant ceruminous exudate (Figure 237-2); *suppurative otitis* is marked by erosions in the ear canal and presence of pus (Figure 237-3); and *stenotic otitis* is characterized by hyperplastic changes of the ear canal (Figure 237-4 and Box 237-1). It is also useful to differentiate, depending on the depth of the inflammatory phenomenon, between otitis externa (OE), otitis media (OM) and otitis interna (OI). OE is an inflammatory condition affecting the external auditory canal, from the pinna up to the tympanic membrane. OE is very common in dogs and cats, with a reported incidence of 5-12% of consultations in dogs and up to 2% of cats referred to a dermatologist.[2,3] OM is present as soon there is inflammation within the middle ear. Both canine and feline OM often are secondary to an accompanying OE. In dogs, cases of primary OM are very rare (e.g., "glue ear syndrome" of Cavalier King Charles Spaniels) but in the cat, primary OM is recognized regularly. The reported prevalence of OM varies from low to high; the latter may be especially true in cases of chronic or recurrent OE.[4] OI is defined as an inflammation within the inner ear. OI generally results from an extension of OM. Clinical signs are principally neurologic, identical to those of peripheral vestibular disease (see ch. 265).[5]

Box 237-1

Various Clinical Presentations of OE in Dogs and Cats

- Acute—clinical signs present for <7 days
- Subacute—clinical signs present for >7 but <30 days
- Chronic—clinical signs present for >30 days
- Recurrent or relapsing—episodes cured after proper treatment but reappearing on a regular basis
- Erythematous—the only clinical sign noted is inflammation of the auditory canal (this is mainly seen in

acute cases); typically associated with pruritus and/or head shaking

- Erythemato-ceruminous—the inflammation is associated with the presence of excessive cerumen, which may occlude the ear canal; pruritus is variable but usually present
- Suppurative—the secretions are variable, but usually the discharge is liquid and malodorous; pruritus may be seen but these cases tend to be more painful than pruritic; head shaking is frequent
- Stenotic—with these cases, the hyperplastic changes of the ear canal eventually lead to occlusion of the external parts of the auditory tube; this is often present in chronic disease

Pathogenesis

Otitis should usually not be considered as just a local phenomenon but rather as one manifestation of an underlying disease[6,7] because it nearly always has a multifactorial etiology. *Predisposing factors* are responsible for an alteration of the microclimate of the ear canal, increasing the likelihood of otitis (Box 237-2). *Primary factors* are responsible for the inflammation, and therefore are able to directly cause otitis. *Perpetuating factors* are responsible for chronicity. All these factors need to be properly identified and corrected in order to successfully manage patients with recurrent otitis. Typically, the pathogenesis involves inflammation of the auditory canal (erythematous phase) initially; this phenomenon is usually very acute and in most cases is not noticed by the owner except if pain and/or pruritus is/are severe (e.g., foreign body in the ear). This first phase is followed by hyperplasia of the epithelium and the ceruminous glands, resulting in excess cerumen production (ceruminous phase). OE also can impair the housekeeping mechanism that results in a movement of cerumen up and out of the ear canal, further contributing to the accumulation of discharge within the auditory canal.[8] These anatomic and inflammatory modifications allow the change in the environment that is favorable to the growth of, and infection with, commensal microorganisms such as *Malassezia* spp. and *Staphylococcus* spp. These microbial components contribute to further inflammation and perpetuate the vicious circle. For more chronic cases, extensive epidermal hyperplasia develops and can reduce the diameter of the ear canal, as apocrine glands become hyperplastic and dilated.[8] Sometimes, ulceration of the epithelium occurs, especially in cases of secondary bacterial infection with Gram-negative bacteria. A dense dermal inflammatory infiltrate occurs, followed by fibroplasia that further exacerbates canal obstruction.[9] Ossification of the cartilages and skin may occur in longstanding cases. When the tympanum is ruptured, the microbial infection can involve the tympanic bulla and OM develops. This further contributes to clinical signs and is a factor in recurrence of disease following apparently successful therapy.

Box 237-2

Predisposing, Primary and Perpetuating Factors of OE in Dogs and Cats

Predisposing Factors

- Conformation of the ear
- Humidity
- Inappropriate cleaning
- Irritant treatments
- Excessive hair growth in auditory canals

Primary Factors

- Ectoparasites
- Allergic dermatitis
- Keratinization disorders
- Pyoderma
- Autoimmune dermatosis
- Foreign bodies
- Tumors

Secondary and Perpetuating Factors

- Yeasts
- Bacteria
- Epidermal and sebaceous hyperplasia
- Ulcerations
- Otitis media

Clinical Scoring of Otitis in Dogs

A recent study described a clinical score (Otitis Index Score [OTIS]) that was demonstrated to be clinically relevant, with good inter- and intraobserver reliability, sensitivity to change, and ability to distinguish affected ears from healthy ears or ears in remission.[10] This score evaluates four different clinical parameters (erythema, edema/swelling, erosion/ulceration and exudate) both in the horizontal and the vertical canal on a scale of 0 to 3. We recommend its use on a regular basis to better evaluate ear disease and the objective improvement obtained after therapy. The evaluation of pain is not yet codified in otitis and further studies are needed.

Diagnosis and Treatment of Acute Otitis Externa[11]

Clinical presentation includes a fairly rapid onset of head shaking and ear scratching, sometimes accompanied by malodor and erythema of the ear canal. These findings should prompt the clinician to undertake a rigorous diagnostic plan instead of just prescribing a topical medication.

History and Examination

A brief history should be taken to help establish possible contributory factors to the episode; early identification of predisposing and primary factors can help to prevent chronicity (Boxes 237-2 and 237-3). A general physical and dermatologic examination should be performed, which should include examination of the ventral and skin fold areas including the feet and the anal area for signs of erythema that would orient the clinician towards a diagnosis of atopic dermatitis. This is followed by an examination of the pinnae and external ear canals.

Box 237-3

History Taking in Chronic Otitis Externa

- Age of onset
  - Young animals are predisposed to ectoparasites, notably *Otodectes cynotis*
  - Adult animals are prone to allergic otitis externa
  - Old animals are predisposed to tumors or autoimmune dermatoses
- Development of signs and seasonality
  - An acute episode of unilateral otitis should prompt a search for a foreign body
  - Recurrent, bilateral OE occurring every spring should suggest allergic otitis
  - A gradually-developing unilateral OE is more suggestive of a neoplastic process
- Evidence of contagion is often (but not always) noted in case of ear mite infestation
- The environment should be studied to evaluate for the presence of foreign bodies, excessive humidity (swimming dogs), and aeroallergens. Free-roaming animals are prone to otoacariasis.
- Feline retroviral status should be assessed, as chronic OE is often linked to FeLV/FIV infection in cats; in this species, one should also remember that herpesvirus infection may trigger facial dermatitis with OE, or a generalized erythema multiforme with frequent ear involvement.
- Prior therapies should also be noted. OE is sometimes linked to trauma induced by poor cleaning technique by the owner (use of cotton buds) or by the use of inappropriate treatment (e.g., alcohol, ether). Allergic reactions to neomycin or glucocorticoids may also occur.

Cerumen Examination

Direct examination of the cerumen should be planned each time a parasitic cause is suspected, because otoacariasis (ear mite infestation) is still a frequent presentation, especially in young dogs.[2] Mites usually are easily demonstrated using the low-magnification objective (×4) of the microscope. The use of a curette instead of a cotton swab is better suited for this examination.

Cytologic Examination

Cytologic examination should be performed in all cases of OE. This allows the clinician to record which microorganisms, if any, are present and will help the clinician decide which therapy is more appropriate and best targeted. Cytologic evaluation also is helpful on follow-up consultation for assessment of the efficacy of treatment and progression of the disease over time. A cytologic evaluation is easy to perform: a cotton swab is inserted into the vertical ear canal to collect material, and usually the best place to sample is at the junction of the vertical and horizontal canals. The swab is then rolled onto a glass slide, which is air-dried and stained with a modified Romanowsky-type stain such as Diff-Quik, Rapi-Diff or RAL (see ch. 87). There are many cytologic presentations in acute OE. Typically, in acute OE associated with underlying atopic dermatitis, there can be increased numbers of squamous epithelial cells but no evidence of microbial infection. In acute OE associated with infection, there may be *Malassezia* yeast overgrowth (Figure 237-5) or numerous cocci (usually *Staphylococcus pseudintermedius*). Cocci appear as round, often grouped, bacteria, whereas rods are elongated. It is unusual to see rod infections in acute OE.

FIGURE 237-5 *Malassezia* yeasts on cytological examination (×1000).

Otoscopic Examination

An otoscopic examination is indicated in every case of otitis (see ch. 85). Both ears, even with unilateral complaints, need to be examined. The unaffected ear is examined first if the problem appears to be unilateral. This is aimed at avoiding the transfer of infection from one ear to the other. Every effort not to cause the animal further discomfort must be made and therefore the practice of inserting a cold, hard otoscope cone into a painful inflamed ear is to be discouraged. Sedation and analgesia should be used anytime the procedure is likely to result in any significant discomfort (see ch. 138).

Otoscopic examination should assess the presence of foreign bodies, the presence of *Otodectes cynotis* (

Video 237-1), the presence and nature of any discharge, the patency of the ear canal and the degree of stenosis, the appearance of the ear canal lining and the presence of ulceration, the appearance of the tympanic membrane, and the presence of neoplasms or polyps (Figure 237-6).

FIGURE 237-6 Polyps in the external ear canal.

Treatment

Treatment for acute OE is aimed at cleaning, resolution of specific primary causes, relief of inflammation, and elimination of any microbial infection.

Cleaning

Ear cleaning is important because it facilitates examination of the ear canal, removes material that can harbor microorganisms and inactivate topical medications (in particular the biofilm), and removes small foreign bodies, toxins, and damaged/degenerated cells.[5,12] Manual cleaning is appropriate in most cases of acute OE, provided this does not result in pain. Owners need to be carefully instructed on the use of topical therapy with a practical demonstration (see Client Information Sheet at ExpertConsult.com). Following application of the ear cleaner, the ear canals should be massaged for 30-60 seconds. Any discharge should be wiped away from the external ear canal using a gauze swab or cotton wool but the practice of inserting cotton buds into the vertical canal should be discouraged as this merely results in impaction of material within the canals. Manual ear cleaning will not remove tightly adherent or material deep within the ear canal and consideration should be given to ear flushing under general anesthesia if there is a significant accumulation of discharge (see below, and see ch. 85). There is a wide variety of topical ear cleaners available with varying actions including ceruminolytics and surfactants that dissolve and soften cerumen, astringents that have a drying effect within the ear canal, and antimicrobial agents. Some ingredients are contraindicated in the presence of a ruptured tympanic membrane.

Topical Antimicrobial and Anti-Inflammatory Therapy

Reflecting the complex etiology of OE, proprietary topical therapies typically contain a combination of an antifungal, antibacterial, and glucocorticoid, and some also have an antiparasitic effect. The clinician should be familiar with the various active ingredients. The selection of a topical antimicrobial should be based on the results of cytological examination. The animal should be reexamined at least weekly and treatment continued until there is both clinical and cytologic resolution of disease (typically longer than generally stipulated on the

label of most ear products).

Systemic Therapy

Systemic therapy is not usually needed in acute cases of OE except for those rare cases where pain prevents the application of topical therapies. For these rare cases, the judicious use of systemic glucocorticoid therapy for 2 to 3 days to resolve inflammation and pruritus prior to the application of topical therapy can greatly facilitate ease of application for the owner.

Diagnosis and Treatment of Chronic Otitis Externa[11]

Uncontrolled, chronic OE is responsible for the development of irreversible lesions (OM, microbial resistance, ear canal stenosis and calcification). As a consequence, these cases require an in-depth investigation and consideration should be given to referral to a veterinary dermatologist.

Chronic Erythemato-Ceruminous Otitis Externa (CECOE)

Clinical presentation includes erythema, ceruminous discharge, pruritus, malodor, and variable degrees of stenosis of the external ear canal. Discharge in these cases is generally creamy yellow to dark brown and is visibly ceruminous rather than purulent. The most common primary cause of CECOE is underlying atopic dermatitis, but other primary diseases include adverse food reactions, otodectic and demodectic otitis, primary keratinization defects, endocrinopathies, and neoplasia.[7]

History

A thorough history can give vital clues regarding the underlying etiology. For example, a first presentation of gradual-onset, unilateral OE in an older animal should greatly raise the index of suspicion for neoplasia, whereas atopic dermatitis would be suspected in a young dog with recurrent OE along with facial and pedal pruritus.

Examination

Before inspecting the ears, a full physical and dermatologic examination should be performed. The clinician should check for evidence of pain on opening the mouth, referable to the ear canals. The pinnae and external ear canals are then examined closely and the ear canals should be palpated for evidence of calcification. Otoscopic examination follows (see ch. 85). Swabs are then taken from both ears for cytologic examination (see ch. 87).

Bacterial Culture and Sensitivity Testing

Samples for bacterial culture and sensitivity testing usually are not needed in cases of CECOE because discrepancies exist between *in vivo* and *in vitro* data, and because the high drug concentrations achieved with topical therapy normally can overcome apparent *in vitro* resistance.

Imaging

Imaging is useful for those chronic cases where severe ear canal stenosis is present, because evidence of marked calcification and/or OM would be expected to respond poorly to medical management and be an indication for surgical intervention.[5,12] Radiography, positive contrast ear canalography, computed tomography (CT) and/or magnetic resonance imaging (MRI) generally are indicated, the latter two techniques being more sensitive for the detection of fluid within the tympanic bulla.[13,14] Impedance audiometry and brainstem auditory evoked response (BAER) may also be useful techniques in the future.

Treatment of Chronic Otitis Externa

Every effort should be made to return the environment within the ear canal to normality. Cleaning the ears to remove discharge, debris, and microorganisms is therefore as much mandatory as the use of topical and/or systemic antimicrobials to treat infection. The use of topical and/or systemic glucocorticoid therapy to relieve inflammation, swelling, stenosis and reduce glandular secretions and hyperplasia also is mandatory.

Cleaning

Manual ear cleaning (see acute OE) rarely is helpful in chronic cases and, therefore, retrograde ear flushing under general anesthesia is indicated whenever there is discharge present in the horizontal and proximal

vertical canals. If stenosis of the external ear canal precludes thorough cleaning and examination, prednisolone 0.5-2 mg/kg PO q 24 h or methylprednisolone 0.4-1.6 mg/kg PO q 24 h for a period of 1-3 weeks should be considered before cleaning. Failure of the ear canals to dilate with glucocorticoid therapy would indicate a guarded prognosis for medical management.

The use of a video-otoscope greatly facilitates retrograde ear cleaning (see ch. 85). Animals undergoing treatment for CECOE should be reexamined on a weekly basis, and if further accumulation of cerumen within the ear canal is observed, flushing procedures need to be repeated until it is clear than manual ear cleaning alone is effective in keeping the ear canals clean.

Antimicrobial Therapy

Antibacterial therapy should be selected on the basis of cytologic evaluation and culture if available.[5] The use of fluoroquinolones to treat Gram-positive infections should be discouraged. Nystatin, miconazole, clotrimazole and the azoles are effective against *Malassezia* spp. Systemic antibiotic therapy should be considered only if there are secondary changes present within the ear canal such as swelling, stenosis or ulceration or in cases involving OM (see suppurative OE, below).

Glucocorticoid Therapy

Glucocorticoids are extremely useful in the treatment of CECOE because they reduce swelling, inflammation and glandular secretion, resolve ear canal stenosis prior to ear flushing, counteract the pro-inflammatory effects of deep ear cleaning, and relieve pruritus.

Further Investigation

As already discussed, CECOE usually is a manifestation of a generalized dermatosis and the diagnosis and treatment of the associated skin disease is the key to prevention of further episodes of otitis. This may include a diet trial to rule out adverse food reactions and intradermal or immunoglobulin E (IgE) serologic testing to identify causative allergens (see ch. 186), histopathologic examination, complete blood count, serum biochemistry profile, urinalysis, and endocrine work-up.

Long-Term Management of CECOE

Antimicrobial therapy should be continued until cytologic resolution of infection. However, it is worth appreciating that the ear canals can take many months to return to complete normality.[12] The topical administration of glucocorticoids on a "pulse" regimen (e.g., twice a week) is very useful to achieve this goal.

Suppurative Otitis Externa (SOE)[11]

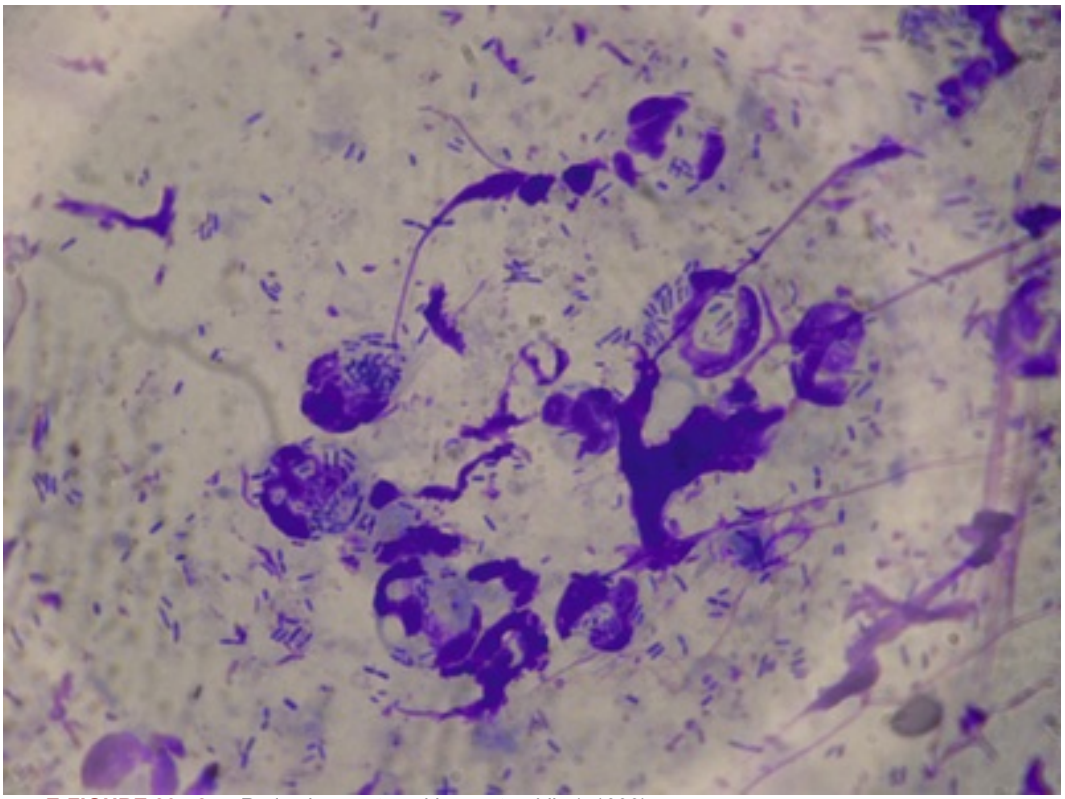
Clinical presentation includes the presence of a malodorous, often liquid, discharge, the color of which varies depending on the type of bacteria involved (from dark grey to greenish yellow, the latter often being seen with *Pseudomonas aeruginosa*). Purulent otitis frequently is accompanied by ear canal erosions or ulcerations (Figure 237-7). Pain often is acute, and pruritus minimal, which may help to differentiate this condition from CECOE.

FIGURE 237-7 Suppurative otitis with many ulcers.

Diagnosis

Definitive diagnosis requires microscopic examination of the exudate, with the presence of large numbers of neutrophils and sometimes macrophages confirming the suppurative nature of the otitis. Most commonly, cocci or rods are seen, but in rare cases of SOE, yeasts (e.g., *Malassezia* sp.) may be seen. The clinician should search for phagocytosis of bacteria specifically, which is diagnostic for active infection.

The work-up of SOE is similar to CECOE (see above). In cases of SOE involving rods (E-Figure 237-8), if OM is suspected, a bacterial culture is indicated to rapidly identify the presence of *Pseudomonas aeruginosa,* which has an unpredictable pattern of antibacterial sensitivity and can present a real therapeutic challenge.[4] Referral should be discussed at the outset with the owner, as diagnosis of OM is not straightforward. Recognition of OM is important because pus in the tympanic bulla can be the source of chronic and/or relapsing OE. Pro-inflammatory toxins and debris may constantly be released from this area.[5] Additionally, treatment will vary depending on whether or not there is infection in the middle ear, as topical antibiotics do not penetrate well into the tympanic bullae. In cases of suspected OM, samples should be obtained from the tympanic bulla(e) for cytologic evaluation and bacterial culture and sensitivity testing. It is necessary to perform myringotomy in order to aspirate material from the tympanic bulla (see ch. 85). Various complementary aids are available to diagnose OM: classic otoscopy may be helpful if the tympanic membrane is visualized and ruptured, but video-otoscopy is much more sensitive (E-Figure 237-9) (see ch. 85). In OM, the tympanic membrane appears either ruptured (small tear or total destruction) or abnormal (inflamed, bulging, grey, not translucent). Radiography and other imaging techniques can be useful for the diagnosis of OM (see CECOE, above).



E-FIGURE 237-8 Rods phagocytosed by neutrophils (×1000).

E-FIGURE 237-9 Cleaning with the help of a video-otoscope allows visualization of the tympanum.

Treatment

Treatment of SOE should focus on killing the bacteria (usually needing antimicrobial therapy), elimination of

the inflammatory process (usually needing glucocorticoid therapy) and proper cleaning of the ear to eliminate the biofilm (usually needing repeated and thorough ear flushing). It is also mandatory to diagnose and control any underlying disease process to minimize the risk of recurrence.

For those cases without involvement of the tympanic bullae, topical treatments are effective, and for these cases the use of systemic agents is debatable as the condition is mainly localized to the ear canal. Systemic therapy is indicated only for treatment of OM, for reasons already discussed.

Antibacterial agents are indicated in the overwhelming majority of cases of suppurative OE/OM. Selection depends on the type of bacteria demonstrated cytologically. *Pseudomonas aeruginosa* is a special case because it is inherently resistant to many antibacterials. Various molecules are available but fluoroquinolones are usually the first choice treatment for *Pseudomonas* otitis. These are concentration-dependent antibiotics; therefore, it is best to use high dosages, such as 10-20 mg/kg PO q 24 h for enrofloxacin and 4-8 mg/kg PO q 24 h for marbofloxacin. Unfortunately, a recent meta-analysis of treatments available for *Pseudomonas* otitis concluded that currently, there is insufficient evidence for or against recommending the use of any treatment for *Pseudomonas* otitis in dogs, due to the paucity of trials, which moreover lack randomization.[15]

Glucocorticoid therapy may be required to control the inflammatory component of OE/OM. Glucocorticoids are a component of the majority of commercial topical preparations and may also be administered systemically. The use of orally administered glucocorticoids can be highly beneficial where there is severe inflammation and exudation, as these medications help restore a normal ear epithelium, decrease the pain, the pruritus and the ear canal hyperplasia. However, they may be detrimental if inflammation is not an important part of the clinical signs and/or if ulcers are present.

Ear cleaning is another essential step for the adequate treatment of SOE, as pus and inflammatory debris inhibit penetration of topical therapies and can inactivate some medications. The initial flushing should be done under general anesthesia (see CECOE, above, and ch. 85). Cleaning agents selected should be non-irritant, especially in case of ulceration, and non-ototoxic, especially in case of a ruptured tympanum. An aqueous solution is best suitable for SOE. Manual ear cleaning should be continued by the owner at home; otherwise, secretions will rapidly reaccumulate.

Follow-Up

The first recheck visit should take place after a few days to ensure good compliance. A decision should be made on whether to continue or withdraw systemic glucocorticoids. Usually, follow-up visits then are done every 2 to 3 weeks (but may be considered weekly in severe cases) to monitor clinical improvement and to perform a complete examination of the ear canal including the tympanic membrane. Cytologic examination of smears should be repeated at each visit and antimicrobial therapy should continue until clinical and cytologic resolution. It may be necessary to reassess therapy if response is unsatisfactory.

Surgery

Surgery is not the treatment for chronic OE/OM by itself. Clinical outcome may first depend on the efficacy of nonsurgical treatment to eliminate the underlying cause of the otitis that must be clearly identified and appropriately treated medically. Two main procedures are usually indicated as part of the treatment for chronic otitis: lateral wall resection of the vertical ear canal, and the total ear canal ablation associated with a lateral bulla osteotomy (TECALBO).

Lateral Wall Resection of the Vertical Ear Canal

Lateral wall resection of the vertical ear canal is indicated when tissue changes related to OE are limited to the vertical ear canal. The skin that covers the lateral part of the external ear canal is resected and symmetrical incisions are made in the auricular cartilage down to the junction with the annular cartilage of the horizontal ear canal to create a lateral cartilage flap, the distal part of which is removed. The proximal part of the cartilage flap is usually reflected ventrally that creates a draining surface still covered by the aural epithelium, and gives access to the entrance of the horizontal canal (Figure 237-10). Lateral wall resection can improve ear canal drainage, increase airflow within the remaining vertical canal and provide better access for potential topical local treatments both on the horizontal canal and the remaining medial part of vertical one. The prognosis for lateral wall resection largely depends on whether the disease was only located to the vertical canal, with the horizontal one being unaffected and the dermatologic problems of the pinna under control. Thus, indications for lateral wall resection of the vertical ear canal remain limited. Even though the surgical procedure is not very demanding technically, despite a few critical surgical points, the rate of failure for lateral wall resection is 40-55%, mainly because it does not respond properly to the indications; in most of the

cases, such a limited surgical procedure is not aggressive enough to eliminate chronic deep infection. In breeds with ear canal abnormalities such as stenosis, excessive hair growth, or extensive thickening of the ear canal epithelium, lateral wall resection usually is unsuccessful. For example, in Cocker Spaniels that usually do not obtain resolution of OE by medical treatment, lateral wall resection has been reported to fail in almost 90% of dogs with OE/OM.[16] A recommendation for TECALBO may be considered earlier in the course of the disease to avoid further progression and complications.

FIGURE 237-10 Immediate postoperative image after lateral wall resection of the vertical ear canal.

Complications of lateral wall resection are mainly local, with prolonged postoperative pain and wound dehiscence or drainage. Wound dehiscence may heal by second intention with appropriate wound care.

If the procedure improves exposure of the ear canal and visualization of masses, the remaining vertical and horizontal parts of the canal can be responsible for persistent chronic infections, and most of the time, lateral wall resection fails to treat chronic end-stage OE/OM.

Total Ear Canal Ablation and Lateral Bulla Osteotomy

TECALBO usually is the treatment of choice for chronic end-stage inflammatory non-neoplastic ear disease such as chronic OE/OM.[17] The long-term success rate for the treatment of chronic otitis is now established around 90%.[18] Although TECALBO is performed by many surgeons and is quite a straightforward procedure, it is not an easy surgery, given the risk for iatrogenic damage of nearby structures and the limited surgical exposure. The surgery by itself has to be sufficiently thorough to ensure the complete elimination of all infected tissues, while sparing important neurovascular structures.

A comprehensive description of the surgical anatomy of the ear canal and bulla has been published.[19] In most cases of end-stage chronic otitis, the thickened but brittle lining epithelium from the ear canal usually is in continuity with the epithelium from the bulla as the tympanic membrane has usually been destroyed by the infectious process (Figure 237-11; Video 237-2). Video-otoscopy with a dedicated endoscope (usually a 30° arthroscope) can be used perioperatively to check the complete elimination of the epithelium from the tympanic cavity (see Videos 237-2 and 237-3). In cases of bilateral disease, it is usually recommended that surgical treatment be staggered, but bilateral single-stage TECALBO can be performed without any additional risk for complications. TECALBO also is indicated in cats, but the incidence of neurologic

complications (facial nerve deficit, Horner's syndrome) is much higher compared to dogs. A ventral approach, while commonly used in cats to treat middle ear inflammatory polyps, is not adequate for the surgical approach to otitis as it does not allow complete removal of the infected tissues from the ear canal.

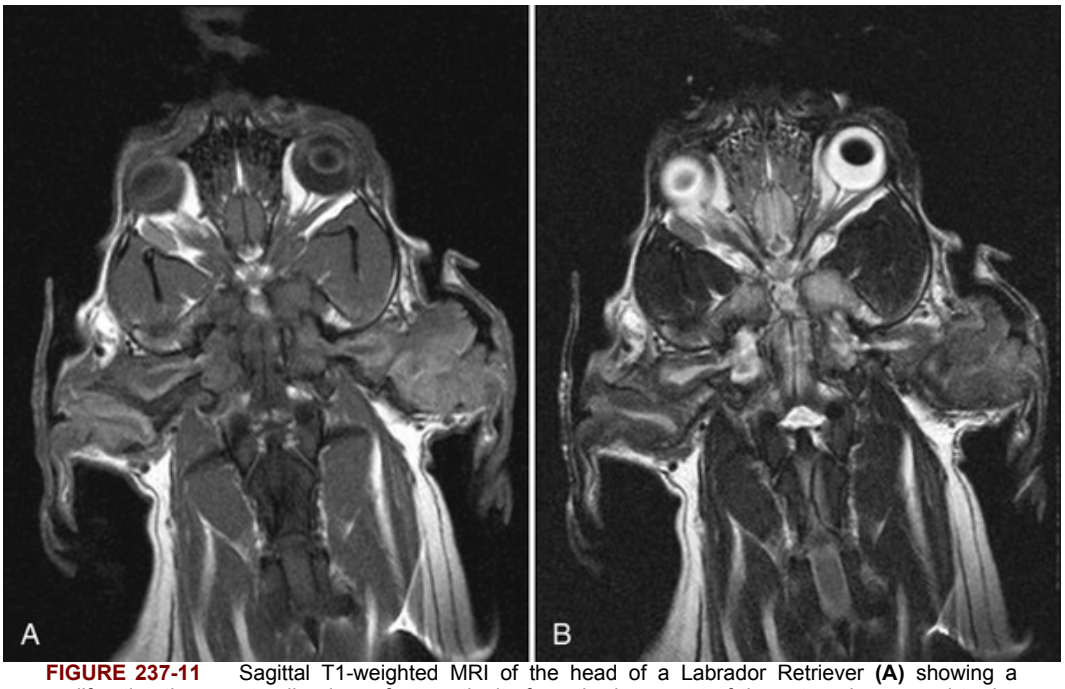


FIGURE 237-11 Sagittal T1-weighted MRI of the head of a Labrador Retriever **(A)** showing a proliferative tissue extending in perfect continuity from the inner part of the external ear canal to the tympanic cavity. The sagittal T2-weighted image **(B)** shows the presence of liquid inside the right tympanic cavity. This dog presented severe chronic bilateral otitis externa and media.

The overall complication rate has been reported to range from 30% to 80%. Common short-term complications include facial nerve neuropraxia (up to 50% of animals; median duration of 2 weeks in dogs and 4 weeks in cats), peripheral vestibular syndrome (can resolve gradually, and either partially or completely), hemorrhage, persistent pain, and wound dehiscence (Figure 237-12).[18] TECALBO usually results in substantial postoperative pain, and local anesthetic infusion has been investigated for postoperative analgesia. However, local infusion of bupivacaine has not significantly improved postoperative analgesia compared to systemic morphine injections.[20] Preexistent preoperative neurologic signs usually do not resolve after surgery. Residual facial nerve deficits after 1 year have reported to be 8% in dogs and 33% in cats. Permanent Horner's syndrome is rare in dogs but is reported in up to 25% of cats. The duration of preoperative clinical signs of ear disease does not appear associated with postoperative facial nerve deficits.[21] Dermatitis of the pinna (up to 20% of cases) and abscessation with para-aural fistulous tracts and pain on opening the mouth (5-10% of cases, occurring 1 month to 2 years postoperatively) are recognized. The risk of such complications can be lowered with thorough surgical removal of cartilage, epithelium, and debris initially, and with the use of antimicrobials that are based on bacterial culture and sensitivity testing obtained from the bulla, because bacteria isolated from the ear canal differ significantly from those isolated from the tympanic cavity.[22] A secondary surgical excision can then be performed with a higher risk of recurrence.[23] Cholesterol granuloma is a long-term complication of TECALBO that can necessitate a second surgical treatment as long as 3 years postoperatively.[24] Although reported by some owners, hearing loss usually is not related to the surgical procedure but is mostly a preexistent consequence of end-stage chronic OE/OM; TECALBO usually does not lead to complete hearing loss, as bone-conducted brainstem auditory evoked potentials may prevent dogs from complete deafness.[25] TECALBO remains a salvage procedure, and although owners' satisfaction after TECALBO usually is about 90%, veterinarians and owners must be aware that serious complications remain possible, particularly long-term infectious ones. As surgical anatomy and techniques have now been precisely described, postoperative outcome may be mostly related to the severity of the ear disease, and TECALBO should probably be proposed earlier in the course of the disease, once appropriate medical treatments are no longer effective to treat or control chronic otitis.

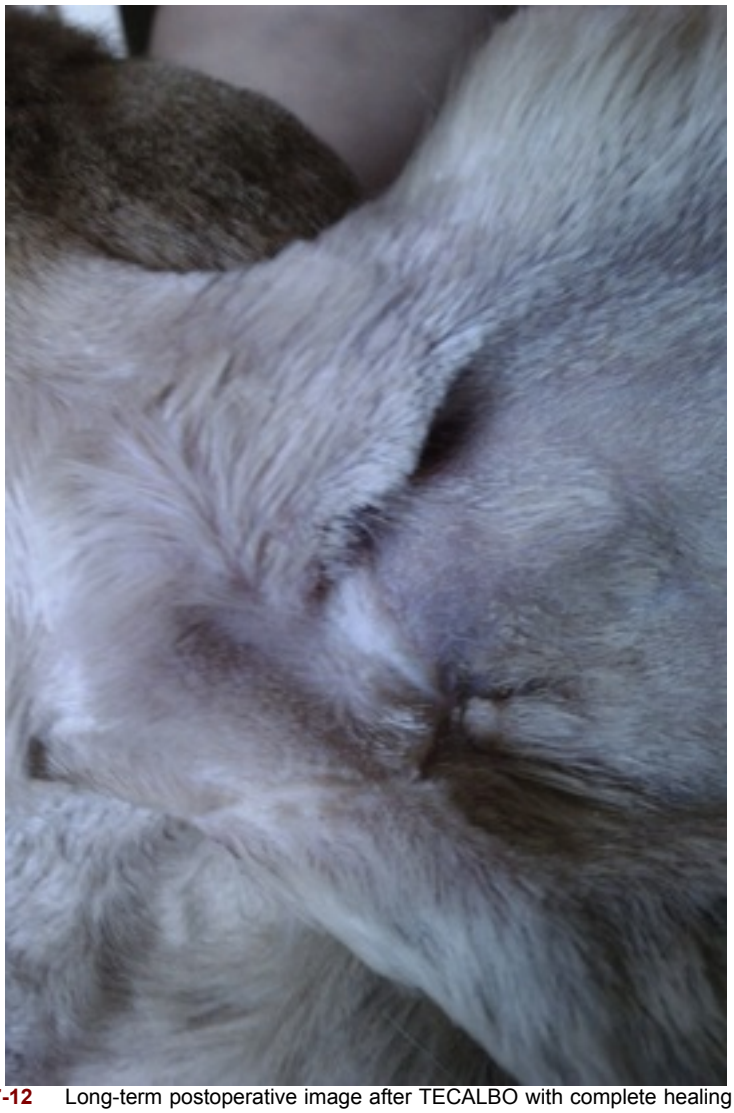

FIGURE 237-12 Long-term postoperative image after TECALBO with complete healing in a Cocker Spaniel.

Otoacariasis

Parasites should always be considered in cases of OE. *Otodectes cynotis,* recovered from the auditory canal of domestic animals (dog, cat, ferret), is a psoroptid mite characterized by long legs with unjointed stalks with stickers (see Video 237-1). These mites live on the surface of the skin, particularly in the auditory canal, and feed on epidermal debris and tissue fluids, irritating the ear epithelium and generating an allergic reaction from susceptible hosts. *O. cynotis* infestation could represent 7-10% of cases of OE in dogs and up to 50% in cats.[26] It is very contagious. Other parasites may rarely be responsible for OE in dogs and cats (e.g., *Demodex* spp., *Otobius megnini*). Otoacariasis often is associated with pruritus, pinnal erythema, and excessive cerumen in the ear canal (usually but not necessarily dark brown). Direct microscopic examination of the cerumen is easy to perform. The use of a curette or a swab allows the sampling of cerumen, which is then diluted into chloral lactophenol or liquid paraffin. Observation at a magnification of ×40 is usually adequate to detect parasites. This procedure must be completed even if there is little cerumen present, particularly in cats.[26] Therapy involves the topical and/or systemic use of acaricidal molecules. Various treatments have demonstrated to be effective for this condition.

Foreign Bodies

Foreign bodies must always be considered in case of acute unilateral otitis, particularly in dogs with

pendulous and hypertrichotic ears and/or if the disease is acute. Young hunting dogs are at increased risk. Generally, grass awns or grass seeds are involved. Some cases of chronic bilateral ear disease may also be due to grass awn. The most frequent clinical presentation is an acute episode of head shaking and/or pain. There is a risk for penetration of the tympanic membrane and OM if the foreign body is not identified and removed. Therapy involves the mechanical extraction of the foreign body and for inflammatory cases the topical application of a steroid-containing ear drop preparation.

Aural Hematoma

Aural hematoma usually is secondary to severe pruritus of the head and/or ear. However, some cases can occur without associated pruritus and a few authors have proposed that initial vascular damage secondary to vasculitis might be responsible for this condition.[27] Blood accumulates within the fractured cartilage of the pinna. Clinical lesions are mainly characterized by swelling and deformation of the involved pinna. Treatment must always be considered, even for small hematomas, because of the risk for a permanent deformation of the ear.[26] Symptomatic therapy includes puncture and bandaging, *in situ* injection of corticosteroids, Penrose drain placement, or surgical incision followed by curettage and closure with mattress sutures. The latter usually is preferred because it leads to better cosmetic results. It is mandatory to look for an underlying cause, which includes a thorough inspection of the ear canal (see ch. 85), to prevent recurrence.

Deafness

Auditory function is a complex process involving all structures of the ear: collection of sound by the pinna and ear canal, vibration of sound waves on the tympanic membrane, transmission of the vibrations through the ossicles, to the oval window of the cochlea and further to the scala tympani and scala vestibuli, with depolarization and synaptic connections occurring between hair cells and spiral ganglion neurons resulting in transmission of information through the vestibulocochlear nerve.[28] Hearing can be evaluated clinically (behavioral response to various noises) but, as vibrations through air can also be felt via extracochlear mechanoreceptors, is best recognized by functional testing, notably BAER testing. Deafness is classified as follows, depending on various factors: inherited/acquired, congenital/late onset, and sensorineural/conductive.

Hearing Testing Principles

Currently, there is no validated, easy-to-use scoring system for hearing evaluation in dogs and cats. Different scales have been proposed both for pet owners and veterinarians, but these scales do not seem to be sensitive or specific.[29] The only noninvasive technique allowing a sensitive objective measurement of hearing is BAER testing. It helps to evaluate the functionality of the various components of the auditory system. Electrical activity arising from the cochlear and auditory pathways is measured in response to stimulation using unilateral click stimuli. BAER recordings include five different waves: peak I (cochlear nerve) and peaks II to V (brain).[30]

Congenital Sensorineural Deafness

Congenital deafness is due to a genetically inherited degeneration of the stria vascularis associated with Reissner's membrane and cochlear alterations usually (albeit not always) associated with pigmentation genes. The loss of hearing usually occurs after 3 to 4 weeks of age. There are strong breed predispositions, notably in white-coated animals. In cats, this condition has been demonstrated to be autosomal dominant with incomplete penetrance (gene W)[31] and is most often associated to other melanocyte problems, such as blue irides. In dogs, the trait is associated with the dominant merle gene (M) in Collies, Australian and Shetland Sheepdogs, Great Danes, and with the autosomal recessive piebald (SP) or extreme piebald (SW) gene in Bull Terriers, Bulldogs, Great Pyrenees and Dalmatians. It seems that the risk is higher in dogs with blue irides, if one of the parents is deaf, and if the coat is white. In other breeds, such as Doberman Pinschers, deafness is due to a direct loss of cochlear cells without primary involvement of stria vascularis.[32] Diagnosis usually is possible after 1 month of age. Clinical diagnosis is not straightforward, as in young puppies the behavior is not easy to detect, especially in case of unilateral deafness. Therefore, BAER testing usually is needed as an objective measure of hearing. Complete lack of waveforms is expected for these cases.

Acquired Sensorineural Deafness

Also named presbycusis, this syndrome is associated with a loss of hearing with age due to various causes (degeneration of the organ of Corti, cochlear nerve, stria vascularis, or basilar membrane). In one study, animals >12 years of age presented modified BAER waves with a higher threshold than younger animals, notably in high frequencies. Histopathologic examination showed a loss of cochlear cells and a neuronal degeneration as observed in humans. Older dogs presented with hearing loss should always be evaluated for any other cause of conductive deafness such as OE or OM before the diagnosis of presbycusis is made. It should also be remembered that various diseases may be responsible for hearing loss in adult animals (e.g., ototoxic substances, trauma, hypothyroidism). Diagnosis is best made by BAER, which demonstrates normal waveforms in response to high-intensity sound.

Post-Inflammatory Deafness

Conductive deafness is associated with any condition that blocks sound transmission through the ear canal to the ossicles and inner ear. This can be seen in any case of inflammation of the ear structures (OE, OM and/or OI). In one study evaluating chronic cases of OE without concomitant OM, defects of hearing were demonstrated, with a complete loss of hearing and BAER showing decreased wave amplitude and increased wave latency in the most severe cases. These defects disappeared after repetitive flushing of the ear canal, which demonstrates the impact of secretions accumulating in the ear canal on the transmission of sound. Owners may state that the dog has a hearing problem, but the diagnosis is best made by BAER with increase in hearing threshold, a loss of air conductive hearing, and the presence of normal bone-conducted hearing.

Aural Neoplasia

Various cutaneous neoplasms can affect the ear, notably squamous cell carcinoma and ceruminous gland tumors. These neoplasms are discussed in ch. 345.

Ototoxicosis[5]

Ototoxicosis is defined as damage to the cochlear and/or vestibular system caused by a medication as a direct effect following topical application, through local inflammation of the tympanic bulla, or by systemic absorption.

Ototoxicosis is potentially of concern with application of any topical treatment in the ear canal. In cases with tympanic membrane rupture, it is theoretically possible that no medication at all should be instilled into the ear, as most products carry some degree of risk. In human medicine, aminoglycosides, cisplatin, and carboplatin, among others, have been demonstrated to be responsible for permanent hearing loss. In veterinary medicine, substances incriminated most frequently are aminoglycosides, polypeptides, chlorhexidine, and iodine products. However, some recent *in vivo* studies have demonstrated in the dog that the topical application of chlorhexidine, gentamicin, Tris-EDTA, and ofloxacin did not modify the BAER responses and therefore, the risk is probably less than previously suspected. The drug concentration, the chemical composition, the vehicle of the preparation, and the duration of administration probably are also important factors leading to ototoxicosis. Therefore, it is mandatory to evaluate the integrity of the tympanic membrane before applying any potentially ototoxic drug.

CHAPTER 238

Diseases of the Nose, Sinuses, and Nasopharynx

Gerhard Ulrich Oechtering

Client Information Sheet: Brachycephalic Syndrome

Nose

The nasal airways of the dog and cat are both anatomically and physiologically an impressively complex structure. On the one hand, they provide a portal through which air can stream to three different locations, each serving a distinct, vital function: (1) the concha nasalis ventralis for thermoregulation and conditioning of air, caudodorsally the (2) conchae ethmoidales for olfaction and via the caudal passageways the (3) pulmonary alveoli for gas exchange. They are not only simple passageways but complicated branches of the nasal conchae providing two huge, functionally different surface areas, serving as active organs of thermal homeostasis and olfaction.

The two nasal cavities are separated by the nasal septum; each cavity is composed of four main functional segments (Figure 238-1). The nasal airway communicates with the paranasal sinuses and connects caudally to the nasopharyngeal airway. Although the nasal part of the upper airway has a parallel oral passageway, dogs breathe predominantly through the nose, except for when they are exercising or panting. The importance of nasal breathing for dogs and cats is often severely underestimated: Human noses fulfill two crucial tasks—respiration and olfaction. Dogs' and cats' noses fulfill a third, vital function—that of thermoregulation.

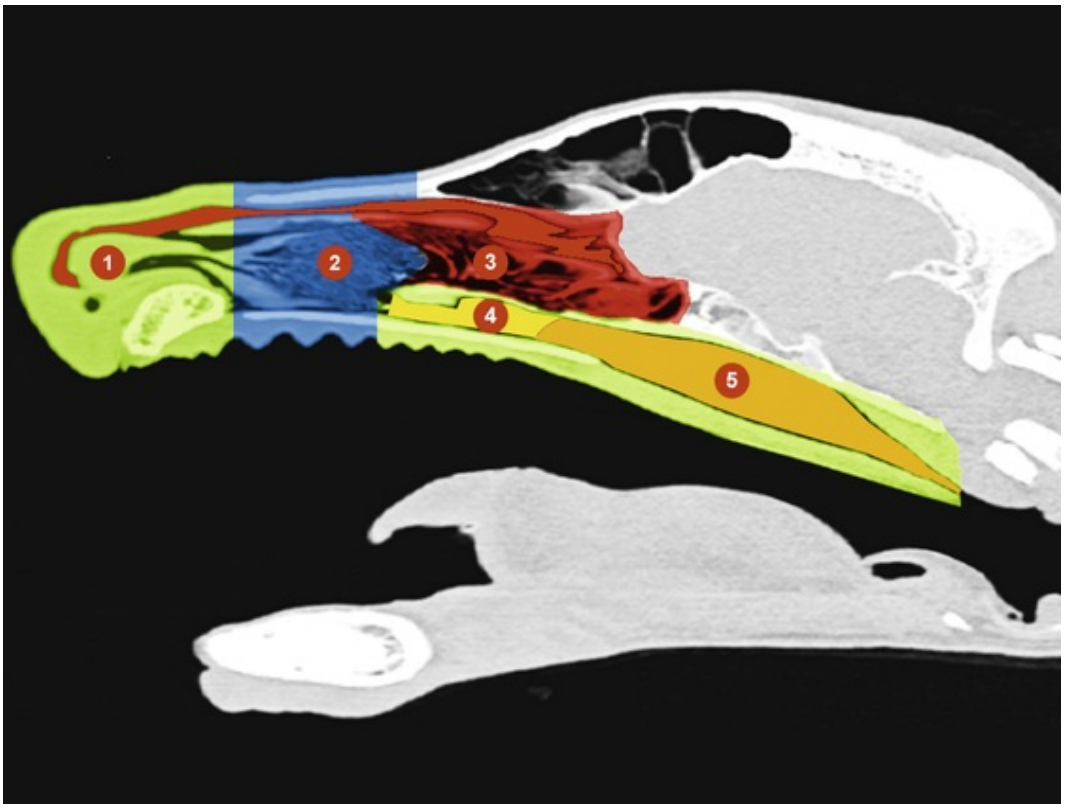

FIGURE 238-1 **Functional segments** of the nasal-pharyngeal airway. **1, Nasal entrance:** distribution and regulation of in- and exhaled air. **2, Respiratory chamber:** thermoregulation and conditioning of inhaled air. **3, Olfactory chamber** (with dorsal meatus): olfaction, the dorsal nasal meatus serves as bypass during sniffing. **Nasal exit** (4 & 5). **4, Meatus nasopharyngeus:** connection to nasopharyngeal airway. **5, Nasopharynx:** functional occlusion during swallowing. Dorsal partition of Waldeyer's tonsillar ring and connection to middle ear.

Anatomy and Functional Considerations of the Nasal-Pharyngeal Airway

The nasal-pharyngeal airway can be partitioned into **four functional segments** between the nares and the ostium intrapharyngeum. This can be useful both for understanding flow-relevant pathologies as well as for a systematic endoscopic examination or systematic interpretation of cross-sectional images. Functional segments of the nose are (1) the **nasal entrance,** (2) the **respiratory chamber,** (3) the **olfactory chamber,** and (4) the **nasal exit** (see Figure 238-1). A rostral to caudal overview of the nasal-pharyngeal passageways gives Video 238-1 as a computed tomographic (CT) study and Video 238-2 as anterior rhinoscopy.

The nasal airway begins with the **naris,** the visible rostral opening plane of a short passageway through the vestibulum nasi. It is formed like a comma with a vertical broad head and a smaller curved tail that rotates horizontally and laterally (Figure 238-2). The **nasal vestibule** is primarily responsible for distributing the in- and expired air and has the highest airway resistance of the upper airways. Unlike in humans, the canine and feline nasal vestibule is not empty. It is filled nearly entirely by a voluminous bulb, evolved from the fusion of the cranial termination of the plica alaris (alar fold) with the internal part of the ala nasi (nasal wing). It is the most mobile portion of the nasal entrance, because it receives the terminal fibers of the levator labii maxillaris and levator nasolabialis muscles. These muscles abduct the bulb laterally, thereby increasing the perpendicular opening within the vestibule (Video 238-3). The configuration of this bulb modifies the nasal entrance into a complex three-dimensional opening. It circles about 300° from ventrolateral around the bulb dorsolateral into a lateral recess, the rostral continuation of the atrium of the medial nasal meatus (see Figure 238-2). The **nasolacrimal duct** that conducts lacrimal secretions from the eye opens into the vestibule by an orifice located rostro-medially to the vestibular bulb (Video 238-4).

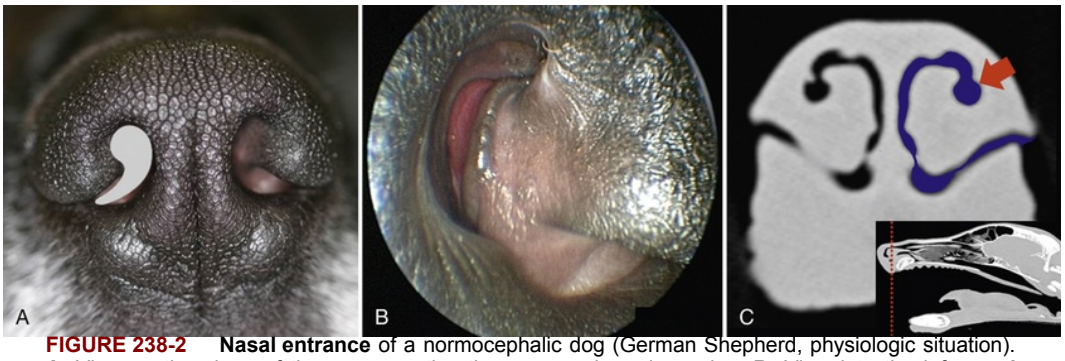

FIGURE 238-2 **Nasal entrance** of a normocephalic dog (German Shepherd, physiologic situation). **A,** View on the plane of the **nares;** notice the comma-shaped opening. **B,** View into the left **nasal vestibule;** notice the voluminous **bulb** that modifies the nasal entrance into a complex three-dimensional opening. **C,** CT image: This opening circles about 300° from ventro-lateral around the bulb into a dorsolateral vestibular recess (arrow). This region serves the tasks of airflow regulation and distribution. See also Video 238-2.

The **nasal cavities** are separated by the **nasal septum.** A medial septal wall, a lateral wall, a roof, and a floor define each nasal passage of the main nasal chamber. Attached to the septum are two vertical protuberances, dorsal and ventral septum swell bodies. The inferior one passes caudally into the wing of the vomer. Each nasal cavity is divided into four air passages: the dorsal, middle, ventral, and common **nasal meatuses** (Figure 238-3). Understanding and differentiating the nasal meatuses as air passages becomes most obvious in the region caudal to the vestibule and cranial to the branching of the ventral concha. Here, the so-called 5-folds-view[1] explains exactly the relation of the nasal folds with the nasal meatuses. Moving further caudally, the alar fold branches intensely into the ventral conchae, nearly filling the entire cross-sectional area of the nasal cavity, and disintegrating the contour of all meatuses except for the dorsal meatus (Figure 238-4). Functionally, the dorsal meatus, located above the straight fold, turns out to be a bypass for odorant-bearing

inspired air around the complicated structure of the ventral concha during sniffing for olfaction (see Figure 238-1).[2,3]

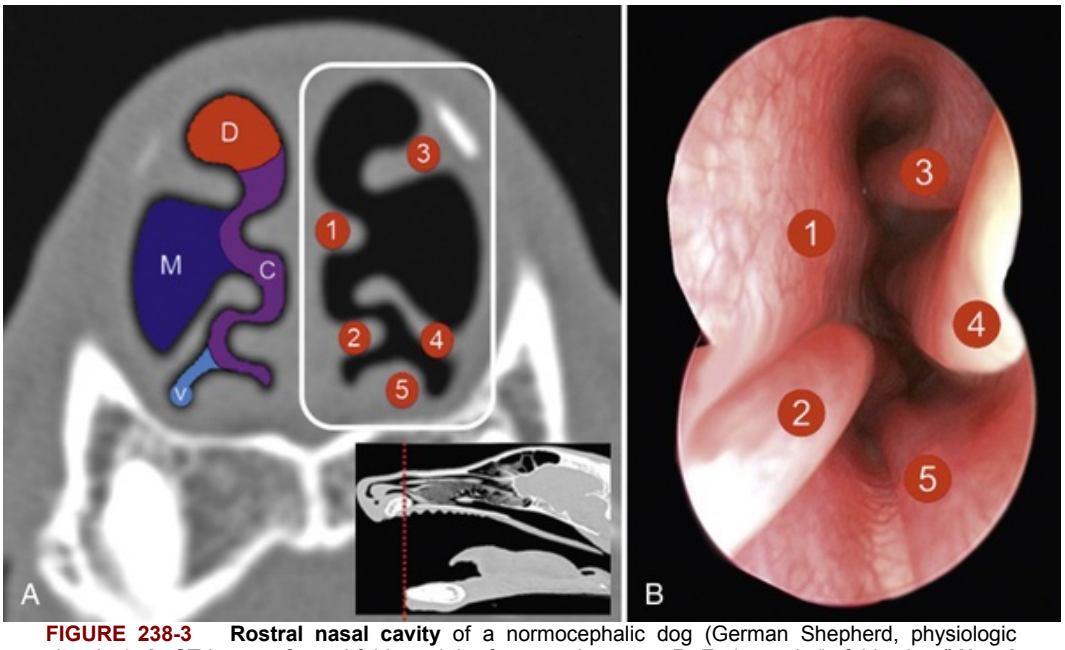

FIGURE 238-3 **Rostral nasal cavity** of a normocephalic dog (German Shepherd, physiologic situation). **A,** CT image of nasal folds and the four nasal meatus. **B,** Endoscopic "5-folds-view." **Nasal meatuses:** C, common; D, dorsal; M, medial; V, ventral. **Five-folds view of nasal folds:** 1, dorsal septal swell body; 2, ventral septal swell body; 3, plica recta; 4, plica alaris; 5, plica basalis.

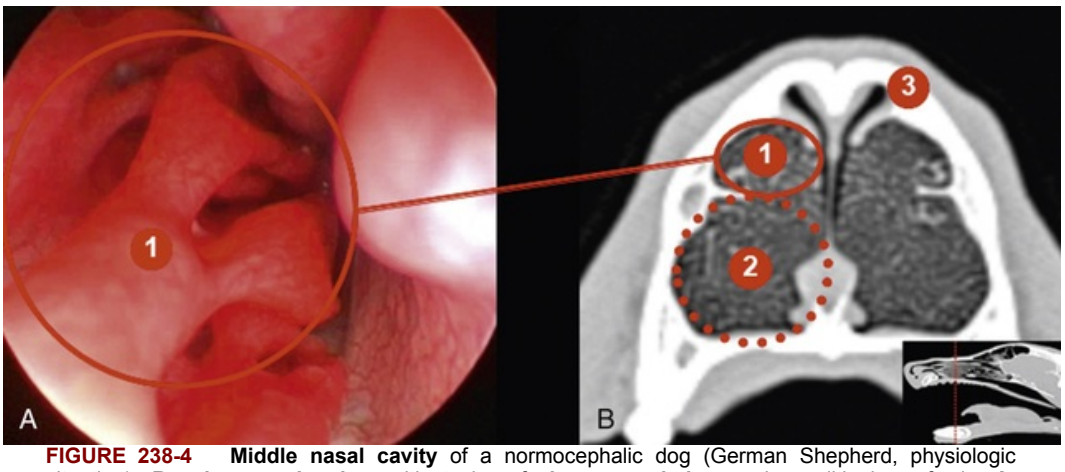

FIGURE 238-4 **Middle nasal cavity** of a normocephalic dog (German Shepherd, physiologic situation). **Respiratory chamber** with tasks of **thermoregulation** and conditioning of air. **A,** Endoscopic view of the (1) dorsal spiral lamella of the left ventral nasal concha. **B,** CT image of the ventral nasal concha with (1) dorsal and (2) ventral spiral lamellae. There are no more meatuses except the (3) dorsal meatus as bypass for sniffing.

Two types of conchae dominate in the nasal cavity; in the middle part is the huge **ventral concha,** formerly called the maxillo-turbinate because of its attachment to the maxilla. The caudal-dorsal part of the nasal cavity is filled with turbinates that are attached to the cribriform plate of the ethmoid and therefore called **ethmoidal conchae.** Both conchae differ not only in function, but also in the anatomical structure of the scrolls and in their relative surface areas. The ventral concha, with the respiratory functions of thermoregulation and air conditioning, shows a branching that is quantitatively more contorted, revealing a very complex airway network. The ethmoidal conchae, with their olfactory function, show a less complicated structure of the turbinates. The total surface area contained within the ethmoidal region is, however, nearly twice the size of

the ventral concha.[2,4]

The **nasal exit** is formed by the **nasopharyngeal meatus,** beginning with a wing of the vomer that crosses dorsally from medial to lateral and ending caudally with the **choanae** (Figure 238-5). This meatus is very delicately constructed: Behind the large diameter of the nasal cavity, the "outlet" is located as a comparatively tiny tube at the bottom. In small dogs, this is only 1 to 3 mm high (see Figure 238-9). This hole can very easily be obstructed. Dogs can usually compensate for the functional loss of one opening as, for example, when a tumor is expanding into the nasopharyngeal meatus. However, as soon as the contralateral meatus shows the first signs of obstruction as well, nasal respiration is impaired severely and clinical signs start becoming obvious. Morphologically and functionally distinct epithelia line the nasal passages—olfactory, respiratory, squamous and transitional.

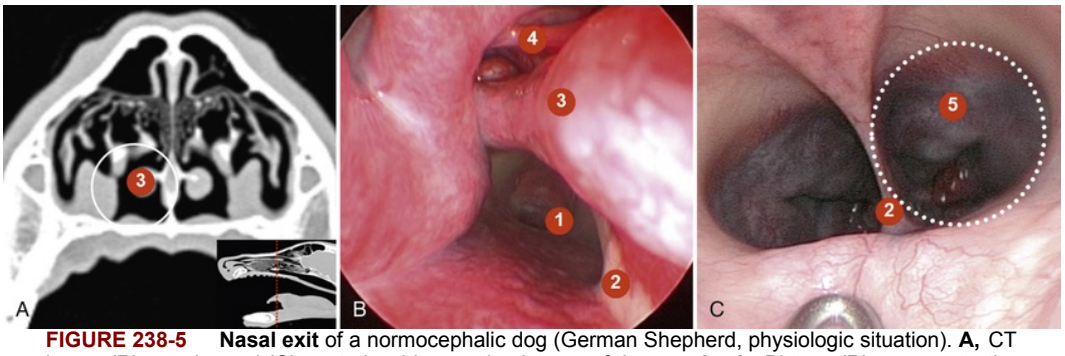

FIGURE 238-5 **Nasal exit** of a normocephalic dog (German Shepherd, physiologic situation). **A,** CT image **(B)** anterior and **(C)** posterior rhinoscopic pictures of the **nasal exit.** Picture **(B)** represents the white closed circle in picture **(A).** 1, View into nasopharynx; 2, nasal septum; 3, right wing of the vomer; 4, entrance into the right sphenoid sinus; 5, view into the right meatus nasopharyngeus with the choanae (white dotted circle), the internal nares as counterpart of the external nares.

Caudal to the vestibulum, most of the luminal surfaces of the nasal mucosa are covered by a watery, sticky material called mucus. Its physical and chemical properties are well suited for its role as an upper airway defense mechanism, filtering the inhaled air by trapping inhaled particles and certain gases or vapors. Goblet cells and subepithelial glands produce mucus. The **mucociliary apparatus** with its synchronized beating of surface cilia propels the mucus at different speeds and in different directions depending on the intranasal location. Mucus covering the olfactory mucosa moves very slowly, with a turnover time of probably several days. By contrast, the mucus covering the transitional and respiratory epithelium is driven along rapidly (1 to 30 mm/min) to the oropharynx where it is swallowed into the esophagus.[5]

The luminal surface of the vestibulum is lined by a **squamous epithelium** similar to that of external skin. A narrow zone of nasal **transitional epithelium** covers the transition into the main nasal chamber. The majority of the non-olfactory nasal epithelium is **ciliated respiratory epithelium.** The ethmoidal conchae and the caudal surface of the septum are covered with **olfactory epithelium.** This olfactory surface is about twice as large as the area covered with respiratory mucosa. Olfactory mucosa is covered with non-motile sensory cilia, enabling the dog to detect odorant concentration levels of roughly 10,000 to 100,000 times that of the human.[2,4,6-8] Of note is the fact that organized nasal-associated lymphoid tissue (NALT) was not identified in normal puppies or adult dogs, although the nasopharyngeal tonsil in this species is well developed.[9,10] The frontal sinuses are covered with respiratory epithelium except where ethmoturbinates extend into these cavities; here olfactory epithelium is found.[11,12]

The normal canine respiratory tract is endowed with a range of different **immune cell populations** and they have the greatest concentration in the mucosa of the nose.[9] The lamina propria of the mucosa of the respiratory part also contains **serous, mucous, and mixed tubuloalveolar glands.** These glands are also present in the mucosa of the nasal vestibule. **Goblet cells** are present throughout the respiratory region, and **olfactory glands** that contain yellow pigment granules (!) are located in the olfactory epithelium, giving this surface a very typical color.[13]

Airway mucus plays a vital role in maintaining respiratory homeostasis. It provides the first line of defense against airborne irritants in the nasal cavity, and is essential in the mucociliary process, ensuring that no foreign particles reach the lungs. Not only does its thick consistency trap foreign particles, but its protein constitution additionally contains bactericidal enzymes, thereby reducing the risk of infection.[14]

Thermoregulation in the Dog

The **lateral nasal gland,** more commonly called Steno's Gland,[15] is the largest of the nasal glands. The gland is located beneath the wall of the maxillary sinus and it releases its product into an extremely long excretory duct, which opens latero-medially at the transition from the nasal vestibule into the antrum of the medial meatus. The functional significance of the lateral nasal gland is that it is part of the **thermoregulatory system** in the dog.[16,17] Whilst humans sweat to evacuate heat from the body, dogs cannot sweat; they pant. But contrary to common beliefs, **dogs do not cool primarily using the surface of the tongue.** Studies have shown that panting dogs inspire through the nose and expire through the mouth, and this begs quite a different understanding of why dogs pant.[16] The ventral nasal concha has an extremely large, richly vascularized surface of mucous membrane rolled into very fine, space-saving, spiral lamellae. The inspired air flows through these. In order for cooling by evaporation to occur, water is required. For this purpose, the dog has a special gland, absent in humans: the lateral nasal gland (glandula nasalis lateralis or Steno's gland), located in the maxillary recess. An excretory duct extends rostrally and opens laterally into the nasal vestibule (Video 238-5). Here, the secretion drips into the gutter-like channel of the antrum of the middle nasal meatus and runs caudally, driven by the inspired air. Where the plica alaris branches into the concha nasalis ventralis, the liquid drips onto the broad ventral concha and is distributed across the whole surface of this concha by the inspired air. The liquid can then evaporate rapidly in the strong airflow, producing cooling by evaporation (Video 238-6). Reduction of nasal airflow or thermoregulatory active surface of the ventral concha or both can lead to serious heat susceptibility, as, for example, in brachycephalic animals (see Figure 238-20).

A rise of air temperature from 25 to 42° C caused a threefold increase in the mucous secretion rate.[18] The excellent vascularization of the nasal mucous membranes enables heat to be exchanged rapidly and effectively. Nasal and lingual blood flow increase during panting.[19] Studies from Baker and Chapman[20] showed that in exercising and panting dogs, brain temperature is lower than the temperature in the carotid artery. They describe a vascular rete that is cooling arterial blood of the carotid artery with cold blood draining from the nose. In another study they had shown that brain temperature rises during physical exercise and panting if dogs are not able to use intact upper respiratory passages but were forced to breathe directly through an experimental tracheostomy.[21] This might be another argument to **consider the decision for a permanent tracheostomy very carefully.**

Clinical Manifestations of Nasal Disease

Clinical signs of nasal disease (E-Box 238-1) can vary; they are, however, rarely specific for the particular underlying cause. Even systemic diseases like coagulopathies can cause nasal clinical signs (see ch. 29 and 197). A thorough medical history can best be obtained by structured questions to the owner (E-Box 238-2).

E-Box 238-1

Clinical Signs of Nasal Disease

- Sneezing
- Reverse sneezing
- Nasal discharge
  - Serous
  - Mucoid
  - Mucopurulent
  - Purulent
  - Sanguineous
  - Mixed
- Stridor (nasalis and/or pharyngealis)
- Open-mouth breathing and/or expiratory cheek puff
- Dyspnea
- Exercise intolerance
- Heat intolerance
- Sleeping problems
- Respiratory problems during feeding

Halitosis (see also ch. 36)
Facial deformity or ulcerations of the nasal dorsum

E-Box 238-2

Key Questions for Obtaining a History in Nasal Disease

- Duration of nasal disease, acute or progressive onset, first signs, progress since then, previous therapies and results?
- Occurrence of sneezing/reverse sneezing, nasal discharge (quality, frequency, uni-/bilateral, changes over time)?
- Problems with breathing (respiratory noise during inspiration or expiration, distinguishing between stridor nasalis and pharyngealis)
- Difficulties with breathing during sleep, specific noise during sleep, expiratory cheek puff, open-mouth breathing at rest?
- Influence of exercise and ambient temperature on breathing?

Sneezing and Reverse Sneezing (also see ch. 27)

Sneezing is a protective reflex. It manifests as an explosive expiratory airflow that is able to dislodge and expel foreign particles from the nasal cavities. Any cause of nasal mucosal irritation or nasal discharge is a differential diagnosis for sneezing. **Reverse sneezing** is defined as a **mechanosensitive aspiration reflex.** It is a labored, short and often stertorous inspiratory effort. Sometimes dogs get into a position with head and neck extension and elbow abduction. Other times, reverse sneezing occurs paroxysmally in certain conditions (i.e., after drinking), though often without recognizable trigger or cause (Video 238-7; also see Video 27-1). Powerful contraction of inspiratory muscles and adduction of laryngeal cartilages generate negative pleural and tracheal pressure. The strong tracheal occlusion pressure with a sudden opening of the glottis while the mouth is closed produces a rapid inspiratory airflow through nose and nasopharynx. This rapid inhalation tends to tear off irritant particles and accumulated mucus, resulting in aspiration from the nasopharynx to the oropharynx, effectively supporting mucociliary clearance and allowing subsequent elimination by swallowing or coughing.[22,23]

While most owners are used to seeing their dog sneeze, they sometimes panic when witnessing their dog with a reverse sneezing attack for the first time (see Videos 238-7 and 27-1). In spite of the fact that reverse sneezing is not associated with obstructive dyspnea, dogs may appear as if they are having extreme air hunger and being close to asphyxia. In general, dogs behave normally again right after the reverse sneezing episode. Even regular episodes of reverse sneezing can be seen in individual dogs without any detectable nasal or nasopharyngeal pathology and it has to be regarded as a physiological cleaning procedure of the nasal-pharyngeal airway. However, as it is the case with sneezing, a sudden onset and continuation of pronounced reverse sneezing attacks can be the first clinical sign of a nasopharyngeal problem (for example, a foreign body). If frequency, duration and intensity of reverse sneezing seem unusual, posterior rhinoscopy should be recommended (see ch. 27).

Nasal Discharge (also see ch. 27)

In contrast to humans, mucopurulent nasal discharge in dogs is generally not a symptom of a transient and self-terminating rhinosinusitis! Often, owners of affected dogs assume that their pet had a head cold and tolerate mucopurulent or purulent nasal discharge for a while. However, usually **mucopurulent nasal discharge in dogs has a serious underlying cause,** requiring intensive diagnostics. Nasal discharge can be produced within the nasal cavity as a reaction to mucosal inflammation and/or infection. Discharge can also drain from the paranasal sinuses, predominantly the frontal sinus. This can be due to blockage of the natural caudal drainage way through the nasopharyngeal duct and the nasopharynx as, for example, with nasopharyngeal stenosis or a completely obstructing nasopharyngeal polyp. Pure mucous congestion can turn purulent after secondary bacterial infection.

Neither quality, nor laterality, nor duration of nasal discharge confirms a diagnosis of nasal disease and none of this information can replace subsequent advanced diagnostics.[24]

Airflow Obstruction

Knowing the unique importance of nasal breathing for dogs and cats, one can conceive of the consequences of nasal airway obstruction. Obviously, the nose is provided with such a reserve capacity that a 50% loss of function, meaning the obstruction of one of the two nasal cavities, may be tolerated at rest.[22,25] During resting respiration, the nasal cavity accounts for about 79% of inspiratory resistance and about 74% of expiratory resistance.[26] Dogs attempt to complete inspiration through the nose, even against a high anatomic nasal resistance. Dogs with partial bilateral nasal obstruction showed other systemic effects, such as a considerable loss of body weight.[25] Taking this into account and considering the meaning of nasal thermoregulation, the dog should be considered an obligatory nose breather.

Obstruction of the nasal-pharyngeal airway, either as a consequence of a permanent stenosing process or due to intermittent collapse of the nasopharyngeal airway, can lead to severe sleeping problems and subsequent day sleepiness (see Video 238-29). Owners of affected animals often report on attempts to sleep in a sitting position and on sleeping pauses of variable length, regularly interrupted by waking up and gasping for breath.[27] This corresponds quite well to the problem of obstructive sleep apnea (OSA) in humans[28] (see also Brachycephalic Syndrome, below).

Examination of the Nose

The diagnostic approach to nasal disease can be challenging. Medical history and physical examination of the awake patient alone rarely provide a definitive diagnosis.[29] Further means of diagnosis require general anesthesia of the patient. However, a well-planned combination of clinical examination, diagnostic imaging and endoscopy with tissue biopsies is a promising approach, establishing a diagnosis in over 90% of dogs[30] and cats.[31]

Physical Examination

A thorough medical history (see E-Box 238-2) is followed by an examination of the external nose. The symmetry or deformity of the face and the external nose, the size of the nares, possibly the mobility of the alae nasi (see Video 238-3), the pigmentation of the planum nasale and the character of unilateral or bilateral nasal discharge can be visible. Expiratory puffing of the cheeks might also be visible, indicating a complete obstruction of the nasal airway (Video 238-8). Stridor or stertor indicate stenotic airway segments within the nose or the nasopharynx, respectively. The rostral movable portion of the external nose is palpable (E-Box 238-3).

E-Box 238-3

Specific Physical Examination of the Nose

- Breathing sounds (stridor)
- Symmetry of the face and muzzle
- Character of nasal discharge, laterality
- Facial deformity or ulceration
- Patency of airflow through each nostril
- Condition of the teeth and gums
- Examination of the roof of the mouth to the pharynx (to degree possible)
- Ability to retropulse the eyes
- Pain on opening the mouth or manipulating the muzzle
- Epiphora
- Pigmentation/Depigmentation of the nasal planum
- Size and texture of submandibular lymph nodes

Special Diagnostic Procedures

However detailed the obtained medical history is and however thorough the clinical examination of the

patient was, in the vast majority of cases with suspected nasal or nasopharyngeal disease, this will neither provide a reliable diagnosis nor allow specific treatment in the awake patient.[30,32] It is advisable to communicate this to the owner early on. Even in the anesthetized patient, many important structures are more or less hidden behind bony walls inside the skull, being neither visible nor palpable. Advanced diagnostic tools like endoscopy and/or cross-sectional imaging in combination with histologic examination are often indispensable to establish a definitive diagnosis.[30,33,34] Once the decision for anesthesia is made, careful planning is required: which special diagnostic procedures should be used within the timeframe of anesthesia and in which order. The owner should be advised that in some cases, combining different special examinations might be a better option to the conventional—and usually preferred—stepwise diagnostic evaluation. The likelihood of establishing a diagnosis of a specific nasal disease relies on a combination of techniques, including radiologic examination (cross-sectional preferred), rhinoscopy (rigid preferred), cytology/histopathology of biopsy samples and culture.[31,32] The final choice of diagnostic modalities depends on both the availability of technical equipment and the owner's preferences and means.

Radiography

For many decades, plain film nasal radiographs have been a key diagnostic feature in nasal disease. Today, computed tomography (CT) or magnetic resonance imaging (MRI) provides significant, additional information and increases diagnostic sensitivity. However, questions of availability and cost may still be a limitation.

CT and MRI

Both CT and MRI allow excellent evaluation of the structures within the lumen and the tissues adjacent to the nasal cavities, the nasopharynx and the paranasal sinuses. Depending on their physical working principle, the depiction of bone, air and soft tissue is different. Nasal CT is a powerful tool and it greatly enhances the ability to establish an accurate, definitive diagnosis of nasal disease in dogs (see Video 238-1). It provides an accurate assessment of the extent of nasal disease and readily identifies areas of the nose to examine via rhinoscopy, as well as suspicious regions to target for biopsy.[33] When there is suspicion of a neoplastic process, MRI is considered the superior technique.[35] For a comparison of imaging techniques for dogs with nasal disease, see E-Table 238-1 and Figure 238-6.

E-TABLE 238-1

Comparison of Imaging Techniques for Dogs with Nasal and Paranasal Disease

	PLAIN RADIOGRAPHY	CT	MRI	RHINOSCOPY
Sensitivity to detect bony changes (lysis or proliferation)	Moderate	Excellent	Good	Poor
Show cribriform plate integrity	Impossible	Excellent	Good to excellent	Poor
Sensitivity to detect soft-tissue changes	Poor to moderate	Good	Excellent	Excellent for intraluminal structures
Ability to discriminate between tissue and mucus	Impossible	Moderate to good (with contrast)	Excellent	Excellent
Ability to take controlled biopsies	Impossible	Moderate	Poor	Excellent
Detection of foreign bodies	Poor	Good to excellent	Good to excellent	Excellent
Guided extraction of foreign bodies	Impossible	Moderate	Poor	Excellent
Visualize mucosal surfaces/fungus plaques	Impossible	Poor	Poor	Excellent
Visualize conchal structure	Poor	Good to excellent	Good	Good to excellent
Mucosal contact points	Impossible	Moderate	Poor	Excellent

Visualize nasolacrimal duct	Moderate	Good	Excellent with contrast	Excellent for the opening
Visualize duct of lateral nasal gland	Moderate	Excellent with contrast	Excellent with contrast	Excellent for the opening
Ability to evaluate the lumen of the paranasal sinuses	Moderate	Excellent	Good to excellent	Moderate to good for maxillary recess and sphenoid sinus Excellent for frontal sinus in advanced sinonasal aspergillosis Poor for intact frontal sinus

Rhinotomy

In the past, without today's possibilities of modern endoscopic equipment (especially rigid rhinoscopy) and knowledge of intranasal explorative rhinoscopy, rhinotomy was a helpful diagnostic tool in certain cases of nasal disease. There is, however, no longer a real indication for explorative rhinotomy. Together with modern cross-sectional imaging techniques, anterior and posterior rhinoscopy provides a sufficient diagnostic spectrum. In most dogs, an experienced endoscopist can visualize nearly all compartments of the nose and the **standard landmarks** (see E-Box 238-4) should be recognizable even for the less-experienced endoscopist.

Diseases of the Nose

Stenoses and Obstructions of Nasal Passageways

Hereditary malformations due to excessive breeding selection for morphological extremes (miniaturization, exaggerated brachycephaly) can cause obstructions on all three segmental levels—the nasal entrance, the nasal cavity itself and the nasal exit (see Diseases of the Nasopharynx below and Figure 238-9).

Stenoses of the Nasal Entrance

Injuries of the nasal entrance due to trauma (bite wounds, car accidents, gunshot injury), chronic ulcerative inflammation (e.g., long-lasting sinonasal aspergillosis) or surgery at the nasal entrance using excessive thermal energy (HF-surgery, electrocautery, surgical lasers) can lead to constrictive and stenosing wound healing (Figure 238-7). Surgical therapy can be challenging due to a high tendency for re-stenosing and temporal stenting; a flap technique may be used to prevent this.

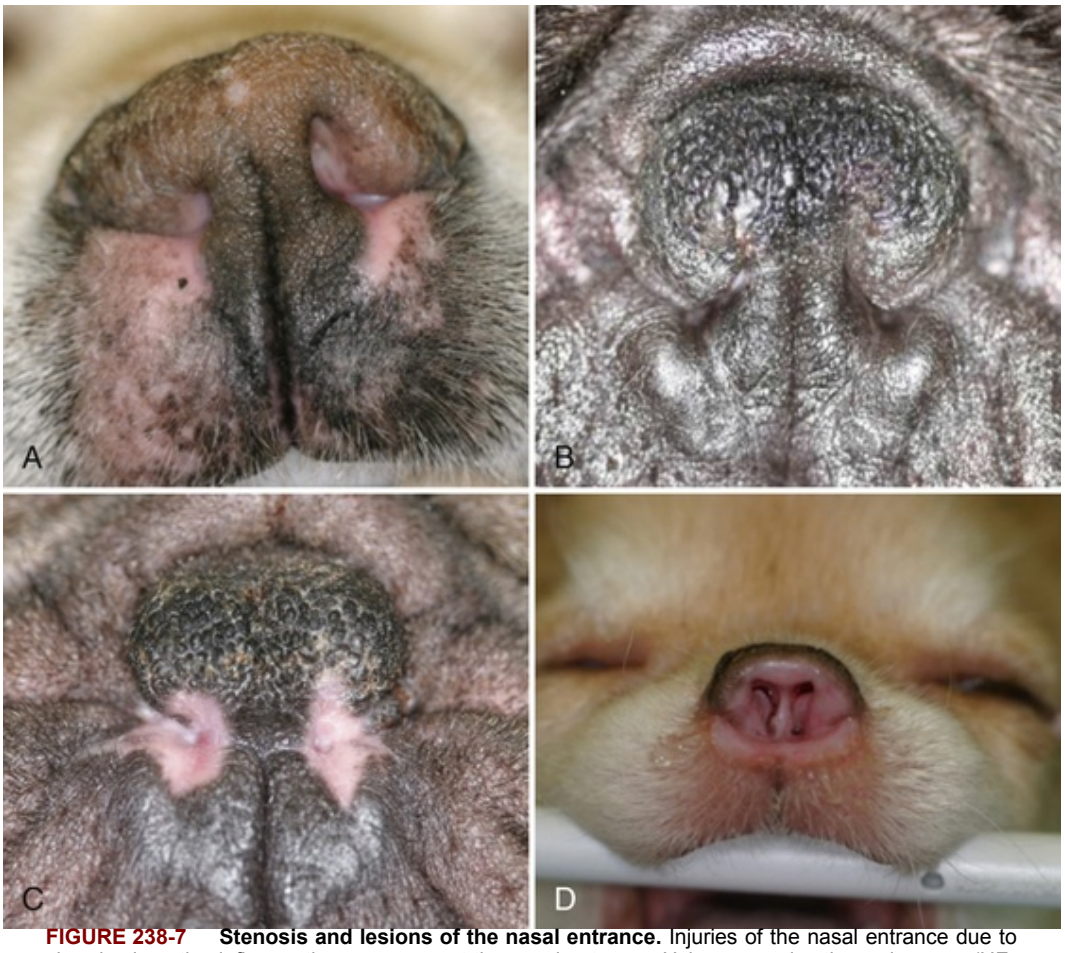

FIGURE 238-7 Stenosis and lesions of the nasal entrance. Injuries of the nasal entrance due to chronic ulcerative inflammation or surgery at the nasal entrance. Using excessive thermal energy (HF-surgery or surgical lasers) can lead to severe lesions and constrictive and stenosing wound healing. **A,** Nares stenosis after long-lasting sinonasal aspergillosis (Golden Retriever). **B,** Stenosis after failed nares surgery with CO_2-laser (French Bulldog). **C,** Stenosis after failed nares surgery with HF-technique (French Bulldog). **D,** Severe lesion of the nares after failed surgery with diode-laser (Chihuahua).

Stenoses of the Nasal Cavity

Causes of intranasal obstruction can be any kind of benign or malignant mass: tumors, expanding granulation tissue induced by chronic inflammation and intranasal cysts of varying origin. Foreign bodies frequently lodge in the nasal cavity. However, they rarely obstruct the intranasal airway due to their size but induce inflammation and purulent discharge. The inspissated discharge can cause complete obstruction of the affected nasal cavity, especially in smaller dogs and in cats. Oronasal defects and other diseases causing purulent rhinitis can lead to intranasal obstruction via the same pathomechanism (Video 238-10). Deviations of the **nasal septum** have probably been more often recognized now that computed tomography (CT) and magnetic resonance imaging (MRI) examinations are widely available. The incidence seems to be higher in small dog breeds and particularly in brachycephalic dogs.[1,36,37] Septal deviations are also described in cats.[38] With that, the question about the clinical relevance of marked deviations arises. In principle, there should be no rise in intranasal airway resistance as long as the smallest intranasal cross-sectional area is larger than the cross-sectional area of the nasal entrance (within the vestibulum) and exit (nasopharyngeal duct). Usually the size of the ventral nasal concha coapts both in the smaller and in the larger nasal cavity, filling the entire lumen.

Stenoses of the Nasal Exit

Because of functional considerations, the stenoses of both the meatus nasopharyngeus and the nasopharynx are described together (see Diseases of the Nasopharynx below; also see ch. 121).

Nasal Foreign Bodies

Various materials have been found lodged in the nasal cavity, mostly parts of plants or foreign material. They can enter the nose either from anterior inhaled via the nares or from posterior during swallowing or regurgitation into the nasopharynx or nasal cavity, respectively. If not immediately expelled by sneezing or removed by a reverse sneezing maneuver, they cause direct trauma and irritation of the nasal mucosa. Depending on the time a foreign body is lodged, its size and location, chronic irritation, inflammation and local tissue destruction may occur. Nasal foreign bodies often result in an acute onset of sneezing and facial pawing, but they can remain in place for a long period, resulting in chronic nasal discharge. **Removal techniques** for nasal foreign bodies vary. In simple cases, the foreign body is endoscopically detected "at first sight" and can be **grabbed with a small forceps** that is introduced alongside a rigid endoscope (Video 238-11). In any case, a thorough systematic endoscopic exploration of the nasal cavity is indicated (see also ch. 96). There is no guarantee that there is not more than one part of the foreign body. Larger pieces in the posterior part of the nasal cavity can possibly be pushed through the nasopharyngeal meatus into the nasopharynx.

Oronasal and Oronasopharyngeal Communications (also see ch. 272)

Congenital or acquired communications between the oral cavity and the nose, respectively the oropharynx and the nasopharynx, allow food and fluids to enter the nasal-pharyngeal passageways. Solid particles, if not expelled by the sneezing reflex or removed with the reverse sneezing maneuver, can cause pronounced inflammatory reactions of the nasal-pharyngeal mucosa. Secondary bacterial infection is common and sometimes even fungal growth can be observed. After severe mucosal damage stenosing wound healing is not uncommon. **Congenital deformities** are **clefts of the lip and palate.** Palatal defects usually affect the midline; however, lateral clefts can be seen in the soft palate as well (Video 238-12). Although the exact cause of clefting is unknown, it is commonly agreed to be multifactorial with a hereditary component. There are a variety of problems associated with facial clefting. Nursing is the major problem of neonates. Due to the close embryologic, anatomic and physiologic connection of the nasopharynx and the middle ear, soft palate clefts, especially the lateral ones, are likely to affect the auditory tube and the middle ear.[39-41] **Acquired oronasal communications** result from trauma of car accidents or due to high-rise trauma (cats). Acquired oronasopharyngeal defects can be the result of oral stick lacerations or complications after palatal surgery. Dental problems, malocclusion and deformity of the normal nasal architecture and lips occur in more rostral defects. In longer-lasting processes, expanding granulation tissue due to chronic secondary bacterial inflammation and/or inspissated discharge can obstruct nasal passageways (Video 238-13).

Rhinitis

Bacterial Rhinitis

Primary **bacterial rhinitis** is uncommon in both dogs and cats. In dogs, bacterial rhinitis occurs most commonly as a sequela to the presence of a foreign body or as a consequence of gross anatomic changes (primarily loss of turbinates) resulting from prior mycotic disease, trauma, or irradiation.[42] Antibiotics can improve clinical signs temporarily. However, when administered in patients with sinonasal aspergillosis, after initial improvement antibiotics can cause a dreadful worsening of the aspergillosis infection.

Lymphoplasmacytic Rhinitis

Idiopathic **lymphoplasmacytic rhinitis** (LPR) is an important cause of chronic nasal disease in dogs with clinical signs similar to those of other chronic nasal disorders and may be more common than previously believed. In a recent study, idiopathic LPR was diagnosed in 30% of the total population that was evaluated.[43] It is one of the most common forms of chronic, non-infectious rhinitis in dogs and cats[30] and it possibly has to be considered a key contributor to chronic nasal disease in dogs. The diagnosis is made by the histopathological identification of a lymphoplasmacytic infiltrate within the nasal mucosa and exclusion of other specific causes of chronic nasal disease. Although the etiology of idiopathic LPR has not been determined, infectious, allergic and immune-mediated mechanisms have been suggested.[34,44-46] Windsor et al[44] reported LPR in dogs of various ages and predominance in large dogs. Nasal discharge was both unilateral and bilateral, and the mean duration of signs was several months. In a recent study, the best response to therapy was seen in dogs that underwent desensitization therapy, followed by those that were treated with both corticosteroids and cyclosporine.[43]

Allergic Rhinitis

Allergic rhinitis is either an unusual or an underdiagnosed condition in small animals. There are sporadic reports of rhinitis of presumptive allergic basis in the dog and cat. Such animals present with oculonasal discharge, sneezing, nose rubbing or head shaking and significant numbers of eosinophils can be demonstrated in nasal exudate or nasal lavage fluid, and infiltrating the nasal mucosa on tissue biopsy.[9,46]

Viral Rhinitis

Despite the widespread use of vaccines (see ch. 208), respiratory disease caused by feline herpesvirus-1 (FHV-1) and feline calicivirus (FCV) remains a significant clinical problem (see ch. 229). In general, the disease is most commonly seen where cats are grouped together, particularly in young kittens as they lose their maternally derived antibody. The initial clinical signs are paroxysmal sneezing, conjunctivitis, and serous ocular and nasal discharge. About 5 days after the onset of sneezing, the nasal discharge becomes mucopurulent and there may be ocular complications. The condition usually persists for 2 to 3 weeks.[47] Viral rhinitis is a prominent clinical sign of **canine distemper** (see ch. 228). Vaccination has reduced the occurrence of the disease to sporadic cases in countries where stray dogs are rare and veterinary care is adequate (see ch. 208). Herpesvirus infection in newborn puppies is characterized by profuse mucopurulent nasal discharge. The diagnosis is usually made at autopsy[47] (see ch. 228).

Nasal, Sinonasal and Nasopharyngeal Tumors

Sinonasal tumors are rare in dogs and occur mostly in middle-aged and old dogs. Approximately one-third of all dogs with chronic nasal disease have nasal neoplasia. 80% to 90% of the nasal masses are **malignant.** They are primarily locally invasive; metastasis is, however, uncommon, or occurs late in the cause of the disease. 60% to 75% of malignancies are epithelial in origin. The three most common ones are adenocarcinoma, lymphoma, and undifferentiated carcinoma. Mesenchymal tumors include fibrosarcoma, chondrosarcoma, osteosarcoma, hemangiosarcoma, and undifferentiated sarcomas. Clinical signs in dogs and cats with nasal tumors include respiratory, ocular, and nervous system–related signs. The most common clinical signs are attributed to upper airway obstruction with decreased airflow through the affected nasal passage, epistaxis, and sneezing. In unilateral nasal obstruction, clinical signs may become obvious to the owner only after the mass has grown through one meatus nasopharyngeus, expanding caudally to the septum and obstructing the contralateral meatus. Other reported signs include reverse sneezing, stertorous breathing, serous, mucoid or mucopurulent nasal discharge, dyspnea, lethargy, weight loss, facial deformity or swelling, and pain. Central nervous system signs include seizures and behavior changes. Sinonasal tumors in dogs can rarely be cured without treatment and euthanasia is generally elected within a few months due to the progression of local disease. Radiation therapy, with or without aggressive cytoreduction, can significantly improve the expected median survival time, and constitutes the treatment of choice.[24,30,31,34,48-51]

Non-Malignant Nasal Masses

Non-malignant nasal masses are rare and infrequently described. Benign tumors, intranasal cysts, inflammatory granulation tissue and other miscellaneous tissues (e.g., hamartoma) have the potential to expand intranasally. They can obstruct the nasal passageways completely. Angioleiomyomas are benign tumors that originate from the smooth muscle of vessels.[52] In dogs, there are few descriptions of nasal or nasopharyngeal angioleiomyoma resulting in clinical signs of sneezing and bilateral nasal discharge[53,54] (Video 238-14) (see ch. 344, 346, and 348).

Nasopharynx

Anatomy and Functional Considerations

The nasal portion of the pharynx extends from the choanae to the intrapharyngeal ostium (see Figure 238-1). While the lumen of the **rostral part** is completely bound and protected against compression or collapse by bony structures (hard palate, vomer and palatine bones), the **middle part** is only dorsally (skull base) and laterally (hamuli of the pterygoid) protected by a bony boundary, and the lumen of the **caudal part** only dorsally (skull base). The non-bony walls are formed by palatopharyngeal muscles, and therefore susceptible to compression from outside or collapse due to negative intraluminal pressure. Nearly all muscles of the pharynx and the soft palate serve as constrictors, protecting the nasal airways during swallowing from aspiration of food or fluids. Only a few (stylopharyngeus and tensor veli palatini muscles) keep the lumen of

the soft part of the nasopharynx open.[13,55] **Collapsibility** of the nasopharynx is a major problem in brachycephalic animals and will be discussed below.

Functionally, the nasopharynx is important for **breathing and swallowing.** During swallowing, the pharynx closes completely, whereas it must be open when nasal breathing. Because of these antagonistic tasks, collapsibility of the pharyngeal wall is precisely regulated by complicated neuromuscular mechanisms.[56] However, in dogs, the functional separation of respiratory and feeding activities might be lost. There is evidence that dogs cannot breathe during lapping or mastication, and it is suggested that this might be due to specializations of the soft palate and epiglottis in order to enable **thermal panting.**[57]

Connection Between the Nasopharynx and the Middle Ear

There is an important and **complex connection between the nasopharynx and the middle ear.** Embryologically, the lumen of the middle ear is an extension of the pharynx. The auditory tube (Eustachian tube) connects the middle ear cavity with the nasopharynx. Opening and closing functions of the Eustachian tube are both physiologically and pathologically important. Normal opening of the Eustachian tube equalizes atmospheric pressure in the middle ear; closing of the Eustachian tube protects the middle ear from nasopharyngeal secretions. Mucociliary clearance drains mucus away from the middle ear into the nasopharynx, thus preventing infection from ascending to the middle ear. Usually, the Eustachian tube is closed; it opens during actions such as swallowing, yawning, or sneezing, and thereby permits equalization of middle ear and atmospheric pressures. Solely the tensor veli palatini muscle induces active dilation/opening during each act of swallowing.[58,59]

Clinical Manifestations of Nasopharyngeal Disease

Clinical signs of nasopharyngeal disorders can vary considerably because the nasopharynx is directly connected to three different systems: Rostrally to the respiratory system of the nose; caudally to the oropharynx and thereby to the crossing of the respiratory pathway with the digestive system; and dorsolaterally via the Eustachian tube to the middle ear. Accordingly, clinical signs can be of **respiratory, digestive** as well as **otological** or **neurological** nature, or a mixture thereof. Typical signs are difficult, noisy and in particular stertorous breathing; reverse sneezing; nasal discharge; expiratory cheek puff (indicates complete obstruction of the nasal-pharyngeal airway); retching (indicating velopharyngeal incompetence); and vestibular signs (when together with Eustachian tube dysfunction).

The lumen of the nasopharynx can either be too small (up to totally obstructed), or "too open" because the closing mechanisms fail during feeding and drinking. Breathing problems predominate if the nasopharyngeal lumen is obstructed (polyp, tumor, stenosis, dynamic collapse). If nasopharyngeal closure is incomplete due to congenital or acquired palatal defects (cleft palate, palatal fistulas after "stick-wounds" or complication after palatal surgery), nasal discharge, digestive and/or middle ear problems dominate the clinical picture. Similar to oronasal communications, food and fluids are pressed into the lumen of the nasopharynx during swallowing and, from there, into the nasal cavities, causing local foreign body reactions and nasal discharge (see below).

Examination of the Nasopharynx

In the conscious dog, a physical examination of the nasopharynx is more or less impossible. Decisive diagnostic procedures for this area require general anesthesia. This should be thoroughly discussed with the owner. Some potentially treatable diseases may otherwise be missed or necessary treatment not instituted. Initially, the soft palate is inspected orally. Digital palpation starts rostrally between the pterygoid boundaries and advances caudally. Advanced diagnostic tools like endoscopy and/or cross-sectional imaging in combination with histologic examination are often indispensable to establish a definitive diagnosis.

Endoscopy

Endoscopic examination is the key diagnostic tool for the nasopharynx (see ch. 96). It can be performed with both rigid and flexible endoscopes, depending on the examiner's preference. Endoscopic access is possible from both directions; in dogs and cats, usually from posterior through the oral cavity (rigid, 120°, 4 mm or flexible) (Video 238-15) and in most dogs also from anterior through one of the nasal cavities (rigid, 0° or 30°, 2.7 or 1.9 mm) (see Video 238-2). The **anatomic landmarks** that should be recognized are listed in E-Box 238-5. Even minor manipulations within the nasopharynx are very irritating and can provoke strong

reactions, particularly in cats. A potent analgesic component should be part of the anesthetic regime; the instillation of a local anesthetic is usually helpful.

Computed Tomography

If a nasopharyngeal mass is palpable or endoscopically visible, or an association to a lesion of the middle ear is suspected, a CT examination is highly recommended. CT gives information on the extension of a mass and on possible relations to the tympanic bulla. Wrong positioning during CT examination can obscure certain pathologies. Recommendations on how to position patients with suspected nasal-pharyngeal disease for CT examination are listed in E-Box 238-6.

E-Box 238-6

Recommendations to Position Patients with Suspected Nasal-Pharyngeal Disease for CT Examination

Prone position
Upper jaw in fixed maxillary suspension
Hard palate parallel to scanning table
Mouth open
Mandible freely moving/hanging
Soft palate freely moving, not dislocated dorsally by endotracheal tube or tongue base
If excessive intraluminal fluids present, careful removal with soft suction-tube prior to scan

Diseases of the Nasopharynx

Because of functional considerations the stenoses of both the meatus nasopharyngeus (as part of the nose) and the nasopharynx are described together. Obstruction can occur as a congenital anomaly or secondary to a foreign body, obstructive wound healing after a local inflammation with mucosal ulceration or expanding tissue of a mass.

Stenosis and Obstruction of the Nasopharyngeal Meatus

The nasopharyngeal duct can be obstructed on three levels: (1) the most rostral point is underneath the wing of the vomer, (2) the tubular canal itself and (3) the bilateral caudal openings of the meatus, the choanae (Figure 238-8).

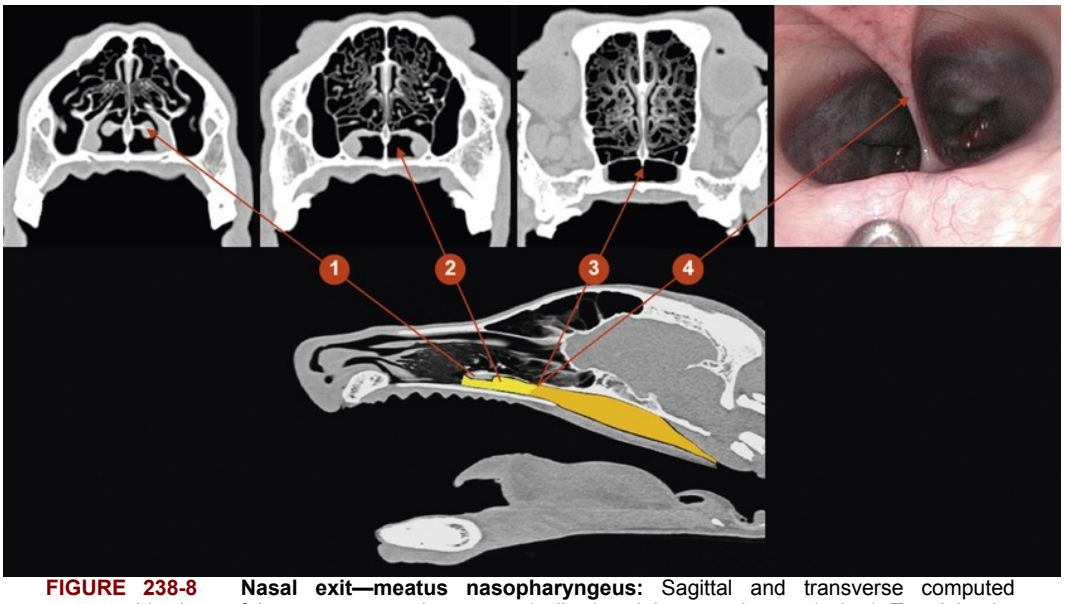

FIGURE 238-8 **Nasal exit—meatus nasopharyngeus:** Sagittal and transverse computed tomographic views of the meatus nasopharyngeus (yellow) and the nasopharynx (ochre). Top right, the postrhinoscopic view into the meatus nasopharyngeus (German Shepherd, physiologic situation). 1, Wing of the vomer; 2, lumen of the meatus nasopharyngeus; 3, caudal border of the septum; 4, caudal border of the septum, postrhinoscopic view.

Hereditary Malformations

Ongoing breeding for exaggerated miniaturization seems to disrupt the anatomical balance between bony boundary and the size of the soft tissues. In toy breeds like Chihuahua, Pomeranian and Shi Tzu the vomerine alae can be too large in relation to the lumen, leaving a passageway of only 1 mm or less (Figure 238-9).

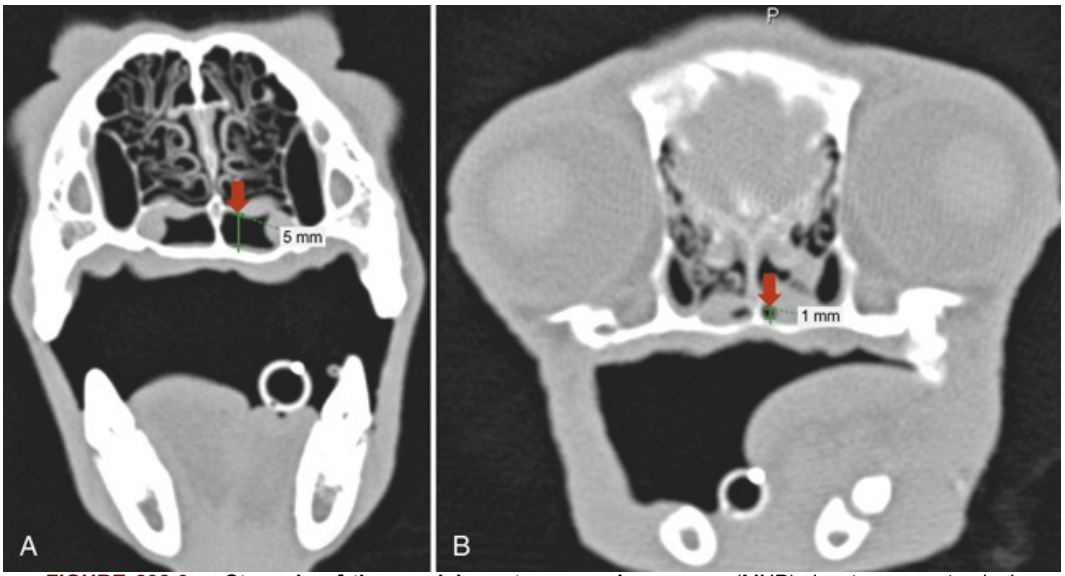

FIGURE 238-9 **Stenosis of the cranial meatus nasopharyngeus** (MNP) due to an anatomical imbalance between the meatus-lumen and the size of the vomerine ala as a consequence of exaggerated miniaturization in certain toy breeds. **A,** Physiologic size of the MNP (5 mm) in an adult Yorkshire Terrier (3 kg BW). **B,** Extreme narrowing of the MNP (1 mm) in an adult Chihuahua (1.1 kg) with clinical signs of upper airway obstruction (stertor, mouth-breathing, respiratory distress during sleeping and feeding).

Obturation of the Lumen

Various reasons can lead to an isolated obstruction within one or both lumina of the nasopharyngeal meatus.

Examples of non-malignant conditions are trauma to the skull base, rhinoliths[60] and hamartoma (Figure 238-10). **Choanal atresia** is rarely reported in dogs and cats.[61,62] It results from an embryological resorption failure of the oronasal membrane that occludes the nasopharyngeal meatuses. The malformation leads to either unilateral or bilateral partial or complete choanal occlusion. The defect can be bony, membranous or a mixture of both.[63] It is probably very difficult to differentiate between a true choanal atresia and obstructing scar tissue resulting from ulceration of mucosal tissue at this location (foreign body, regurgitation into the nasopharynx, infection).

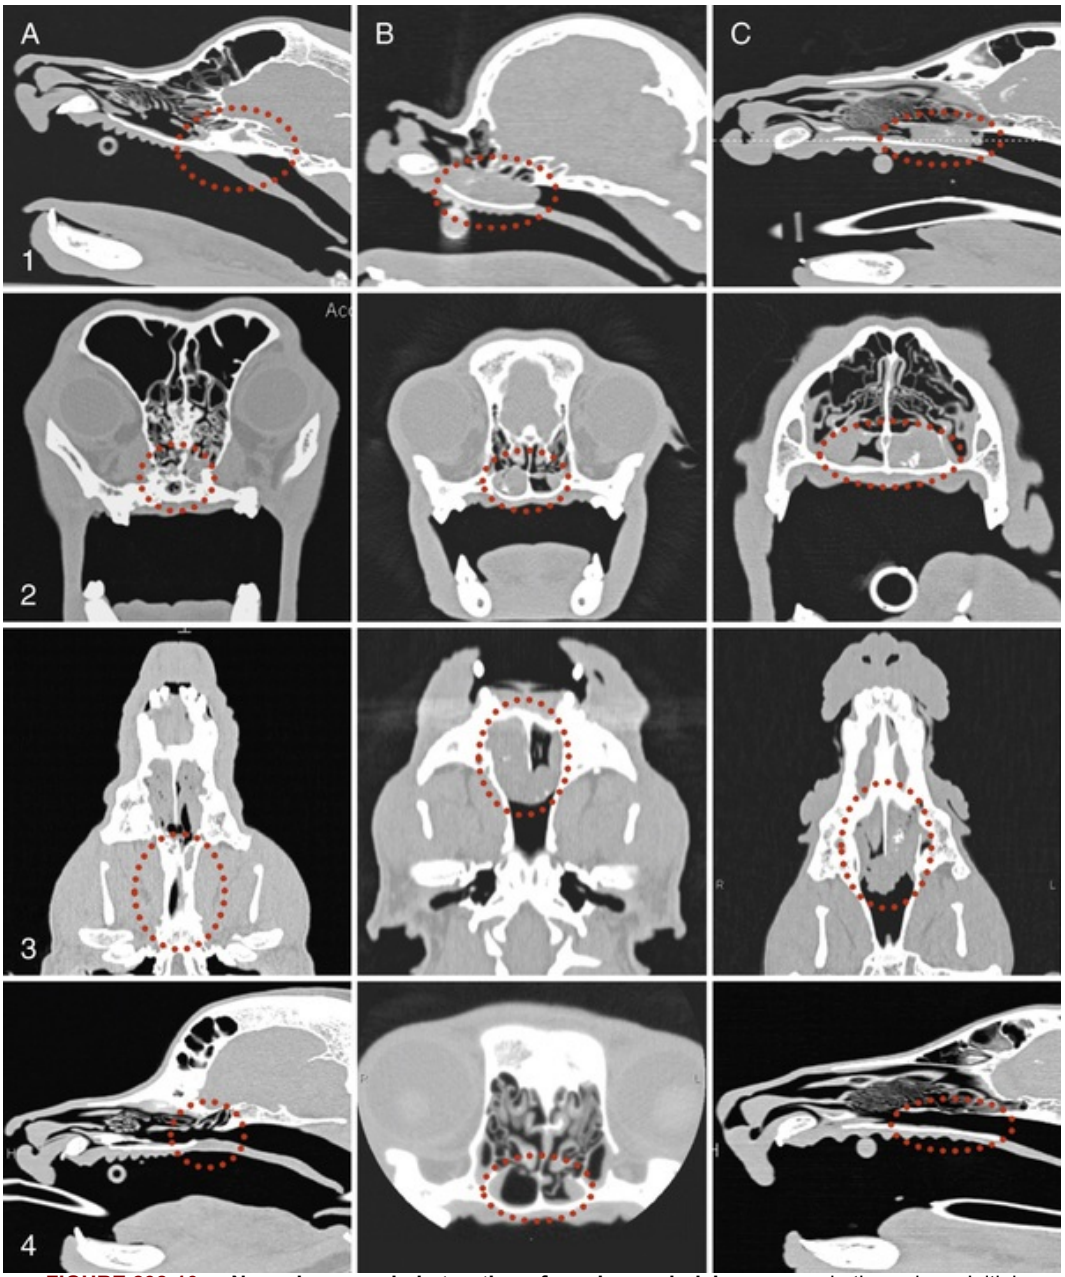

FIGURE 238-10 **Nasopharyngeal obstruction of varying underlying causes** in three dogs. Initial CT images (1) sagittal, (2) transverse and (3) dorsal planes. (4) CT examination after successful transnasal endoscopic intervention. **A,** Trauma—skull base fracture (crossbreed). **B,** Rhinolith with central plant remnant (Chihuahua).[60] **C,** Hamartoma (Weimaraner).

Stenosis and Obstruction of the Nasopharynx

Nasopharyngeal stenosis can occur as a congenital anomaly comparable to choanal atresia or as a

consequence of constrictive wound healing resulting from an inflammatory condition, surgery or trauma. In addition, the lumen can be obstructed by intra- or extraluminal expanding lesions. Intraluminal reasons can be inflammatory polyps (see below) or foreign bodies. Extraluminal reasons are, e.g., expanding lesions from the middle ear like extravasating infections causing inflammation and swelling of the peribullar tissue or other space-occupying lesions like cholesteatoma,[64] intrapalatal masses or subepithelial cysts[65-67] (Figure 238-11).

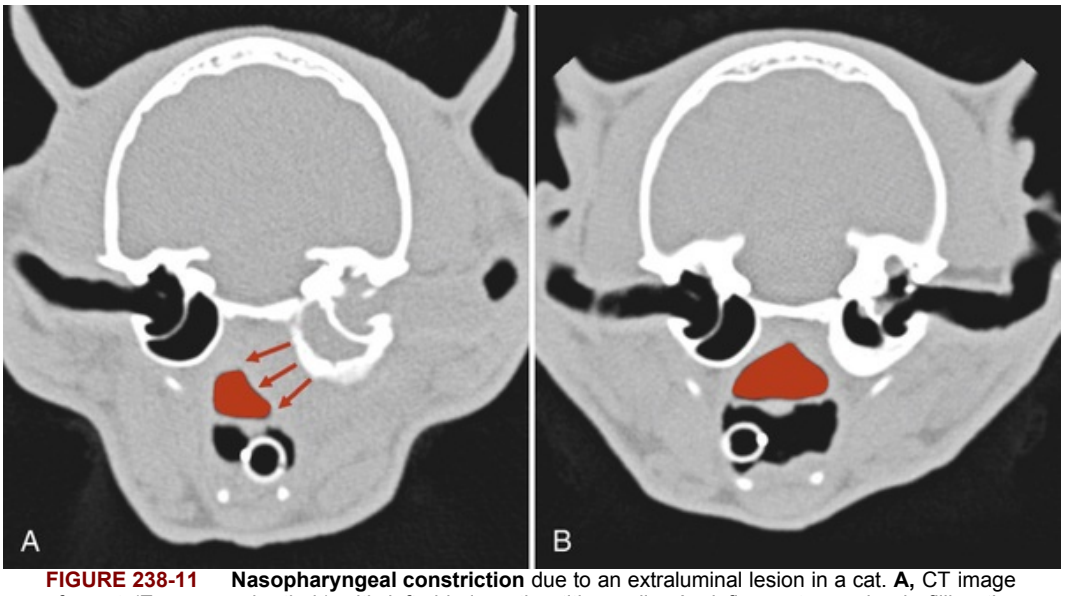

FIGURE 238-11 **Nasopharyngeal constriction** due to an extraluminal lesion in a cat. **A,** CT image of a cat (European shorthair) with left-sided septic otitis media. An inflammatory polyp is filling the external ear canal and both compartments of the bulla tympanica. The extravading infection causes peribullar swelling and narrowing of the lumen of the nasopharynx (arrows). The first clinical sign was stertorous breathing. **B,** Situation 2 months after successful treatment by interventional otoendoscopy.

Treatment of Nasopharyngeal Stenosis

Various methods of treatment have been reported, including surgical mucosal advancement[68] and balloon dilatation (see ch. 121).[65,69] The need for repeated interventions and the occurrence of complications have been reported for all of these techniques—the greatest problem being the recurrence of the stenosis. Promising for treatment in cats and dogs with soft tissue stenoses seems to be the use of a removable silicone stent.[70] For cats, the investigators described a very simple technique for opening the stenosis and preventing re-stenosis with an equally simple technique leaving no foreign material inside the patient. Possibly severe complications like palatal erosion and oronasal fistulation secondary to remaining stent material can thus be avoided.[71] However, even with temporary stenting the function of the auditory tube should be kept in mind. Any occlusion of the nasopharyngeal openings of the Eustachian tube leads immediately to a secondary secretory otitis media (Figure 238-12).

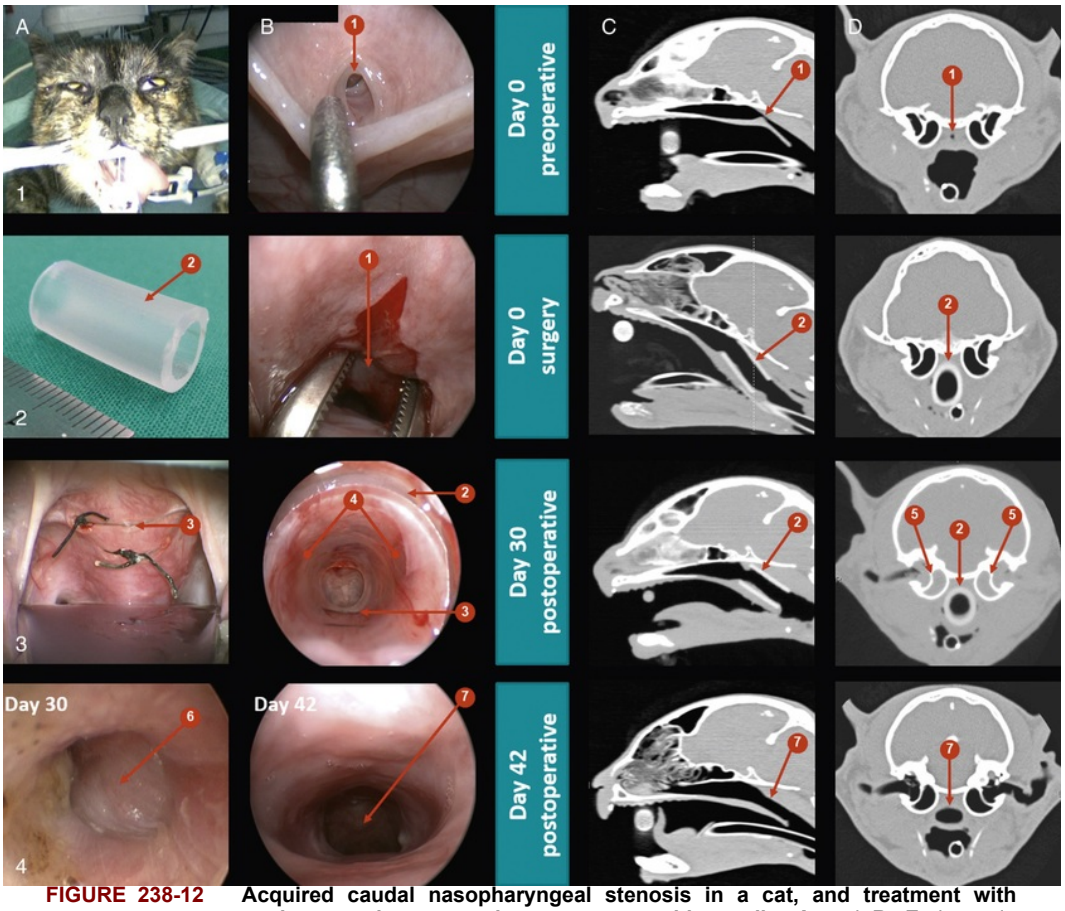

FIGURE 238-12 **Acquired caudal nasopharyngeal stenosis in a cat, and treatment with temporary stent, causing transient secondary secretory otitis media. A** and **B,** Endoscopic images: **(B1)** postrhinoscopic view on stenosis; **(B2)** opening of the stenosis with a curved forceps under postrhinoscopic control; **(A3)** view on the soft palate with transpalatal sutures to prevent stent migration; **(B3)** postrhinoscopic view into lumen of the stent—marks to indicate location of the openings of the auditory tube—the stent obstructs both; **(A4)** day 30, because of the blocked drainage of mucus from the middle ear the congestion bulges the eardrum into the external ear canal—via tympanocentesis the mucus within middle ear was flushed into the nasopharynx; **(B4)** day 42, the lumen of the widened nasopharynx is completely epithelialized and bland. **C** and **D,** Sagittal and transverse CT images: **(C1, D1)** nasopharyngeal stenosis; **(C2, D2)** silicone stent *in situ*; **(C3, D3)** silicone stent *in situ* 30 days later; **(D3)** note the bilateral mucotympanum due to retained mucus; **(C4, D4)** day 42, the physiologic lumen of the nasopharynx is restored; **(D4)** both tympanic bullae are in a physiologic condition again. 1, Caudal nasopharyngeal stenosis; 2, silicone stent; 3, transpalatal sutures; 4, marks to indicate the level of the nasopharyngeal openings of the Eustachian tube; 5, bulla tympanica (dorsolateral and ventromedial compartments filled with mucus); 6, eardrum, bulging into the external ear canal, thickened and non-transparent; 7, restored nasopharyngeal lumen.

Nasopharyngeal Tumors and Non-Malignant Nasopharyngeal Masses

Lymphoma is the most common nasal tumor in cats. 10% were found to be isolated tumors of the nasopharynx; a further 8% involved both nasopharyngeal and nasal tissue.[67,72]

Nasopharyngeal inflammatory polyps are non-neoplastic masses, developing either from inflamed mucosa of the middle ear or the auditory tube. The cause of inflammatory polyps is unknown, and chronic inflammation, ascending pharyngeal infection, congenital origin, and association with feline calicivirus have all been implicated.[73] They usually occur in younger cats. Polyps either extend through the auditory tube into the nasopharynx (nasopharyngeal polyp) or from the bulla tympanica through the eardrum into the external ear canal (aural polyp). When polyps grow within the lumen of the nasopharynx, respiratory signs increase gradually, starting with occasional stertor and possibly leading to a complete obstruction of the nasopharyngeal airway. At this stage, expiratory cheek puff or open-mouth breathing and nasal discharge (even mucopurulent when secondary bacterial infection) can be seen. Owners report increasing breathing problems and restlessness, especially during sleep or attempt to fall asleep. When the polyp grows in size within the tympanic bulla, Horner syndrome and vestibular signs can be seen. When expanding from the

bulla tympanica through the eardrum into the external ear canal, they cause signs of otitis externa with otorrhea and head shaking (see ch. 237). Large polyps can be visible as a mass in the external ear canal. CT is an excellent imaging tool for the supportive diagnosis of nasopharyngeal polyps in cats. Nasopharyngeal polyps are treated by slow traction avulsion. After that, mucus or pus inside the Eustachian tube should be removed with a curved suction pipe attached under videoscopic control to the usually dilated opening of the auditory tube (Video 238-16). The bulla tympanica should be examined, ideally with CT or endoscopically. All remnants of polyp tissue within the tympanic bulla should be carefully removed by endoscopic intervention. The recurrence rate of inflammatory polyps seems to be lower when the patient is treated with corticosteroids.[74]

Nasopharyngeal cysts of varying origin and location can obstruct the cranial nasopharynx and even totally obliterate the lumen. The causes of cyst formation are not fully understood; possible congenital reasons are (1) a pharyngeal bursa of Luschka,[75] (2) a Thornwaldt's cyst[75-77] or (3) a cyst of the Rathke's pouch.[75,78] Acquired conditions can be retentional cysts of the seromucinous glands.[75]

Foreign bodies usually enter the nasopharynx posteriorly and lodge in the middle or rostral segment. Predominant clinical signs are reverse sneezing, and seldom nasal discharge. In cats, often a blade of grass is hooked with its rough surface to the mucosa. Posterior rhinoscopy allows a fast and reliable diagnosis. Extraction of foreign bodies from the rostral nasopharynx can be challenging. A curved forceps is used under endoscopic control (Video 238-17). Foreign bodies remaining undiscovered for a longer time may cause inflammation and serious tissue damage with subsequent nasopharyngeal stenosis.

Nasopharyngeal Closing Failure

Congenital palatal defects result when the two palatine shelves fail to fuse during fetal development.[79] **Acquired defects** of the soft palate can result after stick-wounds or palatal surgery (see ch. 272).

Paranasal Sinuses

Anatomy and Functional Considerations

The reason for the presence of the paranasal sinuses has been a controversial subject for 1,800 years, since the time of Galen, 130-201 A.D.[80] Among many other theories, the following have been discussed for both humans and animals: absorb shock applied to the head for protection of sensory organs, thermally insulate the nervous centers, and lighten the bones of the skull for maintenance of proper balance of the head.[81] In human medicine, the discovery of paranasal sinuses producing nitric oxide (NO) has altered the traditional explanations of sinus physiology.[82] Endogenous NO is continually synthesized in the respiratory epithelium and plays a key role in the physiological regulation of airway functions. NO is upregulated and has diverse roles as a modulator of ciliary function, neurotransmission, bronchodilation, vasodilatation, platelet aggregation and immune function.[83,84]

The frontal sinus, the sphenoid sinus and the maxillary recess are all lined with mucosa and are connected to the middle nasal meatus. In dogs the **frontal sinus** is divided into three different parts *(lateral, medial* and *rostral)* and connects through a nasofrontal opening into the nasal cavity. Ectoturbinates, covered with olfactory mucosa, can extend into the frontal sinus. In brachycephalic animals, the frontal sinus can either be much reduced in size or even absent altogether. A small **sphenoid sinus** is largely occupied by endoturbinate IV. The lumen of the **maxillary recess** is usually empty. The lateral nasal gland (see thermoregulation, above) lies submucosally against the medial wall of the maxilla within the maxillary recess. In the cat there is only one frontal sinus on each side, the maxillary recess is small, and there is a large sphenoid sinus that extends caudally from the nasal cavity into the sphenoid bone, ventrally to the brain.[13,85]

Clinical Manifestations of Paranasal Sinusoidal Disease

Pathologies of the paranasal sinuses are usually associated with diseases of the nasal cavities. Common clinical signs are nasal discharge of varying character and consistency. Smaller amounts of discharge may remain undiscovered as they can be swallowed. The paranasal sinuses are not accessible for clinical examination in the awake patient, except for visible loss of symmetry or deformity of the face. Diagnosis requires general anesthesia, a clinical examination, diagnostic imaging and endoscopy with tissue biopsies (see ch. 96).

Examination of the Paranasal Sinuses

Due to their posterior location and subtle presenting signs, isolated sinusoidal lesions, in the past, have often been missed and were reported as rare occurrences. However, with the availability of endoscopy, CT and MRI, diseases of the paranasal sinuses are now more frequently diagnosed.[86] Studies determining the value of rhinoscopy, radiography, and CT of the head for canine nasal and paranasal disease diagnosis showed that rhinoscopy and rhinoscopy combined with CT contributed significantly to disease diagnosis.[32]

Endoscopy

The endoscopic approach to all three paranasal sinuses is possible, but with a varying degree of tissue perforation. Rigid endoscopes have distinct advantages. They are usually smaller in diameter and provide a larger and clearer view. Various instruments (suction pipe, forceps) can be introduced alongside the endoscope. This allows bimanual manipulation of tissues and foreign material. Flexible tubes and catheters can be guided into certain directions and locations. Flexible scopes allow maneuvering within complex areas like the caudal and lateral compartments of the frontal sinus.

The **sphenoid sinus** is easy to access with anterior rigid rhinoscopy. The endoscope is slowly advanced medially alongside the nasal septum, and navigated at the level of the lower septum swell body through the branches of the ventral concha in the direction of the vomerine ala. The sinus can be entered directly above and caudally to the vomerine ala (Video 238-18).

The **frontal sinus** can be accessed only after perforation of the dorsal concha. In dogs suffering from sinonasal aspergillosis, this passageway is usually already open due to turbinate lysis and destruction. A rigid endoscope (2.7 mm, 30° or 45° in medium- or large-sized dogs, 1.9 mm in smaller dogs and cats) can be used to perforate the thin laminae of the dorsal concha at the caudodorsal border of the ventral concha and is further advanced caudodorsally. This allows the tip of the endoscope at the rostro-ventral part and the view into the rostral part of the sinus is possible in most dogs. If the rigid endoscope is then replaced with a small flexible one, even further exploration of the frontal sinus is possible (Video 238-19).

The **maxillary recess** can be accessed after advancing the endoscope laterally through the middle nasal meatus between the dorsal lamellae of the ventral concha and the dorsal concha. A certain amount of compression upon the ventral concha is necessary to lower the tip of the endoscope behind the ventral concha in order to achieve an angle to look downward into the maxillary recess. Once the pathway through the medial meatus has been widened, the endoscope can be replaced with a small flexible one in order to explore the recess further (Video 238-20).

Diseases of the Paranasal Sinuses

Sinonasal Aspergillosis

The best known sinonasal disease is probably the infection of nasal and sinusoidal cavities with *Aspergillus* spp. Usually, the frontal sinus is affected but large fungal masses can fill the maxillary recess as well (Video 238-21) (see ch. 235 and 236).

Cysts of the Paranasal Sinuses

Cysts of the paranasal sinuses are usually mucous retention cysts. They can be appreciated on routine cross-sectional examinations and are often asymptomatic. The major concern lies in differentiating them from malignant diseases. The mucous retention cyst is found infrequently in brachycephalic and miniature breeds within the sphenoid sinus and seems to be comparable to similar cysts in man[87] (Video 238-22) (see below and ch. 149).

Brachycephalic Syndrome

Brachycephaly is a discrete mutation that has been selected for in many popular dog breeds, e.g., Bulldog breeds, Pug, and Boston Terrier.[88] It is an early-onset, lifelong, ultimately deteriorating and debilitating syndrome with predominantly respiratory restrictions. Brachycephaly predisposes animals to experience severe and unpleasant breathlessness with a strong negative impact on the animal's welfare.[27,89,90] Especially in smaller breeds, adult animals show typical characteristics of young animals addressing the **baby scheme** in many owners.[91] Larger brachycephalic breeds were used in medieval times, until only 200 years ago, in a

blood sport called **bull baiting.** This demanded a maximum of **exercise tolerance** from the dogs and a short head conformation was regarded as advantageous for biting. Today, most brachycephalic dog breeds are described first and foremost as suffering from pronounced **exercise intolerance** due to insufficient breathing. The reason for this dramatic development is an **exaggerated breeding** for a snub-nosed appearance. The shift from functional to aesthetic selection pressure, according to written **breeding standards** of various kennel clubs, malformed the entire upper respiratory tract in these breeds, leading to a series of consecutive airway stenoses. A head conformation that is demanded to be "round" (breeding standard Pug) or "square" (breeding standard Bulldog breeds) is *per se* incompatible with healthy, functional upper airways. However, a pervading acceptance of airway disorders as *"normal for the breed"* may constrain reforms intended to improve the welfare of affected breeds by "blinding" veterinarians, owners and breeders to the welfare impacts of these disorders.[27,92-94] The fact that brachycephaly is a purely man-made disorder with massive consequences on quality of life must raise the question of whether these animals should be bred any longer.[27,89,90,93] Popular **brachycephalic cat breeds** are Persian, exotic shorthair, and Himalayan. In Scottish Folds, the airway malformation is possibly restricted to the nasal entrance.

Pathoanatomy and Functional Consequences of a Multilevel Obstruction

Selective breeding for a short head results in impaired craniofacial development and an obvious discrepancy between the viscerocranium and the neurocranium (Figure 238-13).[95,96] Specific structural deformities lead to the anatomical obstruction of the upper airways. Recent studies have shown that brachycephalic breathing problems are caused by far more numerous obstructing malformations than was previously thought.[1,97-99] Originally, the typical cause of respiratory distress was seen as being threefold: stenotic nares, an elongated soft palate and in some dogs everted laryngeal ventricles (laryngoceles). However, ongoing excessive selection for brachycephaly obviously has changed and deformed the entire upper respiratory tract. E-Box 238-7 lists both well-known and previously less well-recognized anatomical constrictions in the upper airways.

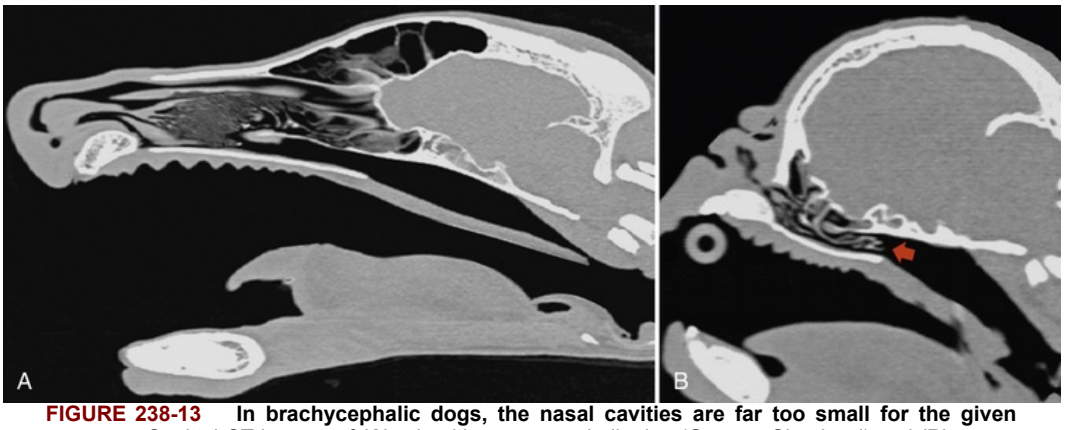

FIGURE 238-13 In brachycephalic dogs, the nasal cavities are far too small for the given contents. Sagittal CT images of **(A)** a healthy normocephalic dog (German Shepherd) and **(B)** a pug. Note the undersized nasal cavity, the missing frontal sinus and the obstruction of the meatus nasopharyngeus in the pug by caudally-growing aberrant turbinates (CATs, arrow).

E-Box 238-7

Overview of Obstructing Malformations in the Upper Airways as a Consequence of Selective Breeding for Brachycephaly

Nasal Entrance

Stenosis of the nares
Stenosis of the vestibulum

Nasal Cavity

Obstruction of intranasal airways due to malformed and aberrantly growing turbinates (rostral aberrant turbinates: RAT) *together with*
Intranasal mucosal contact points

Nasal Exit—Nasopharyngeal Meatus and Choanae

Obstruction due to malformed conchae growing caudally (caudal aberrant turbinates: CAT)

Nasopharynx

Reduced lumen and increased collapsibility of the nasopharynx (see "meat-in-the-box model") due to

- Increased length of the soft palate
- Increased thickness of the soft palate
- Narrowing of the hamuli pterygoidei
- Space-occupying structures in the oropharynx
  - Enlarged palatine tonsils
  - Macroglossia (predominantly Bulldog breeds and Boxer)

Larynx

Collapse due to laryngomalacia with impairment of arytenoid abduction (predominantly Pug)
Obstruction of rima glottidis due to protruding tissue of lateral ventricle (laryngocele) (Pug and Bulldog breeds)
Obstruction of rima glottidis due to malformed over-thick vocal folds
Impairment of opening function (predominantly Pug)

Trachea

Hypotrachea (predominantly Bulldog breeds)
Tracheobronchomalacia (predominantly Pug)

Stenosis at the Nasal Entrance

The stenosis of the canine nasal entrance seems to be influenced by three different factors: a *first and well-described stenosis* is clearly visible to the naked eye. The naris, the visible opening plane into the nasal vestibule, is compressed to a small slit. This slit compromises a vertical and a horizontal part, the latter widening slightly ventrally. In relation to the nose, the exterior part of the nasal wing is far too large and presses against the philtrum/septum from the lateral aspect (Figure 238-14; Video 238-23). A *second stenosis*, less known but even more important and much more difficult to treat, is hidden behind the first stenosis and usually invisible from the outside. It is the obstruction inside the nasal vestibulum due to a large vestibular bulb that is oversized for the given lumen inside the vestibulum (see Figure 238-14; Video 238-24). Finally, as *third stenotic factor*, there is the immobility of the bulb. In brachycephalic animals, its size appears to greatly restrict mobility, thereby impeding abduction. This functional restriction further reinforces the anatomical stenosis.

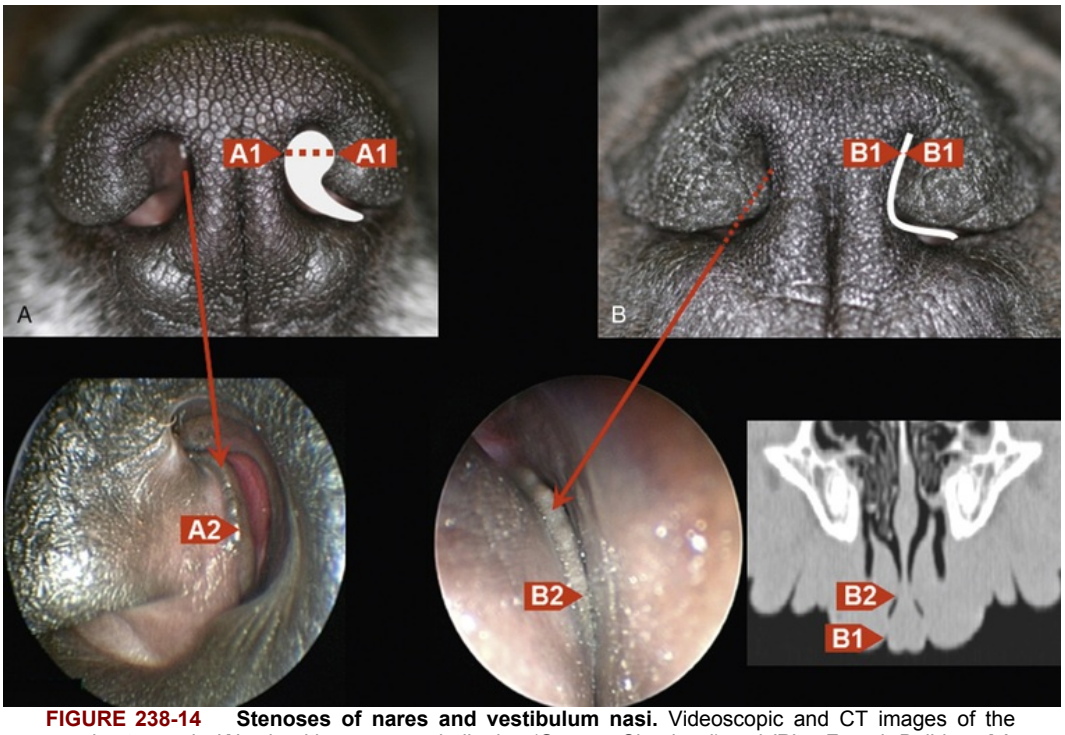

FIGURE 238-14 **Stenoses of nares and vestibulum nasi.** Videoscopic and CT images of the nasal entrance in **(A)** a healthy normocephalic dog (German Shepherd) and **(B)** a French Bulldog. **A1,** Physiologic width of the vertical part of the left naris. The naris is comma-shaped with a wide head of the comma (dotted red line). **B1,** Pathologic narrowing of the vertical part of the left naris—first (visible) stenosis. The naris is slit-shaped, indicating the malformation of the alar wing. **A2,** Voluminous physiologic vestibular bulb. **B2,** Pathologic narrowing within the vestibulum—second stenosis. An immobile vestibular bulb is pressed against the septum. (See Videos 238-23 and 238-24.)

Stenosis Inside the Nasal Cavity and the Nasal Outlet

It is remarkable that the nasal cavity itself has seldom been considered as a contributing factor to airway obstruction despite the fact that the fundamental difference between brachy- and normocephalic dogs is the extremely shortened nose. Various mechanisms contribute to **brachycephalic intranasal airway obstruction:**

The **nasal cavity** itself is far too small for the given contents (see Figure 238-13).[13,37]

The conchae of brachycephalic dogs are **macroscopically**[1,37,100] and **microscopically**[101] **malformed** and **grow aberrantly** into air-conducting spaces, obstructing their lumen and causing a rise in intranasal airway resistance.[102,103] **Conchal configuration** can be assessed as aberrant if turbinates branch into the nasal meatuses, obstructing their lumen. Conchal lamellae spreading rostrally to the point of first branching of the plica alaris into the concha nasalis ventralis (CNV) are classified as *rostral aberrant turbinates* (RAT) (Figure 238-15). Conchal lamellae spreading caudally into the meatus nasopharyngeus (MNP), passing ventrally to the wing of the vomer, are classified as *caudal aberrant turbinates* (CAT) (Figure 238-16).[1]

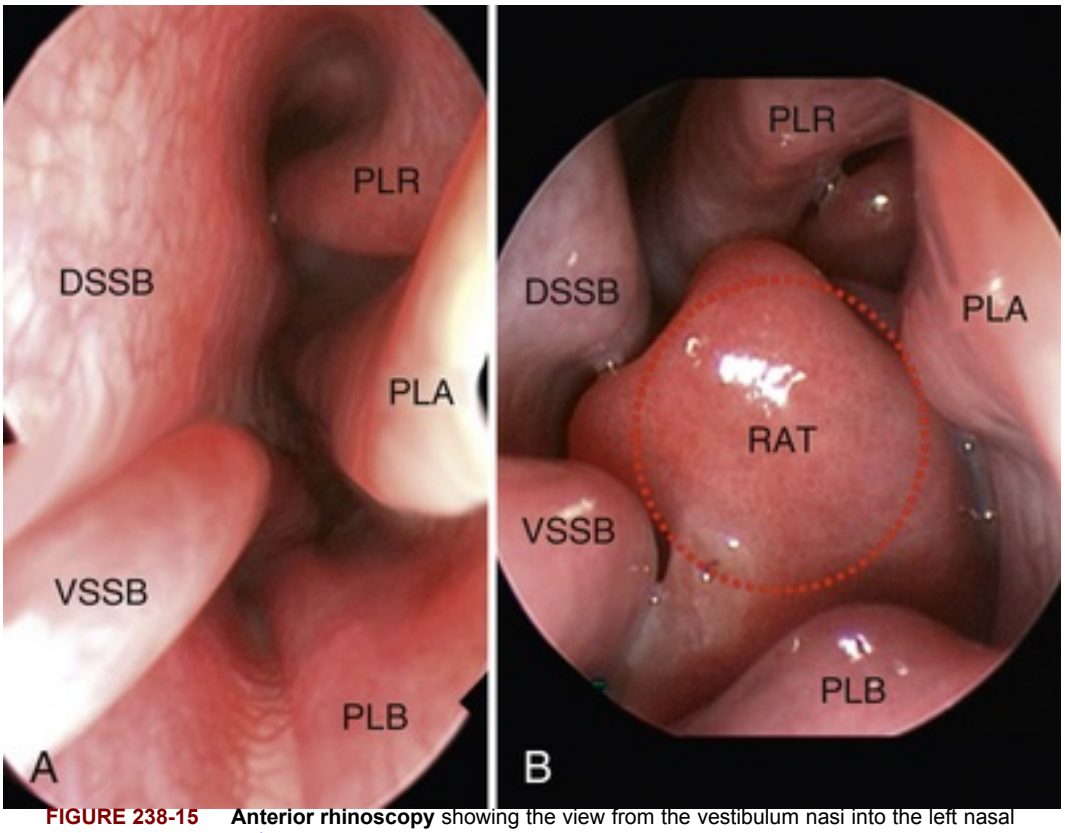

FIGURE 238-15 **Anterior rhinoscopy** showing the view from the vestibulum nasi into the left nasal cavity ("5-folds-view").[1] **A,** In the normocephalic dog (German Shepherd) there is a free view into the nasal meatus and on the five intranasal folds, the ventral septal swell body (VSSB), dorsal septal swell body (DSSB), plica recta (PLR; straight fold), plica alaris (PLA; alar fold), plica basalis (PLB; basal fold). **B,** In the French Bulldog, a huge rostrally growing rostral aberrant turbinate (RAT) arising from the concha nasalis media is obstructing several nasal meatus. Note the multiple points of mucosal contact. (See Video 238-24.)

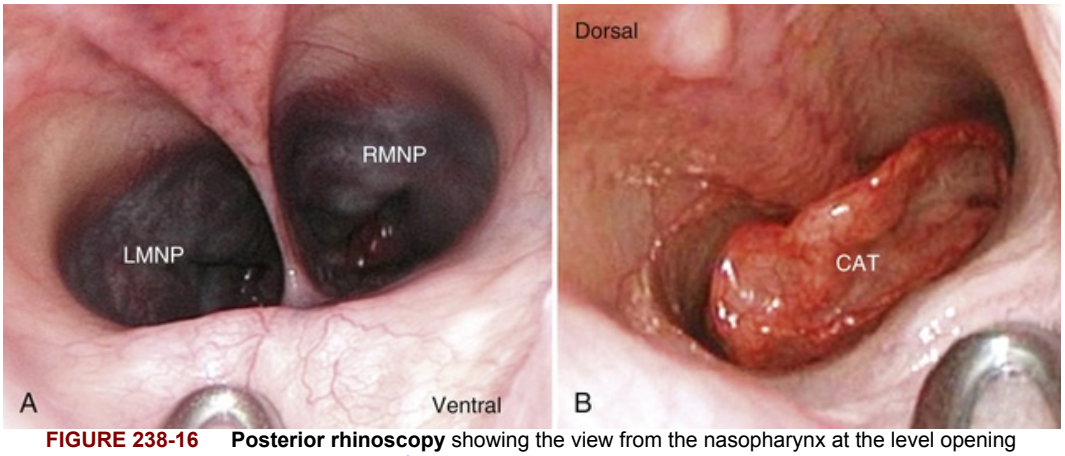

FIGURE 238-16 **Posterior rhinoscopy** showing the view from the nasopharynx at the level opening of the auditory tube (120° rigid optic).[1] **A,** In the normocephalic dog (German Shepherd), both meatus nasopharyngei (left and right MNP) separated by the caudal nasal septum are visible. **B,** In the brachycephalic dog (Pug) the view into both MNPs is blocked by a large caudally growing aberrant turbinate (CAT). (See Video 238-15.)

Intranasal mucosal contact-points contribute to the elevation of intranasal airway resistance. They can be found both between lamellae of the same concha (intraconchal) and between lamellae of different conchae (interconchal), as well as to adjacent mucosal surfaces of the surrounding nasal cavity (see Figure 238-15).[100]

Nasal conchae grow predominantly after birth. Despite the extraordinarily complex structure of the adult

canine conchae, this growth obviously stops before the mucosa of adjacent turbinate lamellae contact each other. The small air gaps surrounding each lamella provide for effective ventilation of the entire turbinate. In healthy non-brachycephalic dogs, even minor direct contact of adjacent intranasal mucosa is extremely rare. Possible intranasal obstruction results from a failure of growth termination, leading to pronounced intranasal mucosal contact. Decreased mucosal shear-stress due to reduced airflow as a consequence of stenotic nares might be involved in this failure of growth termination.

Failure to address intranasal obstruction might be an explanation for the lack of therapeutic success after conventional surgery for the brachycephalic syndrome.

Pharyngeal Obstruction—the "Meat-in-the-Box-Model"

Several factors contribute to the obstruction of the nasopharynx in a very complex mechanism. In general, this can be described as an **anatomical imbalance of the upper airway** with too much soft tissue for a given maxillomandibular enclosure size. A mechanical model can aid a better understanding of its functional importance.[56,104] The **"Meat-in-the-Box-Model"** describes a soft, collapsible tube that runs through a box with rigid outer walls (Figure 238-18). The box is filled with soft material (meat) that surrounds the tube. The tube corresponds to the nasopharynx; the framing outer box is the base of the skull and the lower jaw and cannot expand. Within the box and around the tube is soft tissue in varying quantities and of varying consistency (muscle, fat, connective tissue, tonsils). Since the tube has no rigid wall of its own, like the trachea does, for example, it is collapsible. E-Table 238-2 compares the **factors influencing the width of the nasopharynx** according to this model. The craniofacial malformation in brachycephalic dogs gives rise to a series of factors that either constrict the lumen of the nasopharynx or cause it to collapse:

E-TABLE 238-2

Factors and Measures Affecting the Width and Collapsibility of the Nasopharynx in Brachycephalic Animals

NARROWING/COLLAPSING OF THE NASOPHARYNX	OPENING OF THE NASOPHARYNX
Anatomical	
Increase in tissue mass within the box	Surgical reduction of tissue mass in the box
1. Hypertrophic soft palate 2. Hypertrophic tonsils 3. Relative macroglossia 4. Obesity	1. Reduction of soft palate volume 2. Tonsillectomy/tonsillotomy 3. Ø 4. Weight loss
Increase of stenoses-induced negative pressure during inspiration	Stenoses-reducing surgical intervention
1. Stenotic nares 2. Stenotic nasal vestibule 3. Intranasal obstruction by relative conchal hypertrophy and aberrant conchae	1. Widening of the nares 2. Vestibuloplasty 3. Laser-assisted turbinectomy (LATE)
Functional	
1. Closed mouth 2. Pressure against underside of head/neck (e.g., prone position) 3. Feeding	1. Open mouth

Shortening of the skull, especially of the upper and lower jaw, makes the overall box smaller. As the tissue inside the box is not reduced by the same proportion, narrowing occurs and less space is available for the tube inside the box.

Over-long soft palate: The additional length of the velum *per se* does not reduce the lumen of the nasopharynx anatomically. However, the airtight attachment to the epiglottic surface separates the oropharyngeal from the nasopharyngeal airway. This enhances the negative pressure in the nasopharynx during inspiration, thus increasing its collapsibility (Video 238-25).

Over-thick soft palate: The thickness of the soft palate in brachycephalic dogs can be many times over that of normocephalic breeds of the same or of larger size (Figure 238-17). Amazingly, the increased thickness of the soft palate seems not to be muscle hypertrophy, but due to increased stroma and increased proportions of salivary tissue while muscle mass was reduced. These findings can be interpreted as a consequence of both

acute and chronic muscle degeneration and necrosis due to constant tissue trauma.[105,106]

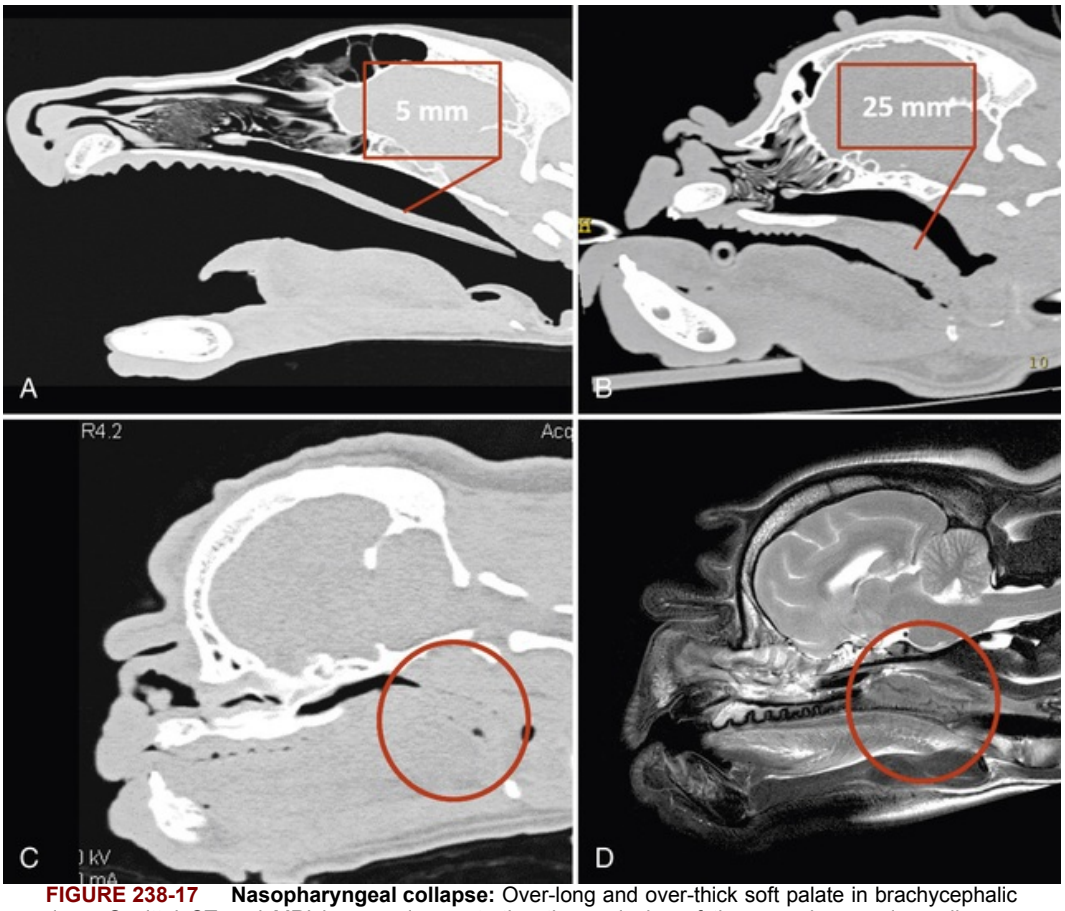

FIGURE 238-17 **Nasopharyngeal collapse:** Over-long and over-thick soft palate in brachycephalic dogs. Sagittal CT and MRI images demonstrating the occlusion of the nasopharynx depending on thickness of the soft palate and position of the lower jaw. **A,** Healthy normocephalic dog (German Shepherd). **B,** English Bulldog. The mouth gap is open and the nasopharyngeal airway open. **C,** Pug, sagittal CT. The mouth is closed and the nasopharyngeal airway occluded. **D,** Pug, same situation as **C** shown in an MRI image.

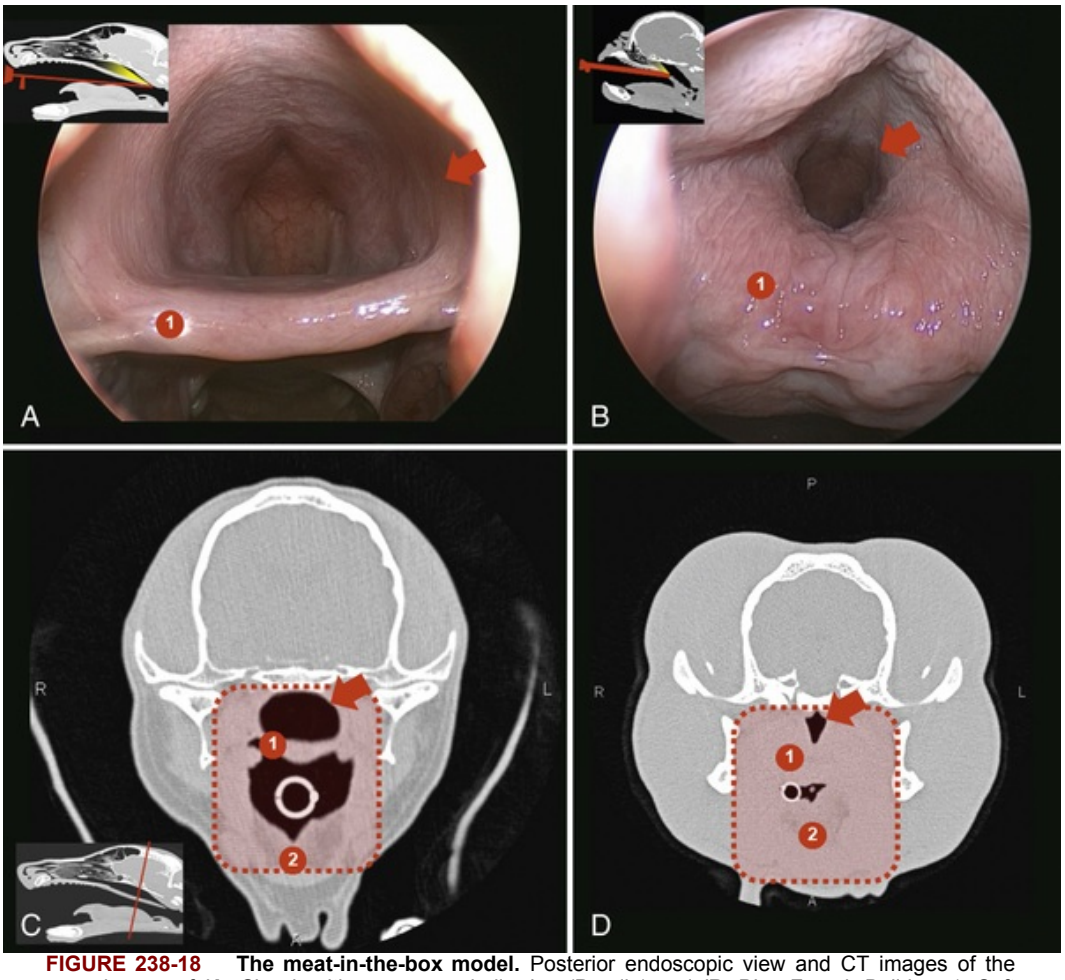

FIGURE 238-18 The meat-in-the-box model. Posterior endoscopic view and CT images of the nasopharynx of **(A, C)** a healthy, normocephalic dog (Poodle) and **(B, D)** a French Bulldog. 1, Soft palate; 2, tongue. The red dotted line indicates the "box" surrounding the "meat." The more "meat" is in the box, the smaller is the lumen of the nasopharynx (arrow).

Obesity probably plays an important role here. Additional fatty tissue stored in the box further narrows the tube.

Hypertrophic palatal tonsils and macroglossia can also be regarded as additional tissue mass. Both are pressed out of the oropharynx against the soft palate, forcing it dorsally into the nasopharynx. This causes compression, and possibly even complete obstruction, of the tube especially when the jaw is closed.

Closing the jaw or any ventral pressure in the head and neck region can hinder respiration in brachycephalic animals considerably (see Figure 238-17). This is why conscious animals very often dislike lying prone with their head stretched forward on the floor. With anesthetized brachycephalic animals, this position, for example, after extubation, can cause asphyxia. Feeding may have a comparable effect.

All the above factors cause constriction of the nasopharynx due to compression from the outside. However, there are also **factors that cause functional collapse** of the tube due to negative pressure in the airways during inspiration. If collapse occurs rhythmically, the tube walls clap together, producing a typical noise: **snoring.** If there is an elevated, pathological negative pressure in the pharynx, the causative stenosis must be located rostrally, in the nose. This is where the typical stenoses in brachycephalic dogs occur: (a) stenosis of the outer nares, (b) stenosis of the nasal vestibule and (c) stenosis of the intranasal airways due to hypertrophic and dysplastic conchae. Mathematically, halving the radius of the airways raises resistance 16-fold. In brachycephalic animals, particularly strong negative pressure has to be generated in the thorax to overcome the resistance produced by the complex nasal stenoses. Typical for this situation is the visible labored breathing. This strong negative pressure causes the tube of soft tissue that forms the nasopharynx to collapse. However, increased upper airway collapsibility enhances this vicious circle even further.

E-Table 238-2 lists the **therapeutic measures that can decrease nasopharyngeal collapsibility.** Again, the "meat-in-the-box" model helps illustrate what effects these measures can have. Too much tissue in the rigid box results in compression of the lumen of the tube. If the tissue is partly fat, it is necessary to reduce that fat

by prescribing weight-loss measures. Even in severe cases, this can be very beneficial, but the clinician is reminded that, as a rule, weight loss has only a supporting, hardly ever a curative, effect. The typical, often impressive enlargement of the soft palate seen in brachycephaly has to be reduced as well, either simply by shortening it or, in severe cases, also by thinning it. If large tonsils are protruding from the tonsillar crypt, they should be surgically removed, or at least reduced in their volume in order to create more space for the nasopharynx.

Larynx (see ch. 239)

Malformations of the brachycephalic larynx can be very pronounced and cause serious clinical consequences. Both the laryngeal skeleton and intralaryngeal structures seem to be affected. They all result in a clinically relevant reduction of the rima glottidis, thus increasing resistance to air flow through the larynx[107] (see E-Box 238-7). In spite of the fact that the brachycephalic pathoanatomy has been known for a long time and is relatively well described, the ongoing debate on etiopathology, especially on the question of primary and secondary abnormalities, is probably of a more anecdotal character. The **eversion of the lateral ventricles** was initially regarded as a single entity[108]; later on, the same author speculated that it could be the first stage in the pathogenesis of laryngeal collapse; additionally the author described a stage II with loss of rigidity and medial displacement of the cuneiform processes of the arytenoid cartilage, and a stage III with collapse of the corniculate processes of the arytenoid cartilages with loss of the dorsal arch of the rima glottidis. He presumed that this eversion and the other stages of the laryngeal collapse could be a consequence of persistent dyspnea causing negative inspiratory airway pressure and subsequent laryngeal overstress.[109] This assumption has been retained by the majority of the veterinary literature since then; it was, however, never proven. There are several indications to question the early interpretations and we probably have to distinguish between two different entities: malformation of **internal laryngeal structures** (everted lateral ventricles and the vocal folds) (Video 238-27) and, malformation of the **laryngeal skeleton** (Video 238-28). **Everted ventricles** rather seem to be a herniation of tissue alongside the caudal border of the ventricularis muscle and can therefore be regarded as a **"laryngocele"** (Video 238-26). The **vocal folds** of brachycephalic animals are often overly thick and have lost their typical slim structure. This also contributes considerably to the narrowing of the rima glottidis. An additional problem within the brachycephalic larynx can be the formation of vocal fold contact granulomas (Figure 238-19). Laryngeal overstress causes continuous microtrauma and direct damage to the tissue covering the vocal process of the arytenoid, leading to the formation of vocal fold contact granulomas. The mechanical trauma can be aggravated by regular contact of the glottis with gastric acids due to regurgitation and laryngopharyngeal reflux.[110] Malformation of internal laryngeal structures seems to occur independently from the stability of the laryngeal skeleton. There are indications that the "collapse" of the skeleton might have different causes: Pugs obviously suffer from a substantial loss of cartilage rigidity—both in larynx and trachea—while in Bulldog breeds the cartilages of larynx and trachea have a firm consistency[111] (see ch. 240).

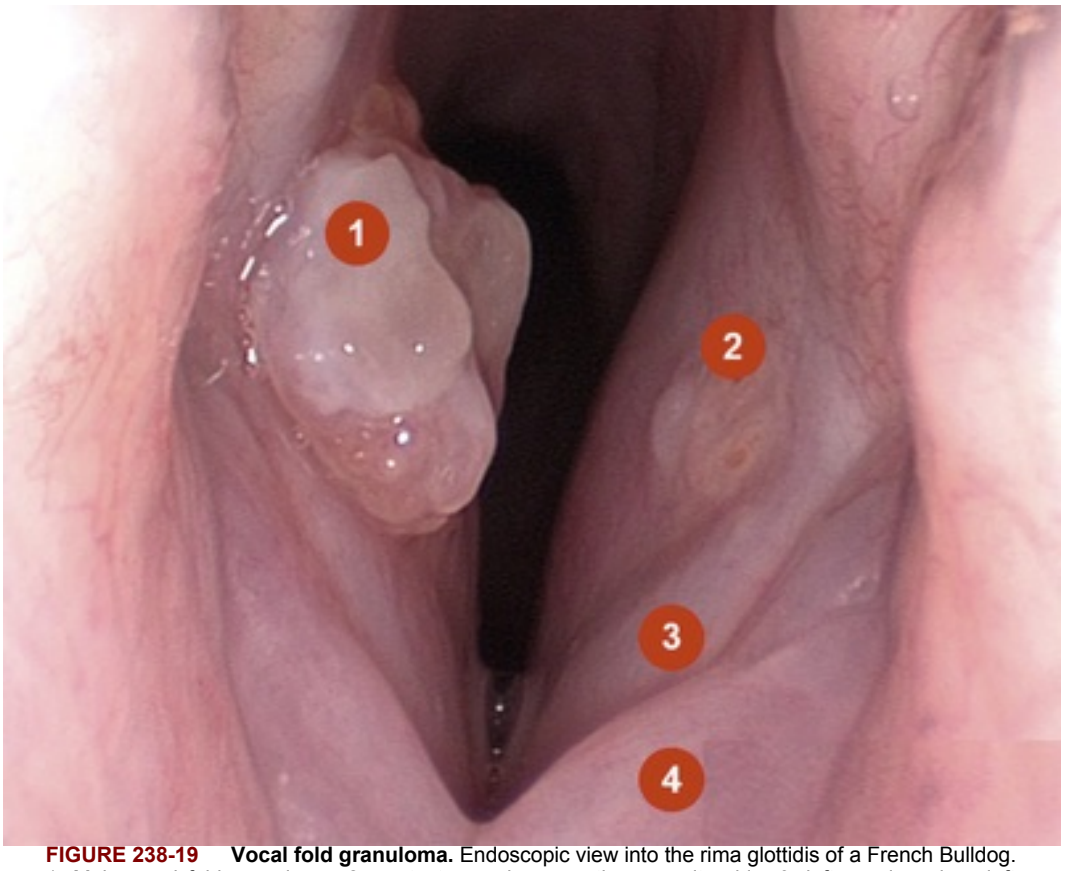

FIGURE 238-19 Vocal fold granuloma. Endoscopic view into the rima glottidis of a French Bulldog. 1, Main vocal fold granuloma; 2, contact granuloma on the opposite side; 3, left vocal cord; 4, left everted lateral ventricle (laryngocele).

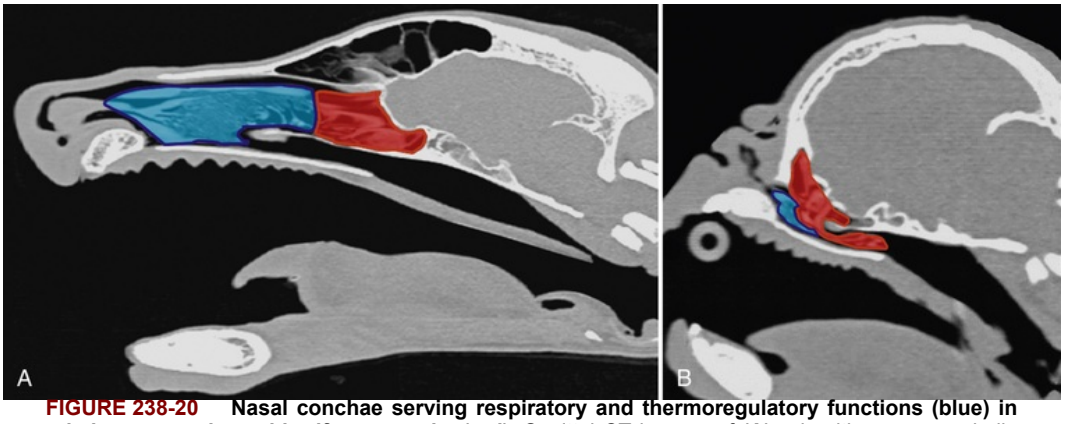

FIGURE 238-20 Nasal conchae serving respiratory and thermoregulatory functions (blue) in relation to conchae with olfactory tasks (red). Sagittal CT images of **(A)** a healthy normocephalic dog (German Shepherd) and **(B)** a Pug. The extreme reduction of thermoregulatory active conchal surface in brachycephalic animals in combination with an impaired nasal airflow possibly contributes to exercise/heat intolerance and collapse far more than impaired pulmonary ventilation.

Trachea (see ch. 241)

Tracheal hypoplasia is a congenital abnormality commonly seen in Bulldog breeds in which the ends of the tracheal rings are apposed or overlap, resulting in a narrow but rigid and mostly round tracheal lumen. Kaye et al[112] describe short dorsal tracheal membranes and tracheoscopic hypoplasia in 100% of the examined bulldogs with no or mild clinical symptoms. In Pugs, the tracheal lumen can also be narrow but contrary to Bulldogs, and comparable to the laryngeal problem, this is a result of a weak cartilage skeleton with flattened

tracheal rings and a widened dorsal membrane that may bulge into the tracheal lumen.

Clinical Manifestations of Brachycephalic Malformations

Brachycephalic dogs show signs of nasal, pharyngeal and laryngeal stridor, expressed as inspiratory dyspnea, loud snoring accompanied by gagging and possibly coughing. Episodes of severe dyspnea can occur with cyanosis, syncope and collapse and even death. Gastrointestinal signs are dysphagia, regurgitation and vomiting. Acute signs of respiratory distress may be seen more frequently if the patient is obese or in stressful situations like high ambient temperatures, excitement or exercise. Brachycephaly may have a severe impact upon the welfare of dogs, compromising their ability to exercise, play, eat, and sleep.[27]

In a recent study, owners of dogs (Pugs and French Bulldogs) that needed surgical therapy described in a structured questionnaire how they perceived frequency and severity of their dogs' impairments. In addition to the well-known clinical signs, they reported exercise intolerance (95%); 75% could go for a walk for at most 10-30 minutes in summer and only 30% of those dogs had recovered afterwards within 15 minutes. Restrictions became obvious above 19° C ambient temperature. 68% of the dogs had sleeping problems; nearly 30% showed signs of sleep apnea or tried to sleep in a sitting position (Video 238-29). 77% of the French Bulldogs had experienced problems with feeding.[27]

Examination of Brachycephalic Animals

Anamnesis and Physical Examination

Initial evaluation involves taking a history of clinical signs, along with an assessment of the degree of respiratory compromise. Depending on the stress level of the dog and ambient temperature, clinical signs may or may not be clearly visible during examination. A structured questionnaire is recommended to obtain comprehensive and comparable information, and to reveal the true extent of compromise. However, it is also known that owners of brachycephalic dogs assess respiratory signs as "normal for the breed."[113] A recently published study showed a disparity in recognition and perception of clinical signs associated with brachycephaly. Dog owners reported a high frequency and severity of respiratory signs but did not perceive them as problems.[93] Therefore, the structure of a questionnaire should address this problem by asking questions that use objective criteria, such as time needed for recovery and questions about activities that could easily be observed by a dog owner.[27] **Physical examination** includes the assessment of the size of the nares with particular attention paid to the width of the vertical slit (see Figure 238-14). Laryngeal, tracheal, and thoracic auscultation helps to determine the location and assess the quality of respiratory noise. In addition, respiratory rate, mucous membrane color, and characteristics of respiratory noise can help to determine the severity.

Surgical Management

The first concerns about respiratory problems in these breeds were raised within the veterinary profession in the 1930s, approximately 60 years after organized breeding in kennel clubs began. This urged veterinarians to criticize these breeding practices and to develop new surgical techniques to correct the problems.[108,114,115] Surgical techniques have remained amazingly unchanged since then, with the exception of relatively minor modifications. Various techniques have been recommended to **enlarge the stenotic nares,** to **shorten the elongated soft palate** and to **resect everted laryngeal ventricles.**

The latest changes in the surgical approach describe a new technique for palatal surgery.[116] In the past, surgery has focused primarily on the shortening of an overlong soft palate. Today, considering the complex relations between the collapsibility of the nasopharynx and the thickness of the soft palate, there are also recommendations to make the over-thick soft palate thinner. However, from human medicine we know the important role of palatal muscles (m. tensor veli palatini) for the physiological function of the auditory tube.[59,117,118] So it is not yet clear how much muscle tissue can be removed without negative consequences for the ventilation of the middle ear.

A more complex and comprehensive approach simultaneously addresses the well-known and the more recently described obstructions by a **multi-level surgery.** The principle of this approach is the aim to treat all serial, multiple airway stenoses at the same time. Novel aspects are (a) the more radical opening of the nasal entrance than is possible with the common "wedge technique" by performing an ala-vestibuloplasty, and (b) the interventional endoscopic resection of malformed obstructing turbinates using diode laser light (laser-

assisted turbinectomy, LATE) to establish intranasal airway patency. These procedures are combined with (c) a bilateral tonsillotomy, (d) a staphylectomy in combination with palatal volume reduction, and (e) a microlaryngoscopic laser ablation of everted laryngeal ventricles.[100,119]

In a recent study examining the results of this multi-level approach using a pre- and postoperative structured owner questionnaire, surgery managed to reduce the clinical signs associated with brachycephaly in all dogs. There was a reduction in life-threatening events by 90% (choking fits decreased from 60% to 5% and collapse from 27% to 3%). The incidence of sleeping problems decreased from 55% to 3%, and the occurrence of breathing sounds declined by 50%. There was a marked improvement in exercise tolerance but only a modest improvement in heat tolerance. However, despite the remarkable improvement perceived by the owners, these dogs remained clinically affected and continued to show welfare-relevant impairments.

Non-Surgical Management

Non-surgical management might have several tasks and covers medical management, emergency treatment of acute respiratory distress and client education. Non-surgical management cannot replace surgical treatment.

Medical Management

The vast majority of brachycephalic dogs with some degree of respiratory distress have been treated, at some time or other, with corticosteroids, often in combination with an antibiotic. However, there seems to be no evidence for the use of these medications.[113]

Emergency Treatment

The first therapeutic goal in acute respiratory distress is sedation and the prevention of hyperthermia (see ch. 139). This is achieved by pharmacological means (see ch. 138) in combination with non-pharmacological measures to prevent overexcitement. Advantages of acepromazine are, besides the desired tranquilizing effects, the usually unwanted effects of central and peripheral mediated hypothermia.[120] Non-pharmacological means, especially for hospitalized animals, are to take them out from a box or kennel into a cool and quiet environment. An easy and fast technique to treat or prevent hyperthermia (see ch. 134) is to moisten the dog's hair coat, if necessary not only with wet compresses but by pouring water over the animal, making the hair coat wet. Mainly Bulldogs seem to suffer from some kind of claustrophobia; a narrow oxygen cage can cause a life-threatening situation for such animals, and there is a considerable number of patients in this stressful situation that simply do not want to be left alone and need human company.

Client education may begin prior to the decision of buying a new dog. Clients should be carefully informed that brachycephalic dogs might suffer lifelong from respiratory and non-respiratory (Figure 238-21) disorders; that puppies usually breathe normally and clinical signs mostly develop not earlier than 6 months; and that the assurance the parents were “free-breathing” should be regarded with caution because it has been shown that many owners of brachycephalic animals do not perceive their animals' respiratory distress as dyspnea but as “normal for the breed.”

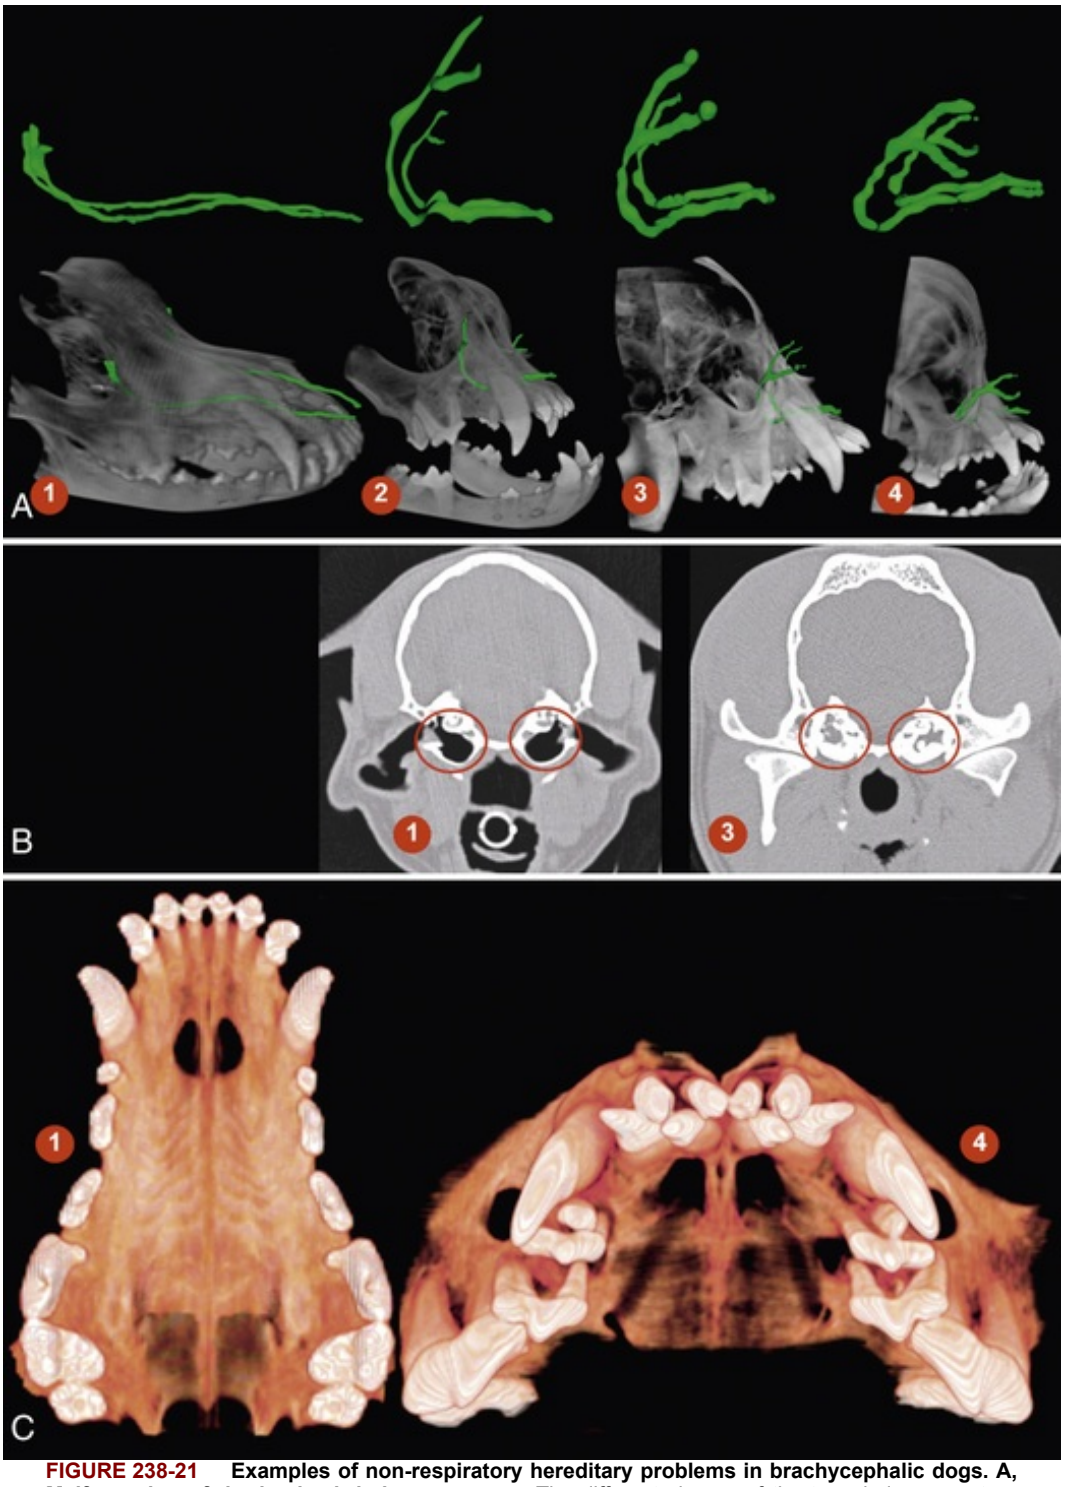

FIGURE 238-21 **Examples of non-respiratory hereditary problems in brachycephalic dogs. A, Malformation of the lacrimal drainage system:** The different shapes of the tear drainage system (green) in a (1) normocephalic dog (Rhodesian Ridgeback) and three brachycephalic dog breeds; (2) English Bulldog; (3) French Bulldog; (4) Pug.[121] **B, Malformation of the middle ear:** CT images showing the air-filled physiologic bulla tympanica with a thin ventral bony boundary in a (1) normocephalic dog (Poodle) and the fluid-filled bulla with a malformed bony structure in a (3) French Bulldog. **C, Malformation of the upper jaw:** three-dimensional CT images showing the physiologic superior dental arch of a (1) normocephalic dog (Beagle) and the impact of an undersized upper jaw on the dental arch and tooth position in a (4) Pug.

Owners of brachycephalic breeds should be educated in the specific features of thermoregulation in dogs and its impairment in brachycephalic animals in particular. Using the "meat-in-the-box-model," it can be explained why obesity worsens upper airway obstruction and why keeping the dog lean often helps to reduce

breathing problems. Dogs with pronounced problems in a warm environment can be put in a tub with water prior to a walk in order to wet their haircoat.

CHAPTER 239

Diseases of the Larynx

Catriona M. MacPhail

Client Information Sheet: Laryngeal Paralysis and Laryngeal Collapse

Overview

Cartilage Anatomy

The cartilages surrounding the rima glottidis are called the larynx and include the paired arytenoids and the unpaired epiglottis, cricoid, and thyroid. Each arytenoid cartilage has a cuneiform process rostrally, a corniculate process dorsally, a muscular process dorsolaterally, and a vocal process where the vocal folds attach ventrally. The glottis consists of the vocal folds, the vocal process of the arytenoid cartilages, and the rima glottides. The laryngeal saccules are mucosal diverticula rostral and lateral to the vocal folds. Unlike dogs, feline arytenoid cartilages lack cuneiform and corniculate processes and true aryepiglottic folds. The sides of the epiglottis are connected directly to the cricoid lamina by laryngeal mucosa.

Muscles and Their Action

The intrinsic muscles of the larynx (cricoarytenoideus dorsalis, cricoarytenoideus lateralis, thyroarytenoideus, vocalis, ventricularis, arytenoideus transversus, hyoepiglotticus, and cricothyroideus) are responsible for laryngeal function. The cricoarytenoideus dorsalis muscle, solely responsible for opening the glottis, originates on the dorsolateral surface of the cricoid and inserts on the muscular process of the arytenoid cartilages. Contraction of this muscle results in external rotation and abduction of the arytenoid cartilages that pulls the vocal processes laterally. The caudal laryngeal nerve is the terminal segment of the recurrent laryngeal nerve, which innervates all but one of the intrinsic laryngeal muscles. The cricothyroid muscle is innervated by the cranial laryngeal nerve.

Laryngeal Function

The larynx regulates airflow, protects the lower airway from aspiration during swallowing, and controls phonation. Diseases most commonly affecting the larynx include paralysis, collapse, stenosis, and masses. Each of these conditions results in some degree of upper airway obstruction. Dogs and cats with any of these conditions are typically brought to their veterinarian due to respiratory stridor, voice change, coughing, or gagging. Progression of clinical signs is highly variable.

Canine Laryngeal Paralysis

Signalment and Etiologies

Acquired Disease

Laryngeal paralysis is a common unilateral or bilateral respiratory disorder that primarily affects older (>9 years) large and giant breed dogs. The Labrador Retriever is the most common breed reported to acquire this condition, but Golden Retrievers, St. Bernards, Newfoundlands, Irish Setters, and Brittany Spaniels are also overrepresented.[1] Acquired laryngeal paralysis, caused by damage to the recurrent laryngeal nerve or intrinsic laryngeal muscles, is most often attributed to a polyneuropathy, polymyopathy, accidental or iatrogenic trauma, or intra- or extrathoracic masses. Many other causes have been proposed (Box 239-1). In most dogs, cause is undetermined and classified as “idiopathic.” However, many dogs thought to have

idiopathic acquired laryngeal paralysis develop systemic neurologic signs within a year, consistent with a progressive generalized neuropathy.[2] Abnormalities in electrodiagnostic tests (see ch. 117) and histopathologic analysis of nerve and muscle biopsy specimens (see ch. 116) were consistent with a generalized polyneuropathy in a small number of dogs with acquired laryngeal paralysis.[3] Thus, it has been proposed that some dogs with idiopathic laryngeal paralysis have a progressive generalized polyneuropathy.[4,5] The abbreviation GOLPP (geriatric-onset laryngeal paralysis polyneuropathy) has been proposed as a more accurate term for dogs with acquired laryngeal paralysis, where other causes have been ruled out.[3,6]

Box 239-1

Proposed Etiologies of Laryngeal Paralysis

- Congenital
  - Genetic trait
  - Laryngeal paralysis—polyneuropathy complex
- Accidental trauma
  - Cervical penetrating wounds
  - Strangulating trauma
- Iatrogenic surgical trauma
  - Cranial thoracic surgery
  - Thyroidectomy/parathyroidectomy
  - Tracheal surgery
  - Ventral slot
- Cervical/intrathoracic neoplasia
  - Lymphoma
  - Thymoma
  - Thyroid carcinoma/ectopic thyroid carcinoma
- Neuromuscular disease
  - Geriatric-onset laryngeal paralysis polyneuropathy syndrome (GOLPP)
  - Endocrinopathy (hypothyroidism, hypoadrenocorticism)
  - Immune-mediated
  - Infectious
  - Myasthenia gravis
  - Polymyopathy
  - Systemic lupus erythematosus
  - Toxins (lead; organophosphates)

Congenital Disease

A congenital form of laryngeal paralysis has been reported in Bouviers des Flandres, Siberian Huskies, Bull Terriers, and white-coated German Shepherd Dogs.[7,8] An autosomal dominant trait in Bouviers des Flandres causes recurrent laryngeal nerve Wallerian degeneration and nucleus ambiguus abnormalities.[9] Although precise modes of inheritance are not established, hereditary predispositions have been identified in Siberian Husky dogs, Alaskan Malamutes, and crosses of those two breeds.[10,11] Laryngeal paralysis-polyneuropathy complexes have been described in Dalmatians, Rottweilers, Leonberger dogs, and Pyrenean Mountain Dogs.[12-15]

Clinical Signs

If the arytenoid cartilages and, consequently, the vocal folds remain in a paramedian position during inspiration, an upper airway obstruction is created called *laryngeal paralysis.* Dogs typically have noisy inspiratory respiration and exercise intolerance. Early clinical signs include voice change, mild coughing, and gagging. Severe airway obstruction results in respiratory distress, cyanosis, and collapse. Some have signs of dysphagia. Progression of clinical signs is highly variable, and dogs may have clinical signs for several months to years before worrisome respiratory distress ensues. Clinical signs are usually worsened by

exercise, high environmental temperature, and/or humidity. These factors can contribute to an acute exacerbation of a chronic condition. As respiratory rate increases, the mucosa covering the arytenoids obstructing airflow may become inflamed and edematous, causing further airway obstruction (see ch. 238). A vicious circle ensues that, if untreated, may become life-threatening.

Diagnostic Testing

Routine Testing

Diagnostic evaluation of dogs thought to have laryngeal paralysis includes physical examination, orthopedic (see ch. 353) and neurologic (see ch. 259) examinations, complete blood count (CBC), biochemical profile, urinalysis (UA), thyroid function screening (see ch. 299), thoracic radiographs, and laryngeal examination. Dogs with bilateral laryngeal paralysis are at risk of aspiration pneumonia both before and after surgery; therefore, thoracic radiographs are necessary in evaluating dogs suspected to have laryngeal dysfunction (see ch. 242). Radiographs are used to rule out aspiration pneumonia and to identify, if present, megaesophagus, pulmonary edema, cardiac, or lower airway abnormalities (Figure 239-1). Dogs with dysphagia or vomiting may be assessed with a positive contrast esophageal study to rule out dysfunction or megaesophagus, sometimes not apparent on survey thoracic radiographs (see ch. 273). Severe progressive esophageal dysfunction has been reported in a series of dogs with idiopathic laryngeal paralysis, consistent with the proposed generalized progressive polyneuropathy syndrome.[3] Acquiring information from esophagography should be weighed against potential risk of aspiration.[16] Hypothyroidism occurs concurrently in up to 30% of dogs with acquired laryngeal paralysis, although a direct causal link has not been established.[1,17] Thyroid function screening is considered important when evaluating a dog for laryngeal paralysis and supplementation begun if indicated, although this does not seem to improve the clinical signs associated with laryngeal paralysis (see ch. 299).

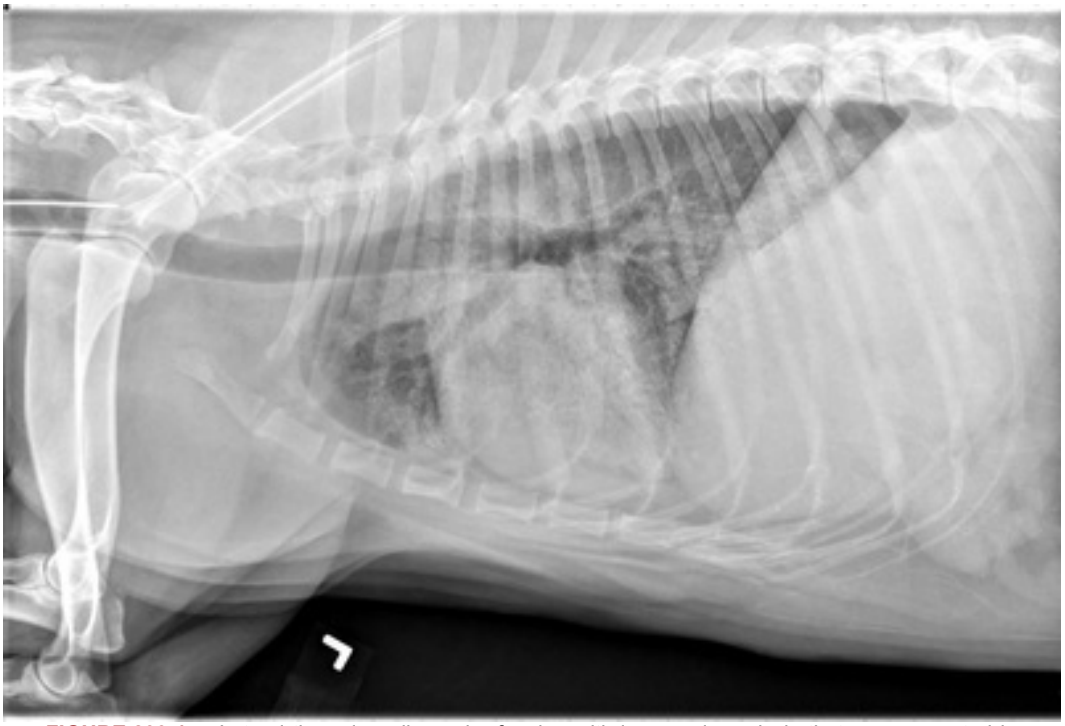

FIGURE 239-1 Lateral thoracic radiograph of a dog with laryngeal paralysis that was presented in acute crisis with noncardiogenic pulmonary edema.

Definitive Diagnosis

Definitive diagnosis of laryngeal paralysis requires examination of the larynx to document lack of arytenoid abduction during inspiration (Video 239-1) . This can be accomplished by direct visualization of the larynx

with a simple laryngoscope, oral video-endoscopic laryngoscopy, transnasal laryngoscopy (TNL), ultrasound (US; echolaryngography), or computed tomography (CT). Findings indicative of laryngeal paralysis on US include asymmetry or absence of motion of the cuneiform processes, abnormal arytenoid movement, paradoxical movement, caudal displacement of the larynx, and laryngeal collapse.[18] CT findings in dogs with laryngeal paralysis included failure to abduct the arytenoid cartilages and collapse into the rima glottis on inspiration, stenosis of the laryngeal inlet, and air-filled lateral ventricles.[19] Laryngoscopy, regardless of method, can be confounding as false-positive results are common due to the influence of anesthetic agents and sedatives (see Video 239-1). Echolaryngography, TNL, and CT avoid need for heavy sedation or general anesthesia. However, none of these tools has been shown to be superior to traditional oral laryngeal examination for definitive diagnosis.[20]

Traditional Oral Laryngeal Examination

Laryngeal paralysis should not be diagnosed based solely on the lack of arytenoid movement; inflammation and swelling of the laryngeal cartilages may also be apparent. Diagnosis may be challenging when there is paradoxical arytenoid movement, resulting in a false-negative result because the arytenoid cartilages move inward during inspiration due to negative intraglottic pressure created by breathing against the glottic obstruction. The cartilages then passively return to their original position during the expiratory phase, creating the impression of abduction. An assistant should state the phase of ventilation during laryngoscopy to help distinguish normal from abnormal motion.

Anesthetic Agents *(Box 239-2)*

Intravenous thiopental administered to effect was believed to be the best choice to allow assessment of laryngeal function; however, thiopental is not currently manufactured. Propofol is the most often used induction agent for laryngeal examination in dogs, even though significant respiratory depression often occurs with this drug, with apnea related to dosage, speed of injection, and use of concurrent premedications. While ketamine has been shown to better preserve laryngeal function in people over thiopental, a recent study found no benefit for laryngeal examination when combining propofol and ketamine; no dosage reduction in propofol was achieved and respiratory depression was more marked.[21] Alfaxalone (2-4 mg/kg IV), a safe and effective anesthetic induction agent in dog, can be used as an alternative to propofol.[22] While alfaxalone still causes respiratory depression, apnea is less likely.[23] However, no study has evaluated the effect of alfaxalone on laryngeal function. Doxapram HCl (1 mg/kg IV) has been advocated for routine use during laryngoscopy to increase respiratory rate and effort and improve intrinsic laryngeal motion. Doxapram significantly improves the ability to discriminate normal from abnormal function.[24,25]

Box 239-2

Drugs Used During Functional Laryngeal Examination

Premedications:
- Glycopyrrolate: 0.005-0.01 mg/kg IV, IM, SC ***and***
- Butorphanol: 0.2-0.4 mg/kg IV, IM, SC ***or***
- Buprenorphine: 0.005-0.02 mg/kg IV, IM, SC ***or***
- Hydromorphone: 0.1-0.2 mg/kg IV, IM, SC

Induction:
- Propofol: 4-8 mg/kg IV, administered slowly
- Alfaxalone: 2-4 mg/kg IV, administered slowly

To stimulate respiration:
- Doxapram HCl: 1-2 mg/kg IV

To decrease laryngeal swelling:
- Dexamethasone: 0.1-1 mg/kg IV

Treatment

Acute Respiratory Distress

Initial treatment for acute respiratory distress is directed at improving ventilation, reducing laryngeal edema,

and minimizing stress (see ch. 139). Typical treatment regimens involve oxygen supplementation (see ch. 131) and use short-acting steroids (e.g., dexamethasone) and/or sedatives (e.g., acepromazine) (see ch. 138). Administration of buprenorphine or butorphanol may be considered (Box 239-3). These dogs are often hyperthermic, and appropriate cooling procedures should be instituted (see ch. 134). If respiratory distress cannot be abated, intubation or a temporary tracheostomy should be considered. However, use of a temporary tracheostomy tube in dogs with laryngeal paralysis has been shown to be a negative prognostic indicator following surgery, as dogs that received a temporary tracheostomy preoperatively were more likely to experience major complications.[1] The presence of a tube within the tracheal lumen causes epithelial erosion, submucosal inflammation, and inhibition of the mucociliary apparatus from the level of the tracheostomy to the bifurcation. Mucus production dramatically increases, and the tube must be suctioned and cleaned frequently to prevent clogging. Intensive monitoring is required of any patient with a temporary tracheostomy tube, to avoid life-threatening complications. Complications (clinical and incidental) have been documented in 86% of dogs with a temporary tracheostomy.[26] 16 different complications were noted, but the most significant and frequent (≈25%) were airway obstruction, tube dislodgement, aspiration pneumonia, and stoma swelling.

Box 239-3

Drugs Used for Acute Respiratory Distress

To decrease laryngeal swelling:
- Dexamethasone 0.1-1 mg/kg IV

To abate anxiety:
- Acepromazine 0.01-0.02 mg/kg IV
- Buprenorphine 0.005-0.01 mg/kg IV
- Butorphanol 0.1-0.25 mg/kg IV

Conservative Long-Term Treatment

Often, dogs are not severely affected clinically until they have bilateral laryngeal paresis or paralysis. Therefore, dogs with unilateral laryngeal dysfunction are not surgical candidates. The goal of conservative management of dogs with laryngeal paralysis is to improve the quality of life through environmental changes, reduction of daily exercise, owner education, weight loss (see ch. 176 and 359), and consideration of antiinflammatory drugs to minimize laryngeal swelling. Unfortunately, this medical treatment path has proven inadequate for long-term management. Dogs diagnosed with concurrent hypothyroidism should be supplemented, but this rarely improves the clinical signs of laryngeal paralysis.

Surgery

Overview

For dogs with bilateral laryngeal paralysis, the decision to recommend surgery is based on the dog's quality of life, severity of clinical signs, and time of year. Surgical intervention is indicated in dogs severely affected by laryngeal paralysis. Numerous techniques have been described. Unilateral arytenoid lateralization is the technique employed by most surgeons, but various types of partial laryngectomy (bilateral vocal fold resection, partial arytenoidectomy) are also performed. Bilateral arytenoid lateralization is not recommended due to unacceptable morbidity.[1] Other techniques include castellated laryngofissure, reinnervation of the laryngeal musculature, and permanent tracheostomy. Castellated laryngofissure is performed rarely because it is technically difficult and outcomes have been inconsistent. Reinnervation does not provide immediate clinical relief and is not practical. Permanent tracheostomy is considered a salvage procedure for dogs most at risk of aspiration pneumonia but is associated with a high rate of major and minor complications and requires diligent postoperative and long-term care. In a series of 21 dogs with permanent tracheostomies, 50% had major complications, 20% required revision surgery, and 26% acutely died, most likely from airway obstruction.[27]

Unilateral Arytenoid Lateralization

Several variations of unilateral arytenoid lateralization have been described. The most common technique

involves suturing the cricoid cartilage to the muscular process of the arytenoid cartilage, mimicking the directional pull of the cricoarytenoid dorsalis muscle and rotating the arytenoid cartilage laterally (Figure 239-2). An alternative technique involves suture placement from the muscular process of the arytenoid cartilage to the caudodorsal aspect of the thyroid cartilage. This pulls the arytenoid cartilage laterally rather than rotating it and increases the area of the rima glottidis to a lesser degree than the cricoarytenoid suture.[28]

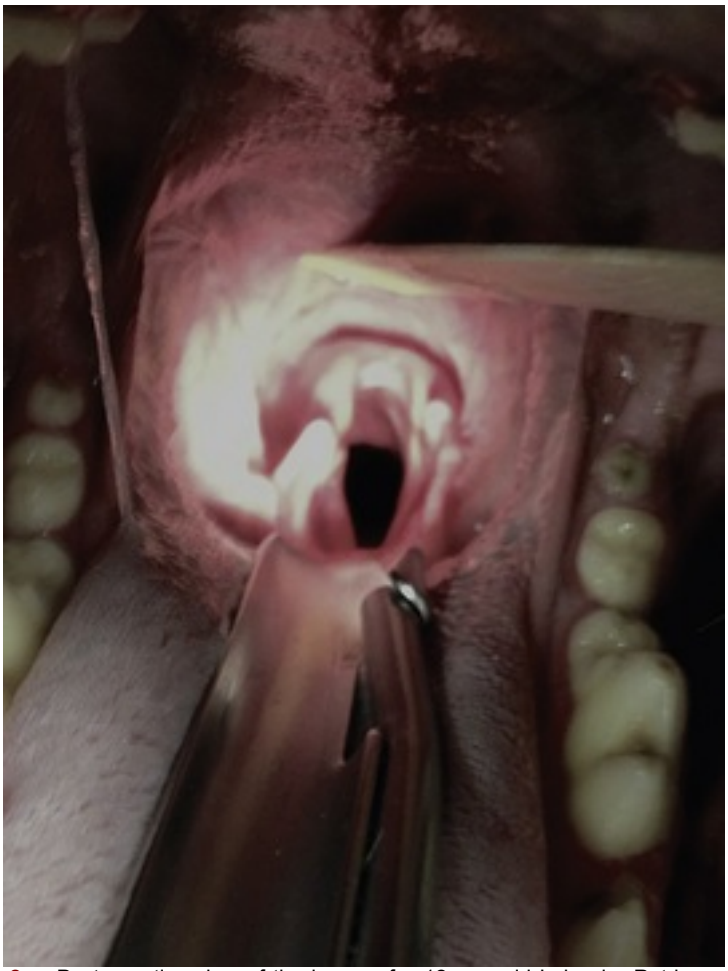

FIGURE 239-2 Postoperative view of the larynx of a 12-year-old Labrador Retriever following left unilateral arytenoid lateralization.

Differences in surgical technique and the degree of increase in surface area of the rima glottidis do not appear to affect postoperative clinical signs and outcome. Increasing the surface area of the rima glottidis beyond the edges of the epiglottis may put dogs at higher risk of aspiration. Limited lateral displacement of the arytenoid cartilage significantly reduces airway resistance within the larynx and may decrease risk of postoperative aspiration pneumonia.[29] This is accomplished by minimizing dissection: separation of the cricothyroid articulation, transection of the sesamoid band connecting the paired arytenoid, and complete disarticulation of the cricoarytenoid joint are not necessary. A partial opening of the cricoarytenoid articulation allows accurate visualization of needle placement through the muscular process of the arytenoid but limits the degree of cartilage abduction. Outcomes are similar to other reports.[30]

Partial Laryngectomy and Bilateral Ventriculocordectomy

Partial laryngectomy encompasses various techniques for vocal cord excision and partial arytenoidectomy aimed at increasing glottis diameter. This procedure has been associated with complications: laryngeal webbing, laryngeal scarring, and aspiration pneumonia. High complication rates have been reported by some; however, bilateral vocal fold resection alone resulted in fewer complications and better postoperative outcome than other partial laryngectomy techniques because it allows better laryngeal protection during

swallowing and decreased laryngeal irritation because the corniculate processes of the arytenoid cartilages are left intact.[1,31-33] Bilateral vocal fold excision and thyroarytenoid lateralization performed through a ventral laryngotomy improved clinical signs and were associated with a low rate of aspiration pneumonia; however, recurrence of clinical signs is common, likely because of narrowing of the rima glottidis.[34] Successful partial arytenoidectomy by photoablation of the left arytenoid cartilage tissue using a diode laser has been reported.[35] Bilateral ventriculocordectomy via ventral laryngotomy has a reasonable long-term outcome (>6 months) with a low incidence of major complications (7%).[33] A direct comparison of outcome between dogs treated with either unilateral arytenoid lateralization or bilateral ventriculocordectomy found dogs that had bilateral ventriculocordectomy were more likely to have chronic lifelong respiratory complications.[36]

Aspiration Pneumonia and Other Complications

Aspiration pneumonia (see ch. 242) is the most common complication in dogs surgically treated for laryngeal paralysis: 10 to 21% of dogs undergoing unilateral arytenoid lateralization.[1,37,38] Although aspiration pneumonia is most likely in the first few weeks after surgery, it has been recognized that these dogs are at risk for the rest of their lives. Factors that have been found to be significantly associated with a higher risk of developing complications and a negative effect on long-term outcome include preoperative aspiration pneumonia, development of esophageal dysfunction, progressing generalized neurologic signs, temporary tracheostomy placement, and concurrent neoplasia. In one study, 10 of 32 dogs had neurologic signs at the time of enrollment into the study, but all dogs had neurologic signs by one year.[2] In the absence of surgical complications, unilateral arytenoid lateralization results in less respiratory distress, less stridor, and improved exercise tolerance. Owner satisfaction with this procedure has been excellent, with the majority believing that the quality of their dog's life was improved dramatically.[1,37]

Feline Laryngeal Paralysis

Laryngeal disease is uncommon in cats, but laryngeal paralysis constituted 40% of cases.[39] Clinical presentation is similar to that of dogs: It occurs most often in middle-aged to older cats (mean 9 to 14 years), and both unilateral and bilateral conditions have been documented. Significant unilateral dysfunction has been reported in 10 to 57% of affected cats. A prevalence of left-sided unilateral laryngeal paralysis is similar to that reported in humans and horses.[39-41]

The specific cause of laryngeal paralysis in cats often is not known. Several cases have been associated with trauma, neoplastic invasion, or iatrogenic damage (post-thyroidectomy). Neoplastic infiltration can lead to fixed laryngeal obstruction with both inspiratory and expiratory dyspnea and noise. Neoplasia should always be considered in the differential diagnosis of laryngeal paralysis in the cat. In addition to traditional laryngoscopy (direct or endoscopically), the use of echolaryngography has been described for diagnosis of laryngeal paralysis in cats.[39,42]

Cats with unilateral laryngeal paralysis can have severe respiratory distress, often requiring surgery. Conservative management of cats with laryngeal paralysis consists of weight loss (see ch. 176) and minimizing excitement/exercise (see ch. 359). Reported survival in 7 cats treated conservatively for laryngeal paralysis ranged from 120 to 2520 days with a median survival of 811 days.[39] Successful surgical treatment, primarily using unilateral arytenoid lateralization, has been described. The reported median survival time was approximately 150 days.[39-41]

Laryngeal Collapse

Definition and Signalment

Laryngeal collapse is a consequence of chronic upper airway obstruction, most often associated with "brachycephalic airway syndrome," in reference to the condition of obstructive airway distress attributable to anatomic abnormalities of breeds such as English Bulldogs, Pugs, Boston Terriers, and Cavalier King Charles Spaniels (see ch. 238). Laryngeal collapse can occur alone or in association with laryngeal paralysis, nasal and nasopharyngeal obstruction, or trauma in both brachycephalic and mesaticephalic breeds. Concurrent laryngeal paralysis and laryngeal collapse have been reported in a small set of nonbrachycephalic small-breed dogs.[43] Norwich Terriers, specifically, have laryngeal abnormalities: redundant supra-arytenoid folds,

laryngeal collapse, everted laryngeal saccules, and narrowed laryngeal openings.[44] Rhinomanometry has been used to demonstrate that Norwich Terriers have skull dimensions consistent with both brachycephaly and mesaticephaly.[45] Chronic upper airway obstruction increases airway resistance and negative intraglottic luminal pressure. Over time, this results in laryngeal collapse due to cartilage fatigue and degeneration. However, early-onset laryngeal collapse is seen in brachycephalic dogs as young as 4.5 to 6 months of age.[46]

Clinical Stages of Severity

There are three stages of severity for laryngeal collapse. Stage 1 is the eversion of the laryngeal saccules into the glottis, increasing inspiratory effort, creating a vacuum, and causing the mucosa of the laryngeal saccules to prolapse. Once the saccules are everted, the tissue is exposed to highly turbulent airflow, resulting in edema and inflammation, which further obstructs the airway. In most studies regarding brachycephalic airway syndrome, everted laryngeal saccules are present in 50-60% of affected dogs.[47-49] In stage 2, the cuneiform processes of the arytenoid cartilages lose rigidity and collapse into the laryngeal lumen. In addition, the aryepiglottic folds also collapse ventromedially (Figure 239-3). The most advanced phase of laryngeal collapse is stage 3, in which the corniculate process of each arytenoid cartilage fatigues and collapses toward midline, causing complete laryngeal collapse.

FIGURE 239-3 Intraoral view of Stage 2 laryngeal collapse in an 8-year-old Pug; note complete collapse of cuneiform processes into laryngeal lumen.

Diagnosis

Diagnosis of laryngeal collapse requires oral laryngeal examination under heavy sedation or a light plane of general anesthesia without intubation. Functional and structural examination of the larynx should be performed. CT imaging and three-dimensional internal rendering was used to document laryngeal collapse in 9 dogs with no sedation or general anesthesia required.[50]

Treatment

The early stage of laryngeal collapse is amenable to surgical treatment. Resection of the everted laryngeal saccules is relatively simple as each saccule is grasped with Allis tissue forceps and then transected with Metzenbaum scissors. Options for treating advanced stages of laryngeal collapse are limited. Underlying components of brachycephalic airway syndrome should be addressed and degree of improvement assessed. Dogs with stage 2 and 3 laryngeal collapse have been shown to markedly benefit from surgical removal of everted laryngeal saccules, reduction of elongated soft palates, and correction of stenotic nares (see ch. 238).[49] Unilateral arytenoid laryngoplasty (cricoarytenoid lateralization combined with thyroarytenoid caudolateralization) has been reported to have reasonable long-term outcomes in a small number of brachycephalic dogs with laryngeal collapse, but this technique should be used with caution as the opposite cartilage may continue to collapse medially.[51] Permanent tracheostomy is recommended when dogs do not respond to other medical or surgical treatment, although many owners consider this an unacceptable option due to the high risk of complications and degree of maintenance required.

Laryngeal Stenosis

Acquired laryngeal stenosis most commonly occurs as a complication following bilateral ventriculocordectomy. Other causes include traumatic tracheal intubation, foreign body, or caustic trauma. The most common clinical sign associated with laryngeal stenosis is exercise intolerance, but inspiratory stridor and respiratory distress occur. Ventriculocordectomy performed through an oral approach can lead to laryngeal webbing from scar tissue formation (cicatrix) as the mucosal defects are left to heal by second intention. This procedure is most commonly performed for devocalization (debarking). The American Veterinary Medical Association opposes devocalization except as a final alternative to euthanasia after behavioral modification to correct excessive vocalization has failed and after discussion of potential complications from the procedure with the owner.[52]

Ventriculocordectomy as a treatment for laryngeal paralysis is best performed through a ventral laryngotomy incision so that the mucosa on each side can be closed primarily, decreasing the risk for scar formation. A similar procedure is performed to treat laryngeal stenosis.[53] A ventral midline approach is made through the thyroid cartilage to gain access to the glottis. The scar tissue is sharply excised back to healthy mucosa rostral and caudal to the web. This mucosa is sutured using a 3-0 to 5-0 rapidly absorbable suture (e.g., poliglecaprone 25, glycomer 631, polyglactin 910) in a simple continuous or simple interrupted pattern. A temporary soft silicone intraluminal stent (keel stent) can be inserted through the thyroid cartilage to separate the healing mucosal surfaces but is often not necessary except in small dogs.[54] Regardless, laryngeal web resection with mucosal apposition has been reported to have a good to excellent outcome.[53]

Laryngeal Masses

Tumors

Description

Tumors of the larynx are uncommon in dogs and cats. Numerous tumor types have been reported in dogs: rhabdomyosarcoma (oncocytoma), squamous cell carcinoma (Figure 239-4), adenocarcinoma, osteosarcoma, chondrosarcoma, chondroma, myxochondroma, lipoma, fibrosarcoma, undifferentiated carcinoma, extramedullary plasmacytoma, and mast cell tumor (see ch. 345, 346, 348, and 349). Squamous cell carcinoma and lymphoma are the most common laryngeal tumors in cats, but adenocarcinoma and other poorly differentiated round cell tumors have been reported.[55]

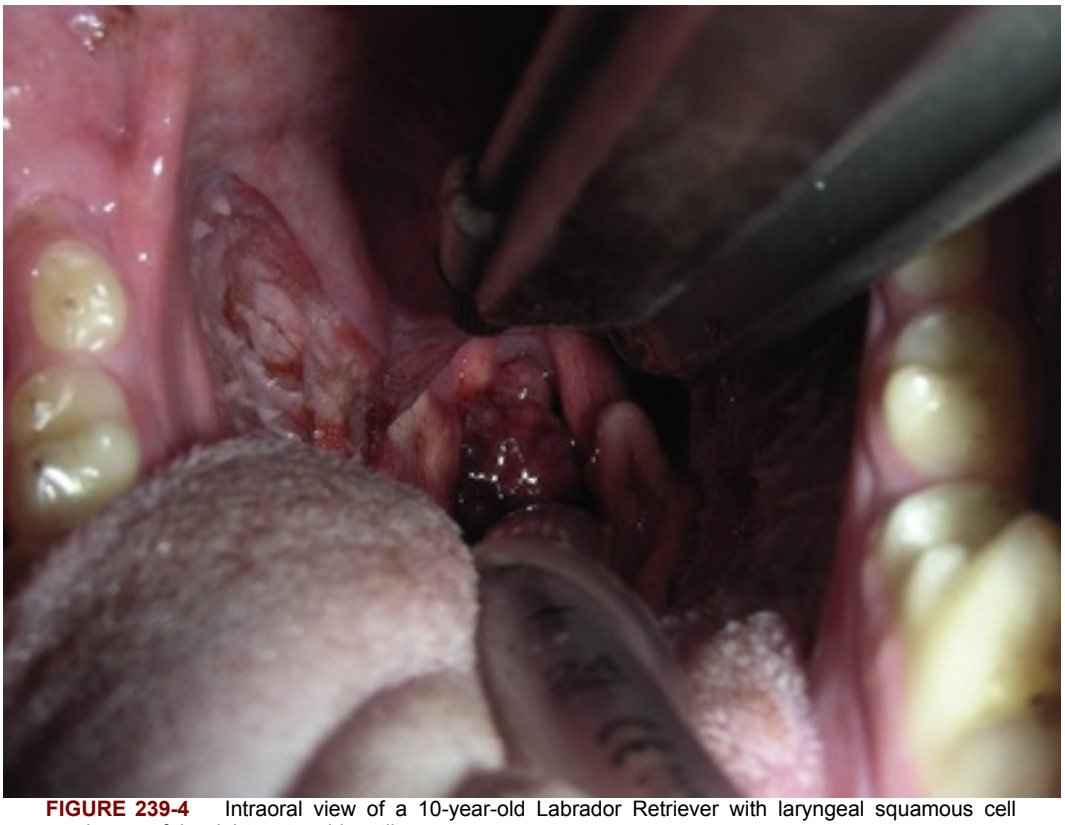

FIGURE 239-4 Intraoral view of a 10-year-old Labrador Retriever with laryngeal squamous cell carcinoma of the right arytenoid cartilage.

Treatment

Small masses may be removed by mucosal resection, partial laryngectomy through an oral approach, or ventral laryngotomy. Cartilaginous tumors (chondroma or chondrosarcoma) can be excised with reasonable success.[56,57] Aggressive intervention involves complete laryngectomy with permanent tracheostomy but has been reported rarely. Radioresponsive tumors may be treated with radiation therapy (see ch. 340). Otherwise, most treatment is palliative, consisting of airflow bypass of the laryngeal area through a permanent tracheostomy.

Prognosis

Prognosis for laryngeal tumors is guarded as most cases are quite advanced at the time of diagnosis. There are only isolated reports of management of canine and feline laryngeal tumors. Treatment of 4 cats with laryngeal squamous cell carcinoma with tube tracheostomy alone resulted in a median survival of only 3 days; chemotherapeutic treatment of 5 cats with laryngeal masses resulted in a median survival of 141 days.[58] Two cats with laryngeal lymphoma treated with chemotherapy survived 60 and 1440 days.[55] In this same study, 1 cat with laryngeal squamous cell carcinoma was treated with prednisolone and had a survival time of 180 days. One study reported on the placement of permanent tracheostomies in 5 cats with laryngeal carcinoma.[59] Survival ranged from 2 to 281 days. Two cats died from tracheostomy site occlusion, and 3 were euthanized because of disease progression.

Inflammatory Laryngeal Disease

Inflammatory laryngeal disease is an uncommon nonneoplastic condition of the arytenoid cartilages in both dogs and cats. It can be granulomatous, lymphocytic-plasmacytic, or eosinophilic. Multiple factors likely contribute to disease development. Severe cases can have laryngeal stenosis and significant upper airway obstruction. Biopsy of the mass is crucial to differentiate this disease from neoplasia, although it is still possible that inflammatory changes may represent a secondary response to underlying neoplasia. Treatment of inflammatory laryngeal disease is palliative: debulking the mass, steroid therapy, or permanent

tracheostomy. Permanent tracheostomy has been associated with a higher mortality in cats with inflammatory laryngeal disease than in cats undergoing permanent tracheostomy for any other reason.[60]

Benign Laryngeal Cysts

Benign laryngeal cysts have been described in a few dogs and cats.[61,62] Cysts are typically epithelial in origin and stem from the ventral aspect of the larynx. Surgical removal is usually curative. Some cysts are very large and can significantly obstruct airflow.

CHAPTER 240

Clinical Evaluation of the Respiratory Tract

Stephan Anthony Carey

Introduction

The goal of evaluating a dog or cat with respiratory signs is to obtain a specific diagnosis by the least invasive means. First, one should *verify* that the historical and current clinical signs are consistent with respiratory disease or dysfunction. Then, *localizing* the dysfunction to a specific region or regions within the respiratory system is important. Once respiratory disease has been verified and localized, the tools used to *specify* the exact nature of respiratory disease often become more invasive (e.g., diagnostic respiratory sampling) and expensive (e.g., advanced imaging, endoscopy).

History and Signalment

Overview

The diagnostic approach to a dog or cat with respiratory signs begins in the exam room. Knowledge of breed- and age-specific conditions often helps streamline the localization process. Signalment alone may allow prioritization of a differential list. Juvenile, immunocompromised, or unvaccinated pets are more likely to have an infectious disease. Disorders known or suspected to have a heritable or genetic etiology will often be breed specific (e.g., chronic pulmonary fibrosis in the West Highland White Terrier, congenital laryngeal malformation of Norwich Terriers, asthma in Siamese and Havana Brown cats).[1-3] Conformation may also lend clues. For example, brachycephalic dogs often have thickened and elongated soft palates, stenotic nares, tracheal hypoplasia, or other issues that contribute to airway obstruction.[4,5] Dolichocephalic dogs are overrepresented in categories such as nasal tumors and aspergillosis.[6,7]

Clinicians should strive to obtain a complete and detailed history, including some concept of when the patient was last normal. Understanding any progression, rate of change, or patterns of when or where clinical signs are noted can help. Willingness to demonstrate a clinical sign to an owner (e.g., reverse sneezing) may also help identify the cause of signs. Owners should be encouraged to video their pet when normal and when demonstrating signs. Questions should be crafted to not only localize respiratory dysfunction but also to verify that the respiratory system is the source of the dysfunction (e.g., coughing vs. retching in cats). One may need to confirm that clinical signs previously attributed to other organ systems are actually respiratory (e.g., vomiting vs. post-tussive retching in dogs).

Historical Findings Suggestive of Respiratory Disease

Sneezing

Sneeze (see ch. 27) is defined as an involuntary protective expiratory reflex following irritation of the nasal mucosa that can be difficult to stifle. During a sneeze, the head usually moves sharply downward. This can help clients differentiate between sneezing and reverse sneezing (below). Sneezing is usually an acute response to irritation and often decreases or stops completely in chronic or progressive nasal cavity disease, obstruction, or irritation.

Reverse Sneezing

The reverse sneeze is a voluntary or involuntary process, involving paroxysms or series of strong, abrupt inspiratory efforts (snorts). Reverse sneezing is a response to obstruction or irritation of the nasopharynx. When reverse sneezing, pets are often walking or standing, neck extended, head tilted backward, lips pulled backward, and nostrils flared (see ch. 238). These postural efforts elongate the nasopharynx and can widen

the nasopharyngeal meatus maximally. Paroxysms may last for seconds to a few minutes and they may occur at night or while the pet is at rest, when the nasopharynx narrows. Although not typically associated with respiratory distress, episodes can be quite alarming.

Nasal Discharge

Nasal discharge (see ch. 27) usually follows an increase in nasal cavity fluid secretions, a change in quality or viscoelastic properties of nasal secretions, impaired nasal mucociliary clearance, or any combination of these conditions. When seen, nasal discharge should be characterized by its appearance and consistency (mucoid, serous, hemorrhagic, etc.). This information may help localize the source of, or reason for, the discharge. Importantly, nasal discharge may not always be obvious. Cats and some dogs can be fastidious groomers, removing discharge before owners see it. In these cases, the nasal planum may become ulcerated or hyperkeratotic, and the hair surrounding the nasal planum may be lost due to licking or pawing at the nose. Also, normal nasal airway mucociliary clearance moves secretions from the nasal cavity back toward the nasopharyngeal meatus and the larynx, resulting in an upper airway cough. Overt nasal discharge from the nostrils will not become apparent until the amount or character of the secretions exceeds the mucociliary clearance capacity or until the mucociliary clearance apparatus has been sufficiently damaged or impaired (e.g., *Bordetella* [see ch. 227 and 229], *Mycoplasma* or parainfluenza virus [see ch. 228] infections, squamous metaplasia [see ch. 238]).[8,9] Nasal discharge may also be a manifestation of nonrespiratory disease (e.g., esophagopharyngeal reflux).[10]

Open-Mouth/Postural Breathing

Postural changes reflect attempts to decrease airway resistance by increasing airway cross-sectional area.[11] In dogs, open-mouthed breathing is a common response to upper airway obstruction. In cats, open-mouthed breathing is rare, indicating that the respiratory system's ventilatory reserve capacity is approaching exhaustion. Extending the head and neck minimizes bending in the trachea and pharynx. Flaring the nostrils and opening the mouth minimize inspiratory resistance at the inlet. Animals may also minimize extraneous (nonrespiratory) activity and eliminate actions that exacerbate airway narrowing (swallowing, vocalizing) (see ch. 28).

Audible Respiratory Sounds

Respiratory noises that are audible to clients without the aid of a stethoscope are almost always due to airway obstruction and are usually upper airway in origin (nasal cavity, nasopharynx, oral cavity, larynx, extrathoracic trachea). Since stress and sympathetic tone associated with a hospital visit may facilitate airway opening, it is common for respiratory noises present at home to be absent in the exam room. Owners should be asked to describe whether noises are continuous (stridor) or discontinuous (stertor), constant (fixed obstructions) or intermittent (dynamic or episodic obstructions), and if intermittent, what events precipitate the noise (exercise, sleep, etc.). Having owners provide videos when respiratory noises are produced can be helpful both in characterizing the sound and evaluating the patient's posture during the event. While the determination of the phase of respiration during which the noise occurs is extremely valuable information, it can be difficult for clients to reliably make this type of assessment.

Cough

Cough (see ch. 26) is a defense mechanism that protects lower airways, usually triggered by inhalation of noxious substances or irritants, or by accumulation of substances in any portion of the larynx or tracheobronchial tree. The sound of a cough originates from the larynx as a result of the acute expulsion of intrapulmonary air through a closed glottis. Dogs and cats with irritation or stimulation originating from different regions of the tracheobronchial tree may exhibit subtle differences in the quality of their coughing.

Differences in coughing sounds may be helpful in localizing site and nature of the stimulus. For example, cough originating in alveoli or small airways (bronchopneumonia, chronic bronchitis) is usually preceded by a deep inspiration. Paroxysms may start quietly and grow louder as tracheobronchial secretions are moved up to the central airways (crescendo). These coughs may be productive or nonproductive and are frequently followed by a post-tussive retch, or swallowing of raised secretions. Cough originating in the central airways (trachea, mainstem bronchi) is often associated with a "goose honk" sound, as air is forcefully expelled through segments of narrowed or collapsed airways. Paroxysms of tracheal coughing are often "nonprogressive:" In tracheal coughing, each one sounds like the preceding one, triggers the subsequent one, and the episodes may be quite prolonged (see ch. 241). Cough may also be elicited with stimulation of the

larynx, trachea, and bronchi by postnasal drainage of nasal secretions or oral cavity contents. With laryngeal coughing, the stimulus is often abrupt and unanticipated, causing reflex laryngospasm. This prevents deep inspiration prior to starting the cough and typically results in a rapid-fire cough that may be weak or ineffective due to the small volume of air expelled. These coughs may also be followed by voluntary efforts to clear the upper airways (gagging). Technically, this mechanism is referred to as an *expiratory reflex* rather than a cough reflex, but it is often included in descriptions with other forms of cough.[12]

Coughing can be induced by airway narrowing during expiration, as a result of pleural space disease (primarily dogs; see ch. 245), cardiomegaly (dogs; see ch. 251), or intrinsic airway narrowing secondary to dynamic small airway disease (chronic bronchitis [dogs and cats], asthma [cats]; see ch. 241), tracheal collapse (primarily dogs), or restrictive lung diseases (see ch. 242). These coughs are typically triggered at higher tidal flows and may only be noticed during exercise in early stages of disease but may become more noticeable as cardiopulmonary reserves diminish. Cough "afferents" may originate outside the lower airways. These would include the nose, nasopharynx, paranasal sinuses, ear canals, diaphragm, and pericardium.[13] The exact role of afferents in these locations is not entirely known; however, their presence suggests that extrapulmonary sites may also be important sources of cough.

Physical Examination of the Respiratory Patient

General Observations

Respiratory signs may be due entirely or in part to intrinsic respiratory disease. However, such signs may represent respiratory manifestations of dysfunction in other organ systems (e.g., gastrointestinal, central nervous system (CNS), cardiovascular, hematologic, adrenal, thyroidal). In addition, the stress associated with a nonrespiratory illness may unmask occult respiratory disease, particularly in cats. Therefore, it is always important to perform a complete physical exam whenever patient stability allows. Examination should begin with close observation of the dog or cat at rest, if possible. With stable patients, this should occur while obtaining the history. Patients can be removed from their carriers or unsecured from leashes in an enclosed exam room, allowing them to wander. Respiratory rate, effort, noises, patterns and posture are assessed. If the pet is in respiratory distress (see ch. 28 and 139), it is still prudent to obtain at least a cursory assessment of respiratory pattern and posture prior to handling the patient.

Breathing Patterns

Normal

During normal respiration, the chest wall and abdominal wall move out together during inspiration and in together during expiration. This coordinated movement allows maximal lung expansion with minimal effort during inspiration. Diaphragmatic contraction, passive muscle relaxation, and elastic lung recoil provide expiration.[14] Normal ratios of inspiratory time: expiratory time during tidal breathing are from ≈1 : 1 to 1 : 2. Some animals at rest may exhibit a pronounced pause at the end of expiration, during which no chest or abdominal wall movements are detectable. Increased respiratory workload may result in altered breathing patterns. These alterations are subconscious responses to minimize work of breathing. They vary as a result of the nature of the increased respiratory burden (Figure 240-1).

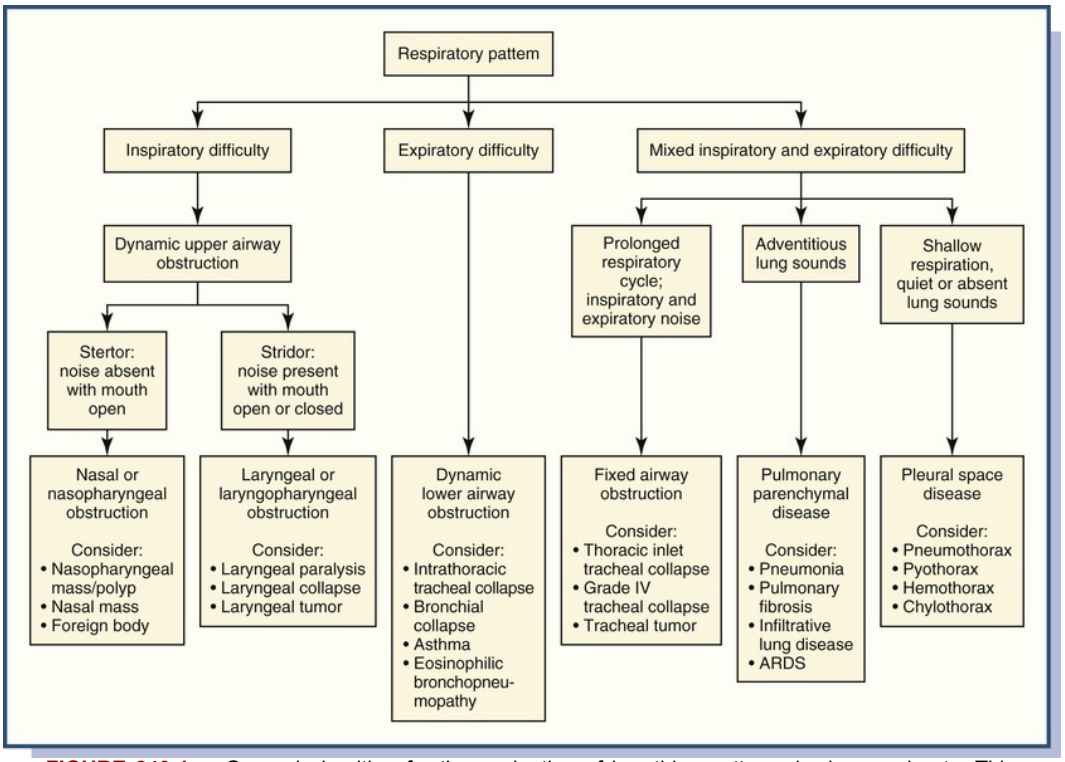

FIGURE 240-1 General algorithm for the evaluation of breathing patterns in dogs and cats. This algorithm is intended to provide general guidelines toward the assessment of respiratory patterns. Exceptions to this algorithmic approach exist. *ARDS*, Acute respiratory distress syndrome.

Obstructive and Restrictive Lung Diseases

Airway *obstruction* causes increased airway resistance or an increase in the pressure necessary to generate airflow. The increase in respiratory effort can exacerbate airway collapse and worsen airflow obstruction. Extrathoracic obstructions (e.g., laryngeal tumors, laryngeal paralysis, nasal or nasopharyngeal obstruction [see ch. 238]) are typically associated with an increase in inspiratory effort and inspiratory noise, while intrathoracic obstructions (small airway disease, mucous plugging, intrathoracic tracheal collapse) are associated with an increase in expiratory effort and expiratory noise. A common compensatory strategy for pets with airway obstruction is to decrease the velocity of airflow to minimize any propensity for airway collapse. The result is slow, deep respirations, often with prolongation of the inspiratory phase with extrathoracic (upper airway) obstructions and expiratory phase prolongation with intrathoracic obstructions.

Restrictive lung disease results in decreased lung compliance or a change in lung volume associated with a measured increase in airway pressure. Pets with conditions causing restrictive breathing patterns (bronchopneumonia, pulmonary fibrosis, pleural space disease) require higher airway pressures to fully expand their lungs. Because the increased workload is associated with lung expansion, restrictive lung or pleural space diseases may be compensated by decreasing tidal volumes and increasing respiratory rates. The result is rapid, shallow breathing.

Obstructive and restrictive conditions each increase the work of breathing. With time, this increased effort can result in respiratory muscle fatigue and a *paradoxical* breathing pattern. As respiratory muscles fail, the negative intrathoracic pressure generated during inspiration will tend to suck the chest wall in. Diaphragmatic fatigue or paralysis can lead to abdominal muscle recruitment, causing outward movement of the abdominal wall during expiration. These chest and abdominal wall movements are the opposite of those seen normally and can be indicative of severe or longstanding respiratory dysfunction. In dyspneic dogs and cats, paradoxical breathing has been strongly correlated with the presence of pleural space diseases (see ch. 244).[15] The presence of this clinical sign can help to prompt implementation of appropriate emergency diagnostic and therapeutic procedures (see ch. 139).

Posture

Pets experiencing significant respiratory compromise may adopt a posture that helps maximize the efficiency

of breathing or decrease airway resistance by increasing airway cross-sectional area and facilitating chest wall expansion. Extending the head and neck reduces redundancy and obstruction in the pharynx. Flaring the nostrils opens the nasal valve (ostium internum). Breathing through an open mouth bypasses nasal and nasopharyngeal resistance altogether and often represents significant loss of cardiopulmonary reserve in cats. Some may sit or prefer to remain sternal with their elbows abducted. Pets may also minimize extraneous activity and eliminate actions that exacerbate airway narrowing (swallowing, vocalizing).

Respiratory System Examination

General

Physical examination of the respiratory system often confirms the historical and observed concerns, but in some cases the history may be vague and overt respiratory signs subtle or absent. Thorough respiratory system examination includes the nasal area (muzzle, head, eyes, dental arcade, hard palate, nasal airflow), oral cavity, palpation of the larynx and trachea, thoracic compression, and auscultation of the thorax and thoracic inlet. Examination of the nasal cavity usually entails visual inspection and palpation of the muzzle, head, eyes, and hard palate for conformation, symmetry, and defects. The external nares and rostral aspect of the nasal passages can be visually inspected for mucous membrane color and for presence and character of any nasal discharge. Each nasal cavity should be evaluated for patency and airflow by holding cotton or gauze in front of each nostril to detect air movement or by placing a refrigerated glass slide in front of the nose during nasal breathing, watching for condensation from each nostril. The hard palate and upper dental arcade should be inspected and palpated, as invasive nasal disease may extend into the oral cavity, and dental disease (e.g., tooth root abscesses) may have nasal manifestations. Eye palpation and retropulsion should be performed to assess symmetry. Invasive nasal tumors or destructive mycotic rhinitis may extend into the orbit. The oral cavity should be inspected for mucous membrane color, capillary refill time, and hydration. The tonsils, tongue, sublingual area, and hard palate should be examined for defects or lesions that may cause airway obstruction and pharyngeal function assessed by checking for a gag reflex. Palpation of the submandibilar and medial retropharyngeal lymph nodes, an otoscopic examination (see ch. 85), and an ophthalmic examination (see ch. 11) are indicated. Signs of systemic or infectious diseases may be first noted on nasal or ophthalmic examination (fungal disease, hypertension).

Sounds

Evidence of upper airway conditions include stertor, stridor, and decreased or absent nasal airflow. Stertor, a discontinuous, low-pitched fluttering sound that usually originates from the nasopharyngeal meatus, is typically associated with inspiratory dysfunction but may be present during both phases of respiration. Because the nasopharyngeal meatus tends to narrow during rest, stertor may be more pronounced at night. Stridor is a continuous, high-pitched inspiratory sound, usually produced as a result of narrowing of the larynx or extrathoracic trachea. In contrast to stertor, stridorous respiratory noise may be absent at rest but exacerbated with large volume airway flows (exercise, panting, etc.). Lower airway conditions may cause adventitious sounds (wheezes, crackles), as well as changes in the character of normal bronchovesicular sounds. Normal inspiratory flow reaches peak velocity near the end of inspiration and normal expiratory flow reaches peak velocity near the beginning of the expiratory phase. Thus, thoracic auscultation of normal airflow is typically loudest at end inspiration and early expiration. Normal bronchovesicular sounds detected via auscultation are primarily generated by laminar flow through larger central airways and are filtered by the alveoli, pleural space, and chest wall. Changes in the volume (increased or decreased) or pattern of bronchovesicular sounds can be early indicators of respiratory disease, even in the absence of adventitious lung sounds. Increased detection of bronchovesicular sounds can occur as a result of increased respiratory effort, while decreases in bronchovesicular sounds can be the result of structural alterations in the pulmonary interstitium, alveoli, or pleural space.

Adventitious respiratory sounds indicate an abnormality. Wheezes (continuous, musical sounds associated with intrathoracic airway narrowing) are usually associated with expiratory dysfunction. High-pitched wheezes can be detected with narrowing of the lower airways or small airways, while low-pitched wheezes may indicate larger airway narrowing. Crackles ("rales;" discontinuous, "popping" sounds most audible during inspiration) represent an equilibration of pressures between two regions of an obstructed airway. Fine crackles, typically alveolar or bronchiolar in origin, are usually loudest near the end of inspiration. Loud, moist crackles often are the result of airflow through airway secretions in central airways, detected throughout inspiration or just during expiration.

A decrease or absence of respiratory sounds can occur as a result of the accumulation of air, fluid, or viscera

within the pleural space (see ch. 28 and 244). Pets with pleural space disorders may exhibit a shallow, rapid (restrictive) breathing pattern. The location of the loss of breath sounds should provide clues as to the nature of the pleural space disorder. Loss of respiratory sounds ventrally is consistent with a fluid accumulation (e.g., blood, pus, transudate, chylous effusion). Loss of breath sounds dorsally is most consistent with pneumothorax. Most pleural space disorders in dogs and cats are bilateral due to their incomplete mediastinums. However, tissue accumulations (e.g., mesothelioma) or visceral herniations may result in asymmetrical auscultation findings.

In many cases, respiratory noises or clinical signs that are present at home may not be present in the exam room. The tremendous reserve capacity of the cardiopulmonary system may necessitate the use of provocative testing during a physical exam. Detection of cardiopulmonary abnormalities may be enhanced by inducing a "sigh" during auscultation (close the mouth and partially obstruct the nostrils for 4-5 breaths), by triggering a cough with gentle tracheal palpation, or with light or moderate exercise. Having owners video- and audio-record abnormalities at home can also help clinicians to accurately verify and localize respiratory disease prior to the implementation of more invasive and expensive diagnostic testing.

Laboratory Diagnostic Techniques

Initial Data Base: Complete Blood Count (CBC), Serum Biochemistries, Urinalysis

Selecting appropriate tests to better understand and manage a pet with respiratory disease depends on the history, signalment, physical examination results, differential diagnoses, and owner choices or limitations. Results of the initial database can help narrow or prioritize likely causes for the signs. Results may also facilitate selection of more advanced diagnostics. On a CBC, polycythemia can result from chronic hypoxemia and tissue hypoxia. Neutrophilic leukocytosis is common in pets with airway infection (canine infectious respiratory disease, feline upper respiratory disease), and those with bronchopneumonia may have either leukocytosis or, in the acute stages, leukopenia. Peripheral eosinophilia is common in dogs with eosinophilic bronchopneumopathy and is occasionally observed in pets with parasitic lung disease, fungal diseases, and in cats with asthma (see ch. 241). Lymphocytosis in a young pet with respiratory disease and fever is consistent with a viral condition. Hypercalcemia in a patient with respiratory signs may be suggestive of a neoplastic or fungal etiology.

The initial database also allows assessment for nonrespiratory diseases that can impact the respiratory system (e.g., hyperadrenocorticism, pancreatitis, severe metabolic acidosis) or may unmask respiratory disease. A systemically ill pet with respiratory distress, an inflammatory leukogram, and hypoalbuminemia may suggest the acute respiratory distress syndrome (ARDS). Severe hypoalbuminemia can lead to pleural effusion and/or ascites with accumulation of a transudate in those cavities. This can cause an increase in respiratory effort. Thrombocytopenia, thrombocytopathia, coagulopathy, and systemic hypertension can all result in pulmonary hemorrhage, hemorrhagic effusions, or epistaxis.

Serologic and Other Advanced Testing

Serologic, urine antigen, fecal, and polymerase chain reaction (PCR) tests can be employed in pets suspected of having infectious or parasitic causes of their respiratory signs. Infectious etiologies (see ch. 227-230) may be influenced by age, geographical location, travel history, lifestyle (e.g., outdoor vs. indoor cats), presence of comorbid nonrespiratory symptoms, or a "herd" health scenario (e.g., multiple affected puppies within a litter, multiple patients from the same boarding facility or shelter, a cat affected after introduction of a new kitten in a household). Recurrent airway or respiratory infections due to opportunistic pathogens are consistent with immunodeficiency. For example, diagnosis of refractory or recurrent nasal cryptococcosis in a cat may warrant testing for feline leukemia virus and feline immunodeficiency virus, while recurrent rhinitis, tracheobronchitis, and pneumonia in a young dog may prompt an investigation for primary ciliary dyskinesia or heritable immunoglobulin deficiencies.[16-18]

The method and timing of sample collection are important factors to consider when screening for infectious or parasitic causes of respiratory disease with laboratory testing, particularly for PCR testing (see ch. 227, 229, and 234). Samples collected for PCR should be obtained using polyester-tipped swabs, as residues found in cotton-tipped or calcium alginate swabs may inhibit PCR assays for the pathogen or pathogen genome. Collection of superficial mucosal samples may yield false-negative results with viral (e.g., canine respiratory coronavirus) or facultative intracellular bacterial (e.g., *Mycoplasma cynos*) pathogens. Pathogen shedding may

cease prior to resolution of clinical signs (e.g., canine influenza virus). PCR testing after the organism has been cleared may yield a false-negative result. In all cases, steps should be taken to ensure that the timing and method of sample collection is appropriate for the differentials being considered (Box 240-1).

Box 240-1

Common Fungal, Viral, Bacterial, and Protozoal Causes of Infectious Respiratory Disease in Dogs and Cats Detectable by Polymerase Chain Reaction Assay

Fungal

Blastomyces
Coccidioides
Cryptococcus
Histoplasma
Aspergillus
Pneumocystis

Viral

Canine distemper virus
Canine adenovirus-2
Canine herpesvirus
Canine parainfluenza virus-2
Canine respiratory coronavirus
Canine influenza virus (H3N2 and H3N8)
Pandemic influenza virus (H1N1)
Canine pneumovirus
Feline herpesvirus-1
Feline calicivirus

Bacterial

Bordetella bronchiseptica
Chlamydia felis
Mycoplasma cynos
Mycoplasma felis
Streptococcus equi subsp. Zooepidemicus

Protozoal

Toxoplasma
Neospora
Acanthamoeba

Diagnostic Imaging of the Respiratory System

Overview

Investigation of suspected respiratory disease relies extensively on diagnostic imaging of the upper airways (nasal cavity, pharynx, larynx, trachea), lower airways (bronchi, bronchioles), pulmonary parenchyma (vasculature, interstitium, alveoli), and nonrespiratory structures (heart, spine, ribs, sternum, abdomen, etc.). Thoracic radiography is the common first assessment. Alternative imaging modalities can provide additional levels of detail and dimension (computed tomography [CT] or magnetic resonance imaging [MRI] scans); an assessment of dynamic airway function in real-time (fluoroscopy, ultrasonography); or be indicative of regional lung function (nuclear imaging). Diagnostic imaging studies should be completed before more invasive procedures (rhinoscopy [see ch. 96 and 238], nasal biopsies [see ch. 96 and 238], bronchoalveolar lavage [see ch. 101]) to avoid iatrogenic hemorrhage and disruption of anatomic structures affecting imaging results.

Radiography of the Upper Respiratory Tract

Introduction

Anatomically, the upper airway extends from the tip of the nose to the thoracic inlet. In animals, investigation of clinical signs and respiratory noises suspected to be localized in the upper airways relies heavily on imaging the upper airway (nasal cavity, pharynx, and larynx; see ch. 238 and 239) and nonrespiratory structures (skull, dental arcade, bony orbits, lymph nodes, salivary glands). Because much of this region lies within the confines of the skull (nasal cavity, nasopharynx) or is surrounded by overlapping soft-tissue structures (larynx, cervical trachea), advanced imaging may be required to confirm abnormalities. Positioning is critical, and motion artifacts must be avoided. Thus, upper airway imaging studies are best performed under heavy sedation or general anesthesia.

Nasal, Facial

Nasal radiographs can be helpful in localization and characterization of intranasal disease (see ch. 238). Nasal and sinus radiographs, however, rarely identify a specific cause for disease (an exception would be a radiopaque foreign body). Benefits of nasal radiographs include the ability to detect asymmetry, bony destruction, and soft tissue opacity in the nasal cavity and surrounding structures. High-quality nasal radiographs can be obtained with minimal cost and no specialized equipment. Nasal radiographs should include a minimum of two orthogonal views. Standard views include dorsoventral, open-mouth ventrodorsal (occlusal), and lateral. Specialized views (oblique lateral view, "skyline" view) can be extremely valuable in detecting frontal sinus and auditory bulla involvement. Dental radiographs can provide detailed information about the involvement of the maxillary dental arcade and tooth roots in the pathogenesis of nasal disease. Nasal radiographs, however, lack the sensitivity and level of detail obtained with CT or MRI scans. The complexity of the canine and feline skull can make detection of early or subtle nasal lesions difficult. While not technically challenging, patient positioning is extremely important because poor positioning provides images of little value or could lead to misdiagnosis.

Pharynx, Larynx, and Cervical Trachea *(see ch. 238, 239, and 241)*

Radiography of the lateral skull or neck is usually adequate when respiratory signs are localized to these areas (e.g., stridor, gagging, ineffective coughing, change or loss of voice). The specific area of interest should be centered in the image to minimize the degree of parallax when viewing symmetrical paired structures (e.g., auditory bulla, arytenoid cartilages). Positioning is critical in evaluating such radiographs, as even the slightest obliquity can make interpretation difficult. Images centered over the larynx are most useful in the assessment of laryngeal stridor, while images centered over the midcervical region are preferred in the assessment of suspected cervical tracheal collapse. Investigation of suspected cervical or thoracic inlet tracheal collapse should also include both inspiratory and expiratory lateral views to document dynamic collapse (when fluoroscopic or tracheoscopic evaluation is not available).

Thoracic Radiography

Technique and Positioning

Survey thoracic radiographs with at least two orthogonal views (a lateral and a ventrodorsal or dorsoventral) may aid in localizing lower airway, parenchymal, and pleural space conditions. Studies including both lateral views and an orthogonal view are ideal. Dependent lung lobes on lateral views tend to collapse due to heart and diaphragm compression and decreased thoracic wall movement during the respiratory cycle.[19] There are occasional cases in which both ventrodorsal (e.g., accessory lobe disease) and dorsoventral (e.g., caudal lobar pulmonary vascular enlargement) projections may be indicated. Positioning and technique are particularly important for evaluation and interpretation of intrathoracic (lungs, heart, mediastinal content) and extrathoracic structures (ribs, spine, sternebrae). Any of these areas may contribute to signs of a respiratory condition. Care should be taken to ensure that the cranial limbs are pulled forward to avoid superimposition over the cranial thorax on lateral projections. Views should be collimated to include the entire pulmonary fields, the cranial abdomen, and the thoracic inlet. Thoracic structures have inherent movement due to respiratory motion and the cardiac cycle, so the length of exposure for thoracic imaging should be kept as brief as possible while still providing adequate contrast.

Classification of Pulmonary Radiographic Abnormalities

Pulmonary radiographic abnormal patterns are interstitial, bronchial, and/or alveolar (see ch. 242). Interstitial pulmonary patterns are further characterized as unstructured or structured (nodular). Unstructured interstitial patterns have a generalized increase in pulmonary parenchymal background opacity and a decreased distinction of the pulmonary vasculature. Common causes of a diffuse interstitial pattern include viral or hematogenous pneumonias, pulmonary edema (cardiogenic and noncardiogenic), neoplastic infiltration (e.g., pulmonary lymphoma), and pneumonitis secondary to systemic diseases (e.g., uremic pneumonitis). Unstructured interstitial patterns may be artefactual due to poor radiographic technique, hypoventilation, or as a variant of normal in an obese patient.[20] Structured or nodular interstitial patterns appear as discrete or coalescing soft tissue nodules within the pulmonary fields. Nodular lesions >2 cm within the pulmonary parenchyma are usually called "pulmonary masses." Nodular lesions may be solitary or multiple and may appear as solid or cavitary. The size, appearance, and number of nodular interstitial lesions may help to narrow the differential list (Table 240-1).

TABLE 240-1

Causes of Interstitial Pulmonary Nodules and Masses

FINDING	CAUSE	PREVALENCE
Multiple solid nodules	Metastasis	Common
	Mycosis	Uncommon
	Septic emboli	Rare
Solitary solid mass	Primary tumor	Common
	Abscess	Rare
Multiple cavitary nodules	Metastasis	Rare
	Parasitic	Rare
	Bullae	Uncommon
Solitary cavitary mass	Primary tumor	Common
	Abscess	Rare
	Bulla	Uncommon

From Thrall DE: The canine and feline lung. In Thrall DE, editor: *Textbook of veterinary diagnostic radiology*, ed 6, St Louis, 2013, Elsevier, pp 608-631.

Alveolar Pulmonary Patterns

An alveolar pulmonary pattern occurs when the air within the alveoli is replaced with soft tissue or fluid, resulting in an overall increase in lung opacity. Pulmonary edema, hemorrhage, and inflammatory or neoplastic exudates are fluids that can replace alveolar air resulting in an alveolar pattern. Atelectasis, or the loss of alveolar air with resulting alveolar collapse, can also cause an alveolar pattern, which usually also results in a mediastinal shift toward the side of the atelectasis. Rarely, solid tumors can result in an alveolar pattern, either by replacing alveolar air or causing bronchial obstruction resulting in atelectasis. The radiographic hallmarks of an alveolar pattern include the presence of air bronchograms, a lobar sign, and soft tissue silhouetting (or border effacement) between the affected lung and the diaphragm, heart, or vasculature. Common causes of an alveolar pattern include bronchopneumonia, pulmonary edema (cardiogenic or noncardiogenic), hemorrhage, and atelectasis. Less common but important differentials for an alveolar pattern include severe inflammatory airway disease (e.g., eosinophilic bronchopneumopathy), pulmonary thromboembolism, and neoplasia (see ch. 242).

Bronchial Pulmonary Patterns

Bronchial pulmonary patterns occur when the bronchial walls become thickened or when the immediate peribronchial space becomes infiltrated with cells or fluid. Radiographically, thickened bronchi appear as rings of soft tissue density with air opacity in the center ("donuts"), or parallel radiopaque lines ("tram lines"). In addition to bronchial wall thickening, other consequences of bronchial disease may alter thoracic radiograph results. These include bronchiectasis, cranial or middle lung lobe atelectasis, and hyperlucent lung

fields due to air trapping and hyperinflation. Common causes for a bronchial radiographic pattern in dogs and cats include allergic airway disease (feline asthma, canine eosinophilic bronchopneumopathy), parasitic bronchitis/pneumonitis, and chronic bronchitis (see ch. 241). The radiographic appearance or distribution of similar conditions may differ between species, e.g., the classic radiographic appearance of left-sided congestive heart failure in dogs is a perihilar interstitial or alveolar pattern while the same condition in cats may be more of a patchy pulmonary distribution; dogs with bronchopneumonia often have a cranioventral alveolar pattern while cats usually have multifocal or patchy, asymmetrical, alveolar patterns (see ch. 242).

Pleural Effusion

The accumulation of fluid (blood, chyle, inflammatory or neoplastic exudates, transudates, modified transudates) within the pleural space can inhibit lung expansion leading to respiratory difficulty, hypoxemia due to hypoventilation, and respiratory distress. Signs can be severe if the fluid volume is large or if it develops rapidly. Presence of clinically significant pleural fluid can be detected with routine thoracic radiographs, understanding that about 100 mL of liquid must be present within the pleural space of a medium-sized dog before it becomes radiographically apparent.[21] Smaller volumes or localized accumulations may require additional imaging modalities (CT, ultrasound) to facilitate detection. Radiographic signs indicative of free pleural liquid include the appearance of pleural fissure lines between lung lobes, retraction of lung lobes away from the chest wall, rounding of the edges of dependent lung lobes, and obfuscation of the diaphragmatic and cardiac silhouettes (see ch. 244).

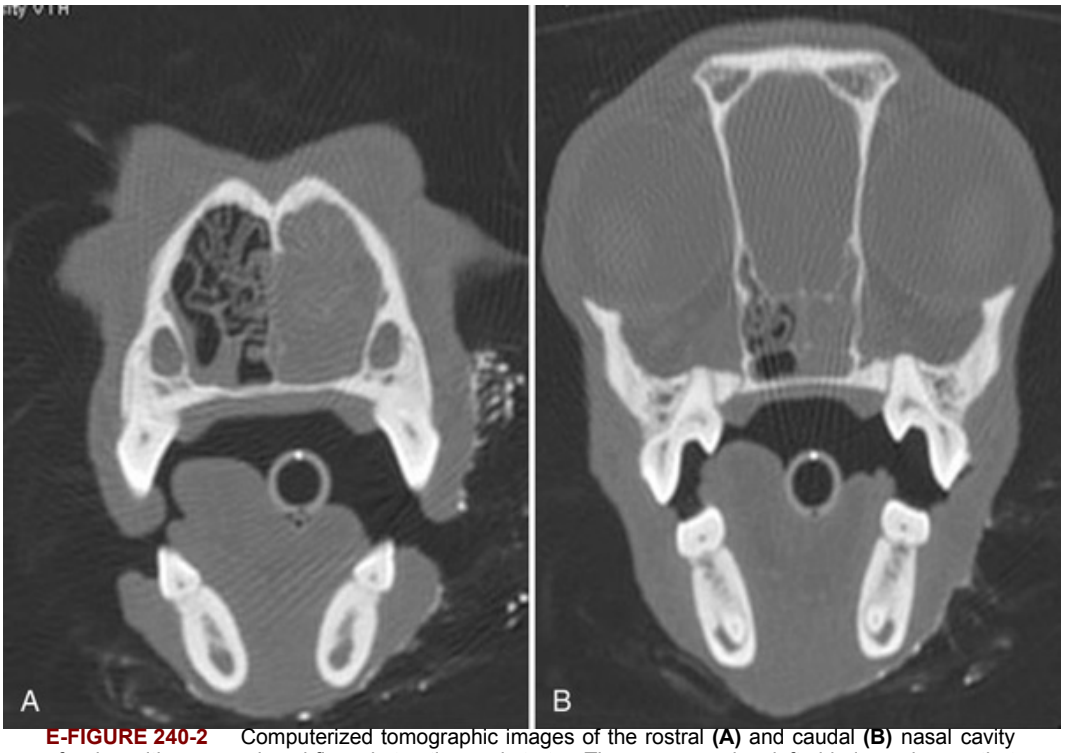
Pneumothorax

Air or other gases within the pleural space (pneumothorax) can cause severe respiratory distress and dysfunction. Air can accumulate within the pleural space from lung rupture, from a mediastinal condition, or from the outside through the chest wall. The most common radiographic appearance of pneumothorax is the retraction of lung lobes away from the thoracic wall on the lateral views.[22] Pneumothorax also causes secondary lung collapse or atelectasis, resulting in an apparent increase in lung opacity. Collapse of the dependent lung lobes on lateral views allows the heart to descend into the dependent hemithorax, resulting in a separation of the heart and the sternum ("floating heart"). Removal of pleural fluid or air via thoracocentesis prior to diagnostic imaging may be required for patient stabilization (see ch. 102) and can also improve the radiographic assessment of the lungs, heart, diaphragm, and mediastinum (see ch. 244 and 245).

Computed Tomography (CT)

Availability and Use in Nasal Conditions

Historically, CT scanning in pets required general anesthesia, but newer scanners with 32- or 64-row detectors can acquire a complete series of images within a few seconds. CT scanning can now be performed in critically ill or unstable pets without anesthesia.[23,24] Avoiding anesthesia allows evaluation of the anatomic position of upper airway structures without the interference of an endotracheal tube.[25] CT provides a detailed, three-dimensional (3-D) view of the nasal cavity, nasopharynx, and sinuses (E-Figure 240-2). Because of its higher sensitivity and resolution, CT is considered the test of choice for evaluating nasal disease (see ch. 238). CT images are excellent for detecting early nasal lesions and for determining the extent of an invasive process (e.g., extension into cribriform plate, orbital involvement). While rhinoscopy and nasal radiography are insensitive in distinguishing noninfectious rhinitis from neoplasia and/or mycotic rhinitis, CT provides valuable detail that may suggest one condition over another. CT is particularly sensitive in detecting changes in bony and cartilaginous structures associated with the nasal cavity. CT alone provides no better distinction of soft tissue structures versus fluid than nasal radiographs. Use of IV contrast enhancement of vascular structures and perfused tissues with CT, however, can aid in delineating the margins of invasive nasal tumors and can be used to distinguish between fluid or mucus accumulation versus soft-tissue structures. Measurements and 3-D reconstructions of CT images can be used to guide subsequent nasal biopsies and are used in planning of surgical approaches and radiation therapy protocols.



E-FIGURE 240-2 Computerized tomographic images of the rostral **(A)** and caudal **(B)** nasal cavity of a dog with progressive airflow obstruction and stertor. The scan reveals a left-sided nasal mass that extends caudally into the nasopharyngeal meatus. The patient was diagnosed with a nasal adenocarcinoma. (Images courtesy Michigan State University Veterinary Medical Center, East Lansing, MI.)

Thoracic CT

One of the major advantages of thoracic CT is the enhanced ability to detect and localize subtle pulmonary, mediastinal, and thoracic wall lesions that may contribute to respiratory signs. The same five radiographic opacities (gas, fat, soft tissue, mineral, and metal) detected on radiography are used in CT interpretations. CT, however, provides better contrast between adjacent opacities (e.g., between air-filled lungs and airway or chest wall) and has higher sensitivity to changes in density within a given opacity. CT (as small as 1 mm) is more sensitive than radiography (7-9 mm) for detecting pulmonary nodules.[26,27] These factors make thoracic CT a preferred method for lung evaluation when staging results may alter treatment recommendations. While CT findings cannot confirm a diagnosis, specific CT findings can strongly correlate with certain diagnoses. In people, a set of CT criteria has been established for a "reasonably accurate" diagnosis of idiopathic pulmonary fibrosis (IPF) with a reduced need for lung biopsy.[28] Similarly, the findings of ground-glass opacities, parenchymal bands, honeycombing, peribronchovascular interstitial thickening, and traction bronchiectasis, with a predominantly subpleural distribution of these lesions, are consistent with canine idiopathic pulmonary fibrosis (see ch. 242). The severity of these findings on CT may closely correlate with pulmonary functional abnormalities and disease severity.[29,30]

The 3-D nature of CT and the ability to obtain thin slices through respiratory structures also contributes to enhanced localization and resolution in the lower airways and alveoli. This level of detail makes CT useful not only in the detection of respiratory abnormalities, but provides methodology for the quantification of morphologic pulmonary lesions. Measurements of airway caliber and bronchial wall thickness relative to adjacent pulmonary arteries can be used to quantify bronchial wall alterations in chronic bronchitis and bronchiectasis.[31,32] Thin-slice CT images through the pulmonary airways can be reformatted into virtual bronchoscopic images used to guide bronchoscopic or surgical intervention.[33] The 3-D localization of pulmonary lesions also facilitates the collection of CT-guided, percutaneous fine-needle aspirates and needle biopsies of chest wall, pleural, and pulmonary lesions in dogs and cats (see ch. 93, 96, and 101).[34]

Magnetic Resonance Imaging (MRI)

MRI provides better resolution of soft-tissue structures than does radiography or CT. It is superior to radiography in the detection of subtle soft-tissue lesions, including early neoplasms and fungal granulomas, and can be used to readily distinguish between soft-tissue structures and accumulated fluid or mucus.[35,36] MRI performs similar to CT in assessment of chronic nasal disease and nasal neoplasia[37] and may be useful in differentiating among different types of nasal tumors.[35] A limitation of MRI is that, compared to CT, it is relatively insensitive in detecting bony or cartilaginous changes in the skull surrounding the nasal cavity. Due to technical and practical limitations, MRI is not well suited for pulmonary imaging. Most MRI sequences are affected by patient motion, so regions with inherent motion, i.e., the lower respiratory system, are not suited to standard MRI. Gas has very little signal on MRI, so gas-filled regions like the lungs tend to image poorly as compared with CT.[19] Other limitations, including cost and the need for specialized facilities, are similar to those of CT.

Fluoroscopy

Fluoroscopy allows real-time visualization of dynamic structures in the upper and lower respiratory tract at rest, when exhibiting a clinical sign (e.g., coughing), or during or immediately after possible triggering events (e.g., swallowing, running). Fluoroscopic studies of the upper airways can be performed during eating and drinking of food or liquid mixed with contrast material (swallowing studies) in cases where the transfer of ingesta across the pharynx may lead to respiratory symptoms. Examples include nasopharyngeal reflux in pets with postprandial sneezing or esophagopharyngeal reflux and aspiration as cause of recurrent bronchopneumonia (see ch. 238). Fluoroscopy is most useful in detecting dynamic tracheal and bronchial disease and is more sensitive than inspiratory and expiratory radiography in detecting dynamic collapse of the trachea, carina, and lobar bronchi. Fluoroscopy is more accurate in estimating magnitude and location of airway collapse.[38] Tracheal and/or bronchial collapse secondary to tracheobronchomalacia can be evaluated with fluoroscopy during tidal breathing, as well as during an elicited cough (Video 240-1). Coughing paroxysms can be elicited with gentle palpation of the cervical trachea. If cough cannot be easily elicited, then intrathoracic pressure can transiently be increased by briefly covering the mouth and nose during expiration. Fluoroscopy also allows assessment of cardiomegaly or cardiac movement as a cause of intrathoracic airway collapse.[39] Tracheal stents can be placed under fluoroscopic guidance, and fluoroscopy can be used as a follow-up procedure to monitor stent function (see ch. 121).

Ultrasonography (US)

Because almost all generated sound waves are reflected at soft tissue/air and bone/air interfaces, US is of limited utility in the evaluation of mural or intraluminal masses in the upper airways. US of the upper respiratory tract can aid in identifying extraluminal masses surrounding or impinging on the airway. US can be useful in determining both the origin (e.g., thyroid, laryngeal, lymph node) and the nature (e.g., fluid-filled, solid) of mass lesions around the upper airway. US has also been evaluated as a diagnostic tool for laryngeal paralysis and tracheal collapse.[40,41] US is sensitive in documenting morphologic abnormalities consistent with tracheal collapse and laryngeal paralysis but insensitive in documenting presence of comorbidities (e.g., laryngeal collapse, bronchial collapse) that must be considered prior to therapeutic interventions. Thus, US is one of several tools that can be used to collate information in determining cause of a respiratory condition. It can be used to identify and characterize chest wall and pleural abnormalities that may impact respiratory function, including pleural fluid or masses in the chest wall or pleural space (see ch. 244). US can be helpful in identifying and characterizing peripheral lung lesions, including pulmonary masses, lung consolidation, atelectasis, and abscesses. US guidance can facilitate collection of fine-needle aspirates of fluid or solid mass lesions and guide percutaneous biopsies from peripheral lung, pleural, or chest wall lesions (see ch. 238 and 239).[42]

Nuclear Imaging

Nuclear scintigraphy is performed by administering a radionuclide (usually technetium 99m [^{99m}Tc]) tagged to a pharmaceutical agent and detecting the radioactive decay. Radionuclide and its pharmaceutical agent are selected to ensure delivery to the region of interest. The primary advantage of nuclear imaging is the ability to provide regional assessments of lung function that are not available by more conventional imaging modalities. Radionuclides can be delivered IV to provide an assessment of regional pulmonary perfusion or

they can be delivered via nebulization to assess regional lung ventilation. Perfusion scans can be used in pets suspected of having pulmonary thromboembolic disease (PTE; see ch. 243). Pulmonary vascular scintigraphy is more sensitive and specific in detecting and localizing PTE than is angiography.[43] However, the cumbersome nature of scintigraphy and the requirement for isolation of potentially critically ill patients makes selective pulmonary angiography more commonly used for diagnosis of PTE. Combination of simultaneous ventilation and perfusion scans (V/Q scan) enables the calculation of regional ventilation-to-perfusion ratios, which can be used to localize areas of low V/Q within diffuse lung disease. V/Q scans can provide important information regarding regional lung function prior to interventional procedures such as lung biopsy or surgical lung lobectomy, as well as an assessment of the response to therapy. Intratracheal or intranasal deposition of ^{99m}Tc has also been used in the assessment of mucociliary transport in dogs and cats.[44-46] The primary limitation of nuclear imaging is poor spatial resolution, so the functional aspects of nuclear imaging are usually combined with other imaging modalities (e.g., CT) when planning intervention or monitoring responses to respiratory therapy.

Endoscopic Examination of the Respiratory Tract

See E-Box 240-2 and ch. 83, 96, 101, and 238.

E-Box 240-2

Endoscopic Examination of the Respiratory Tract

Rhinoscopy (also see ch. 96)

Rhinoscopy provides direct visualization of the lumen of the nasal cavity and nasopharynx. This type of examination is indicated as part of the diagnostic evaluation of any patient presenting with signs referable to the nasal airways (see discussion in main part of chapter). Rhinoscopy can provide information about the location, nature, and extent of nasal disease or airflow obstruction. Rhinoscopy, when combined with nasal cavity imaging (CT) and oral cavity examination, provides a complete evaluation of the nasal cavity. Rhinoscopy is typically performed after advanced imaging of the nasal airways, as the results of nasal CT can be used to guide the rhinoscopic examination, and because the presence of the endoscope can induce bleeding or mild mucosal alterations that may confound interpretation of CT images. Due to extremely sensitive nasal airway reflexes, rhinoscopy must be performed under deep anesthesia. The nasopharynx and caudal nasal cavity can be readily evaluated via retrograde rhinoscopy by maneuvering a flexible endoscope through the oral cavity and over the soft palate, or by visualizing the caudal nasopharynx via the oral cavity using a rigid endoscope with a 120-degree offset. The left and right nasal passages can then be examined via anterograde rhinoscopy by directing a rigid or flexible endoscope through the nares (see ch. 238). Mucosal abnormalities, space-occupying lesions, and excessive airway secretions can be visualized in the nasopharynx or nasal passages via rhinoscopy. Rhinoscopy can also be used to guide nasal biopsies.

In the normal nose, the frontal sinuses cannot be reached via routine rhinoscopy because the ostium entering the frontal sinus lies dorsal and caudal to the nasal cavity and is typically obstructed by normal endoturbinates. In disease processes associated with marked turbinate destruction (e.g., nasal aspergillosis; see ch. 234), the frontal sinuses can be evaluated endoscopically by directing a flexible endoscope through the nasal cavity and into the ostium of the frontal sinus. In cases where imaging studies indicate the presence of frontal sinus disease, but anterograde endoscopy of the sinuses is not possible, trephination of the frontal sinus can be used to gain endoscopic access to the sinuses, as well as to obtain biopsies and administer topical therapy.

Laryngoscopy/Pharyngoscopy (see also ch. 239)

Laryngoscopy and pharyngoscopy is indicated in patients presenting with upper-airway localizing signs, including voice change, stridor, stertor, inspiratory difficulty, or exercise intolerance. Laryngoscopy is useful in the diagnosis of the primary and secondary components of the brachycephalic obstructive airway syndrome (elongated soft palate, laryngeal collapse) and in the evaluation of laryngeal or pharyngeal abnormalities identified on radiographic or fluoroscopic examinations. Laryngoscopy is the test of choice for the diagnosis of laryngeal paralysis and congenital laryngeal malformation (e.g., Norwich Terriers) and is useful in documenting other structural and functional abnormalities of the

laryngeal cartilages and laryngeal mucosa in dogs and cats.[2,46]

Laryngoscopy and pharyngoscopy are most commonly performed via an oral approach under light, general anesthesia, although a transnasal endoscopic approach performed under sedation is also described.[47] Laryngoscopy is performed under light anesthesia, ideally prior to other respiratory diagnostics requiring a deeper plane of general anesthesia (e.g., tracheobronchoscopy, rhinoscopy, CT). Laryngoscopy should be performed with a depth of anesthesia adequate to allow relaxation of the mandible and inhibition of the gag reflex, but shallow enough to permit spontaneous respiration and maintain laryngeal tone and movement.

Direct visual inspection of the oral cavity, laryngopharynx, and larynx can be performed using a laryngoscope and light source. The use of a flexible or rigid endoscope allows closer inspection of the caudal oral cavity and larynx and facilitates recording of still images or video loops to document abnormalities. The oropharynx, laryngopharynx, tongue, tonsils, epiglottis, soft palate, and larynx should be visualized for shape, mucosal appearance, and motility. The epiglottic vallecula should be viewed to look for the abnormal accumulation of secretions or ingesta. The nasopharynx can often be examined by gently retracting the soft palate rostrally with a spay hook and visualizing the nasopharyngeal lumen with a dental mirror. The diagnosis of laryngeal paralysis relies on the documentation of impaired laryngeal abduction during the inspiratory phase of the respiratory cycle. The administration of doxapram (2.2 mg/kg, intravenously) during laryngeal examination has been shown to increase respiratory drive and intrinsic laryngeal motion in dogs and aids in the evaluation of laryngeal function,[48] but may also be associated with transient worsening of upper airway narrowing in dogs with laryngeal paralysis.[49]

Tracheobronchoscopy (see also ch. 101)

Direct visualization of the lower airways can be accomplished via tracheoscopy and bronchoscopy. In small animal patients, tracheobronchoscopy allows evaluation of the lumen and airway walls of the trachea, carina, principal bronchi, lobar bronchi, the segmental bronchi, and, depending on the size of the patient and the length of the bronchoscope, the first few generations of subsegmental bronchi. Most patients with clinical signs referable to the lower respiratory tract would benefit from bronchoscopy and/or ancillary procedures accompanying bronchoscopy (e.g., endobronchial biopsy, bronchoalveolar lavage). Bronchoscopy is the test of choice to determine the cause of unexplained cough, wheeze, and hemoptysis, to investigate radiographic pulmonary abnormalities (infiltrates, atelectasis, hyperlucency), and to assess airway integrity (tracheal/bronchial tears and rupture, bronchoesophageal fistula, tracheal/bronchial collapse, lung lobe torsion). Tracheobronchoscopy is the most reliable method for documenting the presence and grade of tracheal collapse (Video 240-2) and is also the only technique available to document collapse of the principal, lobar, and segmental bronchi.[50] Occasionally, bronchoscopy is also indicated for therapeutic intervention, including removal of foreign bodies, therapeutic lavage, and removal of excessive airway secretions.

Because of the sensitivity of the larynx and lower airways, tracheobronchoscopy must be performed under general anesthesia. In larger patients, the bronchoscope can be introduced through an endotracheal tube fitted with a T- or Y-shaped adapter that also allows concurrent delivery of oxygen and anesthetic gases. In smaller dogs and cats, bronchoscopy can be performed without endotracheal intubation. General anesthesia can be maintained with injectable anesthetic agents, and oxygen can be delivered to the patient through the working channel of the bronchoscope or through a tracheal catheter inserted adjacent to the bronchoscope.[51]

Diagnostic Sampling of the Respiratory Tract

Introduction

In dogs and cats with respiratory disease, results of the physical examination, history, laboratory testing, and radiographic imaging are often nonspecific. Further, it is difficult to perform pulmonary function testing in dogs and cats. Thus, collecting fluid or tissue samples directly from the respiratory tract for culture, cytology and/or histological evaluation can be quite valuable (see ch. 93). Specimens can be obtained from the nasal airways by swabbing, brushing, flushing, and closed biopsy. Bronchoalveolar lavage, endotracheal wash, and transtracheal wash are techniques used to collect fluid samples from the lower airways, while a variety of endoscopic, surgical, and thoracoscopic techniques are available for collection of tissue samples from the

lower respiratory tract (see ch. 96, 101, 102, 244, and 245).

Sampling of the Nasal Airways (see ch. 238)

Nasal Swabbing and Nasal Brushing

Nasal swabbing is a minimally invasive technique which often fails to yield accurate or specific diagnoses.[52] In many instances, collected cells are representative of superficial secondary inflammation and microorganisms representative of colonization rather than true infection.[53,54] For these reasons, culture of nasal swabs is rarely indicated and the utility of nasal swabs is limited to cytological diagnosis of certain specific conditions (e.g., nasal cryptococcosis in cats)[52,55] or for samples to be submitted for PCR testing for respiratory pathogens. Nasal swabbing is most used when a specific diagnosis is suspected. Brush techniques may yield cells that lie deeper within the nasal mucosa than those collected by nasal swabbing and may be more useful for separating inflammatory from neoplastic conditions.[56] However, both false-negative and false-positive results remain possible in identifying neoplastic nasal conditions with nasal brushing. Indications for nasal brushing are similar to those for nasal swabbing (see ch. 96).

Saline Hydropulsion

Saline hydropulsion utilizes a high-pressure saline flush to dislodge fragmented tissue samples from masses or lesions within the nasal airways and may also provide therapeutic benefit to some pets by mobilizing accumulated nasal secretions or debulking space-occupying lesions (see ch. 96).[57] When successful, saline hydropulsion can yield tissue samples suitable for histology, which increases the likelihood of reaching an accurate diagnosis. Because of the sensitivity of the nasal airways and sinuses plus the risk of aspiration, nasal flushing procedures should always be performed in anesthetized patients with a cuffed endotracheal tube in place.

Nasal Biopsy

Nasal biopsy samples can be procured by techniques that are less invasive than via surgery (see ch. 96). Specifically, pinch nasal biopsy using endoscopic forceps is relatively easy. Nasal biopsies can be collected via rhinoscopic guidance, CT guidance, or blindly. The high diagnostic yield of this method comes at the expense of the invasiveness of the procedure. Specific precautions must be taken to decrease likelihood of complications. Nasal biopsy is performed under general anesthesia to allow for repeated sampling and to ensure patient comfort. Samples collected via nasal biopsy can be ideal for both light microscopic evaluation and microbiological cultures. Nasal biopsies can also be a source of motile cilia for the diagnosis of ciliary dyskinesia via transmission electron microscopy. Coagulation status should be evaluated in all pets prior to nasal biopsy as bleeding is expected and can be serious (see ch. 80, 99, and 196).

Diagnostic Sampling of the Lower Airways

Bronchoalveolar Lavage (BAL)

BAL, performed under general anesthesia with or without bronchoscopic guidance, allows one to obtain samples from the alveoli, small distal airways, and the interstitium for cytology and/or culture (see ch. 93 and 101).[52,58,59] BAL is performed by wedging the tip of a bronchoscope into a small distal airway, instilling lavage fluid and then withdrawing as much fluid as possible. For nonbronchoscopic BAL, the pet is intubated with a sterilized endotracheal tube, avoiding oropharyngeal contamination as much as possible.[60] For cats and small dogs, a sterile 7- to 10-French polypropylene or red rubber catheter is used (Figure 240-3). The catheter should be at least as long as the distance from the tip of the nose to the last rib and, while maintaining sterile technique, advanced into the lumen of the endotracheal tube until resistance is encountered after it becomes wedged in a small airway. A sterile adapter may be necessary to tightly connect the catheter to a syringe.

FIGURE 240-3 Nonbronchoscopic bronchoalveolar lavage technique in a cat. (Image courtesy Christine Venema, DVM, DACVIM.)

1 to 2 mL/kg per aliquot of warmed lavage solution (nonbacteriostatic 0.9% saline)[58] can be instilled in large dogs and 2-4 mL/kg in smaller dogs and cats. Fixed volumes of 10-25 mL can be used. Each bolus of fluid should be followed by 5 mL of air to be assured that all instilled fluid has passed through the length of the catheter. The bolus of lavage solution and air is infused into the bronchoscope or catheter via an attached syringe, then immediately aspirated through the catheter using the same syringe. Alternatively, mechanical suction can be used to aspirate a fluid sample into a sterile specimen trap.[59] Recovery of about 40-60% of the instilled volume is expected from dogs and cats,[61] but as much as 80% has been recovered from cats.[62] Sampling of at least two sites is recommended, even in patients with diffuse disease, as BAL cytology can vary in different areas of lung.[63] Collected fluid samples may be submitted for cytological analysis, general aerobic, anaerobic, *Mycoplasma*, and fungal cultures.[52,64,65] BAL samples can also be submitted for PCR analysis for respiratory pathogens. Hypoxemia due to ventilation-perfusion mismatch is the most common complication of BAL and can be severe.[66,67] Administration of supplemental oxygen following BAL is usually sufficient to resolve hypoxemia induced by the procedure, even in severely ill pets (see ch. 131).

Tracheal Wash *(see ch. 101)*

Indications

Tracheal wash is usually used to collect fluid samples from large proximal airways[52,68] in pets with a productive cough, since such samples can yield evidence of lower airway pathology. Since the majority of the instilled fluid does not reach the gas exchange interface, severe hypoxemia is unlikely to occur during or after this procedure. Either endotracheal wash (ETW) or transtracheal wash (TTW) is used. ETW requires intubation and general anesthesia, and as a result, may be a more appropriate option for pets that will not tolerate the restraint required for TTW.

Endotracheal Wash (ETW)

Technique and guidelines for processing retrieved samples are similar to those for BAL. Pets are anesthetized and intubated with a sterile endotracheal tube. A red rubber feeding tube or polypropylene catheter is advanced to the 4th intercostal space, which approximates the location of the intrathoracic tracheal bifurcation (carina). Volumes of 0.5-5 mL/kg of nonbacteriostatic 0.9% saline per aliquot have been

recommended. Up to three aliquots can be instilled and aspirated until an adequate sample is retrieved. Samples can be submitted for cytology, culture, immunologic, and PCR analyses. Complications associated with ETW are rare. Transient deterioration in respiratory status, exacerbation of cough, and bronchospasm may be noted during and following the procedure, which are typically mild and readily reversible.[68]

Transtracheal Wash (TTW)

ETW and TTW samples are similar, but TTW is performed in an awake or lightly sedated patient.[52,59,68,69] TTW avoids concern of oropharyngeal contamination, which can occur with ETW.[70] TTW is limited to dogs >15 kg that are amenable to restraint and is contraindicated in patients with hemostatic abnormalities or ventral cervical pyoderma.[69] TTW has limited utility in evaluating pets with interstitial or alveolar disease because little fluid reaches the distal lung. The pet is usually restrained in sternal recumbency or sitting upright with the nose tipped dorsally. An area of skin around the larynx and proximal trachea is clipped and aseptically prepared.

In medium-sized dogs, a catheter can be inserted through the cricothyroid ligament. In large dogs, the needle can be inserted on the ventral midline of the cervical trachea between two tracheal rings.[68,70] Inserting the needle through the cricothyroid ligament avoids risk of penetrating both tracheal walls in medium-sized dogs. Local anesthesia (2 to 5 mg/kg, 2% lidocaine) is instilled intradermally and SC at the intended needle insertion site and then a stab incision is made through the skin using a #11 blade at that site to facilitate passage of a sterile 14-gauge needle through the cricothyroid ligament. Some clinicians specifically displace the skin upward/cranially before entering the skin and trachea with the needle, so that an open tract is not left by the needle after withdrawal. Prior to inserting a sterile 3.5-French red rubber or polypropylene catheter through the needle (Figure 240-4), the distance from the intended insertion site to the fourth rib should have been marked on the catheter to estimate the distance to the carina. Once the needle is seated, the catheter is inserted through the needle and advanced into the lumen of the trachea to the premeasured distance. Recommendations for lavage volumes vary from 0.5 to 5 mL/kg per aliquot, as for ETW. The sample yield for tracheal washes is often less than that obtained with BAL but can be sufficient for cytology, culture, and/or PCR. After removal of the catheter and needle from the trachea, the area is covered with a sterile, nonadherent gauze sponge and lightly bandaged to avoid leakage of air from the needle insertion site. Samples obtained by TTW should be handled, prepared, and analyzed as recommended for samples retrieved by ETW or BAL.

FIGURE 240-4 Transtracheal wash in a dog. A 14-gauge needle is inserted into the trachea through the cricothyroid ligament, and a 3.5-Fr polypropylene catheter is inserted through the needle into the

trachea for instillation and retrieval of lavage fluid. (Image courtesy Christine Venema, DVM, DACVIM.)

Complications associated with TTW are mild, self-limiting, and uncommon. They include SC emphysema due to air leakage from the needle insertion site, hemorrhage, cardiac arrhythmias, hemoptysis, and tracheal laceration leading to pneumomediastinum, and rarely, pneumothorax. Respiratory status may deteriorate during or following the procedure as a result of airway obstruction from hemorrhage or hematoma, but this is uncommon. Exacerbation of cough may also be noted following the procedure. Infection of the needle tract may develop if a significant break in sterile technique occurs.

Endobronchial Brush and Needle Cytology

Endobronchial samples of the tracheal and bronchial airways can be collected under bronchoscopic guidance using cytology brushes and transbronchial aspiration needles. Endobronchial needles and cytology brushes allow for the targeted sampling of focal airway lesions. Endobronchial sampling of focal mucosal lesions is more sensitive in detecting airway inflammation than bronchoalveolar lavage, but comparable to BAL in detecting epithelial alterations.[61] Endobronchial brushing is safe and well-tolerated in dogs but does increase anesthetic time and cost. Complications of endobronchial needle aspirations have not been widely reported from dogs or cats. Complications described in people include pneumothorax, airway hemorrhage, and pneumomediastinum.[71]

Transthoracic Needle Aspirate and Biopsy

Fine-needle aspirates and needle biopsy samples of lung can be obtained percutaneously from pets with diffuse interstitial disease or in those with peripheral pulmonary mass lesions (Figure 240-5). Fluoroscopic, ultrasonographic, and CT guidance are helpful in maximizing diagnostic yield and accuracy of sampling and also can help to minimize complications.[72,73] Contraindications to transthoracic sampling include bleeding tendency, cystic or bullous lesions, pneumothorax, pulmonary hypertension, and respiratory distress or instability. Potential complications of transthoracic sampling include bleeding, pneumothorax, seeding of the needle tract with neoplastic cells, and death.[74]

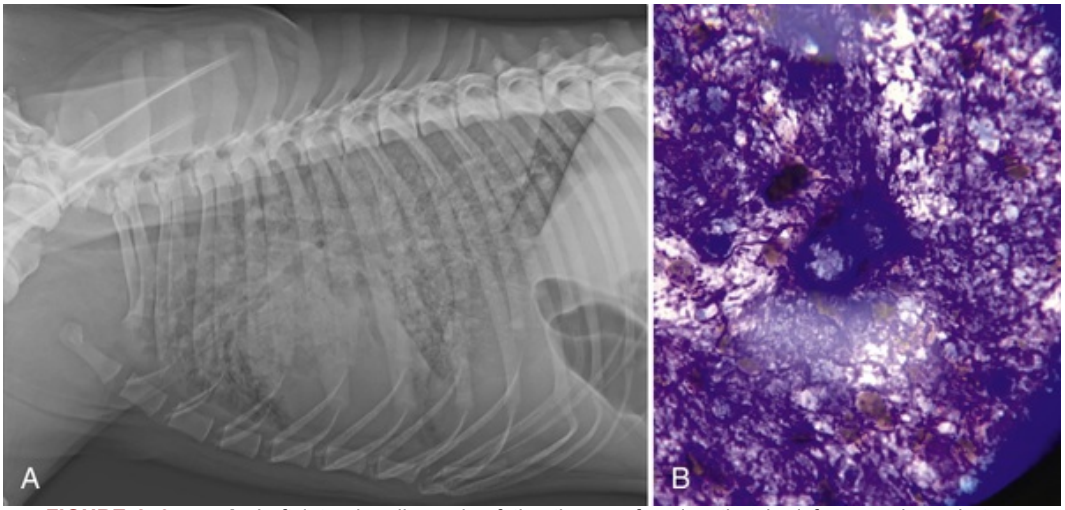


FIGURE 240-5 **A,** Left lateral radiograph of the thorax of a dog that had fever and respiratory distress. **B,** Cytology of a transthoracic fine-needle aspirate of the lung in **(A),** including a thick-walled, broad-based, budding yeast consistent with *Blastomyces*. (Images courtesy Valerie Chadwick, DVM.)

Surgical and Thoracoscopic Lung Biopsy

In cases where needle biopsies or endobronchial biopsies may not be adequate to confirm a diagnosis, larger biopsy samples can be obtained using surgical or thoracoscopic approaches. Standard intercostal or median sternotomy surgical approaches provide good visualization of the lung and access to large biopsy samples. In cases with peripheral or diffuse lung disease, a keyhole or minithoracotomy approach has been effective in providing a diagnosis of canine and feline interstitial lung diseases while also minimizing surgical time and

tissue trauma.[75]

Thoracoscopy is a minimally invasive technique that allows diagnostic evaluation of the lungs and pleural space through a series of 5- to 10-mm diameter portals rather than a large, single incision, minimizing tissue trauma and recovery time.[76] Video-assisted thoracoscopic surgery (VATS) provides better visualization of the pleural surfaces, lungs, mediastinal structures, and chest wall than open thoracotomy. VATS is indicated for the biopsy or removal of pulmonary or mediastinal masses, pleural masses, sampling of pleural and pericardial fluid, biopsy or removal of tracheobronchial lymph nodes, and in the investigation of spontaneous pneumothorax.[76] In one study, VATS was found to be comparable to open thoracotomy in surgical and diagnostic outcome for dogs undergoing lung lobectomy.[77]

Pulse Oximetry and Arterial Blood Gas Analysis

See E-Box 240-3 and ch. 75, 98, and 128.

E-Box 240-3

Pulse Oximetry and Arterial Blood Gas Analysis

Pulse Oximetry (see ch. 98)

Pulse oximetry is a widely available, noninvasive method for estimating the oxygen saturation of hemoglobin in peripheral blood. Standard pulse oximetry is a bedside test that is rapid, inexpensive, and easy to use and interpret. Pulse oximetry has a wide range of clinical utility, including determining the need for oxygen supplementation, monitoring the biochemical response to supplemental oxygen, and monitoring patients undergoing invasive respiratory diagnostic procedures (e.g., bronchoalveolar lavage). A hemoglobin saturation of 95% to 100% is considered normal in most dogs and cats. Saturations between 94% and 91% are consistent with mild to moderate hypoxemia, while values below 90% are consistent with severe hypoxemia. Despite its ease of use and wide range of clinical utility, there are several limitations to the use of pulse oximetry. Severe anemia, hypothermia, hypoperfusion, and hypovolemic shock can cause erroneous values that limit the utility of pulse oximetry in critically ill patients.[78] Excessive ambient light, skin pigmentation, and excessive patient movement may also cause erroneous results.

Arterial Blood Gas Analysis

Arterial blood gas analysis is considered the gold standard for evaluating the gas exchange function of the lung. Oxygenation and ventilation can both be assessed with arterial blood gas analysis. These functions are briefly reviewed here and are covered more extensively (along with acid-base balance) elsewhere in the text (see ch. 128). Arterial blood samples can be collected from the dorsal pedal (metatarsal), femoral, coccygeal, sublingual, and aural arteries in dogs, although the dorsal pedal and femoral are most commonly used in dogs (see ch. 75). The femoral artery is typically used for arterial blood sampling in cats. Arterial blood samples should be collected in heparinized syringes and should be capped immediately after collection to prevent gases dissolved in the plasma from equilibrating with ambient air.

Arterial blood gas sampling provides accurate measurements of the partial pressures of oxygen (PaO_2) and carbon dioxide ($PaCO_2$) in arterial blood. Pulmonary oxygenation is assessed by evaluating the PaO_2. Hypoxemia is defined as a PaO_2 less than 80 mm Hg. Differentials for hypoxemia include a low partial pressure of inspired oxygen (low PiO_2), alveolar hypoventilation, ventilation-perfusion inequality (due to pulmonary disease), right-to-left shunt, and diffusion impairment (interstitial disease, emphysema). Arterial blood gas analysis also provides a method for estimating of the alveolar partial pressure of oxygen (PAO_2) by using the alveolar gas equation:

$$PAO_2 = [FiO_2 \times (PB - PH_2O)] - (PaCO_2/RQ)$$

where PB = barometric pressure in mm Hg, PH_2O = water vapor pressure (at body temperature) in

mm Hg, FiO_2 = the fraction of inspired oxygen, *RQ* = respiratory quotient (ratio of oxygen consumed and carbon dioxide produced during metabolism of mixed metabolic fuels (normally 0.8), and $PaCO_2$ = partial pressure of carbon dioxide in arterial blood.

The difference between the estimated alveolar partial pressure of oxygen and the measured arterial partial pressure of oxygen ($PAO_2 - PaO_2$), also referred to as the *A-a gradient,* is normally < 15 mm Hg in patients breathing room air (see ch. 128). Calculation of the A-a gradient provides a method for quantifying gas exchange dysfunction and also provides a means of differentiating among the causes of hypoxemia. Hypoxemia associated with an elevated A-a gradient is due to ventilation-perfusion inequality, diffusion barrier, or right-to-left shunt. Hypoxemia with a normal A-a gradient is either due to a low PiO_2 (e.g., breathing at altitude) or alveolar hypoventilation and suggests that the gas exchange function of the lung is normal.

Alveolar ventilation refers to the delivery of CO_2 out of the alveolus. Alveolar ventilation is assessed on an arterial blood gas by the partial pressure of carbon dioxide in arterial blood, $PaCO_2$. As alveolar ventilation is impaired, alveolar (and arterial) CO_2 is retained and $PaCO_2$ rises above normal (hypoventilation). Common causes of hypoventilation include central nervous system depression, airway obstruction, pleural space disease, thoracic wall abnormalities, and anesthesia. Hypoventilation also occurs as a compensatory response to a metabolic alkalosis (see ch. 128). As alveolar ventilation increases, CO_2 excretion via the lungs increases and $PaCO_2$ decreases (hyperventilation). Common causes of hyperventilation include hypoxemia, central nervous system stimulation, pain, and excitement. Alveolar hyperventilation can also occur as a compensatory response to a primary metabolic acidosis (see ch. 128).

CHAPTER 241

Diseases of the Trachea and Small Airways

Cecile Clercx

Tracheal Diseases

Most tracheal disorders can involve both the intra- and extrathoracic tracheal segments. Tracheitis refers to an inflammation of the epithelial lining of the trachea. This inflammatory response can be infectious or noninfectious.

Noninfectious tracheal diseases (leading to tracheal mucosal inflammation) are common, and they include tracheal dorsal membrane flaccidity, tracheal collapse, tracheal injury/laceration, posttraumatic stenosis, foreign body, intratracheal tumor, smoke inhalation, prolonged barking (dogs), and tracheal avulsion (cats).

Tracheal disorders also can result from extratracheal diseases, such as extreme cardiac enlargement, mediastinal enlargement (lymph node tumor or thymoma, or megaesophagus [Figure 241-1]), or even parenchymal masses, which can cause deviation of the trachea, with possible effects on tracheal shape or lumen size (Figure 241-2), and subsequent obstruction and/or inflammation. Allergic lower airway disease also can lead to secondary tracheitis.

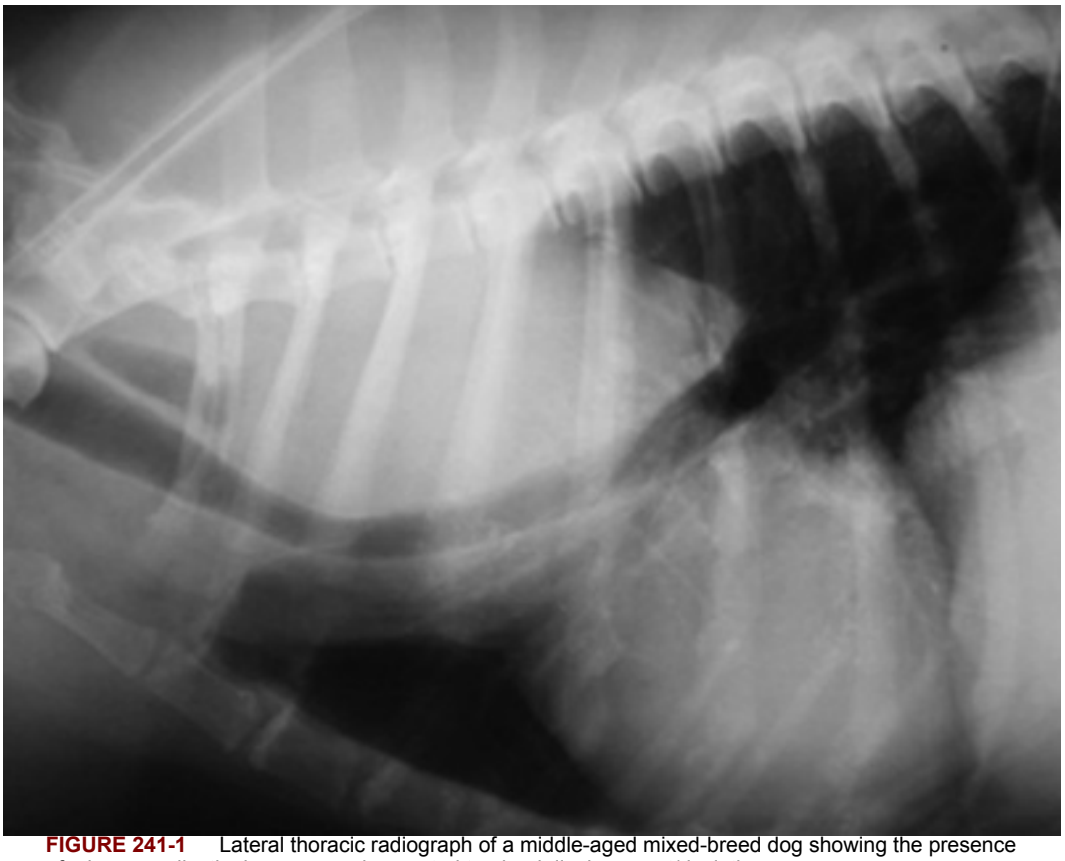

FIGURE 241-1 Lateral thoracic radiograph of a middle-aged mixed-breed dog showing the presence of a large mediastinal mass, causing ventral tracheal displacement/deviation.

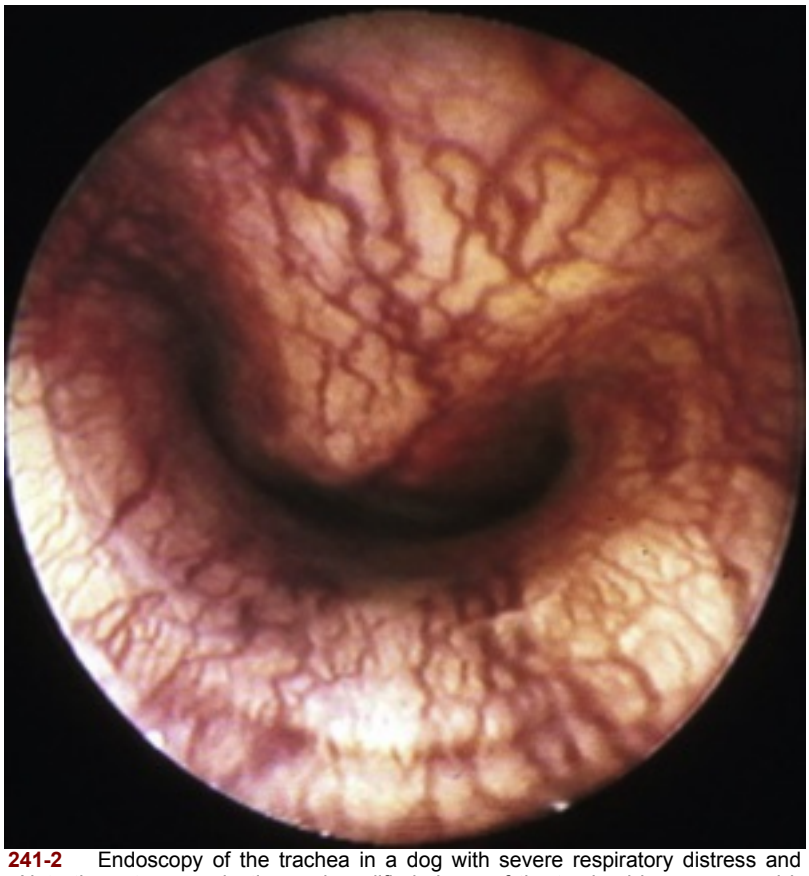

FIGURE 241-2 Endoscopy of the trachea in a dog with severe respiratory distress and cyanotic mucosae. Note the extreme reduction and modified shape of the tracheal lumen, caused by a huge mediastinal mass.

In cats, tracheitis is most likely to be associated with infectious feline respiratory disease (see ch. 229). Tracheitis in cats does not always induce significant cough, as it does in dogs.

Tracheal Collapse (Dogs)

Introduction

Tracheal collapse (collapsing trachea) is a very common disorder, characterized by dorsoventral flattening of the tracheal rings with laxity of the dorsal tracheal membrane. Malacic airways (or bronchial collapse) often can be associated with tracheal collapse, and this would negatively impact therapy and prognosis. The "goose-honk" sound of the cough is characteristic (Video 241-1).

Etiology and Pathophysiology

The cause of primary tracheal collapse is complex and best regarded as multifactorial. The development of the clinical condition requires both a primary cartilage abnormality, resulting in intrinsic weakness of the tracheal rings, and secondary factors capable of initiating progression to the symptomatic stage. Softening of cartilage rings seems to be due to a reduction of glycosaminoglycan and chondroitin sulfate content, which leads to a decreased ability to maintain functional rigidity, i.e., a weakness and flattening of the tracheal rings.[1,2] Potential triggering factors include obesity, cardiomegaly, inhalation of irritants and allergens, periodontal disease, respiratory infections, and recent endotracheal intubation.[3] The dynamic changes of tracheal collapse can be confined to either the cervical or the thoracic regions of the trachea, or both, and frequently are more pronounced at the cervicothoracic junction. The cervical trachea will collapse during inspiration, and the thoracic trachea will collapse during expiration due to the pressures developed during the respiratory cycle (Figure 241-3). Dorsoventral flattening of the tracheal cartilaginous rings causes a stretch of the dorsal tracheal membrane, which becomes inflamed and pendulous, and can prolapse into the tracheal lumen, further reducing tracheal luminal diameter, as soon as extraluminal pressure exceeds intraluminal pressure.[4] Inside the thorax, during inspiration, the redundant dorsal membrane is aspirated by/subjected to

negative intrathoracic pressure during inspiration and it can enlarge the tracheal lumen excessively, as seen on lateral radiographs (see Figure 241-3). In dogs with tracheal collapse, bronchomalacia often is encountered concurrently and does not appear to be related to airway inflammation.[5] On the other hand, bronchomalacia also can occur independently of tracheal collapse.

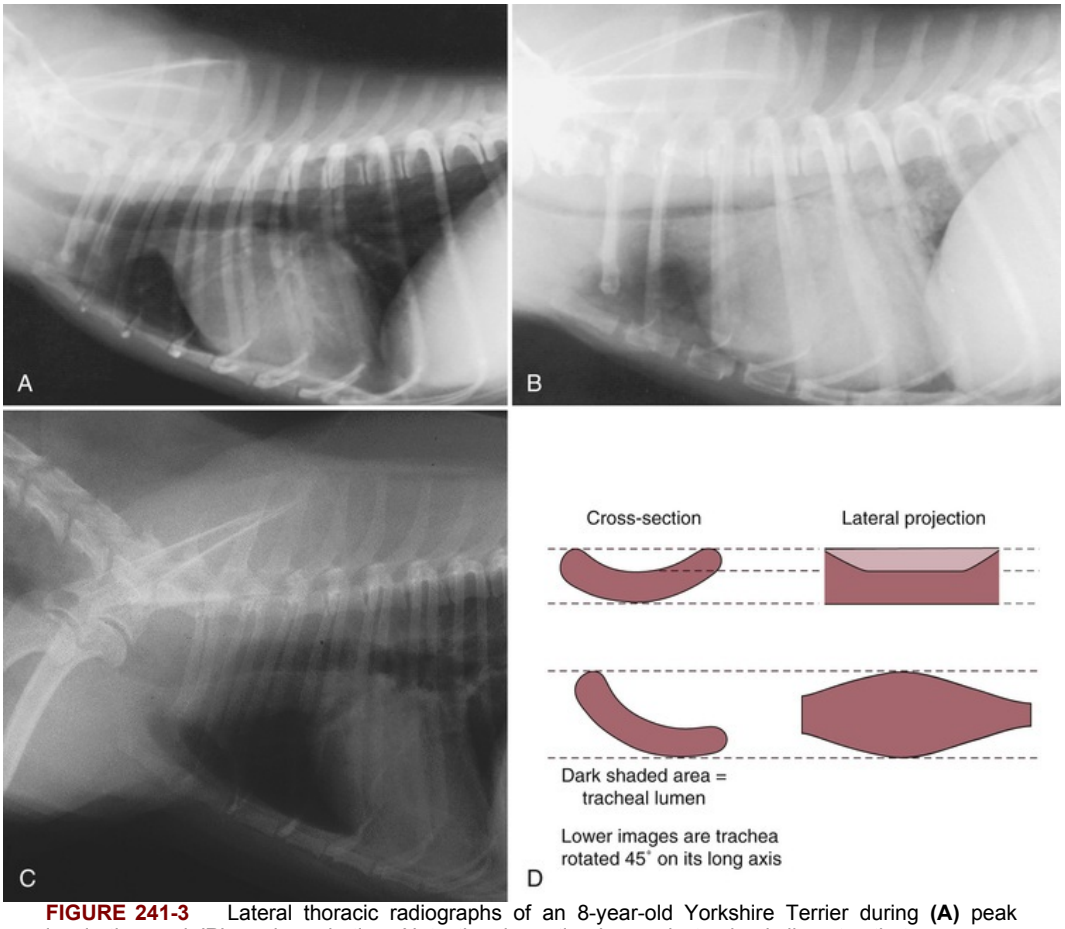

FIGURE 241-3 Lateral thoracic radiographs of an 8-year-old Yorkshire Terrier during **(A)** peak inspiration and **(B)** peak expiration. Note the dramatic change in tracheal diameter that can occur during the respiratory cycle in animals with collapsing trachea and how important it is to obtain inspiratory and expiratory views. In severe cases such as this, the expiratory collapse is not limited to the thoracic segment of the trachea but extends into the cervical region as well. **C,** Collapsing trachea observed at the thoracic inlet in a dog with moderate rotation of the trachea. As a result of the rotation, the trachea appears wide rather than collapsed in the lateral view. **D,** Diagram of the effect of obliquity on radiographs of cervical tracheal collapse. A narrowed tracheal lumen is visible on an inspiratory lateral radiograph (upper right). In the same patient, tracheal collapse is masked when the same view is obtained with the trachea rotated on its longitudinal axis (lower right).

It also appears that tracheal collapse could be induced secondarily by other disorders. In the West Highland White Terrier (WHWT) with idiopathic pulmonary fibrosis (IPF), tracheal collapse is encountered frequently, at least in advanced cases.[6] Since tracheal collapse is not described in WHWT exempt of IPF, it can be suggested that tracheal collapse might be secondarily induced due to increased pressures exerted because of the lack of elasticity/compliance of the fibrotic lung (see ch. 242 for further discussion of IPF).

In either classical or possibly secondary tracheal collapse, when clinical signs are apparent, the syndrome is perpetuated by the cycle of chronic inflammation of the tracheal mucosa, which exacerbates and, in turn, is exacerbated by the cough.

Clinical Presentation

Primary tracheal collapse commonly is seen in middle-aged to older miniature, toy, and small breed dogs. Overrepresented breeds include the Yorkshire Terrier, Pomeranian, Pug, Poodle, Maltese, and Chihuahua.[3,5,7]

Clinical signs include chronic cough in all cases, mild to severe panting, exercise intolerance, and varying

degree of inspiratory and expiratory dyspnea (respiratory distress), as well as a varying degree of cyanosis in advanced cases. A prolonged clinical history is common.

The cough is harsh, is generally described as "honking"/"goose honk," and is precipitated by activity, excitement, tracheal pressure (such as that caused by pulling on a leash), or drinking. This characteristic cough can be easily elicited by palpation of the trachea. A paroxysm of cough often ends with a terminal retch. Collapse of the cervical trachea sometimes can be appreciated as a flattening of the tracheal rings on cervical palpation. In some cases, cough is not audible as such and owners only report a "goose-honk" or "pig-grunt"/"growl-like" sound (Video 241-2). In severe cases, coughing almost never subsides, leading to muscular fatigue and exhaustion of the animal. In rare cases, excitement can lead to cyanosis and syncope (see ch. 30) because of partial or complete airway obstruction, vagally mediated bradycardia, or pulmonary hypertension,[4] especially when concomitant bronchomalacia is present.

Auscultation over the trachea can reveal stridorous sounds on both inspiration and expiration, and this must be differentiated from laryngeal paralysis, which has been reported in dogs with tracheal collapse.[4] During thoracic auscultation, crackles on both inspiration and expiration can be appreciated in dogs with small airway collapse and/or concurrent bronchitis.

Thorough cardiac auscultation is recommended, since a heart murmur associated with mitral regurgitation can be heard; indeed, concurrent myxomatous/degenerative mitral valve disease is a common finding in the same population affected by tracheal collapse, i.e., older, small-breed dogs. However, the role of cardiomegaly and specifically left atrial enlargement causing airway compression and collapse remains unclear. A recent study reported airway inflammation as the likely cause of cough in dogs that had both left atrial enlargement and airway collapse.[8] Hepatomegaly is common in dogs with tracheal collapse and could be a reflection of obesity, although hepatic dysfunction has been reported in dogs with tracheal collapse.[9]

Differential Diagnosis

Differential diagnoses include chronic mitral valvular heart disease, which can be a concurrent disease; chronic bronchitis and/or tracheitis, both possibly induced secondarily by tracheal collapse; and chronic pulmonary parenchymal disorders (e.g., IPF).

Diagnosis

The diagnosis of tracheal collapse is strongly suspected based on signalment, history of cough, and physical examination findings.

Additional diagnostic evaluation (radiography, fluoroscopy, echocardiography,[10] bronchoscopy, and pulmonary function testing)[11] can be used for confirming the extent and severity of the tracheal collapse, for identifying concomitant diseases (e.g., bronchomalacia, cardiomegaly, lower airway diseases), and is needed to obtain adequate measurements to assess the dimensions of a stent, in case stenting is considered as a therapeutic approach (see ch. 121).

Radiographic examination of animals with collapsed trachea can use both still and motion studies. The most useful radiographic examinations include lateral projections of the thoracic inlet, a tangential (rostrocaudal) projection of the thoracic inlet (in this skyline projection, the collapsed trachea is seen as an oval, "C" or crescent shape), and fluoroscopic investigation to demonstrate movements of the dorsal tracheal membrane during the respiratory cycle.

On lateral radiographs, a redundant dorsal tracheal membrane that invaginates into the tracheal lumen can be seen as a soft tissue opacity along the dorsal aspect of the caudal cervical tracheal lumen, while during inspiration, it will cause an increased tracheal diameter. This condition can be seen in both small- and large-breed dogs as a consequence of coughing and must be differentiated from a superimposed esophagus. Therefore, lateral radiographs made during both the maximal inspiratory and expiratory phases of the respiratory cycle are needed to demonstrate a dynamic collapse. Indeed, collapse of the cervical tracheal segment occurs in inspiration because of the decreased pressure within the trachea, whereas the thoracic portion tends to collapse during the expiration phase as a consequence of increased intratracheal pressure. These dynamic changes are best viewed in real time using image-intensified fluoroscopy.[7] When radiography is compared with fluoroscopy, assuming fluoroscopy is correct, radiographic evidence of collapse is noted at the incorrect location in 44% of dogs and is not detected in 8% of dogs with radiographs alone.[7] Moreover, radiographic measurements of the canine trachea consistently underestimate tracheal size, and computed tomography (CT) measurements are preferable for selecting tracheal stent size.[12]

Cervical lung lobe herniation (CLLH), or protrusion of lung parenchyma beyond the musculoskeletal

entrance of the thorax, recently has been identified fluoroscopically as a frequent finding in dogs.[13] Collapse of the intrathoracic trachea and of major bronchi (assessed fluoroscopically) were strongly associated with CLLH in one study; although a redundant dorsal tracheal membrane on radiographs was associated with CLLH, extrathoracic tracheal collapse was not.[13]

Tracheoscopy, although rarely needed to confirm the diagnosis, reveals a decreased dorsoventral diameter due to flattening of the cartilaginous rings with a pendulous dorsal membrane, up to a severe collapse leading to complete obstruction of the tracheal lumen (Figure 241-4). Therefore, tracheobronchoscopy can be helpful in determining the degree of severity of the tracheal and especially bronchial collapse, and for assessing concomitant airway disease (see ch. 101). Indeed, radiographs greatly underestimate the incidence of bronchomalacia.[7] Therefore, bronchoscopy should be proposed in all cases of suspected tracheal collapse, before stent placement can be considered, since the presence of severe bronchomalacia and/or lower airway disease greatly impacts the prognosis after stent placement (Videos 241-3 and 241-4).

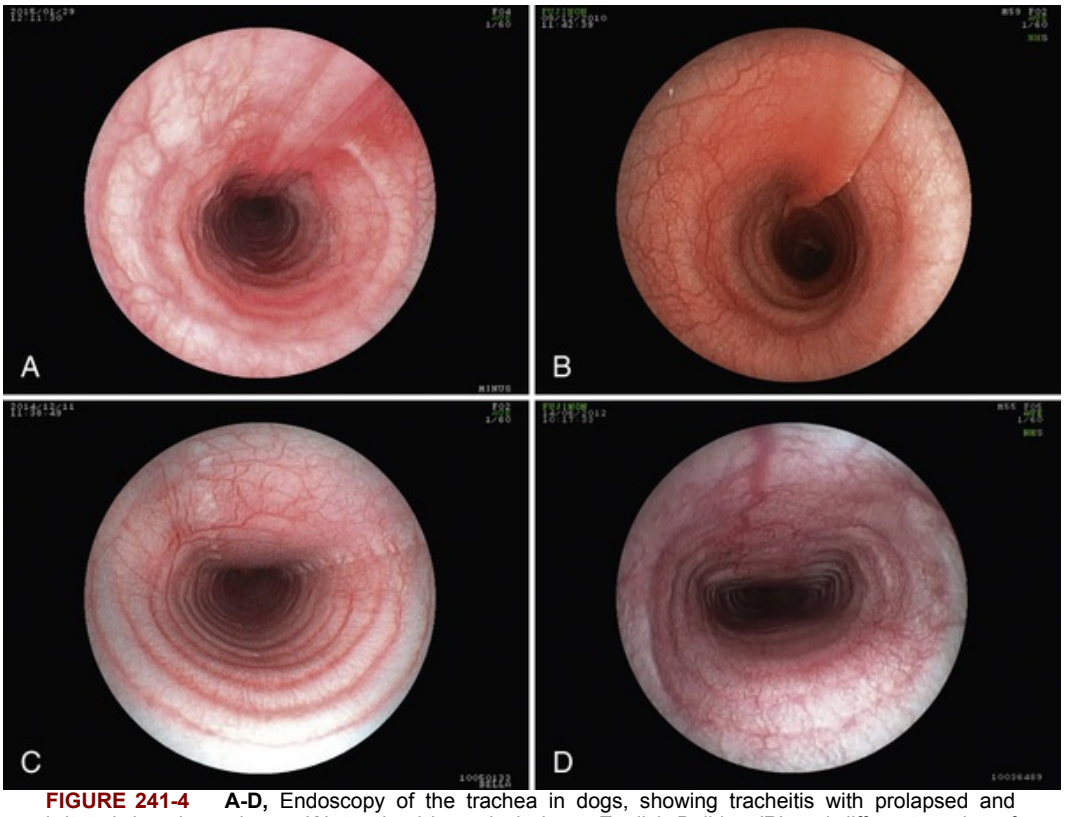

FIGURE 241-4 **A-D,** Endoscopy of the trachea in dogs, showing tracheitis with prolapsed and irritated dorsal membrane **(A),** tracheal hypoplasia in an English Bulldog **(B)** and different grades of severity of tracheal collapse, including grade 1 **(C)** and grade 3 **(D).**

Management

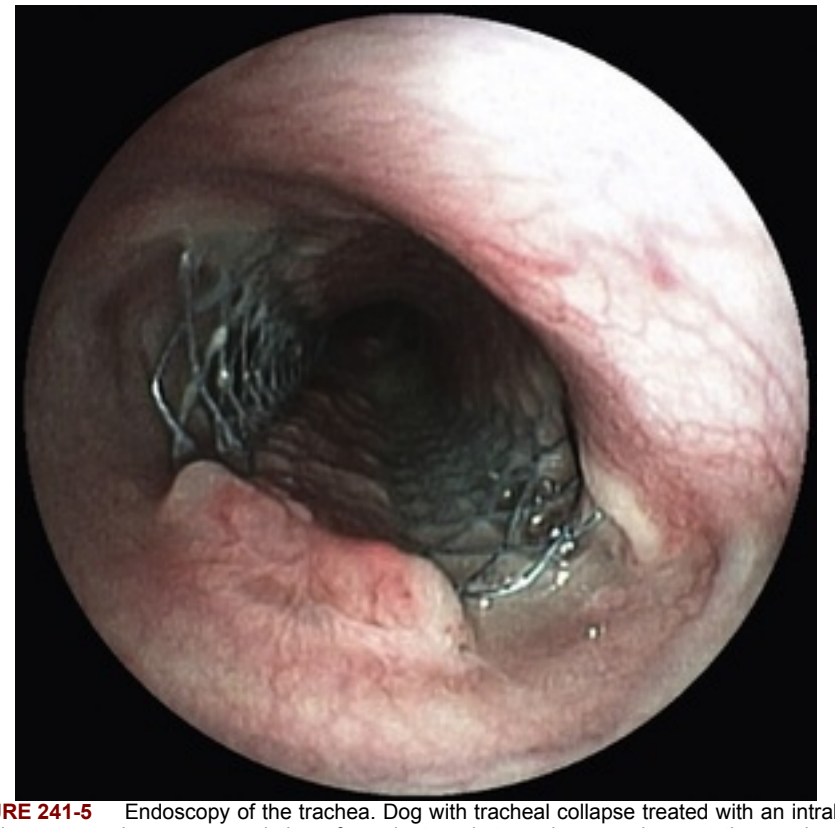
In animals with marked respiratory difficulty, oxygen supplementation can be delivered (see ch. 131), and sedation and antitussive agents are needed (see ch. 138). Butorphanol (0.05-0.2 mg/kg q 4-6 h) or acepromazine (0.01-0.1 mg/kg) can be injected SC, and prednisolone sodium succinate (15-30 mg/kg IV) can be administered to decrease acute inflammation.

Long-term treatment mainly aims to decrease all potential promoting factors and the level of inflammation of the tracheal mucosa.[3,4] Weight reduction in the obese animal is essential (see ch. 176 and 359). Weight loss alone can be curative of clinical signs. Likewise, replacement of neck collars with harnesses can be effective. Removing the dog from respiratory irritants such as noxious gases, smoke, and dust is common sense and should be explained clearly to the owner. It is also important to detect and treat other diseases, including chronic airway disease, cardiac disease, and hyperadrenocorticism.

Long-term therapy consists of very low-dosage corticosteroids (prednisone 0.2 mg/kg PO q 24 h × 1-2 weeks, at 3-month intervals, for instance), or by inhalation (fluticasone, one 120 mcg puff q 12 h using a face

mask and spacer; see ch. 97), often in combination with a sedative-antihistamine. Oversedation must be avoided, since the animal must keep moving to avoid gaining weight and to promote clearance of tracheal secretions. Oral antitussive agents that are effective in controlling cough include hydrocodone (0.22 mg/kg PO q 12 h) and butorphanol (0.55 mg/kg PO q 12 h). Bronchodilators (methylxanthines or beta agonists) also can be used; their possible benefits are attributable to reduction in smaller-airway spasm, which lowers intrathoracic pressures and thus reduces the tendency of the larger airways to collapse; improvement in mucociliary clearance; and reduction of diaphragmatic fatigue.

In dogs that fail medical management, extraluminal tracheal rings are indicated for cervical tracheal collapse and excellent outcomes have been reported in dogs managed by skilled surgeons.[14] If intrathoracic tracheal collapse is diagnosed and cannot be managed medically, treatment may involve the placement of intraluminal self-expanding stenting devices[15,16] (see ch. 121 and E-Figure 241-5).



E-FIGURE 241-5 Endoscopy of the trachea. Dog with tracheal collapse treated with an intraluminal tracheal stent, causing accumumulation of purulent pockets and a granuloma at the proximal edge (note the broad-based, raised lesion at the bottom left of the image).

Prognosis

Most animals can improve with an individualized treatment plan, but the condition generally is progressive, and the long-term prognosis poor, especially when irreversible airway collapse is present.

Tracheoesophageal or Bronchoesophageal Fistula

Tracheoesophageal or bronchoesophageal fistula is a rare disease in dogs. Clinical signs include chronic cough, recurrent lower respiratory tract infections, and gas accumulation in the gastrointestinal (GI) tract due to the passage of air from the trachea into the GI tract. The connection between the trachea and esophagus can be evaluated by bronchoscopy, contrast radiography, fluoroscopy, or CT.[17,18] This disorder is discussed in greater detail under Bronchial Diseases—Primary, below, and in ch. 273.

Obstructive and/or Traumatic Tracheal Diseases

Etiology

Tracheal subobstruction may be caused by collapsed tracheal rings, stenosis subsequent to injuries, foreign bodies, neoplasia, granulomas, external compression, or a complication of tracheostomy.[19,20]

Tracheal Injuries

Tracheal injuries range from small lacerations to tracheal avulsions and can be caused by intraluminal or external trauma. Intraluminal trauma mostly is associated with endotracheal intubation, while external trauma most commonly is seen secondary to a dog fight or automobile accident. In cats, a well-reported problem of intraluminal trauma concerns stenosis after necrosis/rupture following overinflation of an endotracheal tube cuff.[21] Stenosis after intrathoracic tracheal (or bronchial) rupture after blunt trauma to the neck or thorax is a reported cause of external trauma[22,23] (Video 241-5). These problems rarely have been reported in dogs.

Tracheal Foreign Bodies

Generally, when foreign bodies do enter the trachea, they are small enough to pass into a bronchus. Once lodged in a bronchus, a typical foreign body is a cause for bacterial bronchopneumonia, which is responsive to antibiotics but recurrent. When the foreign bodies are too large, they usually lodge at the carina and cause airway obstruction that can be life-threatening (Figure 241-6). Reported cases of tracheal foreign bodies in dogs and cats are rare but have involved mineral oil, hair, bullets, bones, plant material, and toys.[19]

FIGURE 241-6 Lateral thoracic radiograph showing unusual, almost totally obstructive foreign body in the trachea, obtained post mortem. The dog was sent to the hospital as an emergency but unfortunately died just before arrival. (Courtesy G. Bolen.)

Intratracheal Tumors

Intratracheal tumors are uncommon in dogs and cats. In young dogs, osteochondroma can be found while in older dogs or in cats, many other tumor types can be found (e.g., mast cell tumor, squamous cell carcinoma, adenocarcinoma, osteosarcoma, extramedullary plasmacytoma, leiomyoma, or fibrosarcoma).[19,24-26]

Tracheal Granulomas

Tracheal granulomas can be a complication after intraluminal stent placement in dogs with tracheal collapse and can result in a severe reduction of the tracheal lumen. Treatment with corticosteroids, either orally or by nebulization, leads to a decrease in the size of the granuloma in most cases (see ch. 121).[15,27,28]

Parasitic Granulomas

Parasitic granulomas have also been described. Lungworms *(Oslerus osleri; Filaroides osleri)* have been described in dogs, and tracheal cuterebrosis has been described in cats (see differential diagnosis for eosinophilic bronchopneumopathy, below). With tracheoscopy, *Cuterebra* larvae have been described in the trachea, at or just cranial to its bifurcation. Successful treatment consists of removal of the larva during tracheoscopy or via thoracotomy.[29]

Clinical Presentation

Tracheal injuries characteristically result in subcutaneous emphysema over the cervical and thoracic areas due to air escaping from the trachea into the subcutaneous tissue. This is typically associated with inspiratory stridor with a prolonged inspiratory phase followed by a variable expiratory phase. Other clinical signs include coughing, exercise intolerance, gagging, exertional distress, fever, change in bark, intermittant cyanosis or collapse, and open-mouth breathing in cats.[19,20] Furthermore, pneumomediastinum, although rare, can occur. In a recent study, endotracheal intubation and positive pressure ventilation were the most common causes of pneumomediastinum, followed by trauma and tracheal foreign bodies.[30]

After tracheal avulsion injury, the airway lumen is thought to be maintained by either intact tracheal adventitia or by thickening of mediastinal tissue leading to the development of a pseudoairway. Stenosis of the lumen then occurs at both ends of the injury. Therefore, clinical signs are delayed and are due to tracheal obstruction, such as inspiratory distress and tracheal stridor.[22] In tracheal foreign bodies, clinical signs are of acute onset.

Diagnostic Tests

Diagnosis is confirmed by thoracic radiography (see Figure 241-6) and tracheoscopy (Video 241-6, *A* and *B*).

Management

Surgical management of tracheal lesions consists of resection of the stenosed ends of the injured trachea, or portion of trachea involved by a tumor and subsequent repair by anastomosis, and the prognosis is good.[22]

Infectious Tracheitis/Tracheobronchitis

Canine infectious respiratory disease (CIRD) complex is also known as "kennel cough."[4,29,31-39] The disease is commonly seen in young dogs, especially in boarding kennels. This contagious disease is often self-limiting in dogs, but a wide range of respiratory signs can be found. Etiology and pathophysiology are discussed in detail in ch. 227.

Signalment

Young dogs are more susceptible, especially those housed in high-density environment, since the viruses and *Bordetella* are highly contagious. Despite the widespread availability of *Bordetella* vaccines, the disease is still common.

Clinical Presentation

This contagious disease often is self-limiting in dogs. In the classic infection, a mild dry cough is the only clinical sign. Nasal discharge can be present. However, infection with *Bordetella* can provoke chronic cough, which is more challenging to cure. Also, a wide range of respiratory signs can be found, from mild illness to severe pneumonia leading to death, depending on severity of infection and presence of other viral or bacterial pathogens, as well as immune and vaccination status.[29,37]

Diagnostic Tests

The diagnosis of bordetellosis relies on positive bacterial culture or, more recently, on positive polymerase chain reaction (PCR), from bronchoalveolar lavage fluid (BALF; see ch. 101 and 240). More laboratories offer PCR assessment of samples, but studies investigating the reliability of this method are lacking. As *B. bronchiseptica (Bb)* has been isolated regularly in clinically healthy dogs by culture from the upper respiratory tracts and lungs[38] and, more recently, by qualitative PCR from BALF,[36] and since infection and aerosol

shedding can persist for weeks, it is still unclear how a positive PCR result must be interpreted as diagnostic of the disease, or whether it could be considered as an incidental finding, or indicative that the dog is a carrier. The finding of pleomorphic cocci or coccobacilli adhering to the cilia of the epithelial cells is reported as a characteristic cytologic feature (Figure 241-7). The diagnostic accuracy of demonstrating *Bb* in cytological preparations, such as cytocentrifuged smears of BALF or bronchial brush fluid, has been evaluated,[34] together with the respective diagnostic value of qPCR analysis and bacterial culture of BALF, for the diagnosis of canine *Bb* infection. In 24 young dogs with kennel cough, BALF culture and qPCR detected *Bb* in more than half and 100% of dogs (at high CT levels), respectively.[34] Coccobacilli were found adhering to ciliated epithelial cells in most BALF preparations.[34]

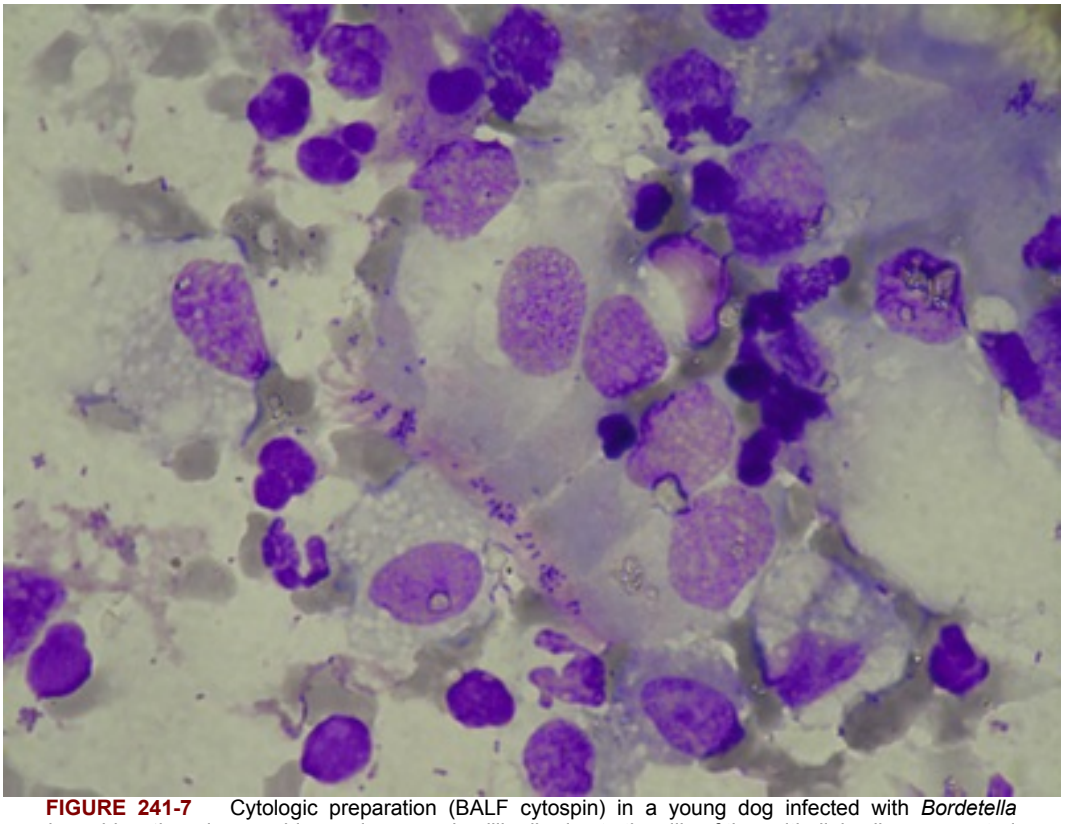


FIGURE 241-7 Cytologic preparation (BALF cytospin) in a young dog infected with *Bordetella bronchiseptica:* pleomorphic cocci or coccobacilli adhering to the cilia of the epithelial cells are reported characteristic cytological features.

Management

Uncomplicated cases of tracheobronchitis probably do not require antimicrobials (see ch. 227). Vaccination has not been proven to have any positive effect in dogs with active infection.[38] Treatment generally consists of empirical antimicrobial therapy; doxycycline (5 mg/kg PO q 12 h) is the antimicrobial of choice due to its efficacy against *Bb*, its low cost, and its ease of use. Dogs that are unresponsive to oral or parenteral administration of antibacterials could respond to nebulized antibacterials. Aerosolized, topically nonabsorbable antibacterials such as gentamicin have been shown to be effective in reducing the population of *Bb* in the trachea and bronchi of infected dogs (see ch. 97).[4,39]

In a recent study of dogs with kennel cough where *Bb* was confirmed, most dogs had been treated unsuccessfully with various oral antibiotics including amoxicillin or amoxicillin/clavulanic acid, doxycycline, marbofloxacin, or enrofloxacin, whereas treatment with nebulized gentamicin for 3 weeks or longer was associated with significant clinical improvement.[34]

Bronchial Diseases—Primary

Chronic Bronchitis in Dogs

Definition and Overview

Chronic bronchitis (CB) is an incurable disease of insidious onset, characterized by chronic and persistent cough, related to chronic inflammation of the airways, and not related to any identifiable, persistent, specific primary cause. It is a syndrome more than a final diagnosis.[40] Therefore, in dogs, it is also called nonspecific/aspecific chronic bronchitis.

Chronic bronchitis in dogs is defined when 3 diagnostic criteria are met: (1) chronic cough (for at least 2 months); (2) evidence of excessive mucus or of mucous hypersecretion; and (3) exclusion of other chronic cardiopulmonary diseases (e.g., congestive heart failure, chronic infectious bronchopneumonia, pulmonary neoplasia, or eosinophilic bronchopneumopathy). However, two separate diseases can coexist (e.g., congestive heart failure and airway collapse), which can complicate diagnosis and treatment. In humans, the most functional sequela of chronic bronchitis is chronic airway obstruction, referred to as chronic obstructive pulmonary disease (COPD), and subsequent emphysema. This mechanism appears to be less frequently observed in dogs, although the diagnosis of COPD relies on documentation of airflow obstruction by pulmonary function tests, which are not widely available in veterinary medicine. Dogs with severe and longstanding chronic bronchitis can exhibit either bronchiectasis (dilation and destruction of the walls of the bronchi) or bronchomalacia (airway collapse during expiration and cough).

Etiology, Epidemiology, and Risk Factors

Primary causes of chronic bronchitis are poorly understood, which is the reason it also is called nonspecific chronic bronchitis. The major difficulty is that the disease is detectable only in its advanced stages, since it has an insidious onset and lengthy pathogenesis. Therefore, the diagnostic evaluation is based on exclusion of all potential specific primary or secondary causes, which can be frustrating for both the clinician and the owner. Indeed, typical clinicopathological findings are variable and inconclusive. Nonspecific chronic bronchitis is diagnosed mostly in middle-aged to older, smaller-breed dogs, but it can also occur in larger breeds. Many dogs with chronic bronchitis are overweight and have periodontal disease, both of which appear to be risk factors.

In humans, the most important etiologic factors include smoking or passive smoking, atmospheric pollution, and infection. The same factors probably account for the development of chronic bronchitis in dogs. Moreover, in dogs, chronic/previous infection with *Bordetella bronchiseptica* or canine distemper virus, or with parasites leading to eosinophilic chronic bronchitis, or the presence of other diseases like tracheal collapse, or chronic cardiac disease, are all potential causes leading to development of chronic bronchitis. A recent study investigating potential demographic and historical factors associated with chronic cough did not identify exposure to environmental tobacco smoke as a risk factor.[41]

In people, gastroesophageal reflux disease (GERD) generally is considered among the most common etiologies of chronic cough. Indeed, cough management guidelines published by numerous respiratory societies worldwide recommend evaluation and treatment of GERD as an integral component of the diagnostic/therapeutic algorithm for the management of chronic cough. However, consensus is lacking in terms of whether this relationship between reflux and cough proves a causal link.[42] Although currently suggested in canine medicine, such a link has not been widely appreciated in dogs.

Pathophysiology

Chronic bronchitis results in inflammatory changes within the bronchial mucosa, including increased mucus production. Bronchial wall thickening and possibly progressive bronchomalacia contribute to airflow obstruction and further worsen inflammation, which induces cough, which, in turn, sustains inflammation.

Clinical Presentation

A persistent, sonorous cough, with paroxysms of coughing often followed by a terminal retch, and without any identified cause, is generally the only major complaint.

Diagnosis

Chronic cough related to specific causes should be ruled out, mainly tracheal collapse, lung fibrosis, eosinophilic bronchopneumopathy, parasitic lung diseases, bronchial or lung primary or secondary tumors, and mitral valve disease (see ch. 26, 240, and 251).

Diagnostic tests are performed to rule out other causes of chronic cough. Results of a complete blood count

usually are normal. Peripheral eosinophilia is of particular interest in baseline laboratory results because circulating eosinophilia can be associated with pulmonary eosinophilia or parasite infection. Other laboratory testing that should be considered includes heartworm antigen testing (see ch. 255), fecal analysis for both eggs and lungworm larva (see ch. 81), and evaluation of circulating concentrations of N-terminal prohormone (NT) of pro–brain natriuretic peptide (BNP), which are elevated in the presence of left atrial enlargement/congestive heart failure, as well as in pulmonary hypertension (see ch. 246). Elevated NT pro-BNP levels should prompt further evaluation with echocardiography.[43]

Thoracic radiographs show bronchial wall thickening or a generalized increase in airway-oriented interstitial opacity, or both. Thoracic radiographs also are useful to exclude other conditions that cause cough, such as congestive heart failure, lung masses, pleural effusion, and interstitial lung disease. Fluoroscopy is useful for evaluating the tracheal and larger airway for collapse. Ultrasound is useful if an isolated peripheral lesion is found on radiographs or in the presence of pleural effusion but is not useful in bronchitis.

CT, which is used widely in people with airway diseases, is growing in popularity for identification of canine bronchial disease as well. CT scanning usually requires brief general anesthesia, so it is commonly combined with evaluation of laryngeal function, bronchoscopy, and collection of cytologic airway samples in dogs suspected of having chronic bronchitis.

Bronchoscopic findings are variable. They can include irregular mucosal surfaces with a loss of the normal glistening appearance, a granular and roughened aspect, and sometimes signs of partial bronchial collapse. However, similar findings have been reported in aging healthy dogs, together with some degree of bronchiectasis,[44] and therefore, such findings must be interpretated with caution. The presence of excessive, thickened, sticky mucus in the airways also is consistent with chronic bronchitis.

Cytologic evaluation of BALF typically reveals excess mucus, possibly with hyperplasia of epithelial cells, and increased numbers of neutrophils, goblet cells, and macrophages.[45] Analysis of bronchial brushings might be a more sensitive indicator of airway inflammation than cytologic examination of BAL, by showing greater percentages of leukocytes and neutrophils.[46] If a sample shows marked eosinophilia, eosinophilic bronchopneumopathy or parasitic infection (heartworm/angiostrongylosis/*Crenosoma* infection) should be considered since these infections are markedly emergent in certain geographic regions, especially in Europe.[47-50]

Echocardiography (see ch. 104) helps to diagnose mitral valve disease, which can occur concomitantly in these older patients and deserves specific treatment, as well as to detect right heart enlargement and pulmonary arterial hypertension, which can occur secondary to chronic tracheobronchial disease.

Management and Monitoring

The bronchial alterations are not readily reversible, if at all. Therefore, treatment does not cure the disease but ideally will prevent or slow disease progression and improve clinical signs. Therapy is based on an assessment of the nature and severity of the individual animal's problems and relies on client education.

Treatment goals for dogs with chronic bronchitis include avoiding exacerbating factors, reducing inflammation, limiting cough, and improving exercise capacity.

Any environmental pollutants should be eliminated. Owners should be advised not to smoke indoors and to limit exposure of dogs to any airborne irritants, including perfumes.

Control of body weight is very important (see ch. 176 and 359). Obesity should be treated intensively because it markedly worsens cough and limits activity. Furthermore, obesity impairs lung function and increases airway hyperresponsiveness as measured by barometric whole body plethysmography (BWBP) and six-minute walk test (6MWT).[51,52] Weight loss induces a significant improvement of cardiopulmonary function assessed by the 6MWT associated with heart rate and blood oxygen saturation monitoring.[52] In obese dogs with chronic bronchitis, marked improvement in clinical signs is often seen with weight loss alone, without addition of any drug.

A harness should be used in place of a collar, and episodes of excessive barking should be curtailed with appropriate behavior modification.

Control of oral/periodontal infection and dental hygiene are advocated since bacteria from dental plaque could be inhaled and reach and deposit in the lower airways, especially during panting.

Glucocorticoids are the mainstay of treatment of chronic bronchitis because they are supposed to reduce mucous hypersecretion and bronchial mucosal thickening, which reduces cough. Glucocorticoids can be administered orally or via inhalation. Prednisone is the most commonly used glucocorticoid and is dosed at 1-2 mg/kg PO q 24 h initially and then tapered to the lowest effective dosage that controls clinical signs. Alternate-day therapy is preferred to allow normalization of the hypothalamic-pituitary axis and to limit

clinical signs associated with the use of exogenous glucocorticoids.

Inhaled glucocorticoids have been used widely in people and are used with growing frequency in dogs with chronic bronchitis. One study has demonstrated benefits of therapy with fluticasone, delivered via a spacer chamber and face mask designed especially for dogs (e.g., AeroDawg).[53] Of clinical relevance, inhaled glucocorticoids currently are more expensive than oral glucocorticoids, although the systemic steroid-sparing effect can be worthwhile in improving quality of life. Bronchodilators (beta-2 agonists, theophylline) are used frequently, although their effectiveness in the treatment of chronic bronchitis has not been widely addressed.

Antibiotics are warranted in dogs with an acute exacerbation of chronic bronchitis and a reasonable suspicion of infection. Doxycycline and macrolides (azithromycin) are good choices for dogs with chronic bronchitis because these drugs have antiinflammatory properties as well as antimicrobial effects.[40] Fluoroquinolones also have good tissue penetration; however, concurrent administration of fluoroquinolones with theophylline can result in theophylline toxicosis (see ch. 169).[54]

Cough suppressants are helpful for the comfort and relief of both dogs and owners, when cough is exhausting and refractory to antiinflammatory therapy. Over-the-counter cough suppressants rarely are effective in dogs, and narcotic cough suppressants are most effective. In some countries, oral preparations containing opioids have become less widely available. In countries where no oral preparation of butorphanol can be prescribed, a couple of drops of injectable solution deposited on the tongue can be effective, but neither the dosage needed nor the dose-effect relationship has been studied (Table 241-1). A study in human medicine has reported on the efficacy of gabapentin for control of cough related to hyperactive cough reflex sensitivity in people.[55]

TABLE 241-1

Cough Suppressants Used in Canine Chronic Bronchitis

DRUG	DOSAGE	COMMENT
Opioids		
Butorphanol	0.25-1.1 mg/kg PO q 8-12 h	Most effective. Potential side-effects include excessive sedation. Tolerance can occur over time.
Hydrocodone	0.2-0.3 mg/kg PO q 6-12 h	
Tramadol	2-5 mg/kg PO q 8-12 h	
Nonopioids		
Gabapentin	2-5 mg/kg PO q 8 h	Unestablished efficacy
Methocarbamol	15-30 mg/kg PO q 12 h	

Modified from Rozanski E: Canine chronic bronchitis. *Vet Clin North Am Small Anim Pract* 44:114, 2014.

Eosinophilic Bronchopneumopathy in Dogs

Etiology and Pathophysiology

Canine eosinophilic bronchopneumopathy (EBP) is a disease characterized by eosinophilic infiltration of lung and bronchial mucosa, considered to be manifestations of immunological hypersensitivity. Although the etiology of EBP still is unknown, the association of eosinophilic infiltration and predominance of CD4+ T cells favors a dominant Th2 immune response in the lower airways.[56] Suspected and known causes of pulmonary hypersensitivities in humans and animals include fungi, molds, drugs, bacteria, and parasites. However, in many cases, no underlying cause is found. The role of inhaled allergens in EBP still is unclear. Eosinophilic bronchopneumopathy mostly is diagnosed in young dogs. Siberian Huskies and Malamutes are affected predominantly, but many other breeds can be affected.

Clinical Presentation

Usually, the patient's general condition on presentation is good, unless the disease is associated with concomitant bacterial bronchopneumonia. Clinical signs mainly include cough, gagging and retching, which

are present in 100% of cases. In acute cases, gagging and retching are sometimes the main complaint, extending the differential diagnosis to dyspeptic problems. Dyspnea is a very frequent sign. A less commonly encountered sign is nasal discharge (≈50% of affected dogs).

Diagnostic Tests

Diagnostic elements for the diagnosis of EBP include signalment-associated and historical factors (breed, young age, previous response to corticosteroids), clinical signs, radiographic and bronchoscopic findings, blood eosinophilia, tissue eosinophilic infiltration as demonstrated by cytological and histopathological examinations, response to adequate treatment, and exclusion of other disorders. The most common radiographic finding is a mixed, moderate to severe, bronchointerstitial pattern (Figure 241-8). Computed tomographic findings associated with EBP are variable and heterogeneous and include marked to moderate bronchial wall thickening, plugging of the bronchial lumen by mucus/debris, bronchiectasis, pulmonary nodules, and lymphadenopathy.[57] Bronchoscopy (see ch. 101) can reveal typical macroscopic features, which include the presence of abundant yellow-green mucus or mucopurulent material, severe thickening of the mucosa with an irregular or polypoid surface and, in some cases, partial airway closure during expiration. Peripheral blood eosinophilia is frequent (≈60% of cases). BALF or brush cytologic examination demonstrates a marked eosinophilic component (E-Figure 241-9); frequently, >50% of inflammatory cells are eosinophils. In most cases, eosinophilic infiltration of the bronchial mucosa also can be observed in biopsies. Elevated BALF levels of procollagen type III amino terminal propeptide (PIIINP), a protein used as a marker of collagen type III synthesis, have been found in dogs with EBP, possibly due to secondary fibrotic changes.[58]

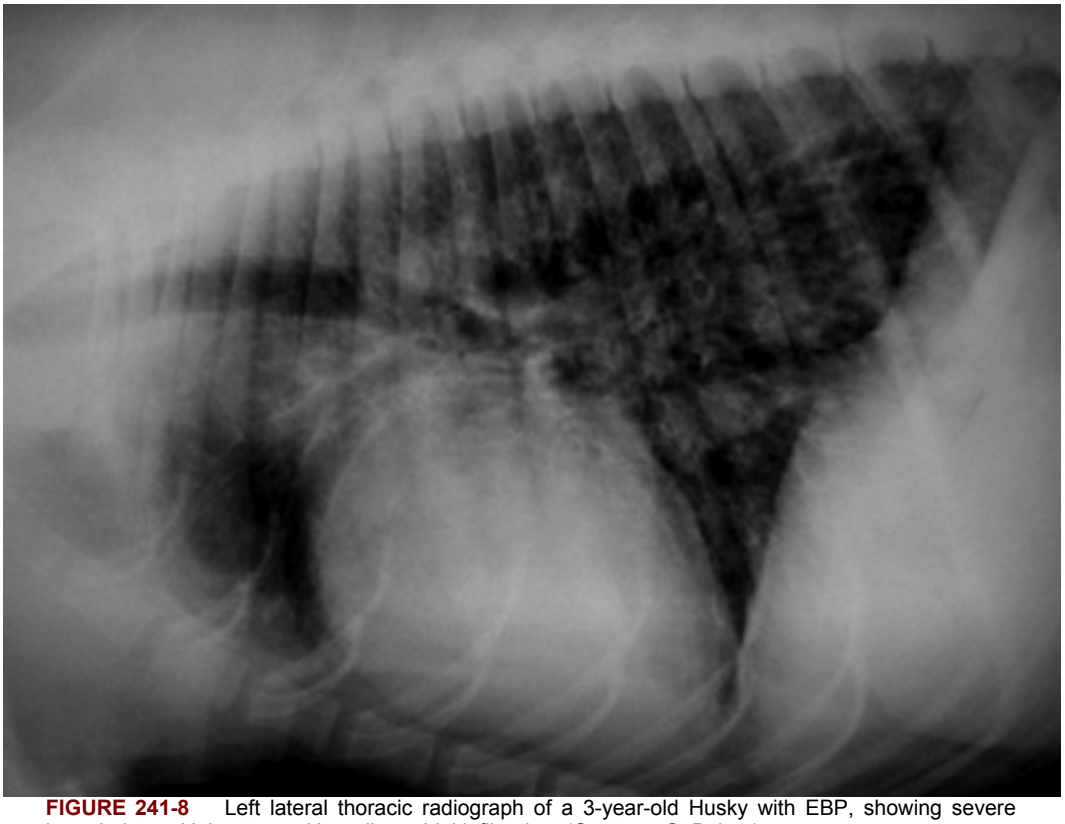

FIGURE 241-8 Left lateral thoracic radiograph of a 3-year-old Husky with EBP, showing severe bronchointerstitial pattern with peribronchial infiltration. (Courtesy G. Bolen.)

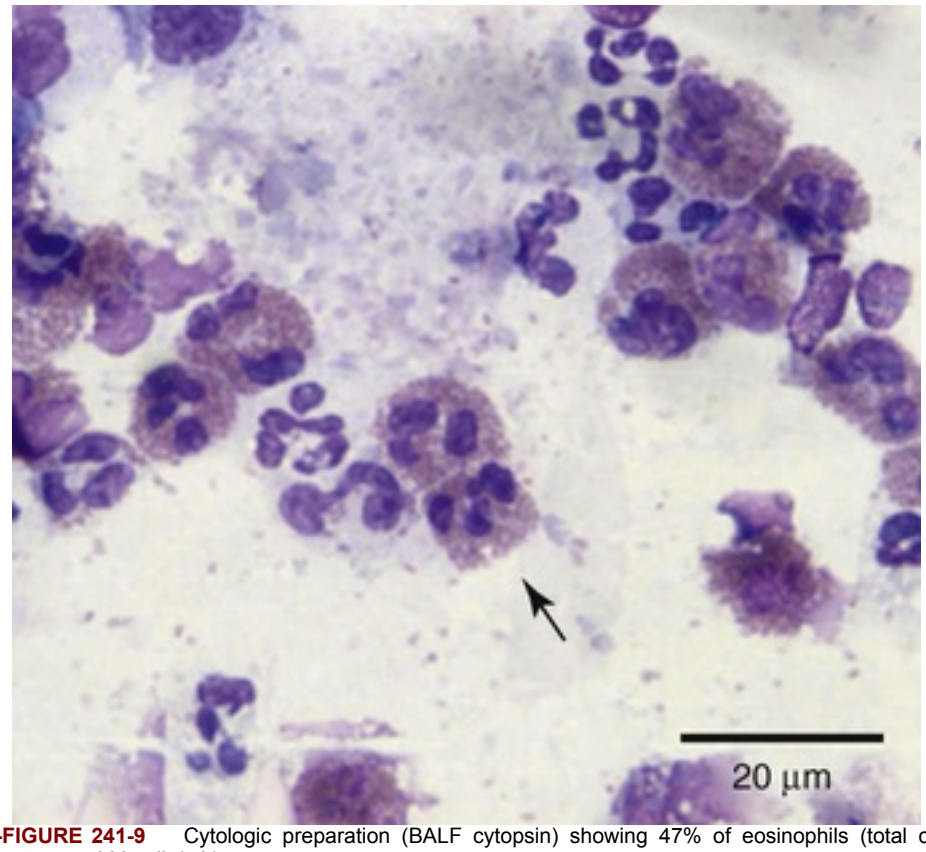

E-FIGURE 241-9 Cytologic preparation (BALF cytopsin) showing 47% of eosinophils (total cell count was 7000 cells/mL).

Differential Diagnosis

Several parasites, like *Strongyloides* spp., *Ascaris* spp., *Toxocara canis*, and *Ancylostoma* spp. can lead to eosinophilic pneumonia in humans, and probably in dogs as well; respiratory signs are only mild and GI signs usually predominate.

In the dog, occult heartworm disease caused by *Dirofilaria immitis* can cause eosinophilic pneumonitis. Migration of larvae of *Angiostrongylus vasorum* through pulmonary parenchyma also can result in eosinophilic pneumonia in dogs (Video 241-7). Infection by this nematode worm (also called the French heartworm disease) is an emerging disease, with reported increases in both distribution and incidence in the United Kingdom, Europe, South Africa, and Newfoundland (Canada). The expanding geographic range might be related to the influence of climate on parasite distribution. The worm infects dogs and foxes and is spread through ingestion of intermediate hosts, including slugs and snails. The main clinical signs include respiratory signs, bleeding disorders, and neurologic signs[59] and are very variable in severity, with a course of disease that often is chronic and subtle. However, early and correct diagnosis is required, since angiostrongylosis can be fatal if left untreated. In cases with respiratory clinical signs and in endemic regions, radiographic pulmonary changes alone can be suggestive of the diagnosis, and they include moderate to severe bronchointerstitial or alveolointerstitial changes, often more severe in peripheral and/or caudodorsal areas (Figure 241-10). Other bronchopulmonary parasites, like *Capillaria aerophila, Oslerus osleri, Filaroides hirthi, Crenosoma vulpis* (Video 241-8), or *Paragonimus kellicotti,* also are implicated in the influx of eosinophils into the airways *(O. osleri)* or lungs (other parasites) in dogs and can mimic EBP. A higher frequency of bronchial disease caused by infection with *Crenosoma vulpis* also is becoming apparent in continental Europe.[60]

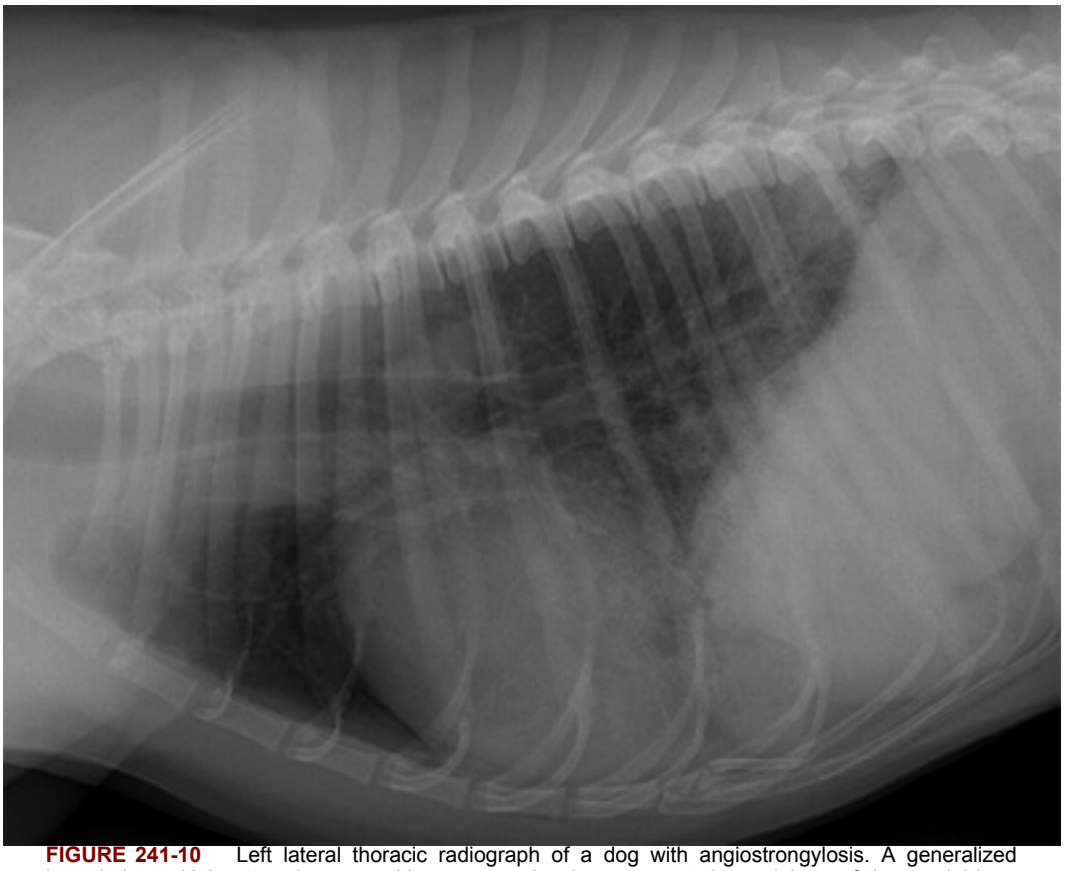

FIGURE 241-10 Left lateral thoracic radiograph of a dog with angiostrongylosis. A generalized bronchointerstitial pattern is seen, with a severe alveolar pattern at the periphery of the caudal lung lobes (note air bronchograms). A pleural fissure line between the left cranial and the caudal lobes and mild lung lobe retraction from the thoracic wall are consistent with mild pleural effusion. The pulmonary arteries and veins are enlarged.

For these reasons, screening for parasites is warranted, using BALF analysis or serial fecal examinations (Figure 241-11, ch. 81). In-clinic detection of an antigen released by *A. vasorum* adults in a plasma or serum sample is possible (Angio Detect, IDEXX Laboratories),[61] or *A. vasorum* PCR detection in BALF can be undertaken.[50] In endemic areas, it is strongly advised to perform a heartworm antigen test to rule out occult heartworm disease. Alternatively, in the meantime, appropriate antihelminthic drugs can be used in order to treat the animal against potential parasites.[47]

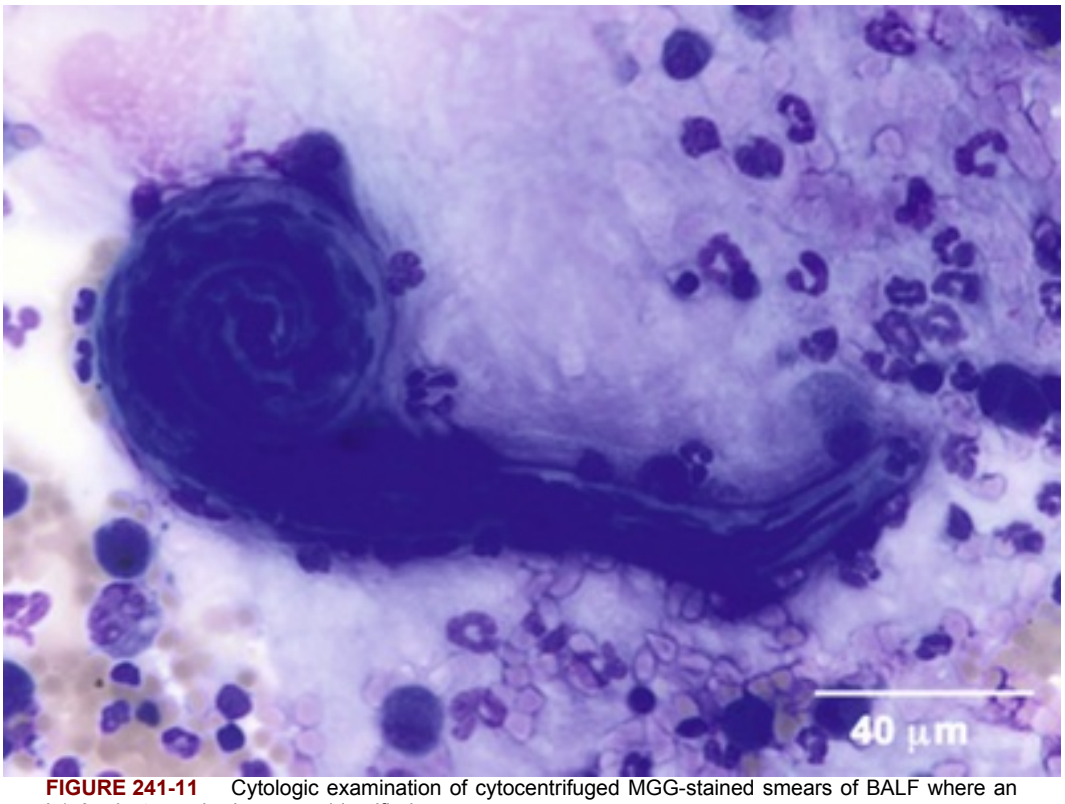

FIGURE 241-11 Cytologic examination of cytocentrifuged MGG-stained smears of BALF where an L1 *Angiostrongylus* larva was identified.

Management

The response to corticosteroid therapy generally is very good, but complete abolition of clinical signs is not always obtained. Prednisolone is initiated at a dosage of 1 mg/kg PO q 12 h × 1 week, then 1 mg/kg PO q 12 h but on alternate days × 1 week, then 1 mg/kg PO q 24 h on alternate days × 1 week, followed by a gradual decrease until maintenance dosage. Since chronic oral corticosteroid therapy unfortunately can lead to well-recognized systemic side-effects (i.e., iatrogenic hyperadrenocorticism), and since its use also can be contraindicated in dogs with other concomitant health problems such as diabetes mellitus, obesity or cardiac diseases (see ch. 358), alternative treatment with inhaled steroid therapy (IST) has been used increasingly in past years in both human and veterinary medicine, with the suggested advantages of providing both high drug concentrations within the airways and a reduced systemic absorption and potentially deleterious secondary effects. Inhaled corticosteroid therapy is well-tolerated, results in improvement in clinical signs and reduction in side-effects, and allows a reduction of oral steroid dosage in steroid-dependent animals.[53,62] However, it seems that treatment of EBP with long-term IST alone does not allow complete management in all affected dogs and that sustained, long-term IST can induce inhibition of pituitary–adrenal axis (PAA).[62] Other drugs with immunomodulatory effect have been proposed, but no trial results are available to date.

Prognosis

Relapse frequently occurs within weeks to months after drug discontinuation, although some dogs can remain free of clinical signs after discontinuation.

Primary Ciliary Dyskinesia (PCD)

Presentation

PCD, previously referred to as immotile cilia syndrome, results from a heterogeneous group of inherited diseases that cause defective ciliary motility. These changes mostly are associated with ultrastructural abnormalities and cause recurrent bacterial infection of the upper and lower airways. In affected dogs, as in affected humans, the ineffectiveness and incoordination of ciliary function result in ineffective clearance of mucus from the airways, which in turn leads to chronic mucus plugging and inflammation of nasal cavities

and airways. The dysfunction of the monocilia of the embryonic node also can lead to the randomization of left-right body asymmetry and transposition of the thoracic and/or the abdominal organs in 50% of the cases called the Kartagener's syndrome.[63] Kartagener's syndrome represents a triad of signs that includes bronchiectasis, complete left-right transposition of viscera (situs inversus) and chronic rhinosinusitis. This syndrome has been reported in humans and in dogs with PCD. In dogs, PCD is a rare disease that has nevertheless been reported in more than 19 breeds.[64-68]

Etiology

Currently, PCD-causing mutations have been identified in more than twenty human genes.[68] Each causative gene can be associated with particular ultrastructural ciliary defects, and these 20 genes explain only 50% of human PCD cases. Dog cases often focus on one individual from a specific breed, but sometimes littermates are affected or different cases can segregate within the same breed.[65,66,68] This genetic disease usually is inherited in an autosomal recessive mode. In dogs, a recent mutation in a new causative gene *(CCDC39)* has been identified in the Old English Sheepdog.[67] This new mutation is dispersed worldwide and is responsible for PCD in this breed. A new genetic test has been developed and is currently available for prebreeding evaluation in this breed, but not yet in other dog breeds.

Clinical Presentation

As a consequence of impaired mucociliary clearance, clinical signs include chronic respiratory abnormalities caused by rhinosinusitis, bronchitis, bronchopneumonia and bronchiectasis. Although the respiratory system signs usually are the presenting complaint, other signs related to dysfunction in other tissues with ciliated epithelia or microtubules can occur, such as otitis media, infertility in females, asthenoteratospermia in males, hydrocephalus, and renal fibrosis or dilation of renal tubules. The signs typically begin at an early age in a purebred, vaccinated dog; however, some dogs have remained asymptomatic until several months to several years of age. Hallmark clinical features, i.e., recurrent bilateral nasal discharge and repeated episodes of bronchitis or bronchopneumonia since birth, should alert the clinician to include PCD in the differential diagnosis.

Diagnosis

Finding the hallmark clinical features in combination with situs inversus is even more suggestive. Most other potential possible causes should be excluded by a complete physical examination, as well as currently available complementary tests. Confirmation of PCD requires both *in vivo* and *in vitro* functional and ultrastructural analysis of cilia. *In vitro* functional analysis of cilia in dogs suspected of having PCD uses scintigraphy as the diagnostic tool to evaluate mucociliary clearance. *In vivo* functional analysis in PCD patients consistently demonstrates an uncoordinated or a dyskinetic ciliary beat.

Motile cilia are composed of a microtubule backbone, the axonema, consisting of nine microtubule doublets surrounding a central pair. Inner and outer dynein arms extend from each outer microtubule doublet and generate the force needed for motility in an ATP-dependent process. Ciliary dysmotility or immotility often is associated with ultrastructural defects of the cilia such as total or partial absence of the outer dynein arms (ODAs) and/or inner dynein arms (IDAs), defects of radial spokes or nexin links and general axonemal disorganization with microtubular transposition.[69] Transmission electron microscopy can reveal specific ultrastructural abnormalities (Figure 241-12), although making the distinction between PCD and secondary ciliary defects caused by another primary disease, based on ultrastructural findings alone, often is difficult. Therefore, the use of a ciliary culture technique, ciliogenesis, has been shown to definitively distinguish primary from secondary eitologies.[64] In the Old English Sheepdog, a Taqman assay with excellent sensitivity and specificity was developed and has led to evaluation of the mutation's prevalence in the breed. The mutated allele has been found both in European and in American Old English Sheepdogs, suggesting a worldwide distribution.[68] This genetic test also allowed the initiation of a breeding program detecting silent carriers and preventing the birth of affected individuals.

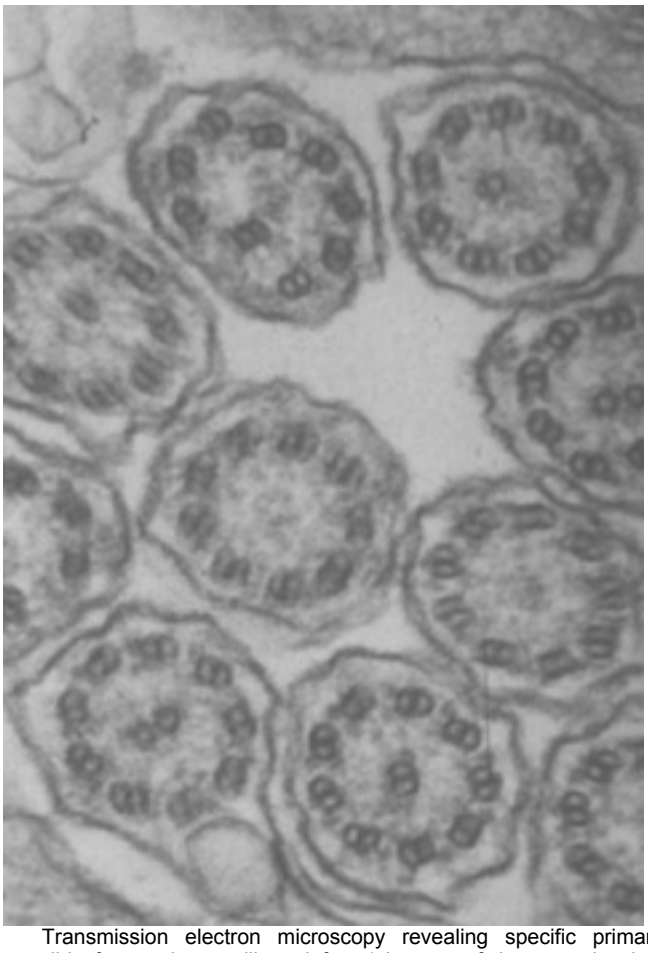

FIGURE 241-12 Transmission electron microscopy revealing specific primary ultrastructural abnormalities responsible for a primary ciliary defect (absence of the central pair, with occasional transposition of a peripheral doublet).

Differential Diagnosis

Other causes of recurrent bacterial infection of the upper (in early cases) and lower airways should be investigated, such as the presence of an immune deficiency, resistant bacteria, or a bronchial foreign body. In Irish Wolfhounds, a rhinitis/bronchopneumonia syndrome, characterized by transient to persistent mucoid or mucopurulent rhinorrhea, cough, and dyspnea since an early age has been described; so far, PCD has not yet been formally identified as the cause of the disease.[70]

Management

Even though PCD is not a curable disorder, frequently it can be managed for some years (see ch. 97 and 242). A key element in this successful management is the adequate monitoring of infecting microorganisms and judicious use of antibiotics over time. Moreover, adequate systemic and local hydration together with daily coupage and vigorous exercise will help to clear mucus from the airways.

Prognosis

Once the diagnosis is established, medium- to long-term prognosis is poor, because despite adequate management, the disease generally progresses over time and the response to treatment becomes poorer.

Bronchoesophageal Fistula[17,29]

A bronchoesophageal fistula is defined as a communication between the esophagus and one or more bronchi. Most cases are seen secondary to foreign body ingestion and penetration in young to middle-aged dogs (very unusually in cats). Clinical signs involve both the respiratory and GI tracts, with noisy rales, depression, fever, and a loss of appetite. Pleural effusion also can occur, in addition to a localized pneumonia.

The diagnosis usually is made on plain radiographs, with evidence of pneumonia, an esophageal foreign body, gas distention of the esophagus, and possible pleural effusion being present. On a complete blood count, an increased white blood cell count with a left shift is expected. Confirmation is best obtained with thoracic radiographs taken following oral administration of a small amount of a barium suspension. Endoscopic examination can provide a direct view, but radiography is considered more likely to be diagnostic. Successful correction of the fistula is best accomplished with thoracic surgery to reduce the defect, lavage the affected area, and very likely perform a lobectomy to remove the infected tissues. If the disorder is identified early and treated properly, the prognosis for recovery can be good. Complications arising from esophageal stricture can be a problem, particularly if identification and treatment are delayed.

Bronchial Mineralization, Broncholithiasis[29]

Bronchial mineralization is rarely encountered. It can occur secondary to any chronic inflammatory or infectious condition. Bronchial mineralization may in fact be totally unassociated with clinical evidence of dysfunction. Peribronchial mucous glands can mineralize in normal cats, appearing as multifocal mineralized opacities.[71]

Bronchial Diseases—Secondary

Bronchiectasis

Introduction

Bronchiectasis is defined as an abnormal and permanent dilation and distortion of subsegmental airways, which results from chronic airway inflammation that damages elastic components of the bronchi and which leads to bronchial wall destruction and impaired clearance of respiratory secretions.[72] It is considered a unique disease entity, although several congenital or acquired conditions that lead to a cycle of chronic airway infection and inflammation can result in bronchiectatic changes.

Etiology and Pathophysiology

In humans, bronchiectasis can be categorized into cystic fibrosis (CF)-related bronchiectasis and non-CF bronchiectasis. CF is an inherited disease caused by a mutation in the gene for the protein cystic fibrosis transmembrane conductance regulator (CFTR). Viscous mucus plugging results in infection and inflammation, leading to airway wall destruction and bronchiectasis. Individuals with CF can be diagnosed before birth by genetic testing or by a sweat test in early childhood. So far, naturally occurring cystic fibrosis (CF)-causing mutations in the CFTR gene have not been identified in any nonhuman animal species. A study conducted in dogs revealed that naturally occurring CFTR mutations are relatively common in domestic dogs but failed to identify a higher expression rate of CFTR mutations in dogs with bronchiectasis.[73] Therefore, bronchiectasis in dogs and cats probably is mainly due to non-CF bronchiectasis. In both humans and dogs, non-CF etiologies of bronchiectasis include congenital or inherited diseases. In dogs, congenital disorders predisposing to bronchiectasis include PCD, with or without Kartagener's syndrome. Whether PCD and Kartagener's syndrome really occurs in cats is an open question; if it exists, it is extremely rare. In dogs and cats, focal bronchiectasis most often results from foreign body aspiration and/or bronchial obstruction.[4,74]

Diffuse bronchiectasis often occurs subsequent to acquired diseases,[4,41,76] including aspiration or inhalation injury, chronic infectious bronchopneumonia (including parasitic origin), chronic infection with *B. bronchiseptica* or *Pneumocystis carinii* in dogs with immune deficiency, eosinophilic bronchopneumopathy, chronic bronchitis and potentially, allergic bronchopulmonary aspergillosis (a rare cause of localized cavitary bronchiectasis).[76] In cats, chronic bronchial inflammation has been suggested as the most common etiology associated with bronchiectasis, especially chronic bronchitis, neoplasia, and bronchopneumonia,[77] and has been described in a case of diffuse fibrotic lung disease.[78] The affected airways are usually partially obstructed by purulent or viscid exudates, since the dilation greatly interferes with normal airway clearance.

Dysfunction of mucociliary clearance, in turn, allows pooling of mucus, exudate, and microbes, and secondary infection stimulates a host inflammatory response, creating a vicious circle of further damage to the airway wall and predisposition to recurrent bronchopulmonary infections (Figure 241-13).

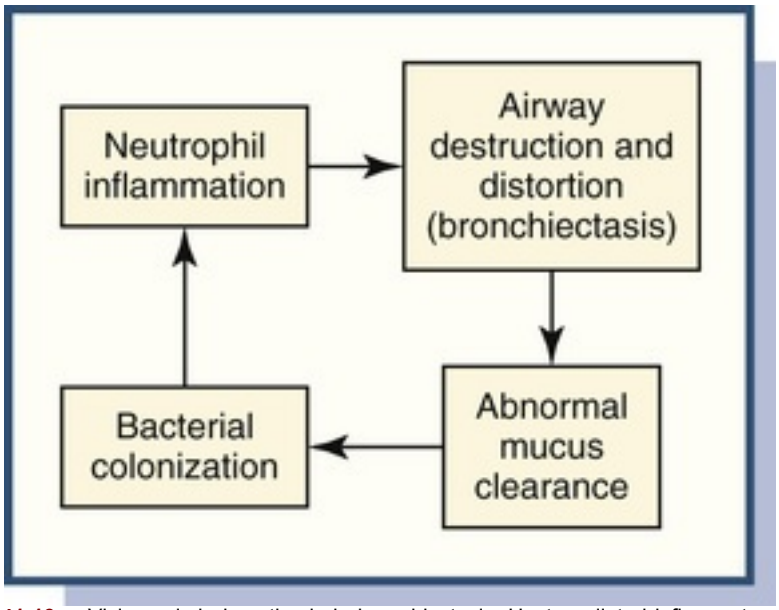

FIGURE 241-13 Vicious circle hypothesis in bronchiectasis. Host-mediated inflammatory response to foreign material and bacteria in the airway causes tissue damage, resulting in bronchiectasis, which contributes to abnormal mucus clearance and further bacterial colonization.

Signalment, Clinical History, and Presentation

In dogs, there appears to be a breed predilection because bronchiectasis is more prevalent in certain breeds such as the American Cocker Spaniel, Miniature Poodle, Siberian Husky, and English Springer Spaniel.[74] Moreover, most dogs with bronchiectasis are ≥7 years old.[74] Clinical signs likely reflect the underlying disease process and generally include cough (most common), gag, tachypnea, dyspnea, and occasionally fever.[74] Bronchiectasis can be detected by thoracic radiography, high-resolution computed tomography (HRCT) or bronchoscopy (Videos 241-9 and 241-10). Radiographic and bronchoscopic characteristics of bronchiectasis in dogs have been described.[74,75] Bronchoscopy is not considered the gold standard, but it is highly helpful to recognize/visualize bronchiectatic lesions and, more importantly, to enable collection of samples for identification and potential treatment of possible underlying diseases (see ch. 101). Bronchoscopic evaluation identifies mucopurulent plugs in the dilated airways and hyperemic, roughened bronchial wall linings.

In people, survey thoracic radiography is not considered a very sensitive technique for evaluation of bronchiectatic changes, nor is bronchography used for this purpose any longer. HRCT has been described as the noninvasive gold standard for diagnosing bronchiectasis. Primary CT features of bronchiectasis in people include abnormal bronchial dilation, lack of peripheral bronchial tapering, and identification of distinct airways within 1 cm of the pleural surface. Secondary features include bronchial wall thickening, mucus plugging within the bronchial lumen, and peripheral air trapping as reflected by measurable reduced pulmonary density in affected regions.[79] The most widely used CT criterion for quantifying abnormal bronchial dilation is the bronchoarterial (BA) ratio (the ratio of the cross-sectional bronchial luminal diameter to accompanying pulmonary artery diameter) >1.[79] In dogs, a recent study revealed that healthy dogs can have a BA ratio of up to 2.0.[80] In a retrospective study of dogs with bronchiectasis diagnosed via bronchoscopy and/or histopathology, the most common CT characteristics of bronchiectasis were dilation, lack of peripheral airway tapering, and lobar consolidation.[80]

In a large series of dogs with EBP, CT revealed bronchiectasis in 60% of the dogs.[57]

Since there is a lack of studies correlating CT with bronchoscopic features of bronchiectasis in dogs, the sensitivity of bronchoscopic diagnosis of bronchiectasis is questionable. Age has been shown to influence bronchoscopic findings in healthy Beagle dogs: bronchiectasis has been described as a normal endoscopic finding in older Beagles, and this finding does not seem to be associated with an increased neutrophilic content of the BALF.[44] Such age-related differences should be considered when interpreting bronchiectasis in old dogs with respiratory disease.

Culture and sensitivity of BALF for both aerobic and anaerobic bacteria are suggested because this is likely

to be helpful in treating the patient. Bacteria frequently isolated from people with bronchiectasis include *Pseudomonas aeruginosa, Haemophius influenzae, Staphylococcus aureus,* and some others.[81] In dogs, no conclusion regarding the frequency of distribution of bacteria in patients with bronchiectasis can be drawn.[74]

Cytologic evaluation of such fluid typically identifies neutrophilia, eosinophilia if allergic in nature or in the presence of parasitic infection, and squamous metaplasia of the epithelial cells. PCR performed on BALF can be useful to identify *Bordetella* spp., *Mycoplasma* spp. or *Aspergillus* spp., since allergic bronchopulmonary aspergillosis might be a cause of localized cavitary bronchiectasis,[76] as described in people.

Management

The goal of therapy for bronchiectasis is to control clinical signs and treat or even prevent bacterial infections. In human medicine, the therapeutic approach includes airway clearance, reducing chronic infection and inflammation, and treatment of exacerbations. Inhaled therapies form the backbone of treatment (see ch. 97). In combination with antibiotics delivered directly into the airway, mucoactive drugs, including mucolytics and hyperosmolar agents, are utilized to improve mucociliary clearance and to reduce infection and inflammation. Antibiotics, especially in the inhalational form, reduce exacerbations and inflammation by decreasing bacterial density. Macrolides reduce exacerbation frequency and are a mainstay of antiinflammatory therapy in bronchiectasis.[82] Macrolide antibiotics have antiinflammatory and immunomodulatory properties (without suppression of the immune system) in addition to antibacterial activity. They are used widely in the treatment of bronchiectasis in humans.[82,83] The advantage of using macrolides instead of glucocorticoids to manage inflammation is immunomodulation without immunosuppression. Studies investigating the risks and benefits of long-term use of macrolides in dogs or cats with bronchiectasis are lacking. At present, there are no definitive data to support the routine use of glucocorticoids, even via inhalation, unless the patient suffers from coexisting asthma or EBP.

Prognosis

Addressing the underlying pathological process is vital to attempt to slow the progression of destruction of bronchial walls. Despite substantial clinical abnormalities, dogs with bronchiectasis can survive for years.[74] Patients with focal bronchiectasis are exceptions because surgical resection of the affected lung lobe can be curative.

Bronchomalacia

Overview and Etiology

Bronchomalacia (BM) is characterized by weakness of the walls of principal or smaller bronchi, leading to collapse of the bronchial wall. In veterinary medicine, bronchomalacia recently has been increasingly recognized.[5,84-86] The etiology is unclear. Based on endoscopy, BM can be classified as static, dynamic, or both.[86] While static BM is common in brachycephalic dogs,[85] dynamic BM (Video 241-11) most frequently occurs in association with tracheal collapse and is called tracheobronchomalacia. Indeed, in a population of 115 dogs admitted for evaluation for respiratory disease and examined by bronchoscopy, tracheobronchomalacia was documented in 50% of dogs examined, with tracheal collapse in 21% and bronchomalacia in 47%.[5] This shows that dynamic BM also can occur as an isolated clinical entity, associated with bronchial infection and/or inflammation[84] or not. Indeed, the role for airway inflammation in BM cannot be confimed in many cases.[5,87] Furthermore, the role of cardiomegaly in the disorder recently has been investigated, but no association between left atrial enlargement and airway collapse could be identified.[9]

Clinical Presentation

Since BM frequently is associated with tracheal collapse, Poodles and Yorkshire Terriers, especially when overweight or obese, are affected most commonly.[5,84] Many brachycephalic dogs show static BM.[85] However, other breeds can be affected, especially older individuals.

Clinical signs include chronic cough, wheezing, intermittent or continuous dyspnea, difficulty in clearing secretions, and possibly signs of recurrent bronchitis and pneumonia. Pulmonary crackles can be heard on lung auscultation.[84] Since radiographs seem to be poorly sensitive for the detection of airway collapse, documentation of BM requires bronchoscopy (see ch. 101).[5] Static and dynamic types of BM can exist concurrently, particularly in larger dogs, those with pulmonary hypertension, a bronchial radiographic

pattern, and nodularity on endoscopic examination.[86]

Diagnosis

Bronchosopy can reveal that both lungs are affected; in about half of cases, the disease appears to affect the left lung predominantly.[84] Analysis of BALF and biopsies of the bronchial mucosa are warranted and can reveal evidence of infectious bronchitis in about half of affected dogs.

Treatment and Prognosis

Treatment is supportive and nonspecific; it should be based on clinical findings in each case. So far, there is a lack of studies investigating how dogs with BM respond to treatment, and detailed information about the prognosis is unavailable.

Feline Lower Airway Disease

In cats, cough is an infrequent clinical sign, unlike in the dog. Furthermore, in cats, cough is fairly specific for tracheobronchial disease since cough of cardiac origin is rare. Feline lower airway disease (FLAD) is a term that encompasses all bronchial diseases, including inflammatory and noninflammatory bronchial diseases. Inflammatory bronchial diseases are by far much more common.

Feline inflammatory bronchial disease (feline asthma or bronchitis) is characterized by inflammation of the lower airways without an obvious identifiable cause. It is recognized clinically by various combinations of cough, wheeze, exercise intolerance, and respiratory distress, attributable to airway obstruction caused by bronchial inflammation.

Many confusing terms are found in the literature, such as chronic bronchitis, allergic bronchitis, eosinophilic bronchitis, and bronchial asthma. Discriminating asthmatic bronchitis from nonasthmatic bronchitis is still challenging. Whether feline asthma and chronic bronchitis are truly separate entities or two facets of the same disease remains uncertain.[88] According to some authors, feline asthma and chronic bronchitis should now been considered as two distinct diseases.[89] Differences in etiology, thoracic radiographic features, bronchoalveolar eosinophil/neutrophil percentages, and response to airway responsiveness testing (ART) have been described, but no clear-cut discriminatory test exists.[106,118,145] Categorization is based on eosinophil and neutrophil percentages in BALF. Several studies have reported values for cell types in feline BALF,[94] but specific reference ranges have not been established. Consequently, both eosinophil and neutrophil thresholds for defining asthma and chronic bronchitis are assigned arbitrarily.[105,106]

Due to this lack of consensus regarding the exact definition of feline asthma, most published studies fail to discriminate spontaneous feline asthma from feline chronic bronchitis. Despite the excellent reviews that have been published recently,[96] it is difficult to present information for both diseases separately. Therefore, information will be presented here under the broader heading of feline inflammatory bronchial disease.

A large volume of interesting information has been gathered by studying feline asthma models. These represent a pivotal advance in the study of this condition, allowing both pharmacological and immunological investigations. However, although interesting and promising experimental results have been obtained (for details, see Reinero's excellent review[90]), great caution must be exercised before results from research can be transposed to practice. Clinical studies are needed to further explore the potential value of the proposed inhaled medications, immunotherapy, or other treatments in feline patients with inflammatory bronchial disease. Additionally, discriminating feline inflammatory bronchial disease from noninflammatory chronic lower airway diseases (e.g., infectious or chronic bronchitis due to a variety of parasitic infections) is necessary because of differences in pathogenesis, treatment, and prognosis.[96]

Feline Inflammatory Bronchial Disease

Pathogenesis and Pathophysiology

According to Reinero,[90] asthma and chronic bronchitis in cats should be considered as two distinct syndromes. Chronic bronchitis is thought to arise secondarily to a previous insult that has damaged the airway permanently, leading to many clinicopathological features that are similar to those of asthma. Feline asthma is thought to be allergic, although presently, it is not yet clear whether an allergic form can be differentiated from a chronic disease of other origin. In humans, asthma is mediated by an allergic response

after exposure to inhaled allergens. This induces stimulation of a T helper 2 response, leading to the secretion of an array of cytokines that drive the immune response responsible for the pathologic changes in the airways. Details of the immunopathogenesis of allergic asthma and evidence to support that allergic asthma exists in cats have been reviewed.[90] In human asthma, clinical signs are related to 3 hallmark features: (1) reversible airway inflammation and (2) consequent obstruction/airflow limitation, linked to (3) airway hyperresponsiveness but also to smooth muscle hypertrophy, excessive mucus production (mucous gland hypertrophy) and accumulation, and bronchial wall edema.[91] Those changes are sometimes reversible. However, chronic inflammation can lead to severe lower airway obstruction, which causes lung hyperinflation, because cats are unable to exhale completely past the narrowed airways, resulting in air trapping. Lung hyperinflation can lead to permanent change, evidenced by progressive airway remodeling, including bronchiectasis, fibrosis, and/or emphysema.

Signalment and Clincal Signs

Young to middle-aged cats are most commonly affected. No clear gender or sex predisposition has been reported,[88,92-95] although middle-aged females (2-8 years)[4] and possibly Siamese cats[92,95] seem to be represented more frequently. Clinical signs consist of cough and increased breathing effort, which vary in severity.[90,96] Clinical signs often are chronic or slowly progressive. In some cats, signs go unnoticed by the owner for long periods of time. In others, complaints include vomiting or attempts at hacking up hairballs, which can mistakenly deviate the clinical management plan toward GI work-up and/or treatment. Mildly affected patients can have only occasional and brief episodes of cough separated by long periods without clinical signs, while in moderately or severely affected cases, cough occurs daily and cats can have a decreased quality of life with breathing discomfort. Cats with severe exacerbations ("asthmatic crisis" or "status asthmaticus") can present acutely with open mouth breathing, dyspnea, and cyanosis. Exacerbation can occur in association with exposure to potential allergens or irritants, such as aerosol sprays, cigarette smoke, or environmental dust, or after stress or exercise, such as the stress associated with a visit to the veterinarian.

Diagnosis

In cats experiencing an asthmatic crisis, excessive handling of the patient is contraindicated. Auscultation, when possible, can reveal decreased heart sounds, due to extreme lung hyperinflation. Cats should first be stabilized as soon as possible (see ch. 131 and 139). In cases that are less severe, physical examination findings are variable; physical examination can be normal at rest or it can include a positive tracheal reflex and/or the presence of tachypnea or obstructive expiratory dyspnea. Auscultation can be unremarkable or it can reveal wheezes during the expiratory phase or, more rarely, crackles. Cardiac function is not impaired, unless the cat suffers from concomitant heart disease. At this stage, additional testing is required because diseases that can mimic clinicopathologic features of asthma need to be ruled out.

Imaging

The classic thoracic radiographic pattern in cats with inflammatory bronchial disease includes evidence of bronchial wall thickening (doughnuts or railroad tracks) or a bronchointerstitial pattern; air trapping also can be evident (increased lucency and flattening of the diaphragm), and some cats show evidence of right middle lung lobe atelectasis.[95,97] In many cases, radiographic findings are not specific enough to confirm the diagnosis, and in some cats, radiographic findings are within normal limits. Thoracic CT can identify abnormalities such as bronchial wall thickening, patchy alveolar patterns, and bronchiectasis[98] and identify lesions that are not appreciated on plain radiographs. In cats, CT can be performed using a plexiglass chamber (the VetMousetrap) allowing acquisition of images without chemical restraint,[99] which is of great benefit in cats that are unable to tolerate stress. Current studies are ongoing to determine the impact of this promising and elegant approach in feline bronchitis.[100]

Bloodwork

Approximately 20% (17-46%, depending on the study) of affected cats have a peripheral eosinophilia,[92,93,95,101] which is not correlated with the degree of airway eosinophilia. A stress leukogram can be observed, and nonspecific hyperglobulinemia is noted in 14-50% of cases.[102] A heartworm antibody/antigen test can be used if clinical features are consistent with heartworm-associated respiratory disease (see ch. 255).

Fecal Analyses

Fecal examination (see ch. 81) is recommended as part of the diagnostic work-up, in an attempt to rule out/detect a parasitic origin for the eosinophilic infiltration such as *Aelurostrongylus abstrusus* (using the Baermann test) or *Toxocara cati* (by fecal flotation).

Bronchoscopy and BALF Analysis

In cats, bronchoscopy is considered less safe than in dogs, mainly due to the small size of the airways and the relatively higher airway responsiveness of the cat.[103] Moreover, as soon as the cat is dyspneic, the procedure is more hazardous since the risks of anesthesia increase, and complications during the procedure or during recovery could be serious and life-threatening. Bronchoscopic findings are not highly specific and can include moderate to large amounts of mucoid or viscous material, with or without airway mucosal hyperemia (see Video 241-11).

Cytologic examination of airway samples, obtained by BAL or endotracheal wash (ETW) (see ch. 101) generally provides evidence of airway inflammation, with increased numbers of eosinophils and/or neutrophils. Although a predominance of eosinophils can be found in fluids from healthy cats, the numbers of eosinophils and neutrophils in BAL fluid have been shown to correlate with disease severity, in cats with either spontaneous disease[94] or experimentally induced bronchial disease.[104] Feline asthmatic disease certainly is primarily characterized by a predominance of eosinophils in BALF; however, so far there is no clear cut-off for distinguishing normal from abnormal based on BALF cellular percentages. According to some authors, in inflammatory conditions, the infiltration can be qualified as being predominantly eosinophilic when the following criteria are met: >20% eosinophils and neutrophil percentage within reference limits, or >50% eosinophils; the infiltration can be qualified as being predominantly neutrophilic when BALF contains >7% neutrophils with eosinophil percentage within reference limits, or >50% neutrophils; finally, inflammation is considered to be mixed when concurrent increases in both eosinophil and neutrophil percentages or absolute numbers are found.[105] On the other hand, many studies mention that eosinophilic infiltration relates to the presence of >17% eosinophils while chronic bronchitis relates to the presence of >7% neutrophils in the BALF, with cats with >17% eosinophils and >7% neutrophils being grouped with asthmatic cats.[106] Such definitions are even less useful when a cat was treated previously with glucocorticoids, which decrease the eosinophil count. A recent study has confirmed that in healthy feline airways a BALF eosinophil percentage of <5% can be expected, and that there is good correlation between the findings (in particular the relative concentration in eosinophils) in BALF and in tissue in feline asthma.[107]

Samples of BAL and ETW fluid may be submitted for culture or PCR testing for bacterial, mycoplasmal and parasitic organisms. *Mycoplasma* infection can cause lower respiratory tract infection in cats[88,108,109] and might be associated with feline bronchial disease,[88,109] and infection with *Aerulostrongylus abstrusus* and *Troglostrongylus* spp. can cause a similar clinical picture.[110] *Mycoplasma* species also can be detected in the BALF of sick cats without respiratory signs and might represent commensal organisms of the lower respiratory tract of cats.[109]

Several inflammatory biomarkers (such as cytokines involved in the allergic reponse, e.g., interleukin-4, interferon-gamma and tumor necrosis factor alpha) have been measured in BALF from cats with feline bronchial disease, in an attempt to distinguish between asthma and chronic bronchitis, but the study failed to detect any difference, even compared with control cats.[106] Concentration of endothelin-1 (ET-1) in BALF has been shown to differentiate normal cats from those with experimentally-induced asthma; therefore, BALF-ET1 might be a potential diagnostic biomarker for asthma.[111] Potential biomarkers might also be assessed by a noninvasive method of exhaled breath condensate collection,[112] and hydrogen peroxide has been suggested as a possible noninvasive biomarker for monitoring lower airway inflammation in allergen-challenged *Ascaris suum* (AS)-sensitized cats.[113]

Pulmonary Function Tests

An important clinical feature of asthma is airflow limitation that is at least partially reversible with bronchodilators. In human medicine, pulmonary function testing is commonly used in the diagnosis and monitoring of therapeutic response in patients with asthma or chronic bronchitis. In cats, spirometry is inadequate since it requires patient compliance to exhale forcefully through a mouthpiece. However, some noninvasive tests have been developed, such as tidal breathing flow volume loops (TBFVL) using a tightly fitting face mask,[94,101] BWBP,[104,114] or a combination of TBFVL and BWBP[115] and forced expiratory flow-

volume curves using a thoracic compression technique[116,117] in healthy cats and/or cats with experimentally-induced asthma. BWBP can be used for estimating basal functional parameters, as well as airway hyperresponsiveness, usually quantified by calculating the concentration of bronchoconstrictor agent that induces a 300% increase in basal enhanced pause (Penh).

TBFVL and BWBP have been used in clinical case series,[101,107,115,118,119] associated with airway responsiveness testing using either carbachol,[118,119] 5amp,[120] or methacholine[121] as bronchoprovocative challenge.

During TBFVL, the presence of airflow limitation is affected by the overall extent of granulocyte infiltration, while most BWBP studies provide supportive evidence of a correlation between airway eosinophilic inflammation and plethysmographic measures of bronchoconstriction and airway responsiveness. The latter suggests that BWBP associated with airway responsiveness testing could offer a new method for the identification of cats with inflammatory lower airway disease, and possibly for monitoring disease progression or response to therapy.

In anesthetized cats, ventilator-acquired lung mechanics recently have been proven to be useful.[121]

Differential Diagnosis

The differential diagnosis for feline inflammatory bronchial disease includes mainly feline bronchial disease of noninflammatory origin (see below) and pulmonary parenchymal diseases (see ch. 242), including infectious pneumonia/bronchopneumonia (e.g., bacterial, viral, parasitic, protozoal)[5,105,122] that are rare but probably are underdiagnosed; airway foreign bodies; neoplasia; pleural effusion of various etiologies (see ch. 244); and rarer diseases such as feline pulmonary fibrosis[123,124] and endogeneous lipid pneumonia.[125]

Feline bronchial diseases of noninflammatory origin include the following:

- Pulmonary parasitic diseases, including infection with *Aerulostrongylus abstrusus, Troglostrongylus brevior,*[126] *Eucoleus aerophilus* (formerly *Capillaria aerophila*),[127] *Dirofilaria immitis,* and *Wolbachia*[128] (in endemic regions), which can result in similar clinical findings including eosinophilic airway inflammation. It is not easy to confidently rule out these diseases because of imperfect test sensitivity; therefore, empiric curative or preventive treatment with relevant drugs (in endemic regions) is recommended.[128a]
- Infection with *Toxocara cati* (see ch. 81 and 276).
- Bacterial/*Mycoplasma* infection[109,129,130] (see ch. 227 and 242).
- Neoplastic origin (see ch. 244, 344, and 346).

Management/Treatment and Monitoring

Acute Respiratory Distress

In cats with severe acute respiratory distress, stress should be minimized and an oxygen-enriched environment should be provided (see ch. 131 and 139). Parenteral therapy with a bronchodilator (e.g., the beta-2 agonist terbutaline 0.01 mg/kg IV, IM or SC) or a rapidly acting corticosteroid (e.g., dexamethasone 0.25-0.5 mg/kg IV or IM) should be administered promptly.[4] Inhaled treatment with a bronchodilator can be used as well, provided that a minimal amount of drug can reach the bronchi (which is uncertain in an animal with severe respiratory embarrassment). These treatments aim to quickly relieve, at least partly, bronchoconstriction. When the cat fails to respond, the presence of spontaneous pnemothorax needs to be considered and emergency thoracocentesis must be considered as a possible life-saving procedure (see ch. 102, 149, and 244). Indeed, asthma has been shown to be the most common cause of spontaneous pneumothorax in cats (4/16 cases, 25%).[131] In this study, all 4 cats with asthma-associated secondary spontaneous pneumothorax survived the initial episode of spontaneous pneumothorax to discharge with medical management.

Chronic Management

Most retrospective studies in cats with lower airway diseases have documented beneficial response to oral or parenteral glucocorticoids and/or bronchodilators.[92-94] Classic therapy for chronic forms of bronchial disease includes the use of long-term, oral corticosteroid (e.g., prednisolone 1-2 mg/kg PO q 12 h for 1-2 weeks, followed by gradual taper), which remains a consistent, reliable, and effective treatment to date.[132] It has been suggested that oral administration of propentofylline, a methylxanthine derivative with bronchodilating actions, to cats with bronchial disease, in addition to a low dosage of prednisolone, might be superior over

monotherapy with prednisolone.[133]

Currently, there are few easily measured parameters to closely assess/monitor response to therapy. Therefore, in practice, treatment monitoring generally relies mainly on improvement of clinical signs. Both airway eosinophilia and airway hyperresponsiveness are considered hallmarks of the disease and would be interesting parameters to monitor during treatment.

A recent study evaluated the correlation between the resolution of clinical signs in cats with lower airway disease receiving oral glucocorticoids and the resolution of inflammation based on BALF cytologic findings.[134] Ten cats with inflammatory bronchial disease received oral glucocorticoids (average prednisolone dosage: 1.8 ± 0.2 mg/kg/day) for at least 3 weeks. All had resolution of clinical signs but 7/10 cats had persistent inflammatory BALF cytologic findings despite resolution of clinical signs. Such a study clearly shows that current recommendations to taper therapy based on resolution of clinical signs are inadequate, and that proper adaptation of oral therapy should rather rely on BALF cytologic evaluation.

BWBP and pseudo-tidal breathing flow-volume loop are noninvasive means of evaluating lung function in conscious, spontaneously breathing cats; both also have been proven to be useful in monitoring response to treatment in both experimental models and spontaneous cases.[118-120,135]

The use of inhaled medications using a face mask and spacing chamber, first described by Padrid,[136] is becoming commonplace (see ch. 97).[137] Medications given via inhalation offer the advantage of high drug concentrations within the the airways while attenuating systemic side effects. Inhaled corticosteroids (e.g., fluticasone propionate), utilized essentially as chronic therapy, and bronchodilators (e.g., albuterol), used for palliating an acute exacerbation of signs, are the most commonly used and were first used in experimental models.[138-140] Several studies have evaluated the response to nebulized therapy in feline patients. One of them showed that inhaled budesonide 400 mcg q 12 h could be withdrawn in 20 cats while in the cats still receiving inhaled budesonide, clinical improvement was noted, as well as improvement of the airway reactivity indices measured by BWBP.[119] The same study showed that although corticosteroid-induced side-effects were not observed, hypothalamic-pituitary-adrenal axis suppression was detected in 3 of 15 cases. In another study, cats were treated with inhaled fluticasone propionate (Flixotide, GlaxoSmithKline, 2 puffs, 250 mcg/puff, q 12 h).[118] Despite a significant improvement in clinical scores—and in some cats, apparent resolution of clinical signs—BWBP values did not change significantly by first recheck, providing further evidence that overt clinical resolution can precede recovery of normal airway function. This does not appear to be due to insufficient dosage of nebulized fluticasone. Indeed, in a study of a feline asthma model, a twice-daily dosage of 44 mcg had an effect that was identical to a twice daily dosage of 220 mcg of inhaled fluticasone[141]; these findings suggested that this low dosage should be evaluated for the management of cats with naturally occurring inflammatory bronchial disease. As only oral prednisolone is capable of eliminating the late-phase asthmatic reaction,[139] a combination of both oral and inhaled glucocorticosteroid medications can be started, followed by a single inhaled therapy in the follow-up period.

Bronchodilators, such as inhaled albuterol (also called salbutamol), are very useful to alleviate clinical signs quickly, but as they fail to control airway inflammation, they should not be used alone (for monotherapy). They should be used with caution, due to possible adverse effects, including tachycardia, central nervous system stimulation, tremors, and hypokalemia. Besides, chronic daily racemic albuterol administration has been associated with increased severity of airway inflammation in experiental models of feline asthma.[142]

Other Therapies

Weight loss should be encouraged in obese cats (see ch. 176). A recent study compared pulmonary function variables between obese and nonobese cats using BWBP.[143] Although obesity was not associated with a significant increase in bronchoconstriction index variable, as previously reported in humans and dogs, a significant impairment in pulmonary function was confirmed, suggesting that weight loss should be encouraged in obese cats with FLAD.

Saline nebulization and use of mucolytics or phytotherapeutic agents (either oral or by nebulization) have not been proven to be beneficial and should be administered with great caution. In cats, all nebulized substances potentially can trigger a bronchospastic reaction and/or occasion extra stress, all having a negative impact on a cat with FLAD. In cats with experimentally induced asthma, endotracheal nebulization of N-acetylcysteine, a drug with mucolytic and antioxidant properties, has caused increased airway resistance and other adverse reactions[144] and therefore is not recommanded.

Prognosis

Feline bronchial disease is associated with substantial morbidty and even mortality in cats. Although most cats are well controlled with oral or nebulized therapy, or both, they generally require lifelong treatment. Importantly, unchecked airway inflammation can lead to irreversible remodeling, resulting in a decline in lung function.

In chronic cases, when remodeling has taken place, alleviation of clinical signs can become challenging and can lead to euthanasia.

Contribution of Experimental Feline Asthma Models in Developing Possible Future Therapies

Development and implementation of feline asthma models have greatly contributed to understanding pathophysiologic mechanisms and diagnosis and facilitated the search for novel therapies. Indeed, by combining structural/morphological imaging (thoracic CT) and functional analyses, models offer the unique possibility for repeated and standardized follow-up of clinical features, lung function, and airway inflammation and immunology.

Two different feline asthma models have been described, based on artificial sensitization to either *Ascaris suum*[104,145] or Bermuda grass allergen/house dust mite allergen.[146] A huge number of novel therapies that might be effective or might help to reverse the immune events in asthma have been or are presently being investigated in experimental asthma models. Indeed, the amount of data generated by one team using the feline asthma model is fabulous and provides interesting and sometimes very promising experimental results (for details, see reviews by Reinero[89] and Trzil[96]). Novel therapeutic approaches evaluated in feline models include nutraceuticals (omega-3 polyunsaturated fatty acids plus luteolin),[147] different bronchodilators,[139,148] the salivary immunomodulatory peptide feG-COOH,[149] leukotriene antagonists,[150] antiserotoninergic drugs,[151] doxycycline,[139] rush immunotherapy,[152-154] inhaled lidocaine,[155] the tyrosine kinase inhibitor masitinib,[121] and long-term evaluation of mesenchymal stem cell therapy.[100]

However, although these investigations in models are very useful, they do not necessarily reflect the situation in feline patients with spontaneous disease.Therefore, these new therapeutic strategies, tested in experimental settings, cannot yet be recommended for clinical practice.

CHAPTER 242

Diseases of the Pulmonary Parenchyma

Leah A. Cohn

The structure of the pulmonary parenchyma permits the primary function of the lung-gas exchange. The lung consists of millions of alveolar airspaces each bathed by a dense network of capillaries. Fine, lacey, supporting interstitial tissues are interposed between the epithelial lining of the alveoli and the surrounding vascular endothelium of the capillary network; these interstitial tissues contain the slightly larger pulmonary arterioles and veins. Parenchymal disease includes disease focused on the alveoli, pulmonary microvasculature, or the interstitial tissues while excluding disease of the larger airways (see ch. 241), pulmonary vessels (see ch. 243), and pleural space (see ch. 244).

Manifestations of Pulmonary Parenchymal Disease

Dogs and cats with pulmonary parenchymal disorders have a variety of clinical signs related either to respiratory dysfunction or to systemic disease. Often, clinical signs and physical examination abnormalities in animals with pulmonary disease are similar to those found in animals with airway, mediastinal, or pleural space disease. Additionally, nonrespiratory diseases (e.g., neuromuscular disease, anemia, acidosis) can cause signs that mimic respiratory disease. Common respiratory manifestations of pulmonary parenchymal disease include cough, exercise intolerance, tachypnea, excessive panting, and increased respiratory effort or respiratory distress. Most often, respiratory distress caused by pulmonary parenchymal disease results in mixed inspiratory and expiratory effort. This contrasts with the predominantly inspiratory effort observed in animals with upper airway obstruction (see ch. 28) or pleural space disease (see ch. 244) or the expiratory effort observed in animals with lower airway/bronchial disorders (see ch. 241). Certain interstitial lung diseases that limit pulmonary compliance offer exceptions to this general rule, in that they are associated with a predominantly inspiratory effort. Less common manifestations of pulmonary parenchymal disease include hemoptysis, collapse or syncope, and cyanosis. It is also possible for animals with marked respiratory compromise to demonstrate minimal clinical evidence of respiratory disease. This is especially true in cats; in this species the first sign of marked pulmonary parenchymal disease can be sudden death.[1-5]

Physical examination of animals with pulmonary disease can be unremarkable or can identify marked systemic or thoracic disease. Weight loss, fever, lymphadenomegaly, and distal limb swelling from hypertrophic osteopathy (E-Figure 242-1) are a few of the many potential systemic manifestations of pulmonary diseases. Abnormalities in respiratory rate or effort, cyanosis, increased or decreased bronchovesicular lung sounds, and/or adventitial sounds (i.e., crackles and wheezes) on auscultation are suggestive of airway, thoracic space, or pulmonary disease (Figure 242-2). Examination of the patient with respiratory disease is described in detail in ch. 2, 28, and 240. Any animal presenting with marked respiratory distress should receive supplemental oxygen during evaluation (see ch. 131 and 139).

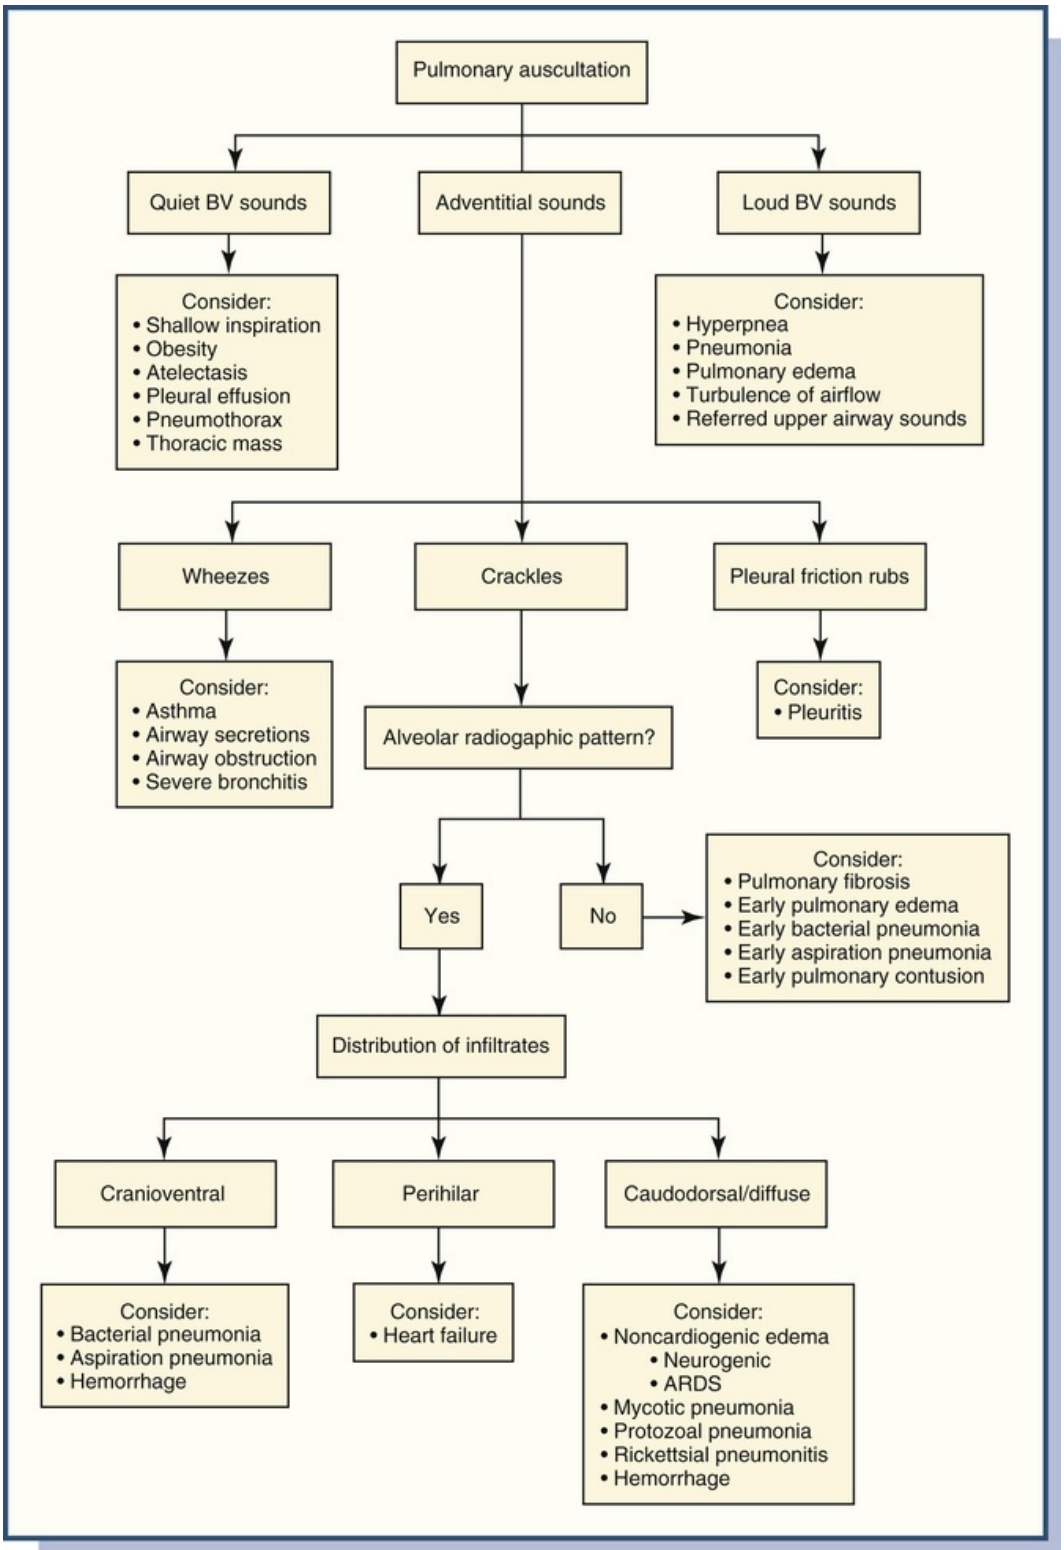

FIGURE 242-2 Thoracic auscultation. *ARDS,* Acute respiratory distress syndrome; *BV,* bronchovesicular.

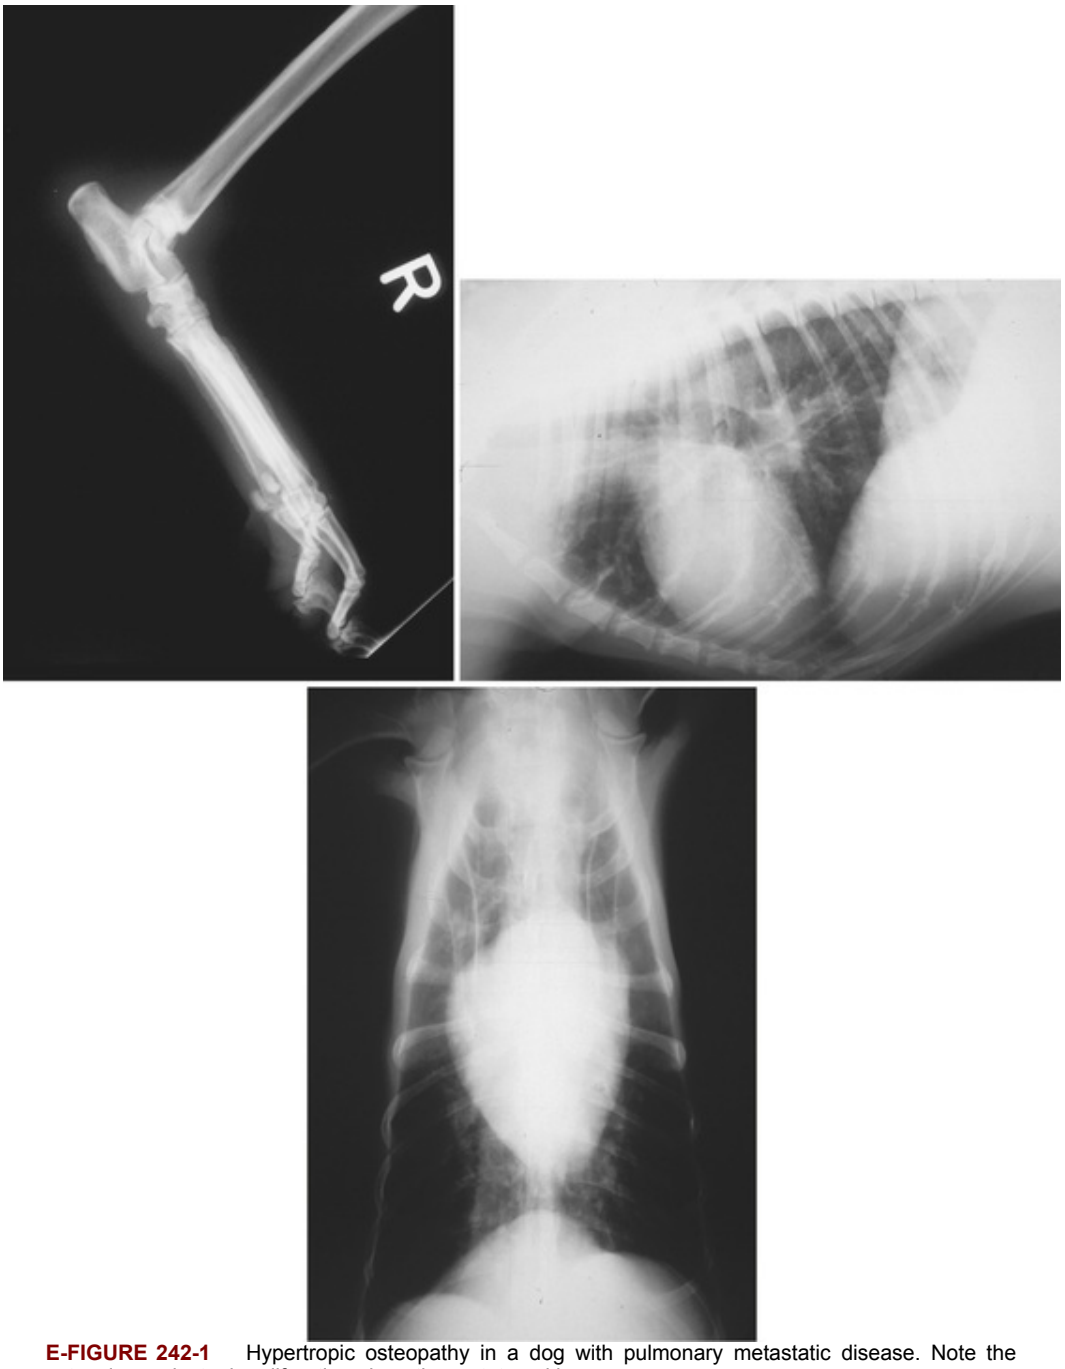


E-FIGURE 242-1 Hypertropic osteopathy in a dog with pulmonary metastatic disease. Note the extensive periosteal proliferation along the metatarsal bones.

Diagnostic Evaluation of Pulmonary Parenchymal Disease

Oxygenation

Evaluation of oxygenation often is useful for animals with suspected pulmonary parenchymal disease, although nonparenchymal diseases also can cause hypoxemia. Visual recognition of cyanosis confirms the presence of hypoxemia but is insensitive, subjective, and not useful in anemic animals. Better tests of oxygenation include pulse oximetry (see ch. 98) and arterial blood gas analysis (see ch. 128). Blood gas analysis can be used for making decisions regarding the need for supplemental oxygen or mechanical ventilation and to monitor response to therapy. Additionally, $PaCO_2$ and simple calculations of alveolar-arterial gradients (E-Box 242-1) can be used to help determine the most likely mechanism for hypoxemia (E-Table 242-1).

E-Box 242-1

Calculation of Alveolar-Arterial (A-a) Gradient

Impaired oxygen diffusion or, more commonly, ventilation-perfusion (V/Q) inequality results in increased A-a gradient (A-a gradient = $PAO_2 - PaO_2$) where PaO_2 is the partial pressure of O_2 in the artery and PAO_2 is the partial pressure of O_2 in the alveoli. Normal A-a gradient is <10 torr, whereas a gradient >20 torr suggests V/Q inequality. There are several methods by which to calculate actual or approximated A-a gradient.

1. Complete calculation:

$$= ((FiO_2 \times (P_{atm} - P_{H_2O})) - (PaCO_2/R)) - PaO_2$$

where FiO_2 is the fraction of inspired oxygen, P_{atm} is the atmospheric pressure, P_{H_2O} is the water vapor pressure, $PaCO_2$ is the measured arterial carbon dioxide tension, and R is the respiratory quotient (ratio of carbon dioxide produced to oxygen consumed).

2. Assuming common values at sea level on room air:

$$= ((0.21 \times (760 - 47)) - (PaCO_2 / 0.8)) - PaO_2$$

3. Extreme simplification, making similar assumptions as earlier:

$$= 150 - (PaO_2 + PaCO_2)$$

E-TABLE 242-1

Mechanisms of Hypoxemia

MECHANISM OF HYPOXEMIA	SELECTED EXAMPLES	CLUES TO RECOGNITION
Hypoventilation	• Drug-induced respiratory depression • Central nervous system or peripheral nerve disorders • Upper-airway obstruction	• Increased $PaCO_2$ • Normal (A-a) gradient • Absent radiographic pulmonary infiltrates
Ventilation : perfusion (V : Q) mismatch	• Bacterial pneumonia • Pulmonary edema • Pulmonary thromboembolism	• Increased A-a gradient • Mildly increased $PaCO_2$ • Improves with O_2 supplementation (except thromboembolism) • Pulmonary radiographic changes variable but common
Right-to-left shunting (intrapulmonary or cardiac)	• Right-to-left patent ductus arteriosus (cardiac) • Pulmonary arteriovenous fistulae with marked pulmonary hypertension (pulmonary vascular) • Atelectatic lung (pulmonary) • Pulmonary thromboembolism	• Increased (A-a) gradient • Fails to improve with O_2 supplementation • Cardiac or pulmonary radiographic changes common
Diffusion impairment	• Asbestosis • Idiopathic pulmonary fibrosis	• Marked interstitial radiographic infiltrates common

		• Improves with O_2 supplementation
Reduced inspired oxygen partial pressure	• High altitude • Anesthetic accident • Suffocation	• Resolves with O_2 supplementation

Screening Tests

Diagnostic modalities used in dogs and cats with pulmonary disease range from the simple to the complex, from noninvasive to invasive, and from the inexpensive to the costly. Screening health examinations such as a complete blood count (CBC), serum biochemical profile, and urinalysis rarely provide a specific explanation for pulmonary signs but sometimes provide clues to an underlying disease process (E-Box 242-2). Results of these tests also are relevant to planning for anesthesia required for many of the more specific respiratory diagnostic techniques. Tests such as fecal flotation, fecal Baermann sedimentation (E-Box 242-3 and E-Figure 242-3), or heartworm antigen tests occasionally provide a definitive diagnosis for pulmonary disease. For some infectious diseases with pulmonary manifestations, specific serologic or polymerase chain reaction (PCR) tests support a suspected diagnosis. Simple blood tests also are available to help distinguish animals with respiratory signs due to heart failure from those with primary respiratory disease.

E-Box 242-2

Implications of Routine Screening Examination in Dogs or Cats with Pulmonary Disease

Complete Blood Count

Neutrophilia: consider infectious pneumonia and inflammatory lung disease, including acute respiratory distress syndrome (ARDS)
Neutropenia: consider sepsis, ARDS
Eosinophilia: consider hypersensitivity disorders, eosinophilic pneumonia, or parasitic disease
Monocytosis: consider mycotic lung disease, histiocytic disease
Thrombocytopenia: consider sepsis, pulmonary thromboembolism, vasculitis, pulmonary hemorrhage
Erythrocytosis ("polycythemia"): supports chronic hypoxemia

Serum Chemistry Profile

Hypoalbuminemia: consider pulmonary thromboembolism resulting from protein-losing nephropathy or enteropathy, systemic inflammatory and infectious disease with pulmonary manifestation
Hypercholesterolemia: consider pulmonary thromboembolism resulting from protein-losing nephropathy
Hyperglobulinemia: consider infectious and inflammatory disease
Hypercalcemia: consider neoplasia and granulomatous fungal disease
Increased alanine aminotransferase: supports hypoxemia

Urinalysis

Proteinuria: consider pulmonary thromboembolism resulting from protein-losing nephropathy, systemic inflammatory disease
Bacteruria: consider sepsis

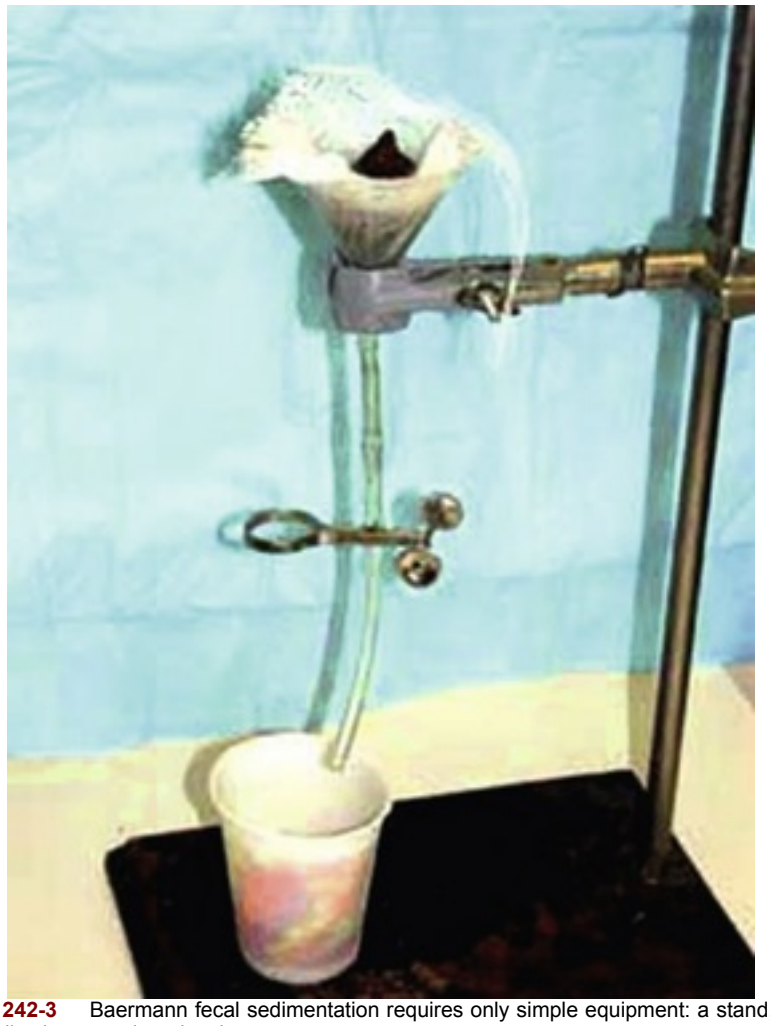
E-Box 242-3

Baermann Fecal Sedimentation Technique (see E-Figure 242-3)

Several types of pulmonary parasites are more likely to be identified via Baermann fecal sedimentation than by routine fecal flotation. However, intermittent fecal shedding associated with all pulmonary parasites makes any fecal technique relatively insensitive. Ideally, at least three negative examinations from different stool samples would be required to effectively rule out pulmonary parasites. Fresh feces should be used because larvated parasite ova from older specimens can confuse results, as can free-living soil nematodes from samples allowed to sit outdoors for more than 20 minutes after defecation. If testing

must be delayed by several hours, stool should be refrigerated. Baermann sedimentation is simple to perform and requires no specialized tools. A step-by-step technique is as follows:

1. Attach a piece of rubber tubing to the bottom of a medium-sized glass funnel.
2. Suspend the funnel and tubing from a stand to keep it upright.
3. Attach a clamp across the tubing and close clamp.
4. Collect ≈10 grams of fresh feces.
5. Place feces in double-layered cheesecloth.
6. Place feces-containing cheesecloth inside the funnel.
7. Fill the funnel with warm water.
8. Allow the feces to stand in the water undisturbed 4 to 5 hours or overnight.
9. Carefully release the clamp and collect the first 10 mL of fluid from the tubing.
10. Centrifuge the collected fluid at 500 to 650 G (similar to the speed used for serum separation) for ≈5 minutes.
11. Place a cover slip on the sample and examine the sediment under a light microscope.
12. If larval movement is detected, a drop of dilute iodine is placed at the edge of the cover slip and allowed to wick through. The iodine kills the parasites and facilitates a more complete morphologic examination.



E-FIGURE 242-3 Baermann fecal sedimentation requires only simple equipment: a stand, a funnel, tubing, a collection vessel, and a clamp.

Natriuretic Peptides

Natriuretic peptides are a group of related hormones that affect circulatory homeostasis.[6] Many have been used as biomarkers of cardiovascular disease. Chief among these is B-type natriuretic peptide (BNP; i.e., brain natriuretic peptide), which promotes natriuresis, increases glomerular filtration rate, causes vasodilation, and antagonizes the renin-angiotensin-aldosterone system in animals with increased extracellular fluid volume.[6] The circulating concentration of BNP increases in animals with volume overload, pulmonary hypertension, and especially with cardiac dysfunction and heart failure (see ch. 246). The peptide is synthesized as a preprohormone and rapidly processed to a prohormone, which is then cleaved into the active BNP and the inactive NT-proBNP fragment. The inactive fragment has a longer half-life than the active hormone, making it convenient for diagnostic measurement. Because it is often difficult to quickly establish if respiratory distress is due to primary respiratory or primary cardiac disease, and because these conditions are treated quite differently, it can be useful to have a simple, safe, rapid test to distinguish the two. Dogs with congestive heart failure have been found to have higher median circulating BNP concentrations than either normal dogs or dogs with respiratory causes of cough or distress.[7,8] However, BNP was also elevated in dogs with noncardiac causes of cough and concurrent heart disease.[7] Similarly, ELISA tests of NT-proBNP have been evaluated in dogs and cats with cardiac and noncardiac causes of cough or respiratory distress. Higher concentrations of NT-proBNP were found in pets with cardiac than respiratory disease.[9-13] In cats, measurement of NT-proBNP in pleural fluid can be used for distinguishing between cardiac and noncardiac origin effusions.[14] Unlike in humans, age and gender do not appear to affect natriuretic peptide concentrations[7,12]; however, NT-proBNP concentrations do increase in association with increases in creatinine. This could be problematic when using the test in animals with azotemia.[12] Although these tests might well have a role in evaluation of pets with acute dyspnea, for now they should be viewed as ancillary tests that do not replace more standard evaluations such as imaging studies.[9,10,13,15]

Diagnostic Imaging Studies

Imaging studies help to rule out airway, mediastinal, or pleural space disease as a cause of respiratory signs and provide substantial information regarding disease of the pulmonary parenchyma. Thoracic radiographs are perhaps the single most important diagnostic test (after history and physical examination) for the pet with lung disease. The presence, location, and intensity of abnormal radiographic patterns provide a wealth of information to guide differential diagnosis and diagnostic plans (Box 242-4). Lung disease sufficient to cause respiratory signs occasionally occurs in the absence of radiographic change in the pulmonary parenchyma. For example, radiographic changes can lag behind acute development of respiratory signs in animals with aspiration pneumonia, acute respiratory distress syndrome (ARDS), or pulmonary thromboembolism. However, when thoracic imaging studies fail to demonstrate abnormalities in animals with lower respiratory signs, additional consideration should be given to conditions that can mimic respiratory disease, such as anemia, pain, acidosis, or nervous system disorders.

Box 242-4

Differential Diagnosis Associated with Common Radiographic Patterns

Alveolar Infiltrate

Pneumonia (bacterial, parasitic, protozoal, viral, aspiration, interstitial)
Edema (cardiogenic or noncardiogenic)
Hemorrhage/contusion
Primary lung neoplasia
Metastatic neoplasia
Atelectasis
Pulmonary thromboembolism
Drowning
Smoke inhalation

Bronchiolar Infiltrate

Feline asthma

Chronic bronchitis
Eosinophilic bronchitis
Peribronchiolar cuffing (e.g., edema, inflammation)
Bronchial calcification

Interstitial Patterns

Aging change (i.e., "old dog lung") (U)
Pulmonary fibrosis (U)
Lymphoma (U)
Primary lung neoplasia (S > U)
Pulmonary metastasis (S > U)
Fungal pneumonia/granuloma (S > U)
Eosinophilic pneumonia (S > U)
Foreign body reaction (S > U)
Hematoma (E)
Abscess (S)
Cyst (S)

Vascular Pattern

Heartworm disease
Thromboembolic disease
Pulmonary hypertension
Congestive heart failure

E, Either structured or unstructured pattern; *S*, structured interstitial lung pattern; *U*, unstructured interstitial lung pattern. Any disease that causes an alveolar pattern can begin with an unstructured interstitial pattern that progressively becomes more severe.

Computed tomography (CT) and ultrasound are used less frequently than plain thoracic radiographs to image the lungs of pet animals. CT offers advantages over standard thoracic radiography including increased sensitivity for the detection of small lesions such as metastasis, a truer three-dimensional image of the thoracic cavity and its contents, minimization of summation artifact, and the ability to view images in axial, coronal, or sagittal planes.[16,17] Until recently, CT scan has required anesthesia or heavy sedation, thus limiting its utility as a screening test. The combination of newer machines with faster image acquisition and the availability of restraint devices (e.g., VetMousetrap, Urbana-Champaign, IL) easily used for cats or small dogs with dyspnea have overcome some of these limitations (Video 242-1).[18] Nonetheless, the best thoracic images still require anesthesia and, ideally, controlled ventilation.[19] Because sound waves do not produce good images when they traverse airspaces, ultrasound is not a particularly useful modality for evaluation of pulmonary parenchyma. Ultrasound sometimes is helpful for evaluation of consolidated lung tissue or to evaluate vascular patency, and it can be used for guiding needle aspirates from thoracic masses.[20,21]

Invasive Tests

Often, invasive tests are required for the diagnosis of pulmonary parenchymal disease. The most commonly employed tests include transtracheal or endotracheal lavage, bronchoalveolar lavage (BAL, with or without bronchoscopic guidance; see ch. 101), fine-needle aspiration (FNA) of lung lesions, and lung biopsy (see ch. 240). Unfortunately, it seems that culture of simple deep oral/pharyngeal swabs is not an acceptable substitute for tracheal or alveolar lavage in dogs with bacterial pneumonia.[22] Tracheal lavage offers a minimally invasive and relatively safe means of collecting airway fluid samples for microbiologic culture and cytologic examination. Because samples are collected from the large airways rather than the parenchyma, tracheal lavage is particularly useful for pulmonary disease accompanied by a productive cough (e.g., bacterial pneumonia). BAL produces diagnostic samples from deeper within the lung and is therefore useful in animals lacking a productive cough. Bronchoscopy can guide BAL collection such that specimens are obtained from a specific site in the lungs.[23] When diffuse disease is present, BAL can be collected in a "blind" fashion without regard to collection site in the lungs.[24] Although FNA of the pulmonary parenchyma is invasive, it is inexpensive and relatively safe. When a focal mass or consolidated lesion is present, the diagnostic yield of FNA is high. However, sensitivity diminishes when lung disease is diffuse.[20,25,26] Lung

biopsy is more invasive than airway lavage or lung aspirates but also provides more information. Biopsy is indicated for the evaluation of animals with continued or worsening lung disease when less invasive techniques fail to yield a diagnosis. Biopsy is required to definitively demonstrate the presence of many interstitial lung diseases. For instance, pulmonary fibrosis cannot be definitively identified in any way other than histologic examination of lung tissues.[1] Lung biopsy can be acquired via thoracoscopy, a key-hole approach, or thoracotomy.[27]

Specific Pulmonary Disorders

Pulmonary Parasites

Parasitic pulmonary disease is caused by both lungworms and non-lungworms. Some intestinal worms, especially *Toxocara* (roundworms) but also *Ancylostoma* (hookworms), undergo pulmonary migration before the adult worm reaches its final destination in the intestine. Usually, pulmonary migration causes little disease and few (if any) respiratory signs. However, massive larval migration can result in both direct and indirect inflammatory damage to the lung, causing verminous pneumonia. Such profound infections typically occur in puppies who may present with cough and tachypnea. A CBC often is not performed in young puppies with cough, but eosinophilia would be expected. Fecal flotation can be negative because larval migration occurs before the mature worms have reached the intestine. Empiric treatment is reasonable if pulmonary migration is suspected as a cause of cough. An anthelmintic (e.g., pyrantel pamoate 5 mg/kg PO) should be administered at least twice, 2 weeks apart. Fortunately, most animals require no further treatment. A short course of an antiinflammatory dosage of glucocorticoid can ameliorate severe cough but should not be used before ruling out other causes of infectious pneumonia.

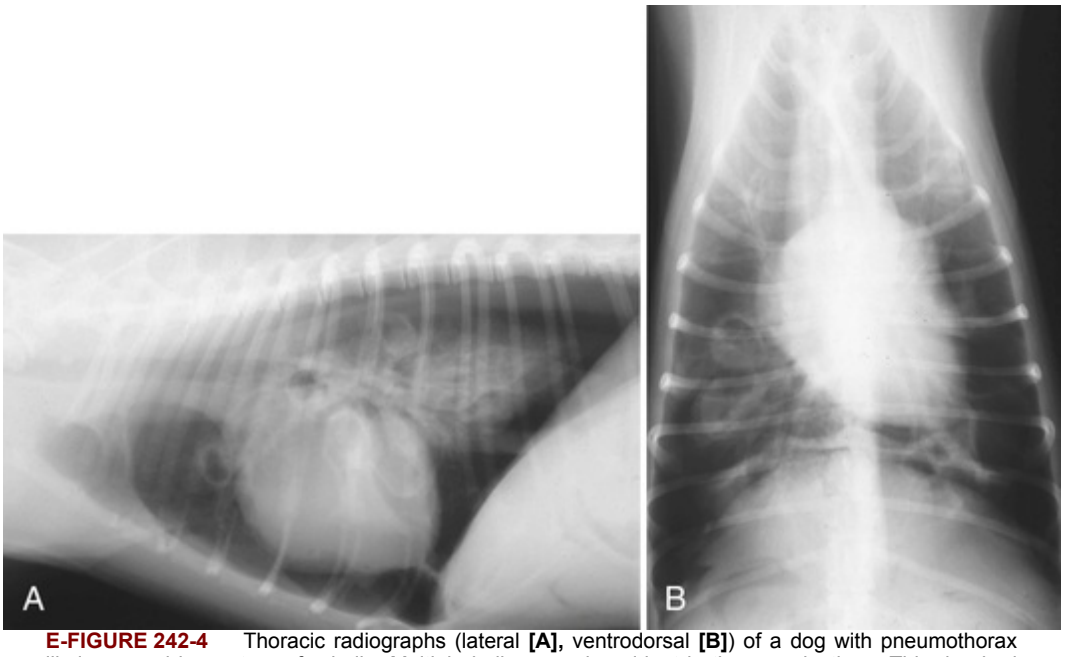
In contrast to intestinal worms that migrate through the lungs on their way to a final destination, for lungworms the final destination is the respiratory tract.[28,29] Several types of lungworms are of relevance to dogs and cats. These parasites can reside primarily in the pulmonary parenchyma, in the airways, or both. Parasitic lung disease easily can be confused with other conditions such as bronchopneumonia, eosinophilic pneumonia, asthma, pulmonary granulomatosis, or even pulmonary neoplasia. Unfortunately, intermittent fecal shedding of parasite ova or larvae after expectoration means that fecal examination is an insensitive diagnostic method. For this reason, therapeutic trials often are employed when lungworms are suspected. High-dosage fenbendazole (50 mg/kg PO q 24 h for 10-14 days) or ivermectin usually are used.[28] Ivermectin must be used with caution in Collies and other breeds with a high prevalence of the MDR-1 (ABCB1) mutation.[30] Although albendazole is an effective therapy for lungworms, it has a greater potential for bone marrow toxicosis than does fenbendazole.[31-33]

Pulmonary Parenchymal Parasites

Paragonimus kellicotti

This trematode lung fluke can infect dogs and cats. Found worldwide, in the United States lung flukes are particularly endemic in the Great Lakes region, the Midwest, and the South. As with most pulmonary parasites, an intermediate host is involved in transmission. Pets are infected after eating crayfish. The parasite migrates from the intestine into the peritoneum, across the diaphragm, and into the pleural space. Soon thereafter, immature flukes invade the subpleural tissues, where they cause eosinophilic and neutrophilic inflammation.[34,35] Often, the parasites form bullae and cysts within the pulmonary parenchyma. The mature flukes have access through a series of communicating "tunnels" to the bronchioles, allowing ova eventually to be coughed up and swallowed before fecal shedding.

Animals infected with *P. kellicotti* are usually well but can present with cough or even respiratory distress.[36,37] Rupture of cavitary pulmonary lesions can lead to hemoptysis or pneumothorax (E-Figure 242-4).[36] Often, the diagnosis is suspected when animals with respiratory signs have concurrent eosinophilia or based on radiographic findings.[38] Although radiographic lesions are not identified uniformly, they can include nodular or cystic lesions or bullae, especially involving the right caudal lung lobes.[34,38-40] Serial CT scans from experimentally infected dogs initially identified pleural effusion and a subpleural ground-glass appearance along with linear opacities. After 1 month, persistent peribronchial nodules, bronchial dilation, and cavitary changes were observed.[41] Ova can be demonstrated either from airway lavage fluid or in feces.[34] Fecal sedimentation techniques are preferred over other methods of fecal analysis for demonstration of parasite ova (E-Figure 242-5).



E-FIGURE 242-4 Thoracic radiographs (lateral **[A],** ventrodorsal **[B]**) of a dog with pneumothorax likely caused by rupture of a bulla. Multiple bullae remain evident in these projections. This dog had *Paragonimus kellicotti* infection.

E-FIGURE 242-5 Ovum of *Paragonimus kellicotti.* (Courtesy Dr. Richard Meadows, University of Missouri.)

In addition to fenbendazole, praziquantel (25 mg/kg PO q 8 h for 3 days) has been used successfully for treatment of *P. kellicotti*[38,39,42] Efficacy of treatment should be assessed with repeated fecal examination for ova.[39] Pneumothorax that results in respiratory embarrassment requires specific therapy (i.e., thoracocentesis; see ch. 100, 102, and 139).

Filaroides

Filaroides spp. are relatively uncommon pulmonary parasites of dogs. Adult nematodes of both *Filaroides hirthi* and *Filaroides milksi* (also known as *Andersonstrongylus milksi*) species reside in the alveolar spaces and

terminal bronchioles; differentiation of these very similar parasites is not necessary.[43,44] *Filaroides* spp. frequently have been recognized as endemic in research dog colonies.[45-51] The ovoviviparous parasite is transmitted directly via the fecal-oral route, allowing transmission between an infected dam and her pups or between infected and uninfected pups. Repeat infection (autoinfection) of the host with larvae before they even leave the host also is possible and increases the potential for "superinfections."[52-57] Dogs can remain healthy while parasitized or can develop severe or even fatal disease. Severe disease is especially likely in young, small-breed dogs, immunosuppressed dogs, or dogs with superinfections.[43,44,56,58,59]

Clinical signs, when they occur, can include cough and respiratory distress. Diffuse bronchointerstitial and alveolar infiltrates result from granulomatous inflammation in reaction to the dead or dying worms.[43,55,56,60] Zinc sulfate centrifugation fecal flotation is used for identifying larvae but lacks sensitivity due to intermittent shedding (a common feature of most lungworm infections). Recognition of ova and/or larvae via airway lavage is an alternative method of diagnosis. A variety of anthelmintic treatments has been employed, but fenbendazole (25-50 mg/kg PO q 24 h for 10-14 days) or ivermectin (0.4-1 mg/kg IV or SC for dogs lacking MDR-1 mutation) is used most often.[28,44,51] An inflammatory reaction to dying worms can worsen disease severity shortly after treatment, a complication that can be ameliorated by a short course of corticosteroids at antiinflammatory dosages (e.g., predniso[lo]ne 0.5-1 mg/kg PO q 24 h for 3-7 days).[44,61]

Airway Parasites

Aelurostrongylus abstrusus

A. abstrusus is a common feline lungworm found throughout the world; in the United States, it is most common in the southern states.[62,63] Although most infected cats remain well, infection can produce clinical signs that mimic feline bronchopulmonary disease. Mature worms reside in the bronchioles; inflammation of these small airways can result in cough, wheezing, and/or respiratory distress. Thoracic radiographs of parasitized cats can appear unremarkable or can demonstrate a diffuse interstitial nodular and/or peribronchiolar pattern, or sometimes an alveolar pattern.[64] In endemic regions, *A. abstrusus* should be considered an important differential diagnosis for feline "asthma," especially in cats with outdoor exposure, which are more likely to ingest the mollusk intermediate host of the parasite. Diagnosis is based on detection of larvae in either airway lavage samples or the feces via Baermann sedimentation (E-Figure 242-6).[28,63,65] A very sensitive and specific diagnostic PCR using either feces or pharyngeal swab material has been developed but is not currently commercially available.[66] Fenbendazole (25-50 mg/kg PO q 24 h for 10-14 days), ivermectin (300-400 mcg/kg SC), or selamectin (6 mg/kg applied topically) can be used for treatment.[29,63] Oral or inhaled antiinflammatory dosages of glucocorticoids can be useful during therapy, as can bronchodilators for cats with increased respiratory effort.

E-FIGURE 242-6 Larva of *Aelurostrongylus abstrusus* recovered from feces via Baermann sedimentation. (Courtesy Dr. Richard Meadows, University of Missouri College of Veterinary Medicine.)

Crenosoma vulpis

Dogs but not cats can be infected with *C. vulpis,* an airway nematode.[28,67] Indirect infections follow ingestion of mollusk intermediate hosts. The infection is reported most often in the northeastern United States and Atlantic Canada but also occurs in Europe. The parasite matures in the airways, where it produces larvated eggs that can be coughed out of the respiratory tract and swallowed. The majority of dogs infected with *C. vulpis* remain healthy, but lower respiratory signs (e.g., cough) and sometimes upper respiratory signs (e.g., nasal discharge) can occur. Diagnosis is accomplished by recognition of the immature parasites either on airway lavage or through fecal Baermann sedimentation or zinc sulfate centrifugal flotation techniques (E-Figure 242-7). Treatment with fenbendazole (50 mg/kg PO q 24 h for 3 days), ivermectin, or milbemycin oxime (0.5 mg/kg PO, once) can be effective.[68-70]

E-FIGURE 242-7 Iodine stained and killed *Crenosoma vulpis* first-stage larva recovered from feces via Baermann sedimentation. After parasite movement is detected on initial examination of the cover-slipped sample, a drop of iodine is allowed to wick through the sample, killing the parasite and facilitating a more complete morphologic examination. (Courtesy Dr. Gary Conboy, University of Prince Edward Island, Atlantic Veterinary College.)

Oslerus osleri

Also known as *Filaroides osleri,* this parasite is morphologically similar to *F. hirthi* and *F. milksi* and, like those pathogens, is transmitted directly without an intermediate host. The primary site of mature residence for *O. osleri* is the distal trachea and the most proximal bronchi, where granulomatous mucosal nodules form.[28,71] Usually subclinical, infection can result in cough or even less commonly exercise intolerance or respiratory distress due to airway obstruction or pneumothorax. Because the parasite-containing nodule can interfere with physical respiratory defenses (e.g., the mucociliary escalator), secondary bacterial infection can occur. Zinc sulfate centrifugal fecal flotation or bronchoscopic identification of the worm nodules can confirm infection.

Eucoleus aerophilus

This nematode respiratory parasite, also known as *Capillaria aerophila,* has a worldwide distribution. The parasite infects the airway mucosa of both dogs and cats. *E. aerophilus* becomes embedded in the tracheal and bronchial mucosa, sometime resulting in eosinophilic bronchitis.[28,72] Although most infections remain subclinical, chronic cough or even occasional respiratory distress can occur. As opposed to most lungworm infections, fecal diagnosis is better accomplished by routine flotation rather than Baermann technique. Airway lavage cytology also can aid identification of the characteristic double-operculated eggs that are similar to, but smaller than, those of the intestinal whipworm *Trichuris vulpis* (E-Figure 242-8).

E-FIGURE 242-8 Ovum of *Eucoleus aerophilus*. (Courtesy Dr. Michael Dryden, Kansas State University College of Veterinary Medicine.)

Troglostrongylus spp.

These metastrongyloid nematodes recently have been recognized to infect domestic as well as wild cats.[29,73] While some species infect the sinuses or trachea, others (especially *T. brevior*) inhabit the bronchi and bronchioles of the definitive host. Reported mostly in cats from Europe and Africa, these parasites are larger than *A. abstrusus* and have the potential for increased pathogenicity, including fatal infection.[73,74] While larvae can be identified in fresh feces, they are difficult to distinguish from other metastrongyloids.[73] A duplex-PCR has been developed that can detect and distinguish between *T. brevior* and *A. abstrusus,* but it is not commercially available.[75]

Other Parasites of Relevance to the Lung

Dirofilaria immitis

D. immitis is responsible for heartworm disease, an important cause of pulmonary and cardiac disease in temperate climates throughout the world. Although heartworm infection of dogs has been well described for many decades, only recently have we begun to understand heartworm infection in cats.[76-80] The host-parasite interaction, clinical consequences, diagnosis, and treatment of *D. immitis* differ greatly between dogs and cats (E-Table 242-2), but efficacious prophylactic mediations are readily available for use in both species. More detail on heartworm infection can be found in ch. 255.

E-TABLE 242-2

Comparison of *Dirofilaria immitis* Infection in Dogs vs. Cats[78-80,468-474]

DOGS	CATS

Host-parasite interaction	• Natural host. • Parasite burden variable but often many mature worms present. • Mature worms persist 5-7 years. • Mature infection often accompanied by microfilaremia. • Prevalence varies with geographic region.	• Atypical host. • Parasite burden typically 1-3 worms. • Mature worms persist 2-3 years. • Mature infection very rarely accompanied by microfilaremia. • Larval forms often eliminated by immune response. • Prevalence of mature infection ≈10% of that in dogs in a given geographic region.

Diagnosis	• Diagnosis of mature infection straightforward.
	  • Recognition of microfilaria on blood smear or via concentration technique (e.g., Knott's test, filtration test) often allows diagnosis. Microfilaria are absent early in infection, with low worm burdens, or in dogs receiving heartworm prophylaxis.
	  • Antigen recognition via ELISA offers excellent sensitivity and specificity for infection in dogs. Antigen becomes detectable ≈5 months after infection.
	• Heat-treatment of sample could increase sensitivity of antigen testing.
	• Thoracic radiographs can be suggestive but not diagnostic of heartworm infection. Radiographs often demonstrate prominent pulmonary artery segments, arterial tortuosity and pruning, and sometimes right ventricular enlargement. A variety of pulmonary parenchymal abnormalities also is possible.
	• Echocardiography can demonstrate right-sided cardiomegaly, worms within the pulmonary artery or right heart.
		• Diagnosis of infection difficult. Often a combination of tests is required to confirm infection in cats with low worm burdens.
		  • Microfilaria seldom present.
		  • Sensitivity of ELISA antigen tests is low due to low worm burden, absence of antigenically detectable female worms, or immature worms. However, antigen test specificity is high.
		• Heat-treatment of sample will increase sensitivity of antigen testing.
		• Feline-specific heartworm antibody tests are moderately sensitive; can miss 15% or more of infections.
		• Feline-specific heartworm antibody tests are moderately specific and confirm only exposure to parasite. They cannot confirm that an infection is mature or active.
		• Radiographic changes inconsistent, although caudal lobar arterial enlargement and parenchymal changes are sometimes identified.
		• Echocardiography may detect mature infection but sensitivity and specificity are operator-dependent (30%-100%). Useful when infection is suspected despite negative ELISA antigen test.

Clinical signs	• Dogs remain well for prolonged periods during infection. • When clinical signs do develop, the most common are exercise intolerance and cough. • Right-sided congestive heart failure occurs eventually in some untreated dogs. • Heartworm caval syndrome is an uncommon emergent complication of infection that occurs when the adult worms occupy the right side of the heart. Caval syndrome includes a tricuspid regurgitant murmur, intravascular fragmentation hemolysis with hemoglobinuria, right-sided congestive heart failure, and disseminated intravascular coagulation. • Antigen-antibody complex deposition can cause glomerulonephritis. • Rarely, aberrant migration leads to disease of other organ systems (e.g., eyes, brain, spinal cord, skin, liver).	• Cats frequently remain well during infection. • Cats can develop a syndrome resembling feline asthma as a result of larval infection without adult worm burden (i.e., HARD). • Cats with mature worm burdens can present with GI signs including hypersalivation and vomiting or respiratory signs including cough or tachypnea. • Cats with mature worms can die suddenly without prior clinical illness or can present with acute onset dyspnea and/or CNS signs.

		• Unlike dogs, right-sided congestive heart failure is rare in cats. • Rarely, aberrant migration leads to disease of other organ systems (e.g., eyes, brain, spinal cord, skin, liver).
Prophylaxis	• Chemoprophylaxis is extremely effective. Options include ivermectin, milbemycin oxime, moxidectin, and selamectin.	• As for dogs, chemoprophylaxis with the same compounds is extremely effective.
Treatment	• Adulticide treatment should be preceded by staging to identify comorbid conditions and severity of disease, and usually by doxycycline treatment for eradication of *Wolbachia.* • Melarsomine is the only approved heartworm adulticide. • If not used beforehand, chemoprophylaxis should be begun when adult infection is identified. If microfilaria are present, the dog should be observed for anaphylaxis after the first dose is administered. • Caval syndrome is treated via physical (surgical) removal of worms. • Complications of infection may require specific therapy (e.g., treatment of congestive heart failure, treatment of glomerulonephritis).	• Adulticide treatment in cats is not recommended due to toxicity, lack of efficacy, and fatalities associated with thromboembolism. • If not used beforehand, chemoprophylaxis should be begun when adult infection is identified. • Cats with bronchopulmonary disease could benefit from corticosteroid therapy. • Bronchodilator therapy and oxygen may be useful in cats with respiratory distress. • Surgical removal of mature worms has been described but entails risk.

CNS, Central nervous system; *ELISA*, enzyme-linked immunosorbent assay; *GI*, gastrointestinal; *HARD*, heartworm-associated respiratory disease.

Angiostrongylus vasorum

Infection with this metastrongylid parasite of canids occurs in Europe, Asia, and Africa, as well as in an endemic focus in Newfoundland, Canada.[70,81-83] It has been dubbed "French heartworm" because, like *D. immitis,* the mature parasites reside in the pulmonary artery, right heart, and pulmonary arterioles. Dogs are infected after consuming infected intermediate (i.e., mollusk) or paratenic (i.e., frog) hosts; L3 larvae are liberated into the dog's intestine before eventually making their way to the pulmonary vasculature. Ova from the mature worms are carried to the pulmonary capillaries, where they hatch. The L1 larvae then migrate into the alveoli. After gaining entrance to the airways, the larvae can be coughed up and swallowed.

Infected dogs can appear healthy or have a range of clinical signs. The predominant syndromes associated with infection are respiratory disease related to an inflammatory response to the parasite and a syndrome of bleeding diathesis.[83] The cause of bleeding is poorly understood but could be related to a consumptive coagulopathy initiated by the parasite, and bleeding can occur without respiratory signs.[84,85] Neurologic signs have been reported in infected dogs as a consequence of central nervous system hemorrhage.[86,87] Severe pulmonary hypertension with resultant cor pulmonale and syncope are reported occasionally, as is spontaneous pneumothorax.[88-91] Although cardiopulmonary disease related to thrombosing pulmonary arteritis can be severe, the most common findings are chronic cough and general unthriftiness. Unlike with heartworm disease caused by *D. immitis,* vascular changes are not appreciated on thoracic imaging. Instead, some combination of bronchial, interstitial, and/or peripheral alveolar lung patterns is described and is seen best on thoracic CT (Figure 242-9).[92,93] Laboratory findings associated with infection can include anemia, eosinophilia, thrombocytopenia, abnormalities of coagulation time, and often, hypercalcemia.[84,94-97]

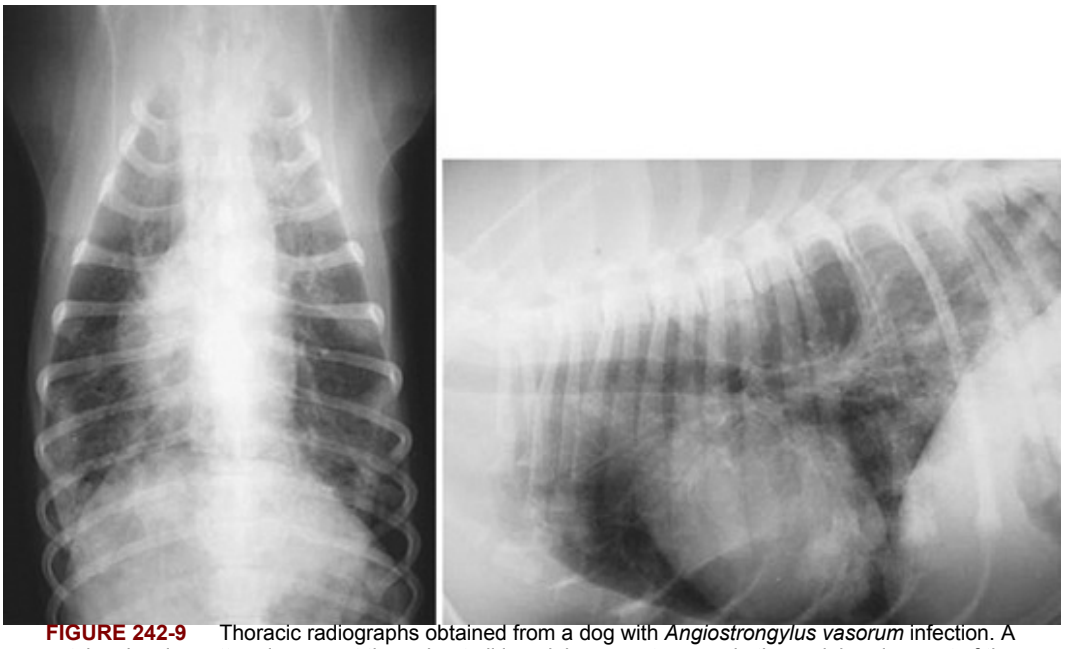


FIGURE 242-9 Thoracic radiographs obtained from a dog with *Angiostrongylus vasorum* infection. A patchy alveolar pattern is present throughout all lung lobes, most severe in the peripheral aspect of the right caudal lung lobe, caudal aspect of the cranial segment of the left cranial lung lobe, and throughout the left caudal lung lobe. A mild degree of peribronchial thickening is also present throughout all lung lobes. Both the cardiac silhouette and pulmonary vasculature remain unremarkable. (Courtesy Dr. Harriet Syme, Royal Veterinary College.)

Appropriate diagnosis and treatment generally are associated with a good prognosis for recovery.[83] As for many pulmonary parasites, Baermann fecal examination (see E-Figure 242-3) is the diagnostic standard and parasites also can be identified on airway lavage.[98] More recently, sensitive and specific serologic and molecular detection tests have been described.[81,98,99] The drug of choice for treatment of *A. vasorum* is fenbendazole (25-50 mg/kg PO q 24 h for 10-20 days), although other effective treatments (e.g., ivermectin [0.2 mg/kg SC each week for two doses], milbemycin oxime [0.5 mg/kg PO each week for 4 weeks], imidacloprid 10%/moxidectin 2.5% spot-on solution, levamisole) have been described.[70,81,100] Treatment with spinosad and milbemycin oxime can be used as a once-monthly prophylactic regimen.[101] Despite recovery of most dogs after treatment, post-treatment reactions including dyspnea, ascites, and sudden death have been observed.[102]

Bacterial Pneumonia

Bacterial pneumonia encompasses a wide spectrum of disease from acute to chronic, unilobar or multilobar, clinically silent infection to fatal infection. There are multiple potential routes of pulmonary exposure to potentially pathogenic bacteria. Bacteria can be inhaled or aspirated into the lung, they can reach the lung through direct extension from the pleural space or intrathoracic structures, or they can gain access to the lung hematogenously. Most bacteria that cause pneumonia are secondary pathogens and only cause disease when allowed the opportunity (e.g., immune suppression, aspiration). Bacterial pneumonia often is the result of mixed flora infections, and obligate anaerobes could account for as many as a quarter of pathogens involved.[103-106] The bacteria most commonly implicated include enteric pathogens (e.g., *Escherichia coli, Klebsiella*), *Pasteurella* spp., coagulase-positive staphylococci, streptococci, *Mycoplasma* spp., and *Bordetella bronchiseptica* (Table 242-3).[5,65,103-111] It is unusual for healthy adult pets, especially cats, to develop bacterial pneumonia. With the exception of infections caused by primary bacterial respiratory pathogens (e.g., *Bordetella bronchiseptica*), most animals with bacterial pneumonia have been compromised in some fashion. The diagnosis of bacterial pneumonia should prompt the clinician to search for a predisposing cause.

TABLE 242-3

Commonly Isolated Bacterial Pathogens Involved in Lower Respiratory Infection/Pneumonia

BACTERIAL GENERA AND SPECIES	ISOLATES FROM DOGS[104-106,108,109]	ISOLATES FROM CATS[5,65,110,111]
Escherichia coli	132	7
Pasteurella spp.	104	22
Bordetella bronchiseptica	105	15
Streptococcus spp.	149	12
Coagulase (+) *Staphylococcus* spp.	101	1
Klebsiella spp.	45	
Enterococcus spp.	15	1
Pseudomonas aeruginosa	66	3
Mycoplasma spp.	95	34

Presentation

Dogs develop bacterial pneumonia more often than do cats.[5,23,104,112,113] Many pets with bacterial pneumonia have a predisposing factor for infection, including extremes of age, debilitation, immunocompromise, or preexisting respiratory disease (Box 242-5).[107,112,114-119] Occasionally, bacterial pneumonia is accompanied by only minor clinical signs or physical examination abnormalities, especially when it is regionally limited to involve a single lung lobe. Commonly, clinical signs include cough (often soft and productive), nasal discharge, exercise intolerance, or respiratory distress. Anorexia and lethargy also are commonplace. Fever is inconsistent at best, and normothermia does not rule out bacterial pneumonia. Loss of body condition, tachypnea, increased (or when consolidation is present, decreased) bronchovesicular lung sounds, inspiratory crackles, sinus arrhythmia, and cyanosis can be identified.

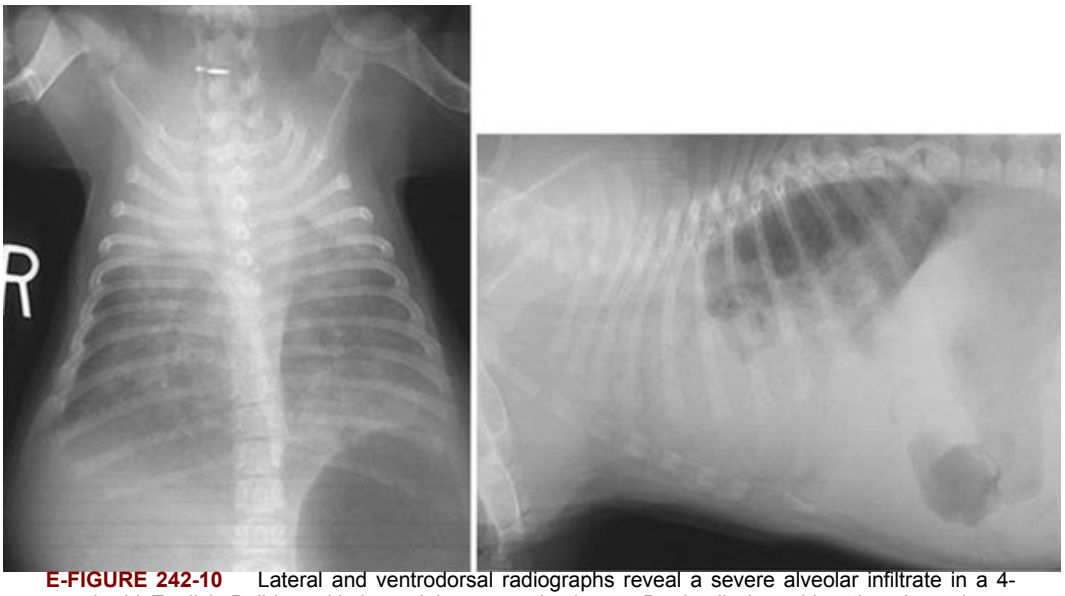
Box 242-5

Factors That Predispose to Development of Bacterial Pneumonia

- Debilitation
- Prolonged recumbency
- Systemic immunosuppression
  - Drug-related (e.g., corticosteroids, chemotherapy)
  - Infection (e.g., feline leukemia virus, feline immunodeficiency virus)
  - Endocrine disorders (e.g., hyperadrenocorticism, diabetes mellitus)
- Immunodeficiency states
  - Extremes of age
  - Congenital immunodeficiency (e.g., breed-related syndromes, severe combined immunodeficiency disease, phagocytic defects)
- Defective respiratory defenses
  - Primary ciliary dyskinesia
  - IgA deficiency
- Damage to respiratory epithelium
  - Smoke inhalation
  - Drowning
  - Viral, parasitic, protozoal, or fungal infection
  - Neoplasia
  - Acute respiratory distress syndrome
- Aspiration (see Box 242-11)
- Pleural/mediastinal/airway infection
- Penetrating thoracic injury
- Airway obstruction (functional or structural)
- Bronchiectasis
- Sepsis/bacteremia

Diagnostic Evaluation

Diagnostic screening tests for animals with suspected bacterial pneumonia include thoracic radiographs, CBC, and arterial blood gas or pulse oximetry measurement. Ideally, a serum biochemical profile, urinalysis, and fecal examination also are performed because they provide potentially valuable information regarding the animal's overall health and sometimes provide clues as to the presence of a systemic disease that might predispose to development of pneumonia. Neutrophilia (± left shift), lymphopenia, and mild anemia are inconsistent but common findings on CBC. Hypoxemia is common but depends on severity of functional lung impairment.[105,120] The classic radiographic appearance of bacterial pneumonia is an alveolar pulmonary pattern with a predominantly ventral distribution.[112,121,122] Sometimes, only a single lung lobe is involved (particularly following foreign body inhalation or aspiration). Dorsocaudal involvement may predominate after hematogenous bacterial exposure, and all lung fields can be involved in cases of severe pneumonia (E-Figure 242-10). In less severe pneumonia or early in the disease course, only an interstitial pattern might be identified. Occasionally, complications such as abscessation, pleural effusion, or pneumothorax are identified concurrently.[121]



E-FIGURE 242-10 Lateral and ventrodorsal radiographs reveal a severe alveolar infiltrate in a 4-month-old English Bulldog with bacterial pneumonia due to *Bordetella bronchiseptica*. A moderate bronchointerstitial pattern is present in the caudodorsal lung lobes, while an alveolar pattern is found in the remainder of the lung lobes.

A specific diagnosis of bacterial pneumonia is confirmed by identification of pulmonary sepsis. Airway lavage provides material for cytologic examination, as well as culture and sensitivity testing. In a recent study from the Ryan Veterinary Hospital at the University of Pennsylvania, the empiric choice of antimicrobial selected for the treatment of pneumonia was found to be inappropriate for the pathogens identified on culture and susceptibility in 26% of dogs.[106] Even more worrisome, for dogs that had received antimicrobials during the preceding 4 weeks for any reason, there was resistence to the empiric antimicrobial choice in 64.7% of dogs with community-acquired pneumonia, underlining the importance of gathering materials for culture and susceptibility prior to initiation of treatment.[106]

Treatment is likely to be prolonged, and culture and sensitivity allow the identification of the safest, most economical, and correctly targeted antimicrobial drugs. However, once the samples have been obtained, antimicrobials should not be withheld pending susceptibility results. It must be recognized that prior antibiotic therapy, incorrect sample handling, or infection with fastidious organisms can result in negative culture even in the face of bacterial pneumonia.[108,123,123a] Because bacterial pneumonia often results in a productive cough, lavage of the large airways (e.g., transtracheal or transoral wash) can be safe, inexpensive, and useful (see ch. 101 and 240).[103] BAL also can be used for obtaining samples for cytology and culture.[107,108] In severe bacterial pneumonia, foreign body pneumonia, aspiration pneumonia, or when areas of pulmonary consolidation are present, anaerobic culture should be requested in addition to routine aerobic

culture.[112,124] Because some *Mycoplasma* spp. might be primary bacterial pathogens of the airways but are difficult to culture using routine methods, specific *Mycoplasma* PCR can be considered as well.[113,125] The airways are not sterile even in health, and noninfectious respiratory disease can be associated with secondary bacterial infection. Therefore, the diagnosis of bacterial pneumonia must be based on integration of all clinical and radiographic findings, ideally in conjunction with cytologically demonstrated neutrophilic airway inflammation and intracellular bacteria in addition to a positive bacterial culture.

Treatment

Bacterial pneumonia should be treated with antimicrobial drugs.[106,124] Initial empiric treatment can be adjusted later, based on results of bacterial culture and susceptibility testing. Initial therapy can be guided in part by cytologic morphology and staining characteristics of microbes recovered from airway lavage.[107,109] For severely affected or unstable animals, initial therapy must include antimicrobials with Gram-positive, Gram-negative, aerobic and anaerobic efficacy. Most often, this approach involves combination therapy administered parenterally (Box 242-6); the author often begins with a combination of ampicillin and enrofloxacin while the recent recommendations of the International Society of Companion Animal Infectious Disease (ISCAID) recommend an initial combination of a fluoroquinolone with either ampicillin or clindamycin.[124] Animals with mild to moderate disease may be treated initially with orally administered antimicrobials with a more limited spectrum of activity (see Box 242-6). Although many antimicrobials (including beta-lactam antibacterials) do not readily penetrate the airway's blood-bronchus barrier, this is less of a concern with pneumonia, which is a parenchymal tissue infection rather than an airway infection. While aerosolized administration of antimicrobials could have an (unproven) benefit in the treatment of certain animals with bacterial pneumonia, aerosol delivery should only be considered as an adjuvant therapy and never as a replacement for systemic antimicrobials.[123,126] Historically in veterinary medicine, the recommended duration of antimicrobial therapy was 1 week past radiographic resolution, typically a minimum of 3 to 4 weeks. This is in extreme excess compared to the duration of therapy recommended for treatment of pneumonia in humans[127,128] and likely longer than is required for pets. Newly developed ISCAID guidelines for respiratory infections suggest reevaluation of animals 10-14 days after treatment has begun, with antimicrobial use extended, altered, or halted on the basis of clinical response.[124]

Box 242-6

Empiric Antimicrobial Choices for the Initial Treatment of Bacterial Pneumonia

Severe, Unstable Disease

Monotherapy:
- Meropenem or imipenem-cilastatin or ticarcillin

Combination therapy:
- Beta-lactam (e.g., ampicillin, amoxicillin/clavulanate, second- or third-generation cephalosporin) or clindamycin
- AND EITHER
- Fluoroquinolone (e.g., enrofloxacin, marbofloxacin, orbifloxacin)
- OR
- Aminoglycoside (e.g., amikacin, gentamicin)

Moderate, Stable Disease

Monotherapy:
- Amoxicillin/clavulanate or trimethoprim-sulfonamide

Combination therapy:
- Beta-lactam AND fluoroquinolone
- OR
- Clindamycin AND fluoroquinolone

Mild, Stable Disease

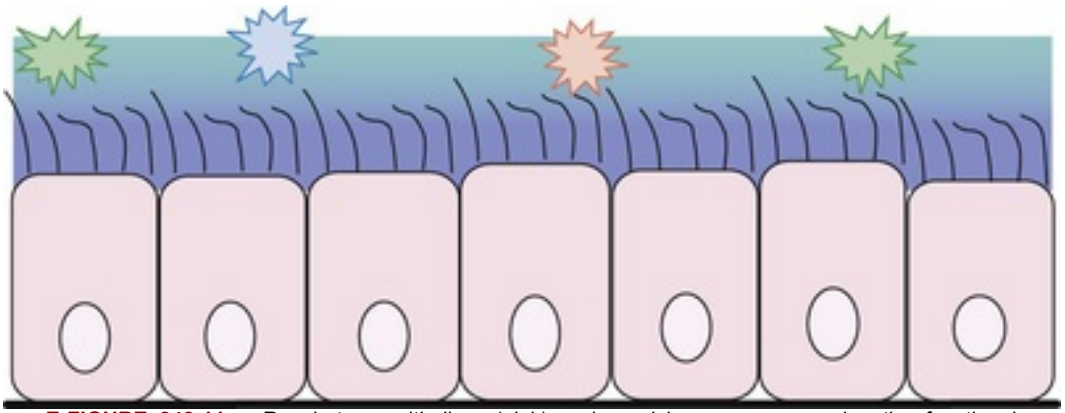
Monotherapy:

Amoxicillin/clavulanate or fluoroquinolone or trimethoprim-sulfonamide

Note: Initial, empiric choice of antimicrobials should be adjusted based on results of microbial culture and sensitivity. The more severe the initial disease is, the more important it is for therapy to provide broad-spectrum coverage.

Dogs with severe bacterial pneumonia often are hypoxemic.[120] Ideally, PaO_2 is determined via arterial blood gas analysis (see ch. 128) but SpO_2 can be used as a rough correlate (see ch. 98). In animals with acute hypoxemia, oxygen supplementation should be provided when PaO_2 is <80 mm Hg or SpO_2 is <94%. The most practical means of delivery include placement of nasal cannula or oxygen cages (see ch. 131). Oxygen should be humidified prior to delivery to prevent drying of the airways with resultant impaired mucociliary clearance. Persistent hypoxemia or continued marked respiratory effort despite oxygen supplementation indicates the need for mechanical ventilation. Unfortunately, the prognosis for recovery of dogs and cats with underlying respiratory disease severe enough to warrant mechanical ventilation is poor.[129] In part, this might be related to the presence of more antimicrobial resistant pathogens in patients with respiratory failure due to pneumonia.[130]

Fluid therapy is indicated for the treatment of animals with severe bacterial pneumonia (see ch. 129). Dehydration is common in weak, depressed, anorexic, febrile, and tachypneic animals. In addition to the systemic effects of hypovolemia, dehydration impairs mucociliary respiratory defenses. Airway mucus functions to trap bacteria and inhaled particulates. The respiratory epithelial cilia propel entrapped particulates craniad to the oropharynx, where they can be expelled through coughing or swallowing.[131] The mucus itself is made of two layers—the watery sol layer through which the cilia move and the overlying gel layer that traps the particulates (E-Figure 242-11). If the sol layer becomes dehydrated, the cilia themselves become entrapped in the gel layer, effectively inhibiting the mucociliary escalator. Crystalloid fluids should be provided at a rate to attain and maintain hydration. Overly aggressive fluid therapy can lead to iatrogenic pulmonary edema and worsen respiratory compromise. Nebulization of sterile saline can enhance mucus fluidity and more effective mucociliary function, although this benefit has not been documented in pets. Saline nebulization 3 to 4 times a day seems to improve breathing in many animals with pneumonia (E-Box 242-7).



E-FIGURE 242-11 Respiratory epithelium (pink) and overlying mucus comprise the functional mucociliary escalator. The apical surface of the respiratory epithelium is covered with a layer of mucus. The mucus layer is not uniform but includes the less viscous sol layer in closest contact with the epithelial surface (purple), as well as a more tenacious, viscous gel layer on top of the sol (teal). Particulates (starbursts) become entrapped in the gel layer, while the respiratory cilia move in a coordinated fashion predominantly in the sol layer. Ciliary movement propels the gel layer with entrapped particulate craniad for expulsion from the respiratory tract. Dehydration of the sol layer impedes ciliary movement and therefore impedes the mucociliary escalator.

E-Box 242-7

Nebulization in Pet Animals

Nebulization creates extremely small fluid particles for inhalation. The site of deposition of these particles depends on their size, charge, hygroscopy, and other parameters. Humidifiers create larger droplets that do not reach lower airways, whereas nebulizers create smaller particles (0.5 to 3 micrometers) that penetrate more deeply into the respiratory tract.

The basic nebulizer types include jet nebulizers and ultrasonic nebulizers. Modifications of these (e.g., spinning disc nebulizers, vibrating mesh nebulizers) exist to improve delivery or modulate particle size. Nebulizers are available in portable sizes at a modest price, certainly suitable for use in veterinary hospitals and even practical for at-home use by owners. In general, jet nebulizers are more bulky but more sturdy, whereas ultrasonic nebulizers are small and portable but prone to malfunction. Ultrasonic nebulizers efficiently deliver small liquid volumes, which can be advantageous when administering expensive medications.

Nebulized liquids can be delivered to dogs and cats via face mask, or the animal can be placed in a closed tent or aquarium-type container. Nebulized aerosols also can be administered via tracheostomy tube. In general, the more removed the particle generator is from the respiratory tract, the more drug is lost outside the respiratory tract. Therefore, while tent/tank nebulization could be adequate for saline nebulization, medications should be administered via mask.

In small animal medicine, nebulizers most often are used for the treatment of respiratory infection. Simple saline nebulization could improve mucus fluidity and therefore function of the mucociliary escalator, but no proof of such efficacy exists in the veterinary literature. The author often treats animals with pneumonia with saline nebulization from one to four times daily. Nebulization also can be used for delivering medications including antimicrobial drugs, bronchodilators, glucocorticoids, or mucolytics agents (caution—not all liquid drug forms are suitable for nebulization!). Administration of drugs not specifically developed for inhalational delivery can be associated with adverse reactions including severe bronchoconstriction and with damage to the equipment. Antimicrobials designed for inhalational delivery (e.g., tobramycin [Tobi]) are prohibitively expensive for veterinary use. Aminoglycosides designed for intravenous administration often are used instead. Specific dosage recommendations have not been developed for nebulized antimicrobials. The author has used gentamicin 6 to 8 mg/kg, qs 5 to 10 mL in saline, via nebulization for animals with susceptible airway pathogens once daily as an adjunct to systemic antimicrobial administration. Bronchodilators and glucocorticoids for inhalational use are readily available for a reasonable price. Nebulization of mucolytic agents results in bronchoconstriction and thus is not routinely advocated. Pretreatment with bronchodilators might improve lower airway delivery of inhaled medications.

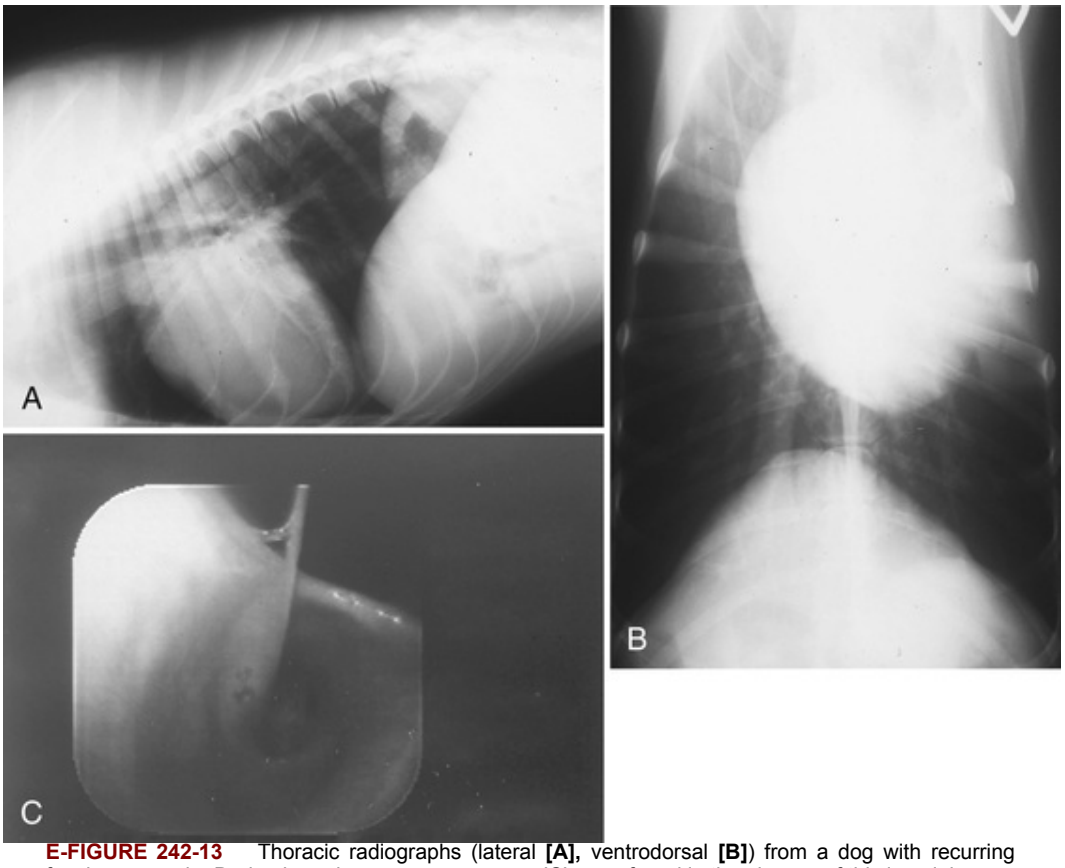
When nebulizers are used in the treatment of pets with contagious respiratory disease, the device itself must be kept meticulously clean to avoid iatrogenic transmission of respiratory infection. Nebulization of nosocomial pathogens could have devastating consequences for an animal with compromised respiratory function.

Cough is encouraged in animals with bacterial pneumonia, and cough suppressants are contraindicated. Coupage (i.e., thoracic physical therapy) is a simple technique of thoracic percussion that aids mobilization of airway secretions and encourages cough (Figure 242-12). Although not documented to be particulary efficacious in adult humans with pneumonia, it has been useful in other settings such as pneumonia associated with cystic fibrosis.[132] As far as the author is aware, there are no studies documenting efficacy of the technique in dogs or cats. Coupage should follow saline nebulization when both are used. Animals should be encouraged to move, and recumbent animals should be repositioned frequently, to aid in mobilization of respiratory secretions.

FIGURE 242-12 Thoracic percussion (i.e., coupage) can aid in the mobilization of airway secretions. Cupped hands are used to "clap" either side of the thorax (with force a bit stronger than used for applause) in a repeated fashion. Saline nebulization prior to coupage can further improve mobilization of secretions.

Additional therapeutic considerations for animals with pneumonia include bronchodilators, mucolytics, and nutritional and supportive care. Bronchodilators are not used routinely for the treatment of bacterial pneumonia. Either inhaled albuterol or oral methylxanthine bronchodilators (e.g., theophylline) are considered in animals that remain hypoxemic despite supplemental oxygen administration, when there is concurrent bronchoconstriction (especially likely in cats), or prior to administration of inhalant drug therapy. Bacterial pneumonia can result in the production of copious quantities of thick, tenacious mucus. Theoretically, liquefaction of mucus can result in more effective mucociliary clearance. Simple maintenance of systemic hydration and airway humidification typically are adequate, but mucolytic drugs sometimes are advocated. The mucolytic N-acetylcysteine (NAC) reduces viscosity by breaking mucin disulfide bonds, but unfortunately nebulization of NAC causes bronchoconstriction.[133] Oral administration of NAC has not been investigated in pets with naturally occurring pneumonia but in other species has demonstrated at least some utility in the treatment of both infectious and noninfectious airway disease associated with excessive mucus secretion.[134-136] The author has used oral NAC (available through health food stores) in animals with excessive mucus accumulation due to pneumonia at a dosage of 125 mg up to 600 mg PO q 8-12 h, to seemingly good effect. Animals with pneumonia might be reluctant to eat, and nutritional support must not be neglected.

Lung lobectomy occasionally is indicated for treatment when pneumonia fails to resolve with appropriate antimicrobial therapy.[137-139] Residual infection in a single lobe can be related to an underlying physical problem such as a bronchial foreign body, abscess, or tumor (E-Figure 242-13). Removal of the lobe can result in cure in such cases. Occasionally, failure to respond to appropriate antimicrobial therapy is the result of an incorrect diagnosis. Any lung tissue removed surgically should be submitted both for tissue culture and for histopathologic analysis.



E-FIGURE 242-13 Thoracic radiographs (lateral **[A],** ventrodorsal **[B]**) from a dog with recurring focal pneumonia. During bronchoscopy, grass awns **(C)** were found in the airways of this lung lobe.

Unique Pathogens Causing Bacterial Pneumonia

Bordetella bronchiseptica

B. bronchiseptica is a primary respiratory pathogen. Essentially, it creates its own opportunity to cause infection via secretion of exotoxins that result in dysfunction of the mucociliary escalator.[140,141] Bordetellosis is contagious; both dogs and cats are susceptible but disease is more common in dogs.[142,143] Infection usually results in tracheobronchitis but can cause severe pneumonia in immunocompromised or young animals (see E-Figure 242-10). In a retrospective study of community-acquired pneumonia in dogs <1 year of age, *B. bronchiseptica* accounted for nearly half of all cases.[105] These infections can be difficult to eliminate despite the use of antimicrobials with demonstrated *in vitro* susceptibility. Pneumonia has been demonstrated in *Bordetella*-infected puppies treated with amoxicillin or amoxicillin-clavulanate even though *Bordetella*'s susceptibility to these antimicrobials had been shown *in vitro.*[105] The addition of nebulized aminoglycosides to systemic antimicrobials has been proposed, but documentation of efficacy in treating *Bordetella* pneumonia is lacking. The use of inhaled antimicrobials should never replace systemic antimicrobial administration for the treatment of pneumonia. For more information, see ch. 97.

Streptococcus equi Subspecies Zooepidemicus

Streptococcus equi subspecies zooepidemicus can cause necrotizing hemorrhagic pneumonia in dogs and recently has been recognized to affect cats also.[144-146] Unlike other causes of contagious canine infectious respiratory disease complex, illness rapidly can become life-threatening.[147-150] The pathogen is particularly likely to cause severe and even fatal hemorrhagic pneumonia in kenneled dogs, including those in shelters and research colonies. As with other types of bacterial pneumonia, airway lavage can be used for identifying infection and guiding appropriate antimicrobial therapy. Dogs dying acutely, or with evidence of pneumonia, in a kennel setting should undergo necropsy with bacterial culture to confirm infection.

Mycoplasma

Mycoplasma species, fastidious microbes that lack a cell wall, include pathogenic (e.g., *Mycoplasma pneumoniae* in humans, *Mycoplasma hyopneumoniae* in swine) and commensal organisms. As many as 15 different species of *Mycoplasma* have been isolated from dogs, and many have been isolated from cats as well.[151] However, because these organisms are difficult to grow and difficult to speciate, their exact role in canine and feline respiratory disease is not well defined.

Mycoplasma species are found commonly in the upper airways and occasionally in the lower airways of healthy dogs and cats.[152-154] Experimental inoculation of some mycoplasmas causes pneumonia, and naturally occurring pneumonia in both dogs and cats occasionally has been attributed to *Mycoplasma* spp. (especially *Mycoplasma cynos*).[153,155-161] However, in a study of 93 dogs with bacterial pneumonia specifically tested for mycoplasmas, *Mycoplasma* species were recovered from only 7 dogs as the sole bacterium and from 58 dogs with additional non-*Mycoplasma* bacteria.[104] This, combined with a favorable clinical outcome even when antimicrobial therapy was not directed at *Mycoplasma* spp., suggests that *Mycoplasma* bacteria primarily were opportunists. Nonetheless, they might contribute to morbidity when present as coinfection with other respiratory pathogens.[151,157]

Special culture or PCR must be requested to identify *Mycoplasma* spp. Compared with culture, PCR identification of mycoplasma from respiratory specimens provided a sensitivity of detection of 81.8% with specificity of 78.9%.[125] *Mycoplasma* spp. usually respond well to macrolides, tetracyclines, chloramphenicol, and fluoroquinolone antimicrobials but do not respond to antimicrobials that interfere with cell-wall synthesis (e.g., beta-lactams), which this genus lacks.

Mycobacterial Pneumonia

Cats and dogs occasionally are diagnosed with mycobacterial pneumonia. Both tuberculosis (i.e., *Mycobacterium tuberculosis, Mycobacterium bovis, Mycobacterium microti*) and nontuberculosis-type (e.g., *Mycobacterium avium* complex, *Mycobacterium fortuitum*) mycobacterial infections cause pneumonia in pets.[162-174] Pneumonia can occur as the primary manifestation of mycobacterial infection or as a component of disseminated infection. Pneumonia due to mycobacteria often is granulomatous, and radiographs can demonstrate lymphadenomegaly and pleural effusion in addition to interstitial to alveolar pulmonary

infiltrates. Mixed pulmonary patterns are common, frequently including bronchial, alveolar, nodular structured interstitial, or unstructured interstitial components.[174] Organisms are found in low numbers, if at all, in samples retrieved by BAL or FNA, or aspiration of lymph nodes. Because they do not take up routinely-used stains, these acid-fast inclusions show up as negatively staining ("empty") rods on routine cytologic examination.[169,170,175] Both culture and PCR have been used for confirming the presence of mycobacterial species from dogs and cats, but tuberculosis-type mycobacteria are notoriously slow growing.[169,170,176,177] *M. tuberculosis* primarily is a human pathogen; when identified in dogs, it is considered a reverse zoonosis.[170,178] With such cases, the local health department should be contacted and owners of infected pets should be instructed to contact their physician. The public health implications of attempting treatment for tuberculosis-type mycobacterial infections must be thoroughly considered. Both tuberculosis and nontuberculosis mycobacterial infections require prolonged, multiple drug treatment regimens to achieve control. For more information on mycobacterial infection, refer to ch. 212.

Yersinia Pestis Pneumonia (Plague)

Practitioners in the midwestern and far-western United States, especially New Mexico and Colorado, must consider plague as a differential diagnosis in any cat with pneumonia. Although infection is relatively rare, its importance relates to zoonotic potential. Dogs are resistant to plague and seldom develop respiratory signs (although zoonotic transmission from dogs has also been reported).[179,180] Plague in domestic cats, on the other hand, has a mortality approaching 50% and can be spread to humans through contact or inhalation of aerosolized droplets.[181-183] Rodents (e.g., prairie dogs and squirrels) are the natural reservoir of the Gram-negative coccobacillus *Yersinia pestis.* Cats can be infected either by ingestion of bacteremic rodents or rabbits, or via the bite of infected fleas. Most commonly, cats that consume infected rodents develop suppurative lymphadenitis (buboes) initially in the submandibular and cervical nodes.[181] This bubonic form can develop into either a septicemic or secondary pneumonic form. Humans can develop primary pneumonic plague after inhalation of infected droplets from coughing cats. Untreated, pneumonic plague is uniformly fatal. In endemic regions, any cat with pneumonia should be strictly isolated and handled with extreme caution. Cytologic examination of exudate or lymph node aspirates typically reveals bipolar, safety-pin-shaped Gram-negative rods. The Centers for Disease Control and Prevention should be contacted if the diagnosis is suspected; confirmation relies on fluorescent antibody testing, culture, or rising antibody titer. Pending diagnosis, cats should be treated for fleas and antimicrobials should be begun immediately. Aminoglycosides, fluoroquinolones, chloramphenicol, and tetracyclines all have been used for the treatment of *Y. pestis.*

Viral Pneumonia

As opposed to bacterial respiratory infection, viral respiratory disease is caused predominantly by primary pathogens and is usually contagious. Some viral pathogens that cause pneumonia target the respiratory tract specifically (e.g., influenza), whereas other viruses are polysystemic (e.g., distemper virus, feline infectious peritonitis). Viral infections implicated as potential causes of pneumonia are listed in Box 242-8. Effective vaccines minimize morbidity associated with many potential causes of viral pneumonia. Although bacterial pneumonia is easily confirmed by routine cytology and culture of airway lavage, there is no single simple test with which to confirm viral pneumonia. Often, infection is merely presumed. Specifically targeted serologic or PCR tests are used for confirming infection more often than is viral isolation. Many of the viruses that cause pneumonia are pathogens of Canine Infectious Respiratory Disease Complex (i.e., CIRDC; see ch. 227) or also cause feline upper respiratory infections (see ch. 229).[184,185] Panels of PCR tests for many of these pathogens are available from many laboratories.

Box 242-8

Viral Infections Implicated in Infectious Pneumonia of Dogs or Cats

Avian influenza (rare)
Canine distemper virus
Canine herpesvirus
Canine infectious hepatitis
Canine influenza (H3N8 and H3N2)

Canine parainfluenza virus
Canine respiratory coronavirus
Feline calicivirus
Feline herpesvirus
Feline infectious peritonitis/coronavirus

Note: Feline leukemia virus and feline immunodeficiency virus lead to immunosuppression and secondary infectious pneumonia but do not directly result in viral pneumonia.

In many respects, bacterial and viral pneumonia are similar. In fact, much of the mortality associated with viral pneumonia results from opportunistic bacterial infections. Because there are few specific antiviral therapies, and little evidence to support the use of these expensive medications when they do exist, treatment of viral pneumonia is largely supportive. Dogs suspected of having viral pneumonia should be isolated due to the contagious nature of these infections. Additional information on viruses relevant to the respiratory health of dogs and cats can be found in ch. 227-230.

Influenza Virus

Until recently, influenza viruses were not thought to infect dogs or cats. In 2004, an outbreak of respiratory disease in a kennel of racing Greyhound dogs was found to be caused by H3N8 influenza virus.[186,187] Since that time, a number of other influenza type A viruses has been recognized to cause sporadic or experimental cross-species infection in dogs and cats.[188-191] Most have not resulted in sustained transmission within the species for which infection is newly recognized. However, H3N2 influenza, like H3N8, has developed the ability to spread from dog-to-dog, resulting in epidemics in Asia and the United States[188,192] (https://ahdc.vet.cornell.edu/news/civchicago.cfm; accessed July 20, 2015). Influenza viruses are RNA viruses adept at mutation either through spontaneous mutations or when one host is simultaneously infected with two viruses that become intermixed.[188,190,193] The H3N8 canine virus apparently originated as an equine influenza virus, while H3N2 seems to be of avian origin. Both of these viruses are highly contagious between dogs. Less is known about the course of disease in dogs infected with H3N2 than H3N8. For both, an acute onset of cough, fever, and lethargy are typical (E-Box 242-9). Morbidity is marked but mortality is uncommon. When fatalities occur, they often are related to opportunistic bacterial pneumonia. It does not appear that H3N8 is zoonotic, but the possibility of multiple reassortment events means that veterinarians must remain vigilant to this eventuality.[192,194] Although specific antiinfluenza drugs are available commercially (e.g., oseltamivir phosphate [Tamiflu]), their use is not encouraged. These costly drugs have not been evaluated in canine influenza. Even when used as labeled for human influenza, they must be administered within 48 hours of illness and result in only minor reductions in disease duration and severity. Inactivated canine influenza vaccines directed at H3N8 or H3N2 are available. Protection from canine influenza currently requires administration of each vaccine type as there is no combined canine influenza vaccine.

E-Box 242-9

Diagnosis of Canine Influenza Virus (CIV) H3N8 and H3N2

1. Serologic diagnosis
   Unvaccinated dogs are assumed to be naïve to CIV, so recognition of antibodies to CIV strongly supports infection. However, antibody formation lags behind clinical signs, resulting in false-negative tests early in the disease course. Therefore, although a single positive titer can be used for confirming infection, it cannot be used for ruling out infection during illness. When both acute and convalescent titers are obtained, serologic testing is the most sensitive means of CIV diagnosis. Hemagglutination inhibition tests that are specific to each virus subtype are offered commercially and may be combined as part of a testing panel (e.g., Cornell Animal Health Diagnostic Center).
2. Antigen identification
   The influenza A nucleoprotein is shared between CIV and human influenza infections, allowing the use of human point-of-care enzyme-linked immunosorbent assay influenza tests in dogs. Samples from nasal or nasopharyngeal swabs or lavage may be used in these kits (e.g., QuickVue Quidel, Directigen Flu-A test by Becton-Dickinson). Unfortunately, these tests are only positive during viral shedding. Shedding occurs early in the disease (peaking at 2-3 days post-infection) and is

inconsistent, resulting in frequent false-negative tests.

3. Virus isolation
   Virus isolation is the gold standard method of testing for viral infection and has the advantage of being able to potentially detect any subtype of influenza. Sampling requirements vary by laboratory. Virus isolation depends on the presence of virus in the submitted sample, so false-negative results are possible because influenza is shed only for the first several days of illness.
4. Polymerase chain reaction (PCR) identification
   Real-time PCR testing can be conducted on samples from nasal or pharyngeal swabs to identify nucleic acid sequences. Often, individual PCR tests are combined into a panel of tests for a variety of respiratory pathogens. Here too, testing will only be positive during viral shedding, which can lead to false-negative test results. The specificity of PCR depends on primers used for the reaction. Most commercial laboratories now use primers that will detect either H3N8 or H3N2, but PCR might miss other subtypes of influenza.

   Antigen detection, virus isolation, and PCR identification of CIV are all prone to false-negative results. During an outbreak in a kennel, sampling multiple dogs (10% to 30% of those affected) and sampling as early as possible in the course of disease will improve diagnostic accuracy.

Influenza is recognized less frequently in cats than in dogs, but cats are susceptible to natural and experimental infection with several types of influenza A.[195-197] Cats have been infected with virulent avian influenza H5N1 both from consumption of infected poultry and through direct cat-to-cat transmission, and the resultant illness often is life-threatening.[197-201] Veterinarians should be vigilant for possible influenza virus infection in pets, both because of the resultant illness in the examined animal, and also because of the potential for contagion to other pets and zoonotic infection of in-contact humans (E-Box 242-10).[196,200]

E-Box 242-10

Feline Influenza

Until recently, cats were not thought to be susceptible to influenza virus.[443] We now know that cats are susceptible to both experimental and natural infection with several different strains of influenza A, resulting in manifestations ranging from subclinical infection to severe illness or even death.[192,198,199,444-450] Fortunately, sustained transmission of influenza from cat-to-cat remains rare.

During the 2005-2006 epidemic of highly pathogenic avian influenza H5N1 in Asia, the virus was documented to infect domestic cats via experimental inoculation, by feeding on infected birds, and importantly, by direct transmission between cats.[201,444] Although many cats develop subclinical infection, others develop extensive pulmonary damage and multifocal organ hemorrhage and necrosis. Neurologic signs including ataxia and seizure in naturally infected cats likely result from nonsuppurative encephalitis. More common signs include fever, depression, elevation of the third eyelids, conjunctivitis, increased respiratory effort, nasal discharge, and icterus. Sudden death can occur within days of infection.[201,444,451]

Domestic cats also are susceptible to the 2009 pandemic seasonal human H1N1 influenza virus, as well as other types of human seasonal influenza.[197,452-454] Although experimental infections produce only minimal to mild disease, there are reports of naturally infected cats with moderate to severe respiratory illness.[197,454,455] In serosurveys from the USA and northeastern China, as many as one third of tested pet cats demonstrated antibodies to seasonal H1N1 influenza.[449,453,454]

There are many other causes of an acute onset of respiratory signs in cats (e.g., herpesvirus, calicivirus, bacterial pneumonia) that are more likely than feline influenza infection, but veterinarians must be vigilant to this possibility. Besides H5N1 and H1N1, cats are susceptible to many other influenza subtypes, including canine influenza.[188,450,454,456-460] Documented influenza infections in birds in the area, respiratory illness in human household contacts, and/or high fever should increase the index of suspicion for influenza in ill cats. Viral isolation from oropharyngeal or rectal swabs, necropsy specimens, or RT-PCR are typical methods of confirmation. Immunohistochemistry can be used on infected organs. Serologic diagnosis using hemagglutination inhibition also is possible. Treatment would be largely supportive. Thus far, transmission of any influenza from infected cats to humans has not been

documented.[200,448]

Protozoal Pneumonia

Protozoal pneumonia is not common among dogs or cats. Of the protozoal pathogens that do cause pneumonia, toxoplasmosis is the most frequently encountered. Cats are the reservoir host for *Toxoplasma gondii* and often are infected without displaying clinical illness.[202] When illness does occur, it can involve the gastrointestinal tract, the central nervous system, the abdominal viscera, heart, eyes, or the respiratory tract. Respiratory manifestations of interstitial pneumonia, either acute or slowly progressive, are among the most common.[203,204] Results of routine laboratory testing vary with organ involvement. Serologic identification of specific IgM supports active disease, but both false-positive and false-negative tests occur.[205] Occasionally, *T. gondii* tachyzoites are identified in airway lavage from animals with pneumonia.[204,206,207] Rapid response to treatment with potentiated sulfonamides or clindamycin is expected, but recurrence is possible. More information on *T. gondii* can be found in ch. 221.

Mycotic Pneumonia

A variety of systemic fungi (especially *Blastomyces dermatitidis, Histoplasma capsulatum,* and *Coccidioides immitis*) can cause mycotic pneumonia in dogs and cats.[208-210] Slowly progressive lower respiratory disease can be the primary manifestation, but extrathoracic manifestations including weight loss and lymphadenopathy also are common (E-Table 242-4). Radiographic changes associated with mycotic pneumonia vary greatly (E-Figures 242-14 to 242-16) and often include nodular or miliary nodular interstitial lung patterns and hilar lymphadenopathy. Treatment is expensive and potentially toxic; therefore, a definitive rather than a presumptive diagnosis is important. Because interstitial mycotic infections do not result in early exfoliation of fungal elements into the airways, airway lavage is not a sensitive technique for identification of fungal elements. Diagnosis often is confirmed from other sites (e.g., lymph node aspirates, impression smears of dermal lesions). Recently, relatively sensitive and specific urine fungal antigen tests have become available to aid in the diagnosis and therapeutic monitoring of mycotic pneumonia.[211-213] Please see ch. 162 and 231-236 for more detail.

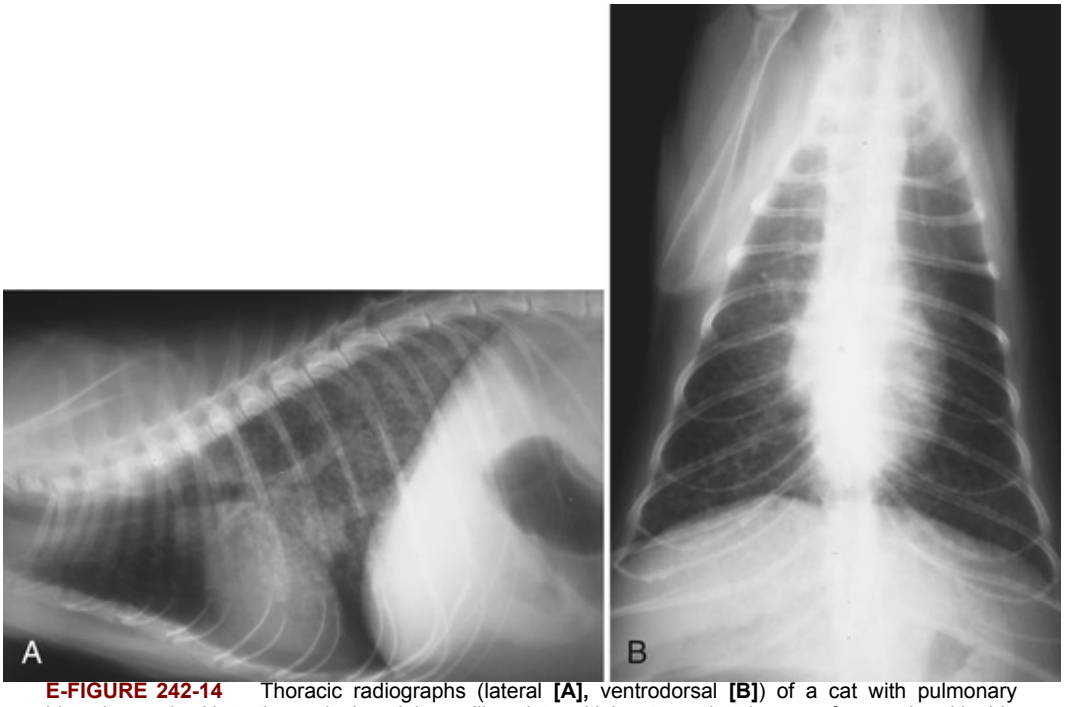
E-TABLE 242-4

Most Common Systemic Mycoses of Dogs and Cats

	GEOGRAPHIC DISTRIBUTION	COMMON SITES OF EXTRAPULMONARY INFECTION	CYTOLOGIC MORPHOLOGY	SPECIES AFFECTED
Blastomycosis	Mississippi, Missouri, and Ohio River Valleys; mid-Atlantic states; Canadian provinces of Alberta, Quebec, Manitoba, and Ontario; Africa; and Central America	Lymph nodes, skin, bones, eyes	Thick-walled, broad-based budding yeast (7-15 micron diameter)	Dogs > cats
Histoplasmosis	Mississippi, Missouri, and Ohio River Valleys, Central and South America	Gastrointestinal tract (especially dog), eyes, bone marrow (especially cats), liver and spleen	Multiple round bodies (2-4 micron diameter) with basophilic center and clear, thin outer rim contained within phagocytic cells, narrow-based budding	Cats = dogs
Coccidioidomycosis	Southwestern United States, Mexico, Central and South America	Perihilar lymph nodes, bones, CNS, heart/pericardium, skin, eyes	Very small numbers of organisms found. Round, double-walled spherules (2-200 micron diameter) containing endospores (1 micron diameter).	Dogs > cats

Systemic aspergillosis	Worldwide distribution	Bone, spine, lymph nodes, kidney, spleen, pancreas, liver	Septate hyphae (2-3 micron wide) with parallel walls and dichotomous branching	Dogs > cats
Cryptococcosis	Worldwide distribution	Nasal cavity (cats) CNS and eyes (dogs)	Round to oval yeast (4-10 micron diameter) with thick clear capsule; narrow-based budding can be seen	Cats > dogs

CNS, Central nervous system.



E-FIGURE 242-14 Thoracic radiographs (lateral **[A],** ventrodorsal **[B]**) of a cat with pulmonary histoplasmosis. Note the typical nodular, miliary interstitial pattern that is seen frequently with this infection. (Courtesy Dru Forrester, Blacksburg, VA.)
