a failure of luteal P4 to be maintained at necessary concentrations for an appropriate length of time, normally 63 days from ovulation to maintain pregnancy. Serum P4 concentrations may decrease to <2.0 ng/mL shortly after ovulation (in late estrus) or at any time during diestrus. Although rare, luteal insufficiency has been reported in pregnant, but not non-pregnant bitches.[78-82] Causes of canine luteal insufficiency have not been reported. In first-trimester women, luteal insufficiency may be due to polycystic ovarian disease. Thyroid and prolactin-related disorders have been demonstrated. It may follow use of GnRH analogs in assisted reproduction. Premature luteolysis had been reported in bitches treated with deslorelin to induce estrus but there is a lack of information on other potential endocrine or stress-related causes of this condition.[83-85] Diagnosis of luteal insufficiency in mated bitches requires elaborate diagnostics as other potential causes of low P4 concentration must be ruled out: e.g., fetal distress or fetal death may result in decreased P4 concentration as a normal physiologic response; therefore fetal viability and viral or bacterial conditions affecting fetal or maternal health must be ruled out.[86] In mated bitches where hypoluteoidism is a concern, serum P4 should always be assayed after pregnancy is confirmed on routine ultrasonography. Assaying serum P4 concentrations when a bitch is found not pregnant on routine ultrasound will help rule in/out luteal insufficiency.

Birth of normal healthy litters has been achieved in hypoluteoid pregnant bitches using parenteral progesterone in oil (2 mg/kg IM every 3 days [range 2-4]),[75,78] oral megestrol acetate (2.2 mg/kg q 48 h from day 25 onward),[80] ally-trenbolone (0.088 mg/kg PO daily),[82] and medroxyprogesterone acetate (0.1 mg/kg PO daily).[53,81] The authors have successfully used oral micronized progesterone capsules (Prometrium Merck; 100 mg/dog or 5 mg/kg q 12 h). During therapy, serum P4 concentrations should be assayed every 2-3 days. It is estimated that additional medication is needed if serum P4 concentrations drop <15.0 ng/mL during weeks 3-7 of pregnancy or <5.0 ng/mL in weeks 8 and 9. When supplementing with a progesterone that can be monitored via blood testing, trying to maintain a normal progesterone profile during the second half of pregnancy is ideal, with peak values of 15-20 ng/mL around mid-pregnancy followed by a slow decline to 5 ng/mL during the last week of pregnancy. All supplements should be discontinued 2-3 days prior to the bitch's due date to allow normal whelping. During the first month of gestation, the use of natural progesterone compounds is preferred to reduce risk of congenital fetal malformations. Use of synthetic compounds is regarded as safe in the second half of pregnancy.[87] Synthetic compounds have the advantage of patient serum P4 concentrations reflecting endogenous production.

Persistent Estrus

Persistent manifestations of estrous behavior can be iatrogenic (i.e., due to treatment with GnRH agonists or estrogens) or may occur naturally during estrus.[88,89] The latter is usually due to an abnormality of ovarian function, characterized by estrous behavior, a fully keratinized vaginal smear and low (pre-ovulatory) serum P4 concentrations that persist for >21 days. Causes of persistent estrus can be ovulation failure, the “slow rise in P4” syndrome, or conditions such as ovarian follicular cysts or granulosa cell tumors. Diagnosis of persistent estrus can be challenging when due to anovulation or slow P4 rise, requiring careful assessment of history as these conditions may go unnoticed prior to presentation, while ovarian abnormalities (follicular cysts or ovarian neoplasia) are easily diagnosed by ultrasound.

Other than the suggestion that persistent estrus may resolve naturally, treatment has not been described. Hormonal preparations stimulating follicular growth (e.g., pregnant mare serum gonadotropin) should not be used as they may further increase estradiol secretion, increasing risk of bone marrow arrest and/or pyometra. Use of human chorionic gonadotropin (hCG; 22 IU/kg IM once daily for 3 days) has been anecdotally reported as effective in terminating estrus by triggering onset of diestrus or anestrus.[90] We have used a combination of hCG (500-1000 IU IM, 2 doses, 48 h apart) and GnRH (1.5 mcg/kg IM q 24 h × 4 days; or placement of a 2.1-mg deslorelin implant until luteinization is documented: progesterone >5 ng/mL). Rarely, ovulation occurs. More commonly, luteinization of follicles or a follicular cyst allows the bitch to exit estrus. Fertile ovulation is unlikely because oocytes have degenerated by the time diagnosis is made and therapy started. Breeding or insemination should not be done.

Prognosis for fertility following a persistent estrus is anecdotally reported as poor. It still may be worth attempting natural breeding on the next estrus, if preceded by a normal interestrous interval. Pyometra has been reported in a bitch with persistent estrus following successful hCG treatment. Ovariohysterectomy is always an option for successful resolution.

Short Interestrous Intervals

Interestrous intervals vary with breed and within breeds. Intervals of 4 months between consecutive heats are considered normal in some bloodlines of German Shepherd, Rottweiler, Akita, Labrador Retriever, Cocker Spaniel, and Basset Hound, despite their more common interestrous intervals of about 6 months. Short interestrous intervals in these and other individual bitches are an occasionally described.[53,91] Bitches with short interestrous intervals have a tendency of brief luteal function.[91] Incidence of this condition is unknown, but may occur in as many as 5-10% of healthy dogs. Causes of short interestrous intervals are unknown but the role of ovarian progesterone production is likely to be relevant. It has been suggested that "a progesterone rise of sufficient amplitude and duration is necessary to be recognized as a cycle by the hypothalamus and institute an anestrus of sufficient duration (>3 months) for a normal interestrous interval."[75] A subsequent study concluded that bitches with short interestrous intervals have a tendency towards deficient luteal function.[91] Therefore, a direct relationship between length of diestrus and length of anestrus is likely.

Anestrus plays an important role in uterine involution and resumption of cyclicity. In the non-parous bitch, endometrial repair is complete about 135 days after the onset of estrus. The number and amplitude of hypothalamic GnRH pulses and pituitary and ovarian responsiveness increases as anestrus progresses.[32,73] A short anestrus will shorten the duration of the interestrous interval, thereby negatively affecting fertility of the subsequent cycle by preventing normal endometrial repair to be completed and/or a normal response of the hypothalamic-pituitary-ovarian axis. Fertility following a short interestrous interval may be decreased. Diagnostically, karyotyping should be considered as chromosomal abnormalities may cause short interestrous intervals and infertility.[92,93] Successful management has been reported by giving mibolerone at least 30 days prior to the next anticipated cycle, daily, as needed.

Breeding Management

Pre-breeding

Age of First Breeding

The age recommended for a first mating depends on breed, use, health and owner preferences. It is recommended that small and toy breeds be >18 months of age and medium-giant breeds >24 months. These recommendations should allow full maturation and growth of the bitch prior to becoming pregnant. While puberty may occur long before these ages in most breeds, physical and psychologic development is not complete and the negative effects of pregnancy are permanent.

Genetic Testing

Necessary tests vary with breed and may include radiographic screening (e.g., OFA and PennHIP), specialist evaluation (e.g., cardiology, ophthalmology), and genetic screening of blood, hair or cheek swabs (e.g., OptiGen, PennGen, VetGen) (see ch. 3 and 4).[94] If concerns are raised by genetic test results, the breeder must consider these concerns. There is no perfect dog, so there are times when breeding an animal with a genetic disorder may be acceptable to introduce specific preferred traits into the bloodline or breed. Careful consideration of the mate for these individuals can reduce the risk of passing on the disorder to the offspring (i.e., breeding an affected animal to one free of disease).

General Health and *Brucella* Testing

Complete blood counts (CBC), serum chemistries and urinalysis are recommended, particularly when breeding bitches >4 years of age. Specifically, bitches should be screened for renal disease since the renal and ovarian arteries arise from the same vessels and pregnancy may divert blood away from the kidneys in favor of the gravid uterus. Urinalysis, urine microalbuminuria, and/or urine protein : creatinine ratios are recommended in older bitches. Other specific tests may depend on the area where the bitch resides (i.e., tick titers, heartworm testing). Thyroid testing is generally not necessary unless there are clinical signs, since it has been documented that hypothyroidism has little impact on fertility (may impact the length of stage 2 and 3 labor).[95-103] Since autoimmune thyroiditis may have a genetic basis, bitches with thyroid disease should be evaluated. Those with clinical hypothyroidism due to idiopathic thyroid atrophy may be bred following treatment with thyroid replacement hormone and confirmation of an acceptable response. They should then have thyroid concentrations monitored monthly during pregnancy, since pregnancy affects metabolism and may increase the demand for thyroid supplementation. Both bitch and male should be tested for brucellosis

within 8 weeks of breeding (see ch. 213).[104-106] Brucellosis may be spread by aerosol contact or breeding. Screening tests include the rapid slide agglutination test (RSAT), enzyme-linked immunosorbent assay (ELISA), and tube agglutination test (TAT). If positive, confirmatory testing can be performed (agar gel immunodiffusion test [AGID], blood cultures, polymerase chain reaction [PCR]).

Physical Examination

A complete physical examination of the bitch and dog should be performed prior to breeding to ensure both are adequately healthy for breeding and that the bitch is able to carry pregnancy to term (see ch. 2). Special attention should be paid to body condition. Obese bitches have reduced ovulation rates, decreased stamina, may have more difficulty breathing in late pregnancy when the gravid uterus compresses the diaphragm. Overweight bitches (see ch. 176) have a higher incidence of uterine inertia and obstructive dystocias due to increased pelvic fat. Obese males may not have the stamina or capability to accomplish a natural breeding. Scrotal insulation with fat may affect semen quality. The mammary glands should be palpated for masses or other abnormalities and a digital vaginal exam should be performed to rule out the presence of vestibulo-vaginal strictures, septa, hymenal remnants, vulvar strictures, vaginal masses or cysts or other impediments to copulation or whelping.

Ovulation Timing and Semen Management

Ovulation timing is recommended for all breedings to minimize the matings needed, conserve sperm, maximize use of males, reduce the number of sperm inseminated into bitches predisposed to mating-induced endometritis, improve rates of conception, maximize litter size, allow determination of a whelping date window (see Tables 312-1 and 312-2; see also Figures 312-1, 312-2, and 312-3). Knowing the whelping date is valuable for elective or emergency C-sections, management of high-risk pregnancy, and provision of care during whelping by the caregivers and the veterinary team. For breedings using fresh semen, ovulation timing does not need to be as closely monitored as for chilled or frozen semen because sperm survive for extended periods in fresh semen as opposed to chilled or frozen semen. Also, unlimited access to the male should maximize conception rates. In situations where the male is being bred to multiple females at the same time, closer monitoring is indicated to maximize sperm quantity for each breeding. Frozen semen breedings require the most accurate ovulation timing because sperm survival is brief, usually only 8 to 12 hours, making it imperative that all oocytes have been ovulated and are mature enough for fertilization prior to insemination.

Behavior and Physical Changes

Best conception rates are achieved by combining behavior assessment with physical changes, perineal anatomy, vaginal cytology, vaginal speculum examination, P4 concentrations and LH testing (see ch. 119). These complimentary techniques offer the best opportunity to accurately determine the fertile period by timing from the onset of ovulation. While there is a typical pattern that the majority of bitches follow, exceptions in healthy normal bitches do occur. In early proestrus (and sometimes for up to a month before) males are attracted to the female perineal area and areas where she urinates. Urine marking behaviors increase as the bitch approaches and enters proestrus. The vulvar lips will begin to swell and vulvar discharge will begin. Initially, the bloody discharge is dark red/dark brown. Its source is the uterus due to increased capillary fragility as a result of increasing estrogen concentrations. As the bitch progresses from proestrus to estrus, bleeding decreases and the discharge becomes more straw colored. Some bitches stop bleeding during the fertile period while others will bleed through the fertile period into diestrus. As the bitch gets closer to the fertile period, the vulvar edema subsides resulting in softening of the vulvar lips, allowing intromission. Bitches with a hooded or infantile vulva may have improved conformation during estrus or the vulvar opening may continue to make natural breeding difficult.

Breeding behavior by the bitch and the highest male interest coincides with changes in the estrogen (E2):progesterone (P4) ratio. E2 concentrations begin to decrease prior to the rapid rise in P4, causing receptive behavior. Bitches with atypical cycles (short or long proestrus or estrus) may not appropriately correlate receptive behavior with their fertile period. This can be mistaken by breeders who believe the male can determine when the bitch ovulates. However, due to survival of sperm in the bitch's reproductive tract as long as 11 days, breeding up to 7-10 days before ovulation may still result in pregnancy.[107-109] If the breeder believes that the bitch was bred at ovulation when she was actually she was bred much earlier, calculated due dates (based on breeding dates) will be significantly early. For these reasons, veterinarians must use extreme

caution determining due dates from breeding dates. As a general rule, the bitch's due date can be anywhere from 54-72 ± 2 days from any given breeding date.

Use of Vaginal Cytology (see ch. 119)

Slides for vaginal cytology should be obtained beginning 5-8 days after the bitch starts having bloody discharge or earlier in bitches with a history of early ovulation. Some bitches may not bleed much, some may pool blood in the cranial vagina, some lick meticulously and remain free of blood in the perineal region, and sometimes the first few days of the cycle are missed by inattentive or inexperienced owners. If there is swelling and male interest for several days, performing an early cytology (and speculum exam) will ensure that the early stages of the cycle were not missed. Cytology should be done every 2-4 days until there are at least 50% superficial cells, at which point P4 testing should be added. Use of vaginal cytology should be continued at least every 2-4 days to ensure that the cycle is progressing normally. Cycle abnormalities will typically be noted on cytology long before endocrine results indicate any concern (e.g., split heat or anovulatory cycles). Vaginal cytology can also be used to document day 1 of diestrus, which is as useful as progesterone in determining a bitch's due date, especially if the day of ovulation is missed (see progesterone section).

Use of the Vaginal Speculum Examination

Speculum examination can be performed simply using an otoscope and clean otoscope cone and should be performed each time a cytology is obtained (see ch. 44 and 119). Progression from a pink edematous mucosa in early proestrus to a white and prominently crenulated mucosa is another indicator that the cycle is progressing normally. The rate at which the changes occur are an indicator of the development and maturation cycle of the follicles. These changes, coupled with cytology, P4 concentrations, and behavioral changes help the practitioner determine when to see the bitch for the next ovulation timing appointment. Once ovulation is confirmed, continuing to do cytology and speculum examinations can help determine diestrus day 1, as the mucosa begins to flatten and becomes a blotchy pink on this transitional day.

Progesterone (P4) Monitoring

Early in proestrus, P4 concentrations are basal; typically <1 ng/mL (when reported in nmol/L divide by 3.14). As follicles become mature, small pulses of LH begin to cause pre-luteinization of the follicular wall, resulting in a slow but gradual rise in P4. Once the follicles are mature, the pre-ovulatory LH surge is stimulated. Generally, when the P4 doubles from basal, the LH surge is likely (see Tables 312-1 and 312-2). Once ovulation occurs, P4 concentrations increase rapidly for 2-3 weeks. The rise in P4 between the LH surge and ovulation is more gradual than the rise after ovulation. Some bitches have a plateau in P4 between 2 and 8 ng/mL for one or more days, making it critical that P4 be monitored until ovulation is confirmed by a rise of 3 or more ng/mL in a 24-hour period. It is important to remember that ovulation does not occur at any specific P4 value, but rather is confirmed by a rapid and progressive rise, typically of 3 or more ng/mL in a 24-hour period once it reaches about 4-10 ng/mL. After the initial post-ovulation increase, daily changes may be faster or slower. Occasionally, the P4 may only rise by 2-2.5 ng/mL on the day(s) post-ovulation. Addition of LH testing on these bitches may be helpful. P4 testing can be done less frequently in early-mid-proestrus (every 3-5 days). Once cytology indicates the majority of cells are superficial it should be performed more frequently. Once progesterone reaches the ovulation range (3-5 ng/mL), daily to every other day testing is recommended.

Luteinizing Hormone (LH) Monitoring

LH is initially released in small pulses during mid-proestrus, followed by a large pre-ovulatory surge in late proestrus-early estrus, lasting 12 to 96 hours. The LH surge is usually followed 2 days later by ovulation. Because of the variability in LH surge duration, daily blood draws are necessary for documentation and its beginning is considered the inciting event for ovulation, so even if a surge is 2-3 days long, using the first day as “day 0” is correct when ovulation timing. LH testing is typically performed using a membrane flow assay (Witness LH, Zoetis Corp; see Figure 312-2). The in-house test kit is useful because it allows for interpretation of the intensity of the color change compared to the control, as well as reducing turnaround time, which can be quite limiting. In some, the LH surge must be identified by extrapolating from P4 data. Remember that a LH surge does not ensure ovulation. So, it is critical to always confirm ovulation by assessing P4 concentrations. Waiting until ovulation is documented helps reduce the number of LH tests to be run.

Artificial Insemination

See ch. 118 and E-Box 312-1.

E-Box 312-1

Artificial Insemination (AI)

Advantages of AI include prevention of injury or transmission of disease between the bitch and dog; it allows the semen to be evaluated prior to insemination to ensure that fertility is adequate and that the AI technique being performed is appropriate for the semen quality; it allows for semen to be shipped to the bitch rather than shipping the bitch to the dog or vice versa, thereby reducing shipping stress and transportation costs; it increases the number of bitches that may be bred at the same time by a single male.[206] Disadvantages of AI include increased time and labor for collection, evaluation, preparation and insemination; increased costs of equipment and staff; requisite training for programs to be successful.

Artificial insemination may be performed using one of 3 techniques: vaginal AI (VAI), transcervical AI (TCAI), or surgical AI (SAI).[207-215] Either TCAI or SAI may be used to bypass the cervix and inseminate directly into the uterus. This is advantageous when the cervix may be closed towards the end of the fertile period but while oocytes are still viable for fertilization.[23,216,217] Vaginal AI is typically used for males with normal semen quality and sperm numbers being bred to bitches with normal fertility.[213,214] The larger the bitch, the more vaginal folds and vaginal capacity, thus the greater the number of sperm needed for successful AI. With VAI, an insemination pipette is passed over the urethral orifice using the guidance of a finger in the vaginal canal, into the mid-vagina and the sperm is deposited. Care must be taken to not mistakenly pass the pipette into the urethra. After insemination, the bitch's hindquarters are often elevated for 10-20 minutes to facilitate the ejaculate volume "bathing" the cervix with fluid; however, this practice may not be necessary for success.[218] After insemination, feathering (stroking the dorsal wall of the vaginal canal) is performed to elicit uterine contractions that will facilitate sperm transport to the oviductal reservoirs. Vaginal AI may be used for fresh or fresh-chilled semen, but is not recommended for frozen semen because sperm numbers in each breeding dose are so low that it requires multiple breeding doses (at least 3-5) for each breeding and also because motility of frozen semen is thought to be lower than motility of fresh semen which may delay or make it very difficult for frozen/thawed sperm to cross the cervix.

Transcervical insemination involves either the use of an endoscope to visualize the cervix or the Norwegian catheter, where the cervix is cannulated blindly using a rigid catheter system.[207,209-211] Both techniques require significant training. Endoscopic equipment is expensive but with the newer endoscopes (ureteroscope), bitches of any size or weight can be inseminated while with the older style (cystourethroscope), it may be impossible to inseminate bitches under 25 pounds and some of the largest giant breeds. Occasionally, the position of the cervix may preclude catheterization but with practice, almost 100% of bitches can be catheterized with the newer scopes. TCI is beneficial for poor quality semen; fresh, fresh-chilled, or frozen semen of any quality; and with subfertile bitches (to ensure intrauterine insemination [IUI]). Insemination volumes have traditionally been small, but use of larger volumes has recently been recommended to more closely approximate what occurs with natural breeding. Slow, steady insemination techniques allow the use of much larger volumes of inseminate. Most bitches stand quite readily for the procedure, although rarely, very nervous bitches may require very light sedation. Location of insemination (intrauterine) is exactly the same for TCAI and SAI.

Surgical insemination requires the use of general anesthesia and a midline laparotomy.[208,210,212,215] This allows for direct visualization and palpation of the uterine horns to assess for pathology and possibly address any problems that are found. Because the ovaries are surrounded by the ovarian bursa, their direct visualization is not possible. The inseminate volume used is much lower because uterine tone is very high and the lumen does not distend well. Semen may be deposited equally into both horns, into the uterine body or into one horn. Care should be taken to not extravasate any sperm into the abdominal cavity as this can cause a sperm peritonitis.[219] SAI can be used with any type of semen but is more commonly used with poor quality semen, very low sperm numbers and with frozen semen.

Insemination Frequency

Natural breeding or use of fresh or fresh, chilled semen should be performed once or twice, beginning 2 days post-ovulation (4 days post-LH) and again 2 days later. Planned single inseminations (including surgical insemination) are usually done in the middle to end of the fertile period. Frozen semen breedings should be performed only after complete maturation of all oocytes; day 3 or 4 post-ovulation (days 5 or 6 post-LH surge).

Strategies for Misalliance (Figures 312-4 and 312-5)

Confirm Pregnancy

If an accidental breeding occurs, it is ideal to examine the dog as soon as possible for vaginal cytology and a serum P4 concentration. This allows staging of her cycle and helps determine likelihood of pregnancy being established. Sperm are often seen on vaginal cytology if the bitch was bred recently. If she is in early in proestrus or diestrus, pregnancy is unlikely. If she is in estrus, pregnancy is quite likely if she was actually bred. Before initiating pregnancy termination, pregnancy must be confirmed (see ch. 315). Only about 60% of bitches seen for pregnancy termination are pregnant after an unwanted mating, likely because they were suspected as having mated, but did not. Palpation, even by experienced clinicians, is not perfect. Thus, pregnancy should be confirmed via ultrasound (US; as early as 19 days post-LH), relaxin test (100% accurate >30 days of gestation) or radiographs (after day 43 post-LH).[110-115]

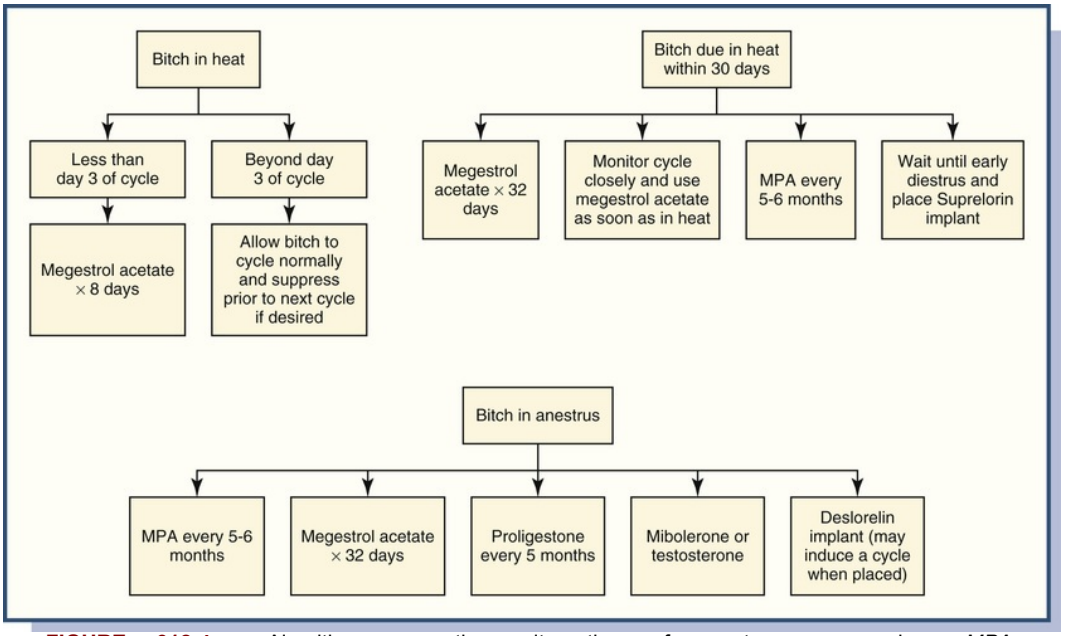

FIGURE 312-4 Algorithm presenting alternatives for estrus suppression. *MPA,* Medroxyprogesterone acetate.

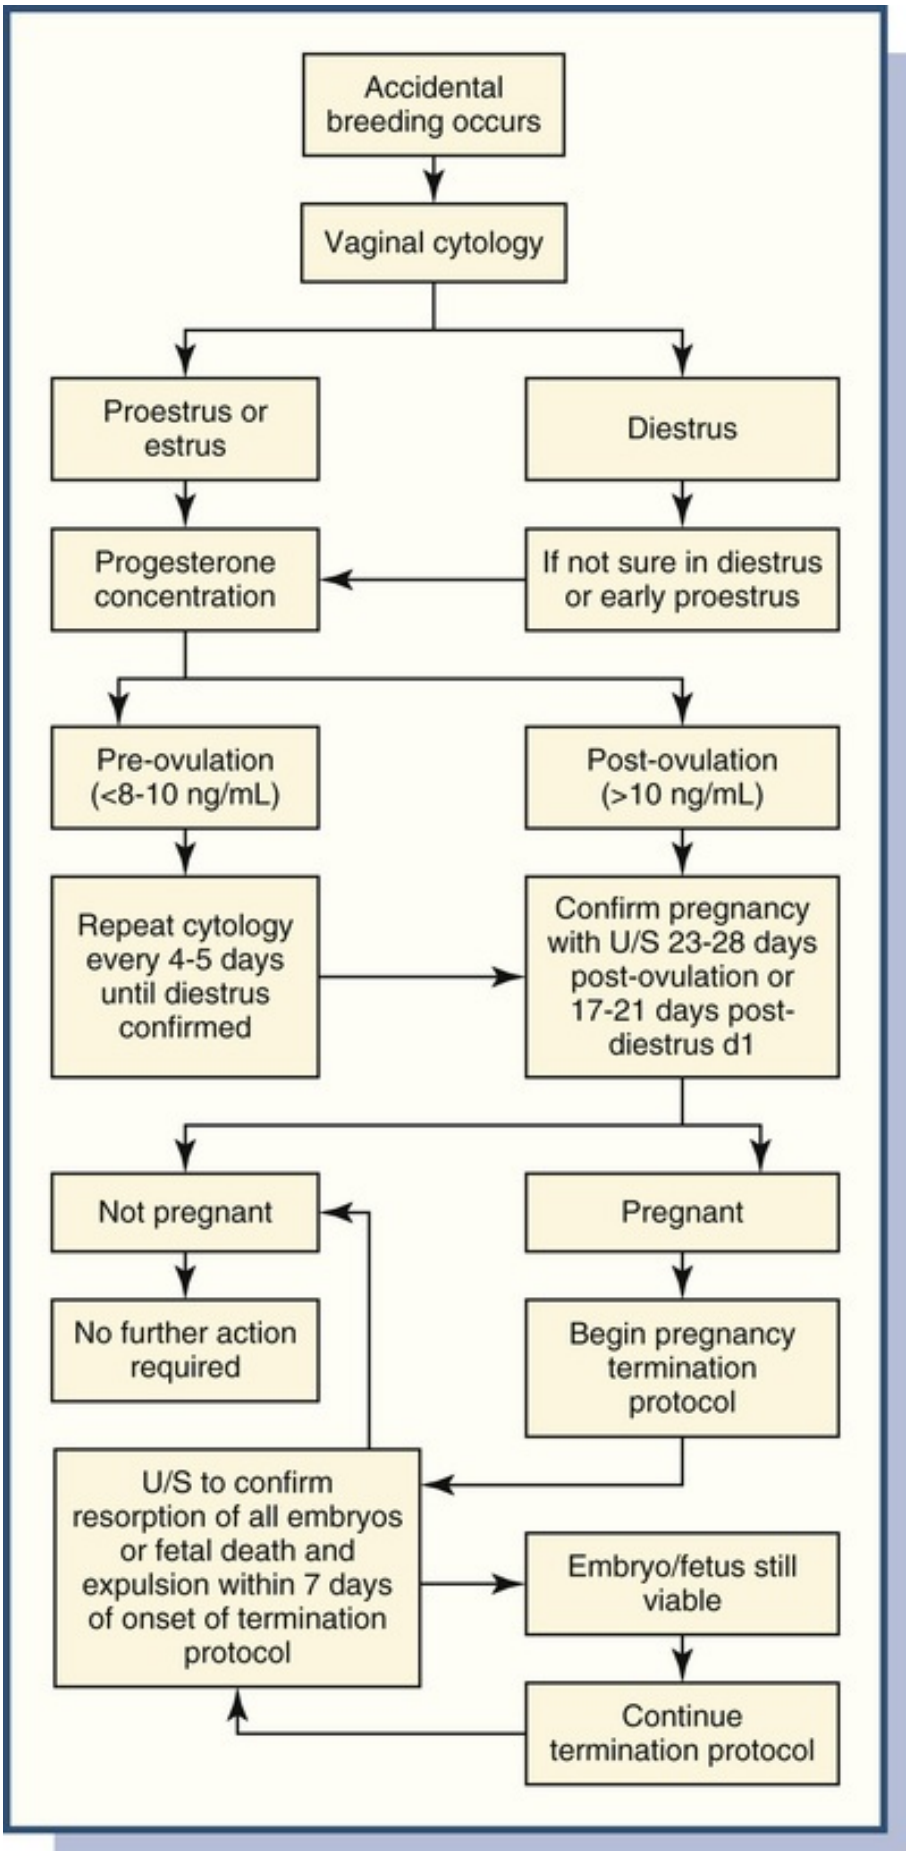

Accidental breeding occurs
Vaginal cytology
Proestrus or estrus
Diestrus
Progesterone concentration
If not sure in diestrus or early proestrus
Pre-ovulation (<8-10 ng/mL)
Post-ovulation (>10 ng/mL)
Repeat cytology every 4-5 days until diestrus confirmed
Confirm pregnancy with U/S 23-28 days post-ovulation or 17-21 days post-diestrus d1
Not pregnant
Pregnant
No further action required
Begin pregnancy termination protocol
U/S to confirm resorption of all embryos or fetal death and expulsion within 7 days of onset of termination protocol
Embryo/fetus still viable
Continue termination protocol

FIGURE 312-5 Algorithm presenting recommendations for pregnancy termination in bitches following misalliance.

Surgical Management

Bitches not intended for breeding should be ovariohysterectomized (OHE; spayed) any time after an accidental breeding, regardless of whether she is pregnant.[110-118] Surgical risk is low and ovariectomy can be considered for very young dogs in estrus or early diestrus, but any bitch with possible uterine pathology or who has had an estrous cycle should undergo OHE, as leaving the uterus may result in stump granuloma or pyometra. Bitches that are spayed in mid-late diestrus may develop pseudocyesis due to the abrupt decline in P4. If lactation is excessive, use of antiprolactin agents may be considered.

Reasons for Pregnancy Termination, Background

Owners may wish to terminate pregnancy in their dog for numerous reasons: disease in the bitch threatening her life if pregnancy continues; accidental unwanted breeding; or unintentional breeding of related animals or juveniles. With most pregnancy termination protocols, the interestrous interval may be shortened because diestrus has been effectively shortened. Numerous protocols have been recommended for pregnancy termination, depending on stage of pregnancy.[110-117,119-134] P4, synthesized and secreted from CLs is required to maintain pregnancy in the dog.[135-137] The CLs are supported by LH and PRL.[41,118] Most protocols involve suppressing production of one or both, or prevent P4 from binding to uterine receptors. Bitches in the last 10 days of pregnancy will abort live fetuses, requiring owner or veterinarian to monitor, support, or humanely euthanize premature fetuses. If stage of pregnancy is unknown, serial US examinations at 1-week intervals beginning 3 weeks after the bitch was bred, is appropriate until pregnancy can be confirmed or confidently refuted. The number of exams will depend on operator experience, facilities, patient size and preparation (clipping, lubricating gel, positioning, respiratory rate).

Prostaglandins (PGF2-alpha)

These compounds may be used alone or in combination for pregnancy termination without affecting future fertility.[110-118] PGF2-alpha initiates luteolysis and causes uterine evacuation.[110-118,138-148] It can be used as early as diestrus day 8-10, but pregnancy cannot yet be confirmed. "High likelihood" of pregnancy can be assumed if the mating was seen and vaginal cytology is consistent with estrus.[142,147] PGF2-alpha may be given q 12 h or q 48 h, depending on protocol and on use of the natural or synthetic product (Table 312-3). It has been shown that low dosages are as effective as the previously-used dosages but cause far fewer side effects.[147-149] When started in early diestrus, PGF2-alpha therapy should be continued until luteolysis is complete, while in later pregnancy the end point of treatment is complete uterine evacuation. Canine CLs are notably resilient; they may resume function after luteolysis appears complete.[110-118,149] Thus, P4 concentration should be <1.5 ng/mL at the conclusion of therapy and 48 to 72 hours later, to ensure that pregnancy is not maintained. Luteolysis usually requires at least 7 days during the first 30 days of gestation while as few as 4 days after day 30. Adding PGE1 (misoprostol) daily to the cervix beginning at the time of PGF2-alpha and continuing until vaginal discharge is noted, can reduce the number of days necessary for uterine evacuation by facilitating cervical relaxation. PGE1, however, does not have luteolytic properties.[150]

TABLE 312-3

Drug Protocols for Termination of Pregnancy

DRUG 1	DOSAGE	DURATION	DRUG 2	DOSAGE	DURATION
Natural PGF2-alpha	10-50 mcg/kg SC q 8-12 h	4-7+ days			
Natural PGF2-alpha	10-50 mcg/kg SC q 12 h	4-7+ days	Cabergoline	5 mcg/kg PO q 24 h	7-10 days
Natural PGF2-alpha	10-50 mcg/kg SC q 12 h	4-7+ days	Bromocriptine	10-20 mcg/kg PO q 12 h	10 days
Natural PGF2-	10-50 mcg/kg SC q	4-7+ days	Aglepristone	10 mg/kg SC—2	If pregnancy still viable in

alpha	12 h			doses 24 hours apart	7-10 days, repeat 3rd dose
Cloprostenol	1 mcg/kg SC q 48 h	3-4 doses (6-8 days)			
Cloprostenol	1 mcg/kg SC q 48 h	1-3 doses	Cabergoline	5 mcg/kg PO q 24 h	7-10 days
Cloprostenol	1 mcg/kg SC q 48 h	2-3 doses	Bromocriptine	10-20 mcg/kg PO q 12 h	10 days
Cloprostenol	1 mcg/kg SC q 48 h	2-3 doses	Aglepristone	10 mg/kg SC—2 doses 24 hours apart	If pregnancy still viable in 7-10 days, repeat 3rd dose
Aglepristone	10 mg/kg SC—2 doses 24 hours apart	If pregnancy still viable in 7-10 days, repeat 3rd dose			
Dexamethasone	200 mcg/kg PO q 12 h	10-12 days: continue until abortion is completed			

Side effects caused by PGF2-alpha are varied and their severity depends on dosage.[110-115,118,139-141,143,151] Bitches gain a tolerance to PGF2-alpha when it is repeatedly given. PGF2-alpha affects smooth muscle and common side effects include tachypnea, bronchoconstriction, hypersalivation, nausea, vomiting, defecation, and bradycardia. High dosages may cause mild motor incoordination and central nervous system depression. The effects of PGF2-alpha analogues, which have a higher affinity to bind to PGF2-alpha receptors, are more pronounced than natural PGF2-alpha; thus dosing is less frequent.[110,114,144,145,148] Extreme caution should be used in brachycephalic dogs, as bronchoconstriction and tachypnea may be life-threatening. Administration of atropine, prifinium bromide or metopimazine 15 minutes prior to PGF2-alpha injection minimizes effects on smooth muscle and the negative side effects in more than 50% of dogs.[151]

Dopamine Receptor Agonists (DRA)

Bromocriptine and cabergoline, ergot alkaloid derivatives with dopamine receptor agonist activity, inhibit synthesis of luteotrophic PRL.[68,110-118,152-155] PRL secretion begins in mid-pregnancy. Thus, the DRAs are useful after 30-35 days of gestation. Either medication can cause pregnancy termination but duration of treatment is much shorter with concurrent PGF2-alpha (see Table 312-3). The added benefit of DRA therapy is that mammary gland development is also suppressed. Lactation is unlikely if pregnancy is terminated with combination PGF2-alpha and DRA.[153,154] Bromocriptine causes more vomiting and anorexia. Fertility on subsequent cycles is not affected by this treatment.

Dexamethasone

Dexamethasone (regardless of route of administration) induces abortion when given for 10 days or more to pregnant bitches (see Table 312-3).[156-158] Fetal death begins 5-9 days after therapy is initiated but some fetuses may remain viable up to 12 days. This drug should not be used in late pregnancy because it may induce delivery of live fetuses. If treatment is started before day 40, fetal resorption occurs, while after day 40, abortion will result. It is critical that therapy be continued until all fetuses are confirmed dead; otherwise pregnancy may continue to term and fetuses may be affected by palatoschisis or cheiloschisis (cleft palate or hare lip). Side effects include polydipsia, polyuria, and anorexia lasting for the entire treatment. Fertility on subsequent cycles is anecdotally unaffected by these medications.

Progesterone Receptor Antagonists

Mifepristone (RU486) and aglepristone (RU534) have been used successfully for pregnancy termination (see Table 312-3). These drugs have 3 times the affinity for uterine receptors as compared with P4.[159-162] They have slight anti-glucocorticoid activity and do not lower serum P4 concentrations. Aglepristone is available for SC (<5 mL/injection) administration commercially in Europe, South America, Canada, Australia and Asia but not in the U.S., without special permit. Since the drug is in an oil base, injection sites should be massaged to facilitate absorption and reduce local irritation. These drugs can be administered from day 1 of diestrus until day 45 of pregnancy. If administered after day 45, live and possibly premature fetuses may be delivered. In early pregnancy, before day 30, fetuses are usually resorbed. Between days 30 and 45, bloody vaginal

discharge or expulsion of dead fetuses may be observed. These medications should not be used in patients with hypoadrenocorticism, diabetes mellitus, chronic obstructive pulmonary disease, endocarditis or hepatic disease. Side effects may include local irritation at the injection sites, anorexia, vomiting, diarrhea, excitation or depression. Pseudocyesis may occur following pregnancy termination.

Megestrol Acetate

Bitches bred on the first 2-3 days of estrus can have the cycle suppressed by 8 days of 2.2 mg/kg megestrol acetate.[114] There is some risk of pyometra or endometritis when adult or older bitches are treated with this medication while healthy, young adult bitches are unlikely to develop any uterine condition (see ch. 315 and 316). It is important to confirm the cycle has been interrupted (no ovulation occurs) because if the cycle progresses, the bitch may become pregnant and the client may not recognize this until later in pregnancy when termination protocols may not be possible or may result in delivery of live fetuses.

Estrogens

Historically, estrogens have been used for pregnancy termination.[163-169] Their use is now contraindicated because there are other effective options with less severe and significant side effects. Estrogens, administered early in pregnancy, can affect oocyte or embryo movement through the oviduct and into the uterus, alter the oviductal environment causing oocyte degeneration, be directly embryotoxic or interfere with embryo implantation. Estrogens increase uterine contractility and relax the cervix. Side effects include bone marrow suppression, cystic endometrial hyperplasia, pyometra, and suppression of future fertility via long-term effects on gonadotropin secretion. Estrogens are no longer considered safe for pregnancy termination.

Tamoxifen Citrate

Tamoxifen citrate likely terminates pregnancy via its estrogenic activity by altering embryo transit time through the oviducts or interfering with implantation.[170] This medication may be effective when given in proestrus through day 15 of diestrus, but not after. Negative side effects include ovarian cysts, endometritis or pyometra.

Manipulating the Canine Reproductive Cycle

Estrus Suppression

Manipulating a reproductive cycle includes performing estrus suppression, defined as stopping or reducing an activity which is in progress. Thus, *estrus suppression* is used for treating bitches in proestrus/estrus (to stop their heat). The terms *estrus postponement* or *prevention* for bitches in anestrus involves complete avoidance of proestrus/estrus. The indications for these distinct conditions separate owner concerns and drugs needed. Estrus suppression is requested most often for show, racing or hunting dogs as a sudden, almost emergency-type concern. As such, once the sport or show event during which proestrus occurs is over the bitch may be allowed to cycle again, which makes suppression a short-term treatment. Therefore, short-acting progestins are preferred.

The only short-acting progestin currently available on the veterinary market is megestrol acetate (MA). It is sold as an oral drug in most European countries, Australia, South America, and elsewhere. MA has a half-life of a few hours and an affinity for P4 receptors 15-25 times higher than the activity of endogenous P4 but also remarkable affinities for the androgen (75%) and glucocorticoid (37%) receptors, respectively.[171,172] MA likely acts on the ovaries and the hypothalamic-pituitary axis. It suppresses pituitary function, thereby suppressing ovarian activity and causing cycle activity to cease. When given for 8 consecutive days (2.2 mg/kg/day) in early (within the first 3 days of) proestrus, MA is effective in suppressing heat in 92-97% of treated bitches, within in 3-8 days.[173-175] Effectiveness may not be as good in bitches with quite short or long proestrus periods.[173-175] The interval from treatment to return to estrus averages 4-6 (range 1-9) months and post-treatment fertility is usually normal.[174,175] Treating bitches for three or more consecutive cycles or at the puberal estrus should be avoided. Proligestone, a long-acting progestin, is marketed for estrus suppression using a single administration of 10-33 mg/kg SC (varying the dosage inversely with body weight).[176] While proligestone is effective for estrus postponement, little information is available on its use for estrus suppression in the bitch.

The use of MA at the above dosage in bitches which are young and healthy may stimulate appetite and decrease activity (thereby causing weight gain). Some dogs exhibit mild mammary and endometrial

enlargement, but this is not worrisome.[175,177] Evidence of pyometra was reported in 0.8% of 389 MA-treated bitches and the incidence of mammary neoplasia was not increased in another survey of 700.[173,175] MA is diabetogenic and it may cause adrenocortical suppression, but only after using dosages higher than and/or treatment length longer than 2.2 mg/kg/day PO for 8 days.[178-180] When used at low dosages (see later section), MA can be administered daily for up as long as a year without side effects.[172] Because of its endocrine actions, MA is contraindicated in diabetic bitches or bitches with a history of mammary, uterine or liver disease.

Estrus Postponement with Megestrol Acetate (MA)

Overview

Postponement of estrus is used when trying to avoid a bitch coming into proestrus/estrus or becoming pregnant, usually for a period of 6 to 18 months. Progestin administration causes the bitch to be in an artificial luteal phase that blocks cyclicity via negative feedback suppression of LH and FSH release. Progestin administration reduces target tissue estrogen receptors, promotes endometrial growth and secretion, causes cervical closure, alters gamete transport, decreases motility within the reproductive tract and suppresses ovulation.[21] The antiovulatory effect of progestins on the LH surge depends on timing of administration: if given at or shortly after the E2 peak, ovulation can be stimulated while the same treatment several days or longer before the E2 peak suppresses it.[176] Medroxyprogesterone acetate (MPA) alters canine ovarian E2, inhibin, and activin secretion, inhibiting the pituitary pre-ovulatory FSH-LH peak.[181,182] Progestin-induced postponement is less effective as anestrus advances. Therefore, progestin treatment in early-mid-anestrus is more effective and causes a later return to cycle activity versus treatment in late anestrus, often characterized by a shorter effect.

Protocols

MA (0.55 mg/kg/day PO for 32 days) effectively suppressed estrus in 199 late anestrous bitches, 98% failed to show cycle activity throughout treatment.[173] This estrus suppression dosage has become quite popular. However, much lower daily doses (0.01-0.05 mg/kg PO for 32 days) are effective in preventing cycle activity for as long as a year.[172] The effect of beginning MA at varying times within anestrus was not clear.[172] Return to heat following MA administration in 5 bitches was 218 days (range 116-311) with the 0.05 mg/kg/day dosage 94 days in 5 dogs (range 22-243) with the 0.01 mg/kg/day dosage and 120-180 days in 199 bitches (range 30-210) with the 0.55 mg/kg/day/32-day protocol.[172,173]

Side Effects

The side effects associated with estrus postponement with MA are similar to those reported for estrus suppression, although the dosage of MA for estrus postponement is much lower and risk for side effects less. No information regarding side effects to MA treatment was provided in the low-dose study.[172] In cats treated with low MA dosages (2.5 mg/week PO for 30 weeks), the most common side effects were increased appetite and body weight, temperament change and mammary enlargement.[183] Short-term, reversible, adrenocortical suppression and/or diabetes mellitus may follow use of intermediate dosages (2.5 mg/day for a few weeks), while long-lasting, potentially non-reversible mammary gland, uterine and endocrine conditions may follow use of high dosages (2.5 mg/day for months or 2.5 mg/week for years).[183] Although reports of MA-induced side effects in dogs are not as worrisome, there are indications that similar concerns do develop in some.

Estrus Postponement with Medroxyprogesterone Acetate (MPA)

Protocols

MPA has been used in dogs for many years and a great deal of scientific information is available regarding efficacy and side effects. MPA's receptor affinity is less than MA: it is only 5 times as potent as P4 and its affinity for androgen and glucocorticoid receptors is 100 and 1000 times less than that of MA. However, MPA has a longer half-life: 12 to 17 hours after oral administration or 40-50 days when given parenterally. Since injections are required only twice a year to dogs in anestrus, MPA has been used for prolonged postponement at dosages of 2 mg/kg/3 months, 3 mg/kg/4 months, or 2.5 mg/kg/5 months SC.[176,177,184] However, lower dosages are probably effective. Giving MPA (1.5 mg/kg) every 13 weeks inhibited ovulation in Beagle

bitches.[185] Also, 5 adult Beagle bitches treated daily with oral MPA (0.05 mg/kg) did not show estrus for the entire 365-day treatment period.[172]

Side Effects

Relationship between MPA dosage and side effects is likely in dogs, with lower dosages only controlling cyclicity and behavior while higher dosages can cause long-lasting uterine, mammary and endocrine effects. Epidemiologic studies have demonstrated greater risk of malignant mammary tumors in bitches treated chronically with MPA.[186] Unfortunately, reports on side effects caused by MPA have been vague and independent of treatment dosage or duration. Results from chronic MPA toxicity studies in dogs may overemphasize some side effects.[177,185,187-189] MPA acts on the same target tissues as MA, i.e., uterus, mammary gland, endocrine system, basal metabolism and appetite. Parenteral treatment with dosages <2 mg/kg every 5-6 months can likely be used safely in young to young-adult healthy bitches for more than one year (i.e., up to 3 consecutive administrations). Shorter treatment periods are recommended for middle-aged or older bitches with age-related changes within their uterus and mammary glands. Lower dosages may be associated with an earlier return to estrus; however, this would be counterbalanced by a lower health risk for treated bitches. Doses >2.5 mg/kg or those given more often than every 5 months are too high and should not be used. Such higher dosages increase risk of (benign and/or malignant) mammary nodules, cystic endometrial hyperplasia, insulin resistance, and mammary secretion of GH leading to acromegaly.[182,190,191]

Estrus Postponement with Proligestone (PGS)

Overview

PGS is an injectable progestin marketed for use in small animals in Europe with an indication for estrus postponement. PGS should be administered at the dosage of 10 (for large size bitches) to 33 (for small size bitches) mg/kg at 0, 3 and 7 months, and then every 5 months. Efficacy of this protocol is reported to be >95%.[177,192] Breakthrough heats may occur during chronic administration, although little is known on the incidence. Although initially thought to be characterized by a milder progestational and hypothalamic-pituitary-gonadal axis action when compared to MA and MPA, later studies demonstrated that the same side effects of MA and MPA can be achieved with proligestone.[177] Endometrial stimulation leading to cystic endometrial hyperplasia and pyometra as well as mammary hypertrophy accompanied by secretion of GH leading to acromegaly have been reported in dogs during chronic PGS administration, although admittedly at a higher than normal dosage, 5-10 mg/kg SC every 3 weeks. Incidence of pyometra and/or mammary tumors when using the normal protocol is reported as low or irrelevant.[193] The interval from treatment to cycle activity following treatment with PGS can be from 3 to 9 months.[177]

Estrus Postponement with Androgens

Testosterone and its derivatives are widely available. Stanozolol and nandrolone decanoate–based drugs have been available for veterinary use in Europe, North America and elsewhere. Their non-reproductive indications have been described but their action on the canine reproductive cycle has not been accurately investigated. Prolonged high levels of androgens given to males cause negative feedback to the hypothalamic-pituitary axis, reducing pituitary LH and FSH secretion and also binding to androgen receptors. Similar actions may occur in bitches given androgens, with pituitary suppression and consequent decreases in response to E2 since they also bind androgen receptors on E2 target tissues.[176] Parenteral formulations of testosterone propionate (100 mg/dog/week) or mixed testosterone esters (25 mg/kg every 4-6 weeks) or oral formulations of methyl-testosterone (0.25-0.5 mg/kg/day or 25 mg/dog/week) are commonly used to postpone estrus in racing Greyhounds. A depot formulation of testosterone cypionate (2 mg/kg IM) has been effective in postponing estrus for 239 days in 4/5 treated bitches.[194] Treatment should be started at least one month prior to the onset of proestrus to enhance efficacy.[195] Return to estrus following treatment withdrawal may vary from a month to years.

Mibolerone, a synthetic androgen marketed in North America, is an oral, once daily formulation for bitches to postpone cycle activity for as long as 3 years. However, treatment for longer than 2 years is not recommended. Dosage depends on breed and body weight. German Shepherds and German Shepherd mixes should be given the maximum dose (180 mcg/day), while Bedlington Terriers should not be treated at all due to their history of liver dysfunction. Other dog breeds can be treated based on body weight with bitches of

<12, 12-23, 23-45 and over 45 kg receiving 30, 60, 120 and 180 mcg/day, respectively. The interval from treatment to the following estrus is about 2 months (7 to 200 days).

Any androgen can cause increased muscle mass, clitoral hypertrophy (potentially irreversible after prolonged therapy), deepening of the bark, change of temperament (aggressiveness), and mounting behavior. Anestrus should always be confirmed and pregnancy ruled out (to avoid risk of potential masculinization of female fetuses) before administering an androgen.[196]

GnRH Agonists and Antagonists

See E-Box 312-2.

E-Box 312-2

GnRH Agonists and Antagonists

GnRH agonists have been available for experimental use in small animals since the turn of the century, and for the last decade or so a GnRH agonist-based product has been marketed for use in male dogs to suppress fertility. These compounds suppress the reproductive system by downregulating the pituitary reducing its LH and FSH secretion, thereby causing a blockade of follicular growth. In bitches, the use of GnRH agonists such as deslorelin or nafarelin has proven effective but not practical as a flare-up reaction induces a fertile estrus within days when females are treated in anestrus.[201,220,221] A concomitant administration of short-acting progestins has proven only partially effective to avoid this problem.[222] Treatment in diestrus avoids this estrus induction effect[211] but estrus induction has been occasionally reported in bitches treated in diestrus.[202,204] A serum P4 concentration of 5 ng/mL at the time of implantation is reported as a potential threshold above which estrus is not induced.[223] Also, middle-aged or elderly bitches may have some degree of cystic endometrial hyperplasia which may cause pyometra to develop coincidentally with a GnRH agonist treatment performed in diestrus. For these reasons, the use of GnRH agonists for prolonged estrus suppression is acceptable only in healthy, young adult bitches. The authors currently do not recommend using GnRH agonists for estrus suppression in the bitch.

GnRH antagonists are human drugs which temporarily suppress fertility by inhibiting GnRH receptor gene expression leading to a rapid pituitary suppression without an initial flare-up stimulation of the pituitary-gonadal axis which is typical of GnRH agonists. Their experimental use in bitches prevents ovulation and interrupts pregnancy, but not enough information is available for their use in field trials to be advised.[224]

Immunocontraception

See E-Box 312-3.

E-Box 312-3

Immunocontraception

The use of vaccines against GnRH, LH or zona pellucida antigens has been an active area of research over the last decade with several products tried in bitches with varying degree of success.[225] An LH vaccine has provided a (fully reversible) 11-month estrus suppression in adult bitches.[226] Zona pellucida vaccines have produced inconsistent results on antibody production and have not been effective at preventing fertility in bitches, although recent studies show promising results.[227] A GnRH vaccine developed for use in wild female ungulates (deer, horses, burros) and currently marketed for use in boars in Europe has been successfully used as part of population and rabies control efforts in Mexican free-roaming dog populations.[228] However, dogs are prone to developing adverse reactions at the injection site when using this product. Experimental use of these vaccines in dogs is ongoing and the GnRH vaccine looks the most promising one. However, there is currently no anti-fertility vaccine which can be considered safe or appropriate for field testing in dogs.

Estrus Induction

Overview

Estrus induction may be requested when trying to shorten a normal or longer than normal interestrous interval, and can be achieved with gonadotrophins, dopamine agonists or GnRH agonists. While suppression or postponement of estrus is relatively easy, inducing estrus is a challenge because of the lack of consistency of response to different treatments. A variety of treatments have been tried in the bitch with variable and often unsatisfactory (when considering pregnancy rate and litter size) results, including LH and FSH alone or in combination, pregnant mare serum gonadotropin (PMSG) as well as estrogens and naloxone.[67] The use of GnRH agonists and dopamine agonist antiprolactinic drugs is characterized by satisfactory results and should be preferred in clinical practice.

Dopamine Agonists

When administered at their normal antigalactogenic dosage daily starting in anestrus, dopamine agonists such as cabergoline (5 mcg/kg PO q 24 h) and bromocriptine (20-50 mcg/kg PO q 12 h) can shorten the duration of anestrus, thereby advancing the onset of proestrus.[71,197,198] A low dosage of cabergoline (0.6 mcg/kg) has been used with success.[70] Serotonin antagonists can also be successfully used to induce heat but only at higher than normal dosages (metergoline, 0.56-1.2 mg/kg IM q 72 h until proestrus); a high metergoline dosage will exert dopamine agonist effects as opposed to the normal antigalactogenic dosage of 0.5 mg/kg which cannot shorten anestrus.[69,199,200] A dopamine-agonist treatment length of 2-4 weeks is normally sufficient to induce onset of proestrus, although occasionally bitches may not respond until 35 or 40+ days of therapy. There are not enough data on the percentage of bitches responding and what is the maximum duration of administration beyond which the treatment should be stopped. Success rates of 50-80% and potential breed differences in the effectiveness of dopamine agonists for termination of anestrus have been reported. Treatment should be continued until mid-proestrus. Fertility of a cycle induced using a dopamine agonist is regarded as normal. The use of hCG once estrus becomes manifest does not seem to provide any significant help.[70]

GnRH Agonists

When used in anestrous bitches, GnRH agonists such as deslorelin (at the dosage of 1.05 mg, 2.1 mg or 4.7 mg) will induce resumption of cyclicity within 2-9 days.[83,85,201,202] The interval from proestrus onset to ovulation may be shorter in deslorelin-induced bitches than in spontaneously cycling bitches; however, all other fertility parameters appear to be normal.[83,85,202] Because of the well-known suppressive effect of a deslorelin implant on progesterone secretion around mid-pregnancy,[83-85,201] implants administered to induce estrus should be removed between proestrus onset and ovulation in order to avoid pregnancy loss due to premature luteolysis.[83,85,203] Placing an implant in an easily accessible location such as the periumbilical area, the vestibular mucosa or the medial side of the limb helps with locating it and removing it quickly at the proper time. Deslorelin tends to be more effective when administered in late, as compared to early anestrus, and in general is regarded as a very safe and effective drug to induce fertile estrus in the canine. Bitches treated in late anestrus show heat within 4.2 +/− 1.4 days in 97% of cases, ovulation occurs in 83% of cases and quite constantly 12 +/− 3 days after treatment, and pregnancy rate is approximately 70%.[85] However, the need to act invasively to achieve early removal in order to avoid premature luteal failure remains an issue. Also, prolonged heats and anovulatory cycles have been reported.[84,85,201,204,205] In order to avoid unnecessary ovarian stimulation, implants should be removed no later than 15 days post-treatment even if the bitch has not ovulated yet.[85]

CHAPTER 313

Effect of Spay or Castration on Long-Term Health of Dogs and Cats

Hilde de Rooster, Nathalie Porters

Client Information Sheet: Recommendations Concerning Neutering in Cats and Dogs

Background

Surgical gonadectomy (i.e., the removal of the ovaries from females or testes from males) remains the most reliable and only permanent, rapid onset, neutering method for reproduction control in companion animals.[1] Neutering is by far the most common surgical procedure in small animal practices.[2] Elective gonadectomy, however, is still prohibited in a few countries, but in most it is well accepted, and generally viewed as harmless or beneficial for the animal's health.

Veterinarians have the important role of informing pet owners about the benefits and risks of gonadectomy, but the optimal age for gonadectomy is not known. In this debate, distinction should be made between unowned animals (population) and those privately-owned (individuals). Traditionally, elective gonadectomy in dogs and cats is performed at 6 to 9 months of age despite a lack of evidence for this recommendation.[3,4] Since many cats enter puberty before 6 months of age, females may become pregnant prior to gonadectomy. In dogs, timing of their first heat cycle is size- and breed-dependent. First heat would seem a better decision point than actual age. Prepubertal gonadectomy (PPG), defined as gonadectomy performed before 4 months of age or sexual maturity, has been promoted for shelter animals, first in the US, then in the UK, and more recently in other countries.[5-16] The literature has few studies that evaluate short- and long-term effects of neutering at various ages. Rather, information usually compares neuter status at the time of disease, rather than pediatric versus traditional-aged gonadectomy. In studies where age at the time of surgery was taken into account, interpretation of data is complicated by the varying definitions used to group dogs as having been neutered "early" or "late" in life. A comparison of pre- and postpubertal neutering would reveal the most relevant data about risks and benefits.

Anesthesia and Surgery

Elective gonadectomy should only be performed on animals that can safely undergo the procedure, reducing risk of complications.[7,17,18] Particularly in shelter animals, infectious diseases are the main cause of health issues and mortality shortly after PPG.[4,19] Kittens and pups are more vulnerable to infectious diseases than immunized adults and their response to vaccination is often unknown due to presence of maternally-derived antibodies (see ch. 208).[20] It is suggested that gonadectomy be delayed until privately owned pets are fully vaccinated.[15,18,21]

Different anesthetic protocols have proved to be safe and effective for gonadectomy in kittens and puppies.[9,15,17,22-26] Compared to adults, puppies and kittens have immature organ systems, placing them at greater risk for hypoglycemia, hypothermia, bradycardia, hypotension and hypoxemia.[12,17,27-29] These physiological differences are important in anesthetic and surgical planning. While protocols for gonadectomy in pediatric animals are similar to those for adults, their immature tissues are more fragile and even minimal blood loss can quickly become worrisome.[4,9,15,17]

Long-Term Health

Despite the high prevalence of (early age) gonadectomy in veterinary practice, there are few studies of adequate quality and size regarding effect of gonadectomy, as well as age at time of gonadectomy, on health and disease in dogs and cats. Evidence regarding risks of various disease entities following neutering is generally poor, given the practical difficulties in controlling for confounding variables. Most data are obtained through database searches and thus report the difference in simple counts. The neuter status of diseased animals is often not adequately compared to the status of the general hospital population. Furthermore, confounding variables are not taken into account. Owners of neutered pets may present their animal more regularly to a veterinarian, increasing likelihood of diagnosing a disease. Similarly, neutered animals have longer lives and have more time to develop age-related conditions. It is quite conceivable that (early-age) gonadectomy not only influences the genital tract, but other organ systems as well. The majority of health advantages related to neutering outweigh potential disadvantages (see ch. 319).

Benefits

Societal

A societal benefit of elective gonadectomy is the animal's contribution to population control and animal welfare.[3] Unwanted puppies and kittens contribute to the increasing number of animals entering animal shelters, joining feral populations, or being killed.[30-32] Neutered animals are less likely to be relinquished to a shelter.[32-35]

Health

Gonadectomy in dogs and cats is accompanied by an array of health benefits, first by decreasing risk of many genital tract diseases later in life. Removal of both gonads completely eliminates pregnancy- and parturition-related diseases as well as ovarian disease (cysts, neoplasia) in female dogs and cats. Similarly, testicular diseases are eliminated in castrated males. Elective ovariohysterectomy (spay) eliminates any possibility of cystic endometrial hyperplasia, pyometra, or uterine neoplasia. Elective spay also decreases the incidence of vaginitis, vaginal prolapse, false pregnancy and feline mammary hypertrophy. Castrated males are less likely to have benign prostatic hyperplasia or prostatitis. Timely removal of the ovaries is also associated with a smaller risk of mammary cancer.[3,36] Risk of feline mammary carcinoma is drastically reduced in cats spayed before 1 year of age.[37] Early studies on canine mammary gland tumors reported a significantly reduced risk of malignant transformation by PPG, but more recent systematic review only found some evidence to suggest such protective effect.[38,39] Other studies in dogs with mammary gland cancer showed a positive effect on survival by spaying at the time of mastectomy.[40] Other substantial health advantages of gonadectomy include reduced incidence of injuries associated with roaming and a decreased transmission risk of infectious diseases because of reduced copulation and inter-male fighting.[41] Any advantage associated with neutering should be further studied with regard to additional sparing effects gained by prepubertal versus postpubertal gonadectomy.

Potential Detriments

Non-Neoplastic Urogenital Disorders

External Genitalia

Gonadal hormones are responsible for the normal development of the external genitalia in cats and dogs.[42-44] Female cats neutered at 7 weeks or 7 months had a smaller vulva compared to sexually intact cats at 12 months of age.[43] Similar observations have been made in female dogs.[44] Complete penile extrusion was impossible in PPG male cats and possible in only 60% of cats gonadectomized at 7 months.[42] Likewise in male dogs, early neutering resulted in smaller prepuces.[44] There is no evidence of clinical significance of these anatomic differences.

Urethral Diameter

There is concern that (prepubertal) gonadectomy may result in smaller diameter urethras in male cats and dogs, increasing risk of urethral obstruction (see ch. 335).[44,45] Studies have failed to demonstrate urethral narrowing in intact male cats versus those neutered at different ages.[42,46] In long-term cohort studies, no

correlation has been found between age at gonadectomy and incidence of feline lower urinary tract disease (FLUTD) in either gender.[11,19,47] Nevertheless, gonadectomy at any age in cats has been described repeatedly as one of the potential risk factors for FLUTD.[48-51] There is no reported clinical sequela of castration on the male urethra in dogs whereas conflicting data have been reported on the risk of cystitis in female dogs. More gonadectomized than intact bitches had persistent or recurrent cystitis in one study.[52] Several studies showed that bladder stones were more often observed in neutered versus intact dogs (see ch. 331).[53] Two studies had differing conclusions regarding PPG influencing likelihood of developing cystitis later in life when compared to traditional-aged gonadectomized dogs.[47,54]

Incontinence

Fewer than 1% of sexually intact bitches develop acquired urinary incontinence (AUI) at some point in life (see ch. 335).[55,56] However, AUI in neutered bitches varies from 2 to 20%.[57] When female dogs spayed between 12 weeks and 6 months of age were compared to postpubertally neutered bitches, breed and body size rather than the timing of the gonadectomy were associated with observed rates of incontinence.[58] In a case-control study, prepubertally neutered bitches were less likely to develop urinary incontinence than dogs spayed later in life.[59] The lower incidence was also observed by others, although more distinct clinical signs of urinary incontinence were noted in affected prepubertally spayed dogs.[60]

Skeletal Growth

There is ample evidence that most physes close postpubertally.[44,61,62] Lack of gonadal hormones negatively affects closure of selected physes.[43,44,63-67] Some have concluded that this delay, especially observed following PPG, may result in longer bones.[65,66] In parallel, it was hypothesized that affected growth plates may be more susceptible to injury and fracture.[43,44,66,68] The clinical relevance of delayed physeal closures following PPG compared to traditional-age gonadectomy, is largely questioned.[11,19,47] Most cats with femoral capital physeal fractures were obese neutered males.[66,69] Because gonadectomy increases incidence of obesity, gonadectomy might be an independent risk factor.

In dogs, hip dysplasia (HD) and cranial cruciate ligament disease (CCLD) have been associated with neutering (see ch. 353).[70-72] It is hypothesized that asymmetric closure of growth plates could cause deformity and laxity of hip and stifle joints.[44,73] Castrated male dogs are considered more likely to have HD and early neutered dogs seem at higher risk.[47,70,74] Both neutered males and females have a greater likelihood of CCLD.[70,74] There does not seem to be evidence of a difference in the risk to develop CCLD between pre- and postpubertal gonadectomy dogs.[47,54] Both these orthopedic conditions, however, are multifactorial in development. Genetic background, breed predisposition, and obesity are among the factors that may influence risk of developing these orthopedic disorders.[75]

Overweight and Obesity

Overweight companion animals are common. Gonadectomy is one of many risk factors for becoming overweight (see ch. 176).[76-84] Some dog breeds appear more prone to weight gain after neutering.[85] Risk of being overweight was not different according to age at gonadectomy.[86] Surprisingly, some suggest that dogs neutered prepubertally would be less likely than dogs neutered at a later age to gain excessive weight.[47] More objective novel insights in cats challenge the previous suggestion.[87] Given the potential contribution of obesity to most other conditions, the role of the veterinarian to tactfully instruct pet owners to avoid excessive weight gain following (early age) gonadectomy by means of energy restriction as they reach maturity is crucial.[77,86,88,89]

Neoplastic Disorders (also see ch. 344-351)

In dogs, the increased prevalence of a variety of neoplastic diseases attributed to gonadectomy implies that gonadal hormones may have protective qualities against neoplastic proliferation in selected tissues.[90-92] Yet, the role of sex hormone removal in the pathophysiology of such neoplastic diseases remains largely unknown. The fact that individual dog breeds may vary in predisposition further complicates interpretation

of data. For cats, only isolated equivalent data of risk analysis for neoplastic conditions have been produced. Prostatic carcinoma is relatively uncommon in both neutered and intact male dogs (see ch. 337). However, a significantly higher incidence of prostatic cancer is described in castrated dogs.[92-94] In contrast, one report suggested that prepubertal castration of male dogs reduced the risk of neoplastic prostatic disease.[95] An increased prevalence of canine bladder cancers has been noted in neutered male and female dogs.[93] Neither of these studies separated dogs by pre- versus postpubertal gonadectomy.

It has been hypothesized that development of canine lymphoma is suppressed by endogenous gonadal hormones in intact female dogs. Intact males and especially neutered animals of both genders are at greater risk.[91] In Golden Retrievers, a study focusing on health implications of neutering demonstrated that males castrated before 1 year of age were nearly 3 times more likely to develop lymphoma as compared with intact males (see ch. 344). No dog castrated when older developed lymphoma.[74] Neutered cats have increased risk of intestinal lymphoma, but it might have been a direct reflection of age rather than neuter status itself.[96]

Gonadectomy in dogs of either gender was found to be correlated with a two-fold increased risk of osteosarcoma (see ch. 348).[97] A cohort study of Rottweilers, a predisposed breed, further indicated that gonadectomy performed before 1 year of age resulted in the highest risk.[90] Although this might suggest a protective effect of gonadal hormones, nothing is known about a possible mechanism.

Compared with sexually intact female dogs, gonadectomized bitches were at significantly increased risk to have cardiac and/or splenic hemangiosarcoma (see ch. 347), but equivalent differences were less obvious in males.[98,99] In Golden Retrievers, no differences in disease rate were apparent between early spayed and intact females, but female dogs spayed later than 1 year of age had a significantly increased risk.[74] In studies on canine cutaneous mast cell tumors (see ch. 349), neutering was identified as a risk factor in females.[74,100]

Other Diseases (Endocrine, Reproductive, Immune-Mediated)

Vaccination Reactions, Asthma, and Skin

In studies in dogs and cats, hypersensitivity reactions following vaccination were more common in neutered animals.[101,102] It was hypothesized that a lack of negative feedback by the gonadal hormones increases pituitary hormone secretion, influencing the immune response to vaccination. It has been suggested that neutering before 5.5 months was associated with a reduced incidence of feline asthma and gingivitis compared to cats undergoing gonadectomy between 5.5 and 12 months of age.[47] Another cohort study, however, did not observe a significant increase in incidence of disorders of the integumentary system (including minor skin allergies) between animals neutered before versus after 24 weeks of age.[11] Also, based on recent findings, age of gonadectomy is unlikely to be associated with feline hypersensitivity skin disorders.[19]

Diabetes Mellitus

Neutering is associated with an increased risk of diabetes in dogs and cats of either gender, though weight was not considered (see ch. 304 and 305). Spaying female dogs prevents progesterone-induced diabetes mellitus (quite rare) but increases the risk of diabetes mellitus due to obesity.[103,104] In neutered cats, greater risk of diabetes may reflect obesity as a risk factor rather than neutering.[105] Obesity and neutering are associated with decreased sensitivity to insulin.[106]

Other Conditions

Conflicting data on the incidence and prevalence of many other disease conditions and longevity after neutering have been reported. Neutered dogs may be at higher risk for hypothyroidism.[107,108] Similarly, acute pancreatitis was diagnosed more often in neutered animals than in intact animals.[109,110] Although exceptional longevity was claimed in female intact Rottweilers, most studies suggest that neutered animals live longer.[111-114] A major methodological issue regarding potential effects of neuter status on lifespan is that the animals are roughly categorized as neutered or intact based upon gonadal status at time of death, with no indication of age at neutering.[115]

Summary

Decisions regarding elective (prepubertal) gonadectomy in an individual animal depend on several factors. In cats, from a population control perspective, it is vital for neutering to occur before they can reproduce. This implies that shelter kittens and cats be gonadectomized before adoption. Client-owned cats, not intended for breeding, should be neutered around 4 months of age, once adequately vaccinated. Harmful outcomes associated with neutering in cats are extremely rare.

The decision-making in dogs is less clear-cut. For a privately owned dog, numerous and interacting variables factor into determining the best age for neutering. Sexually intact female dogs are at risk for common and serious diseases (mammary gland tumors, pyometra) that can be successfully reduced or prevented by timely elective spaying. Ideally, they should be neutered before or just after their first heat cycle. In male dogs, the health benefits of elective castration are far less obvious and may not outweigh the potential detriments of neutering. Breed-specific disease vulnerabilities should be thoughtfully considered in the decision about neutering.

Whereas it should be easy for veterinarians to promote client education regarding societal concerns, such as pet population, owner education on individual animal concerns, and altered incidence of disease, remains far more complex. More prospective research is needed, not only to quantify incidences of clinically relevant diseases, but also to identify confounding variables that might influence the observed risks.

CHAPTER 314

Clinical Feline Reproduction

Eva Agneta Axnér

Client Information Sheet: Clinical Feline Reproduction

Seasonality

The domestic cat is a "long-day breeder" because increases in day-length stimulate cyclicity.[1,2] The duration of the reproductive season will differ with geographic location, with no seasonality near the equator.[1] Individual cats kept under identical photoperiods, however, show wide variations in length of reproductive season and number of estrous cycles.[3] There are also breed differences in the tendency for seasonal reproduction. For example, Persian cats have a more pronounced seasonality than do Burmese cats. Husbandry conditions may also affect cycles, as artificial light may interfere with seasonality. To stimulate estrus, cats can be kept in a controlled light environment with at least 12-14 hours of light each day.[2] Estrous activity will cease when day-length is set to less than 8 hours of light.[2] The effect of season or day-length on male reproduction is less pronounced, but there are seasonal fluctuations in testicular activity and sperm quality. Males usually sire kittens throughout the year, although sperm quality may be lower in the non-reproductive season.[4,5]

Puberty

The first estrus usually occurs between 4 and 21 months of age in female cats. Pregnancy has, however, occasionally been observed in kittens younger than 4 months of age.[6-8] Because cycles are seasonal, age at puberty is affected by the month of birth. Females may enter their first estrus the first breeding season after being born or in their second year.[3] Puberty is less obvious in males. Testes are descended at birth or within a few days.[9] Spermatogenesis is usually established by 6-8 months and puberty is associated with an increase in testicular weight and in serum testosterone concentrations.[10,11] Age of first mating, however, may be affected by various factors.[12] Secondary androgen-dependent characteristics develop in males in association with increased androgen production. Mature males have well developed penile spines (Figure 314-1). These spines will regress after castration when testosterone drops to basal levels. In kittens, the prepuce is tightly adhered to the penis and partially detaches around 5 months of age. The penis and the prepuce are separated under the influence of androgens.[12] If the male is castrated before puberty, this adherence may therefore remain (see ch. 313).[13] Other physical characteristics of mature intact male cats include thick skin, well developed cheeks, and territory marked by urine. Urine of intact males has an androgen-dependent, strong odor. The tendency and age of urine spraying varies. At puberty, roaming behavior and a tendency to fight with other intact males also increases.[14]

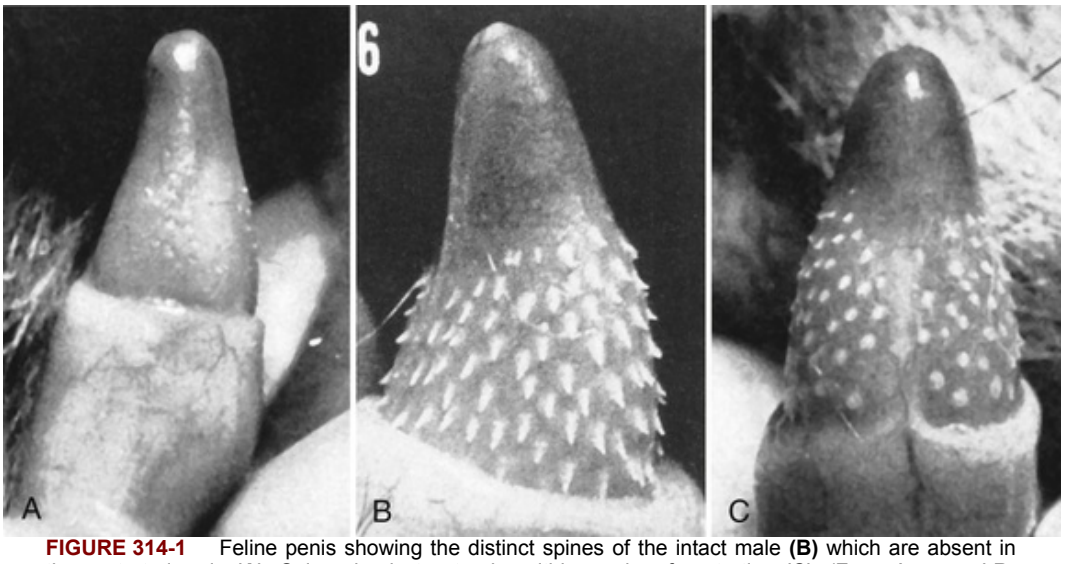

FIGURE 314-1 Feline penis showing the distinct spines of the intact male **(B)** which are absent in the castrated male **(A).** Spines begin to atrophy within weeks of castration **(C).** (From Aronson LR, Cooper ML: Penile spines of the domestic cat: their endocrine behavior relations. *Anat Rec* 157:71-78, 1967; used with permission.)

Estrous Cycle

Queens are seasonally polyestrous. Although the cat is considered to be an induced ovulator, spontaneous ovulation may occasionally occur. The cycle can be divided according to ovarian activity.

The Follicular Phase (Proestrus and Estrus)

The follicular phase is characterized as the stage in the estrous cycle when there are active follicles in the ovaries and serum estradiol concentrations increase (Figures 314-2 and 314-3). Onset of the follicular phase is abrupt and can be subdivided into proestrus and estrus. Proestrus is usually less than a day in length, is not longer than 2 days, and may not be seen at all. Proestrus begins with development of ovarian follicles and the queen displaying estrous behavior but not mating. Increased concentrations of serum estradiol induce estrous behavior, defined as the period when the queen allows mating. Ovarian follicles have usually reached a size of 2-3 mm in diameter at the beginning of estrus.[15] Typical estrous behavior includes vocalization, lordosis with lowering of the chest, elevation of the pelvis and lateral deflection of the tail, rubbing and rolling. When the female displays lordosis, she will often tread with her hindlegs. A scant amount of clear vaginal discharge may be observed. The specific day of estrous behavior in relation to follicular maturation varies.[16] The duration of estrus is usually 5 to 8 days but can be as short as 2 to as long as 19 days.[16,17]

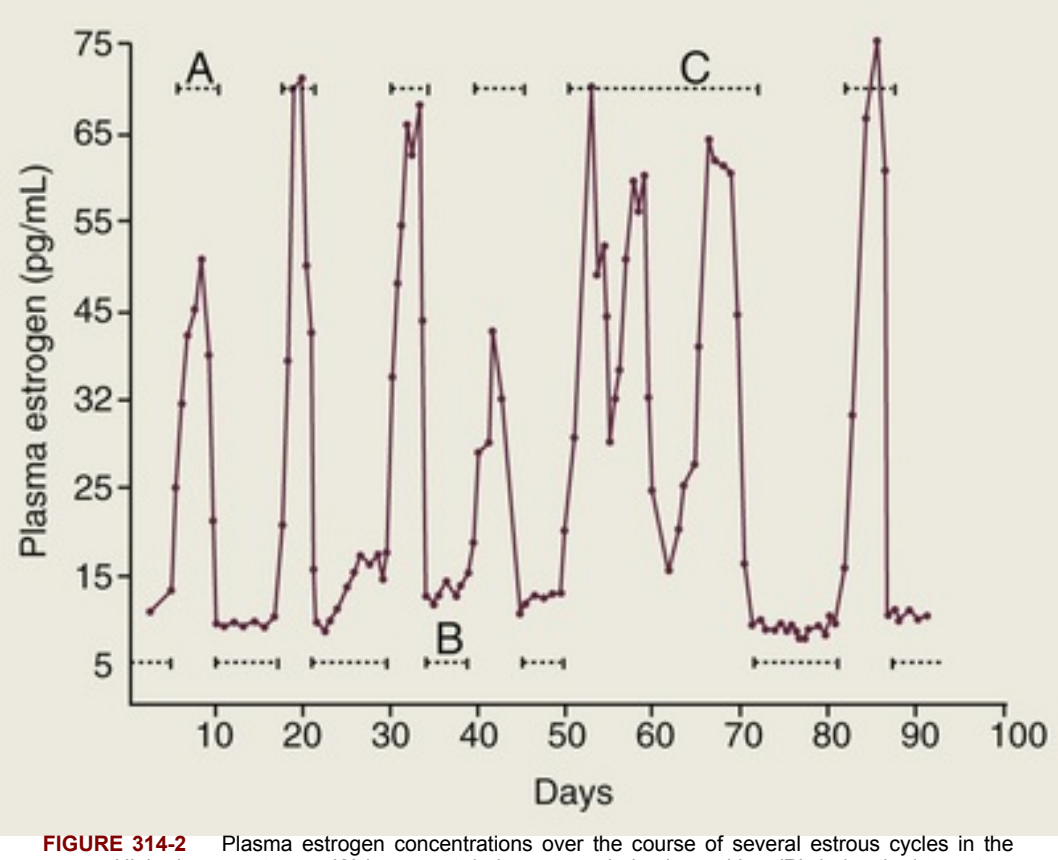

FIGURE 314-2 Plasma estrogen concentrations over the course of several estrous cycles in the queen. High plasma estrogen **(A)** is present during estrous behavior and low **(B)** during the interestrus interval. Plasma estrogen may not return to baseline between cycles and could cause an apparent prolongation in estrous behavior **(C).** (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction, ed 3,* St Louis, 2004, Elsevier; used with permission.)

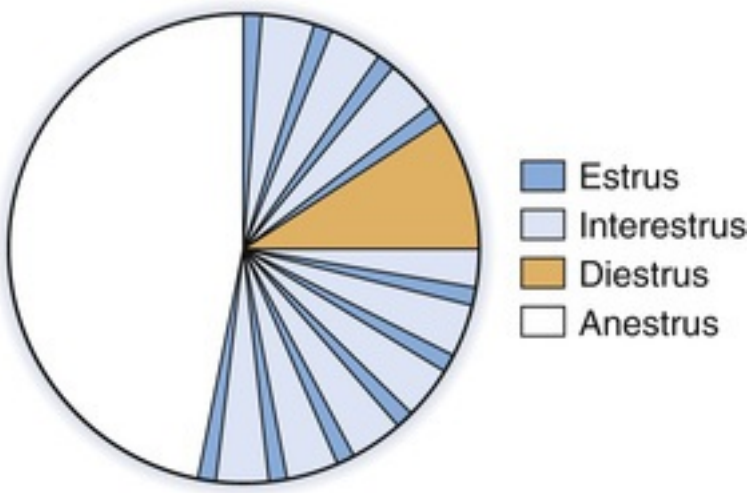

FIGURE 314-3 The reproductive pattern in the non-pregnant domestic cat in a 12-month period. In the average queen, the reproductive season is during the photoperiod with long days. In the absence of ovulation, there will be follicular atresia and no increase in serum progesterone. After a spontaneous ovulation or a sterile mating, serum progesterone is increased and the queen will be in diestrus. A period of diestrus will typically prolong the cycle. Individual variability is, however, very large with some queens cycling more or less throughout the year while other queens may only be in estrus once or twice in a year.

Vaginal cytology can be used to diagnose the follicular phase (Video 314-1). Elevated serum estradiol

concentrations cause thickening and cornification of the vaginal epithelium. In order to take a vaginal smear, the queen is grabbed firmly by the scruff of the neck and a cotton swab moistened with saline is inserted into the vulvar opening, advanced into the vestibule of the vagina, rolled and withdrawn. A smear with >80% cornified cells indicates that serum estradiol is above basal concentrations (Figure 314-4). The initial rise in serum estradiol often precedes estrous behavior and vaginal cornification by a day.[16]

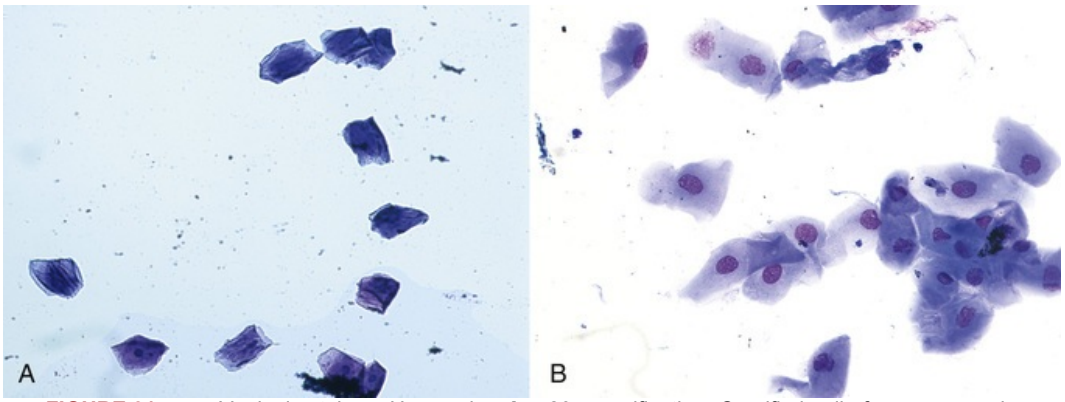

FIGURE 314-4 Vaginal cytology. Hemacolor. **A,** ×20 magnification. Cornified cells from a queen in estrus. **B,** ×40 magnification. Intermediate cells from a queen that is not in estrus. Note the granulated nuclei compared with the cornified cells in **A.**

Interestrus

Interestrus is defined as an inactive period between two estrus periods during the active season. If the queen does not ovulate, ovarian follicles will regress and serum estradiol will return to basal concentrations. Estrous behavior will cease and the ovaries are in an inactive stage. The duration of interestrus can be as short as 2 days but is typically around 1 to 2 weeks (see Figures 314-2 and 314-3).

Diestrus without Pregnancy (Pseudopregnancy)

Diestrus, the luteal phase, is the stage in which active corpora lutea in the ovaries are synthesizing and secreting progesterone. This phase can occur after a sterile mating or a spontaneous ovulation. Serum progesterone increases above basal concentrations (>3 nmol/L). The duration of the non-pregnant luteal phase (pseudopregnancy) varies from about 4 to 8 weeks, with a mean of 38 days (see Figure 314-3).[18]

Anestrus

Anestrus is a longer period without cycle activity. Ovaries are inactive and serum estradiol and progesterone concentrations are basal (see Figure 314-3). There is no definition that characterizes the difference in length between interestrus and anestrus phases. Anestrus typically begins as day-length begins to shorten, but there is significant individual variation in the length and timing of anestrus. Many cats remain in anestrus during warm-to-hot summers.

Estrous Cycle Duration

The length of the complete estrous cycle (i.e., from day 1 of estrus to day 1 of the next estrus) varies between and within individuals. In part, variation depends on whether or not the queen has ovulated. Typically, a queen will come into estrus every second or third week during the reproductive season (see Figures 314-2 and 314-3). The interestrous interval may, however, be as short as 2 days in a normal queen. If the queen ovulates, the cycle is usually 6 to 10 weeks in duration because of pseudopregnancy and the suppressive effect of progesterone on follicular activity.[18] A period of anestrus will also prolong the time between estrus periods. Some queens will cycle more or less throughout the year while other queens may cycle only once or twice a year.

Mating and Ovulation

Considering that cats are territorial, it is advised that mating take place in the male's "territory."[19] However, sometimes the chance of success is better if the male is moved to the female's territory, especially if the female appears frightened. The male initiates mating by grasping the female by the scruff of the neck, often inducing a more pronounced lordosis. Intromission is rapid and ends when the queen emits a characteristic shriek. Unless the male quickly retreats, the female may strike at him. She then begins the typical post-coital reaction: rolling intensely on the floor and licking the genital area. Mating will be repeated when the queen allows. Mating usually stimulates release of gonadotropin-releasing hormone (GnRH) from the hypothalamus which, in turn, induces release of pituitary luteinizing hormone (LH). Several matings may be required to reach the LH threshold to induce ovulation.[20] Follicles are not always mature the first days of estrous behavior. Thus, it is advised to not separate cats before day 3 or 4 of estrus to ensure that ovulation will occur. Once the threshold for LH secretion has been reached, all mature follicles ovulate. Ovulation is completed 25 to 32 hours after mating.[21] Oocytes can be fertilized up to 49 hours after induction of ovulation.[22]

Pregnancy and Parturition (see ch. 315)

Permanent and Temporary Control of Reproduction

Neutering

Cats not intended for planned breeding should be spayed or neutered. This avoids unplanned litters and behaviors related to gonadal hormones (see ch. 313). In breeding catteries, there is often the need to temporarily control reproduction. Frequent estrous cycles are associated with weight loss and it becomes difficult to keep a queen in good condition. Further, repeated cycles likely increase the risk of cystic endometrial hyperplasia (CEH) and pyometra (see ch. 316). The most natural method to suppress estrus would be to decrease the amount of daily light, but this is often complicated in a home environment. There may be a desire to temporarily reduce androgen-related behaviors in males. Male cat behavior, particularly urine spraying, often makes it difficult to keep an intact male cat free in a home as a pet.

Ovulation Induction

Ovulation increases the interestrous interval (see Figures 314-2 and 314-3) and can be induced by vaginal stimulation with a cotton swab. Some cats can be induced to ovulate when petted. Some castrated males continue to mate and some breeders keep them with estrous females to prolong the interestrus intervals. The risk of pyometra must be considered when a luteal phase is induced.

Progestagens

Progestagens used in cats include medroxyprogesterone acetate (MPA), proligestone, and megestrol acetate (MA). Their availability for veterinary use varies. Other progestagens have been used off-label in cats, but detailed studies on their effects and side effects are lacking. Depending on the active ingredient and dosage, effects and the risk of side effects vary.[23] Proligestone is only available for IM deposition while MPA and MA are available as tablets for oral use and in a depot formulation for IM administration.[23] For breeding females, the short-acting tablets are preferable as the duration of the treatment effect is easier to control. Progestagens have also been used to suppress male behavior via their anti-androgenic actions. Although sperm quality may decrease as a result of progestagen treatment, males can usually still sire litters.

Potential side effects include development of CEH, pyometra, mammary hypertrophy, acromegaly, diabetes mellitus, and mammary tumors. Skin alterations at injection sites, including discoloration, alopecia, skin atrophy, and calcinosis circumscripta, have been reported.[23-27] It is recommended that progestogen administration begin during interestrus or anestrus phases at dosages high enough to completely suppress estrus but as low as possible to avoid side effects. Also, it is best to avoid treating for extended periods, as side effects are likely to be total-dose dependent. Pregnancy should be ruled out before initiating treatment because progestagens can masculinize fetuses and inhibit parturition. Although progestagen administration can induce unwanted side effects, regular and frequent estrous activity may not be a better alternative.

GnRH-Agonists

Although not licensed for use in cats, slow-release GnRH-agonist implants have been studied and commonly

used for reversible suppression of fertility in cats.[27] After initial stimulation, the implant down-regulates secretion of FSH and LH which, in turn, suppresses testosterone and estradiol production from the testes and ovaries. Deslorelin is available as 4.7 mg and longer-acting 9.4 mg implants. Initial stimulation may induce estrus or, if implanted during estrus, ovulation. If the queen is mated in the induced estrus, she may become pregnant and carry the litter to term or she may abort. Maternal care and lactation may be absent even if the queen goes to term.[27] Duration of effect has been reported to vary between 16 months and more than 37 months with the 4.7 mg implant.

Males, after an initial stimulation, exhibit downregulation of spermatogenesis, decreased testicular volume, and basal serum testosterone concentrations. Penile spines regress and treated males behave like neutered tom cats. The duration of the 4.7 mg implant varies between 430 and 705 days, but may be >3 years.[27] Because of significant variability in response and reversibility of infertility, owners must be informed that pregnancies can occur despite treatment. In order to be able to shorten the duration of the treatment effect, implants are usually placed SC in the umbilical area for easy removal.

Melatonin

Although not licensed for use in cats, an 18 mg implant licensed for sheep (Melovine, CEVA Sante Animal, Libourne, France) has been used for short term (2 to 4 months) reversible suppression of estrus in queens. Duration of effect is longer when the implant is placed during interestrus.[28] No side effects were reported.[28,29]

Termination of Pregnancy

Medical termination of pregnancy should always be followed up with ultrasound 7 to 10 days after treatment to confirm treatment effect.

Ovariohysterectomy (Spay)

The most common method of terminating pregnancy in cats is by spay, preferably as early in pregnancy as possible.

Medical Abortion

Progesterone Receptor Blockade

Queens intended for breeding may be medically induced to abort. There are, however, no drugs licensed for this purpose in cats. Aglepristone (Alizine, Virbac S.A. France) is licensed in several countries for induction of abortion in bitches and is effective in queens by blocking progesterone receptors. Two injections of 10-15 mg/kg, SC, are given 24 hours apart.[30,31] Efficacy approaches 100% in early pregnancy but is lower (≈88%), in mid-pregnancy.[30,31] Side effects are more common and more pronounced in mid- or late pregnancy compared to treatment in early pregnancy and may include anorexia, partial abortion, no effect, retention of dead fetuses, retention of placental membranes, vaginal discharge, uterine infection, and reversible swelling at injection sites. Treatment can be initiated from the day of mating and should begin as early as possible, preferably before implantation. Treatment initiated on day 45 of pregnancy induced abortion in 4/6 cats (67%) but treatment is not recommended after day 45.[32] Late treatment in the queen decreases efficacy and increases risk of delivering live premature kittens.

Cabergoline

Cabergoline, a dopamine agonist, can be used to block prolactin. It is licensed in some countries to block milk production in the bitch and queen and to treat psuedopregnancy in the bitch. Prolactin is a necessary luteotroph in the second half of pregnancy in the queen and the administration of a dopamine agonist after this time causes a drop in serum progesterone concentrations and subsequent termination of pregnancy. Treatment can be initiated after day 30 of pregnancy. Combining cabergoline with cloprostenol is more efficient than cabergoline alone. Daily treatment can be started on day 25 (5 mcg/kg cabergoline PO q 24 h) for 7 to 10 days until pregnancy termination, combined with cloprostenol 2.5 mcg/kg, SC, on days 1, 3 and 5. Starting treatment after day 48 is not recommended, as it may result in birth of premature live kittens that will starve because lactation will have been suppressed.[33] Other dopamine agonists are associated with more side

effects than cabergoline.

Prostaglandins

$PGF2_{alpha}$, used to terminate pregnancy in cats, is luteolytic and induces uterine contractions. Its weak luteolytic effect, not as effective in cats as in many other species, explains why relatively high dosages are required for termination of pregnancy. A dose of natural $PGF2_{alpha}$ (2 mg/cat IM q 24 h for 5 days) starting about day 33 after mating induced abortion in 4/4 cats.[34] Side effects included nausea, vomiting and diarrhea. Because of these side effects, combination with cabergoline as described is recommended to enable use of lower dosages with fewer side effects.

Estrogens and Glucocorticoids

Neither estrogens nor glucocorticoids are recommended for pregnancy termination because of the paucity of documentation, potential risk of side effects and the availability of better alternatives.

Estrous Cycle Abnormalities

Prolonged Estrus

Estrous behavior lasting longer than 16 to 19 days is likely to indicate an abnormality within the ovaries. However, sometimes queens display estrus-like behavior in the absence of increased serum estradiol concentrations.[16] Vaginal cytology can be used to distinguish true estrus from estrus-like behavior in the absence of elevated estradiol. Prolonged estradiol secretion caused by ovarian disorders must be differentiated from a normal cycle with a short interestrus interval before initiating treatment. Follicular cysts or functioning ovarian tumors can secrete estrogen and cause chronic increases (see ch. 351).

Ultrasound (US) cannot be used to diagnose hormone-producing cysts as there may be other types of cysts within or near an ovary without clinical significance (e.g., rete ovarii cysts and remnants of the mesonephric duct). Hormone production can be confirmed with vaginal cytology (see Figure 314-4). Ovariohysterectomy is the treatment of choice for ovarian cysts. However, medical treatment may be attempted for valuable breeding queens. Induction of ovulation with human chorionic gonadotropin (hCG; 250 IU, IM q 24 h for 2 days) may cause cyst luteinization.[35] Treatment with short acting progestagens (medroxyprogesterone acetate) is an alternative that usually causes cyst atrophy. However, risk of inducing uterine disease must be considered before medical treatment is initiated. Surgical removal of the cysts may be an alternative for a valuable breeding queen.[36]

Primary Anestrus

Puberty can occur as late as 21 months of age. If a queen has not exhibited estrus before 2 years of age, primary anestrus is suspected. Developmental disorders are uncommon in cats but can cause primary anestrus. Hermaphroditism, X-chromosome monosomy, pseudohermaphroditism, and defective androgen receptors have been reported. Karyotyping and laparotomy to evaluate the inner reproductive organs and histology of the gonads may be required for a definitive diagnosis. Sometimes, ambiguous external genitalia may raise a suspicion of a developmental disorder.[37]

Secondary Anestrus

Some healthy cats have only one or two estrous cycles per year. The most common reason for prolonged anestrus is insufficient amount of light. Endocrine disorders as a cause of prolonged anestrus have not been described. Iatrogenic anestrus can be caused by administration of or exposure to progestagens or long-acting GnRH-agonists.

Previous Ovariectomy

If the history of the female is unknown, spay status can be evaluated with estradiol evaluation after buserelin stimulation, measuring serum LH concentrations, or evaluation of antimüllerian hormone (AMH).[38-40] Measuring LH is easy to perform in-house, has high sensitivity and specificity, but is not as reliable as the other two tests. Intact females have low serum LH concentrations while spayed females have increased

concentrations, due to absence of negative feedback. Measuring LH is best performed together with vaginal cytology to rule out estrus, which may cause increased LH concentrations in intact females. Both false positives and false negatives may occur. Basal serum estradiol is not useful as serum concentrations in intact and spayed females overlap. However, 120 minutes after an injection of 0.4 mcg/kg IM buserelin, intact females have increased concentrations of serum estradiol that do not overlap with concentrations from spayed females.[38] In females, antimüllerian hormone is only produced by granulosa cells and is therefore basal in spayed females and above basal in intact females.[40] Evaluation of AMH is thus a reliable test for the presence of ovaries.

Induction of Estrus

The best and most natural method to induce estrus is to increase the amount of daylight in a controlled light environment. This may require covering the windows during the dark photoperiod, otherwise the stimuli from outdoor daylight changes may be stronger than indoor artificial light. Contact with cycling females or male cat odor may also have a stimulatory effect. Medical induction can be accomplished with eCG (100-150 IU, IM). Higher doses may cause ovarian hyperstimulation.[41] Repeated injections with FSH will also induce estrus but may be less practical than eCG. Medical estrus induction should not be attempted in prepubertal queens. Diestrus should be ruled out before treatment by confirming basal serum progesterone concentrations.

Silent Estrus

Estrous behavior is usually quite obvious but can sometimes be vague or absent, even in a female with normal follicular waves (see Figure 314-2).[16] Silent estrus can be diagnosed with repeated samples for vaginal cytology. However, it may be necessary to take samples as often as two to three times per week in order to detect a silent estrus.

Uterine Disorders and Vaginal Tumors

See ch. 316 and 351.

Problems Related to the Mammary Glands

Mammary Gland Tumors

See ch. 351.

Mastitis

See ch. 315.

Mammary Hyperplasia

Abnormal mammary enlargement, known as feline mammary hypertrophy, mammary hyperplasia or mammary fibroadenomatous hyperplasia is a non-neoplastic condition. It is progesterone-dependent, with most affected animals being young intact females that have ovulated or cats that have been treated with progestagens.[42] A few cats have been described who did not have known previous exposure to progesterone or exogenous progestagens.[43,44] Although the condition is usually benign, it may become fatal due to necrosis and overwhelming infection. While spontaneous remission is possible, treatment may be necessary. Ovariohysterectomy in intact females that have ovulated removes the source of progesterone and results in regression of the mammary tissue. It may, however, take as long as 5-6 months before the condition regresses completely. Removal of affected mammary glands has been recommended but surgery may be difficult in advanced cases. Although not licensed for cats, treatment with the progesterone blocker aglepristone (Alizine, Virbac S.A. France; 10-20 mg/kg SC once weekly) will cause remission.[44] Marked response can be expected within 1-2 weeks with complete remission after 4 weeks.[44] It is important to remember that treatment with aglepristone will terminate any pregnancy.

Mating Problems

Most mating problems are related to management and temperament rather than pathological conditions. Partner preference, insecurity, and a female being in proestrus or in the interestrus phase rather than estrus are potential causes for failure to breed. If more than one tom is kept in the same area, the dominant male may suppress mating by subordinate toms.[19] A persistent frenulum can make it impossible for the male to breed and is easily corrected. It is not known if the condition is heritable.[45] Penile hair rings may cause mating problems in long-haired males and are easy to remove once identified. Cats with mating problems because of poor libido should be removed from the breeding pool to avoid the same problems in future generations.

Conception Failure With Apparently Normal Estrus and Mating

Anovulation

If a queen returns to estrus 2-3 weeks after mating, it is most likely that she failed to ovulate. Mating too early in estrus or too few matings may result in anovulation. It is not always obvious if cats actually mate. Failure to mate is the most likely reason for apparent anovulation. Failure to ovulate can be confirmed with a progesterone sample 1-3 weeks after mating (Figure 314-5).

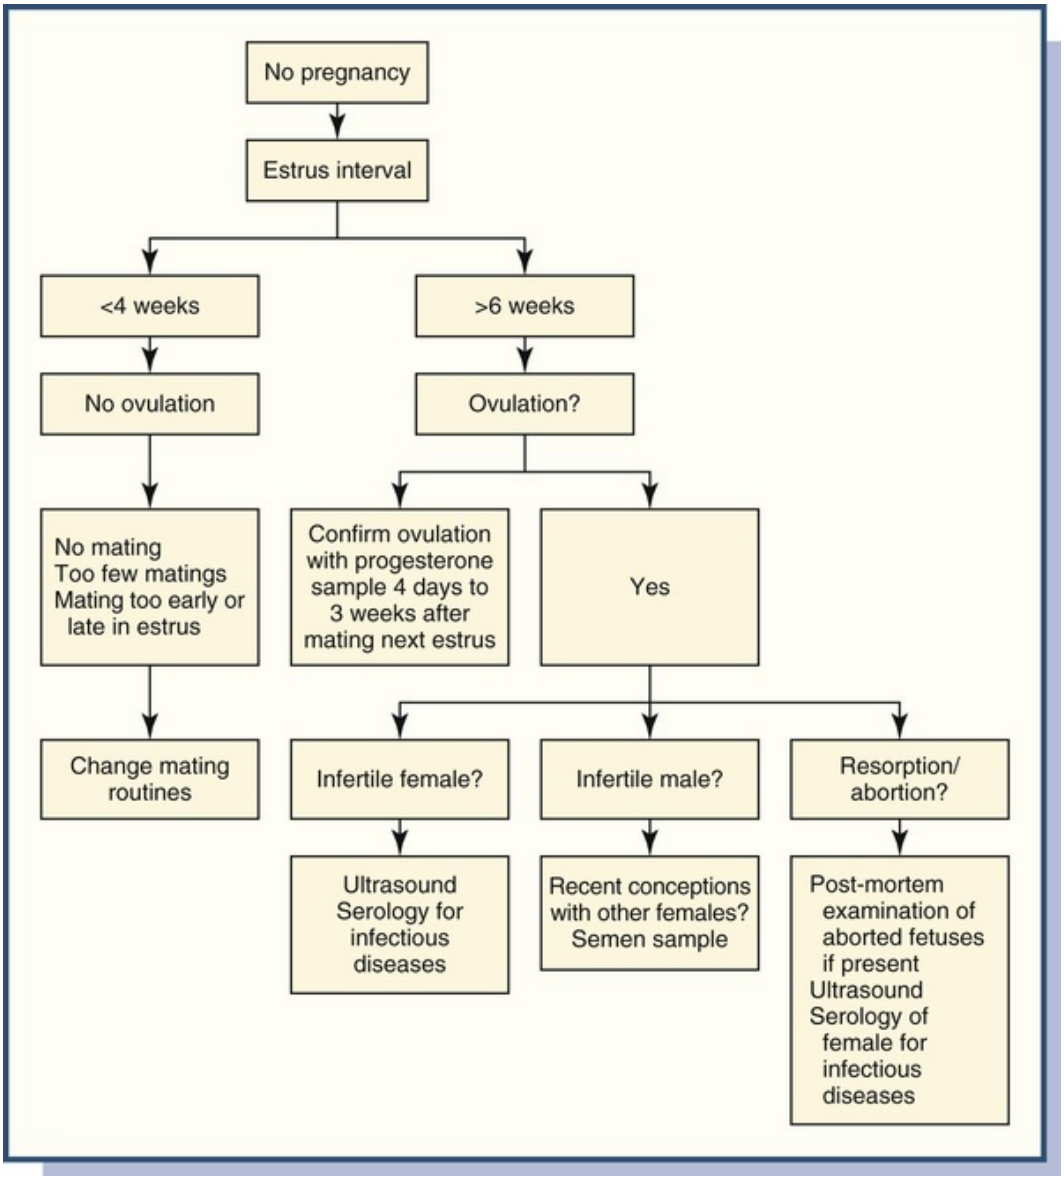

FIGURE 314-5 Algorithm for evaluation of infertility in cats.

Developmental Abnormalities

Abnormal development of the Müllerian duct can cause aplasia of the cranial vagina and absence of the cervical os, resulting in failure of sperm transport.[46,47]

Nutrition

Insufficient dietary taurine, arachidonate or copper are associated with lowered conception rates.[48-50] With increasing use of homemade diets, including raw food diets, there is a risk of nutritional imbalances as well as ingestion of food-borne pathogens (see ch. 192).

Chromosome Aberrations

Fetal chromosome aberrations have been identified as a cause of pregnancy failure but are extremely difficult to diagnose under clinical conditions.[51]

Stress

Stress may enhance synthesis and secretion of stress hormones, including catecholamines, glucocorticoids, and progesterone. Although stress is not a proven cause of fertility problems in cats, abnormal hormonal profiles associated with stress are known to interfere with early pregnancy in other species.

Infectious Causes for Infertility and Subfertility

See ch. 317.

Infertility in the Male Cat

Poor Semen Quality

Poor semen quality can be due to congenital issues in males with testicular hypoplasia or acquired in males with testicular degeneration. In the male with poor semen quality caused by testicular degeneration, the condition may improve while the prognosis for testicular hypoplasia is hopeless.[4,45] The two conditions can not always be distinguished clinically or even histologically. A male that previously has produced kittens is, however, likely to have a better prognosis than a male without previous proven fertility. Small testes and complete azoospermia are unfavorable signs. Chromosomal disorders in male cats have mostly been described in tortoiseshell males. Both red and non-red coat colors are linked to extra X-chromosomes needed for the tortoiseshell coat pattern. Although the tortoiseshell pattern is a marker for a chromosomal disorder, extra X-chromosomes occur also in males with other coat colors.[45]

Disorders of the Penis

Hypospadias is a rare congenital condition with abnormal localization of the urethral opening and has been described in the cat.[52] Priapism, persistent painful erection, is unusual and will usually require penile amputation due to ischemic damage.[53]

Cryptorchidism

Cryptorchidism is the result of failure of one or both testes to descend into the scrotum. Although testes are normally descended at birth in cats, they may move freely up and down the inguinal canal prior to puberty. Definitive diagnosis should not be made before a cat is at least 6 months old. Incidence has been reported to be 1.3-1.9 % of all male cats, with an over-representation of Persians.[54-56] Unilateral is more common (83-90% of cases) than bilateral and the inguinal location is most common.[54,55] Bilateral castration is recommended as these males should be removed from breeding programs and to avoid male cat behavior. It is not known if cryptorchidism increases the risk of testicular neoplasia in cats as there are few cases of testicular neoplasia

reported. Ultrasound can be used to locate undescended testes.[57] When the history of the cat is unknown, inspection of the penis for the presence of penile spines or evaluation of serum AMH will distinguish bilaterally cryptorchid males from previously neutered males.[40] Polyorchidism (extra testes) and monorchidism (absence of a testis) are extremely rare.[55,58]

Semen Collection

Most but not all toms in a cat colony can be trained for semen collection. Semen is collected with a custom made artificial vagina and the tom is allowed to mount an estrous female.[22] In a clinical situation, semen collection with an artificial vagina is unlikely to be successful. Electroejaculation under anesthesia or urethral catheterization under deep sedation with an alpha-2-agonist are alternatives that don't require prior training or the need to keep the male in his own territory.[59,60] For the urethral catheterization method, an open-end urinary catheter is inserted approximately 9 cm into the urethra in a male that is deeply sedated with an alpha-2-agonist, and then the catheter is withdrawn. Seminal fluid will accumulate in the catheter and can be flushed into a small test tube.[59]

Semen volume and sperm numbers are low when compared with dogs. Normal semen volume usually varies from 10 to 200 mcL and is affected by collection method. Larger mean volumes are collected with electroejaculation than with other methods. Sperm numbers vary from 3 million to 150 million, with higher values when collected with an artificial vagina. Sperm morphology is highly variable among individual males, with a large proportion of males producing high proportions of abnormal spermatozoa. Sperm morphology may also vary within individuals. It seems that toms can produce high proportions of abnormal spermatozoa without being infertile, depending on the type of sperm abnormalities. However, males with poor fertility often have high numbers of sperm abnormalities originating from the testes or may be completely azoospermic.[4]

Artificial Insemination

Artificial insemination is not a routine procedure in the cat. However, demand from cat owners is increasing and methods for semen preservation and intrauterine insemination are improving. In the absence of mating stimuli, ovulation can be induced with hCG (75-100 IU, IM). Determining the optimal time for ovulation induction is complicated by individual variations among healthy queens, but most queens will respond on day 3 or 4 of estrus. Ultrasound can be used to follow oocyte maturation for more exact timing, with induction of ovulation when at least one ovarian follicle has reached 3 mm in diameter.[15] Fresh semen can be deposited in the cranial vagina using a thin open-ended tom cat catheter. Frozen semen should be deposited in the uterus for better results.[61] Vaginal insemination can be performed without sedation or anesthesia, depending on the temperament of the cat, while intrauterine insemination requires anesthesia. Surgical intrauterine deposition has been used but transcervical deposition methods have been developed and should be considered as the first choice alternative.[61]

Pre-Breeding Examination

Cat registries often require that breeding cats be documented to be free from umbilical hernia and that stud cats have normally developed testes. These criteria for breeding animals should be applied, whether or not required by a cat registry. There are also breed-specific recommendations for heritable disease testing.[62] Breeding cats should be tested routinely for feline leukemia virus (FeLV) and feline immunodeficiency and only cats tested negative allowed in contact with cats in the cattery. FeLV vaccines are not 100% effective and will not prevent infection (see ch. 223). Therefore, routine testing is preferable to vaccination for breeding catteries.[63] Routine testing for other infectious diseases may also be warranted in some circumstances but the strategy for handling a positive test for agents that are widespread in the population should be considered first. For some breeds, such as the Rex breeds, British Shorthair and Sacred Birman, blood group testing before breeding is recommended to avoid feline neonatal isoerythrolysis.

It is beneficial to boost core vaccines for breeding catteries before each breeding to increase the amount of maternal antibodies that will be transferred to the kittens with colostrum and to protect fetuses from infections (see ch. 208). Vaccination during pregnancy is, however, not recommended.

CHAPTER 315

Pregnancy, Parturition and Periparturient Problems in Dogs and Cats

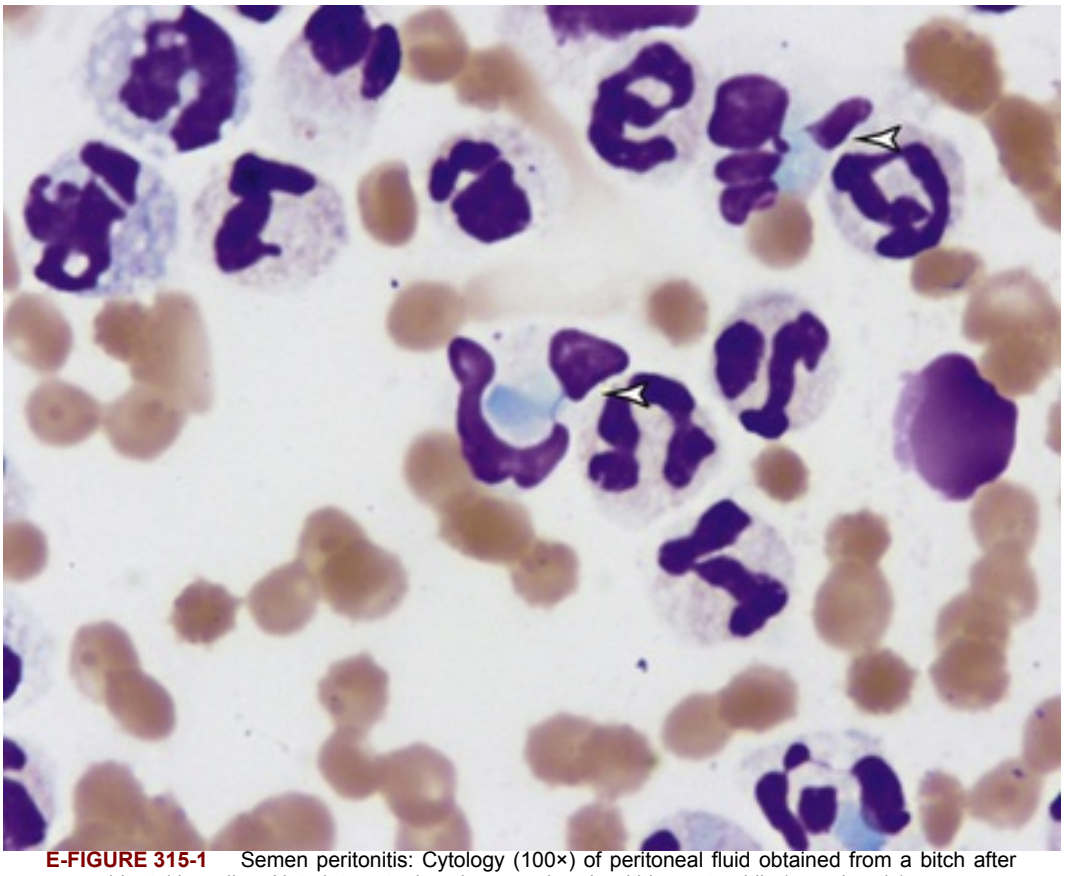
Autumn P. Davidson

Client Information Sheets:
Brucellosis in Dogs
Use of Cabergoline in Dogs and Cats
Canine Dystocia
Herpesvirus Infection in Dogs
Normal Whelping in the Bitch
Nutrition for Pregnant and Nursing Bitches
Post-Cesarean Section Neonatal Puppy Care
Canine Pseudopregnancy
Vaginal Hyperplasia in the Dam
When to Schedule an Elective Cesarean Section (C-section) in Your Bitch

The periparturient period begins about 9 weeks before parturition (pre-partum) and continues for about 30-45 days postpartum until weaning. Diagnosis of periparturient problems first requires differentiation from normal events. Effective treatment then depends on both a timely diagnosis and therapeutic intervention. The periparturient period can be associated with high morbidity and even mortality for the dam and neonates.

Semen Peritonitis

The common differential diagnoses for a sexually intact bitch with acute onset signs of abdominal pain should include pyometra, uterine rupture and uterine torsion. Acute peritonitis secondary to the deposition of semen into the abdominal cavity, an extremely unusual condition, should be considered among the possible conditions that could cause those signs in the estrual bitch. Usually such dogs have recently had exposure to an intact male dog or artificial insemination. Semen is forced into the uterus during the copulatory lock due to the large amount of prostatic fluid in the final fraction of the canine ejaculate. Normally, semen does not enter the peritoneal cavity of bitches after mating. However, if mating involves a much larger male or a diseased uterus, semen could be forced into the peritoneal cavity through trauma or via the fallopian tubes. Intraperitoneal deposition of semen may cause suppurative peritonitis and a systemic inflammatory response because prostatic fluid contains a large amount of foreign antigen (E-Figure 315-1). Stabilization followed by exploratory laparotomy and lavage of the abdomen are indicated. Inspection of the vagina and uterus for perforation should be carefully performed. This syndrome has high morbidity and mortality.



E-FIGURE 315-1 Semen peritonitis: Cytology (100×) of peritoneal fluid obtained from a bitch after an accidental breeding. Note intracytoplasmic sperm heads within neutrophils (arrowheads).

Hyperemesis Gravidarum

Bitches can experience a transient loss of appetite and, sometimes, vomiting during the second and third weeks of gestation. While this usually resolves spontaneously, marked anorexia can hinder adequate nutrition during gestation. Metoclopramide (0.1-0.2 mg/kg PO or SC q 12 h) can help. Alternative antiemetics may not be safe or recommended in pregnant dogs. Clinicians must evaluate risk vs benefit. In uncommon cases, force feeding must be undertaken.

Vasculitides: Pregnancy Thrombosis

Pregnancy results in a hypercoagulable state, which becomes problematic in people with genetic prothrombosis. Hypercoagulability has been documented in pregnant dogs. Affected bitches are at risk for either arterial or venous thrombosis, as evidenced by elevated D-dimer levels (see ch. 196). Ultrasound (US) can be used to document thrombosis, most commonly involving the caudal vena cava and causing pelvic limb venous congestion (E-Figure 315-2 and Video 315-1). Antithrombotic therapy with low molecular weight heparin is used in women but has not been evaluated in the pregnant bitch. Abortion due to placental or fetal hemorrhage is a risk. Warfarin is contraindicated in pregnancy as it crosses the placenta. Aspirin causes congenital defects (cleft palates). The condition is believed to be inherited in women; affected bitches should probably be removed from the breeding pool.

E-FIGURE 315-2 Venous congestion in a term pregnant Labrador Retriever bitch with venal caval thrombosis.

Pregnancy Edema

Marked edema of the distal pelvic limbs, caudal mammary glands, and perineum is occasionally observed in large breed bitches with large litters and normal serum albumin concentrations (E-Figure 315-3). Venous thrombosis should be ruled out with Doppler US. Vaginal hyperplasia can occur at term and be mistaken for pregnancy edema (E-Figure 315-4; see ch. 146). Mild normal estradiol increases near gestation term can induce reformation of vaginal hyperplasia (more commonly seen during estrus), and compromise the birth canal, which is an indication for elective cesarean section. Vaginal hyperplasia can be confirmed by digital examination of the vagina and finding a mass originating cranial to the urethral papilla. If pregnancy edema is confirmed, mild exercise (walking or swimming) can be helpful. The use of diuretics is not advised because complications have been noted (fetal polyuria, dehydration) and teratogenicity suspected. Severe edema of the perineum can cause dystocia.

E-FIGURE 315-3 Vulvar edema in a term pregnant Boxer bitch.

E-FIGURE 315-4 Vaginal hyperplasia in a term pregnant Labrador Retriever bitch. This is an exuberant reaction to elevated estrogen levels at term pregnancy in the periurethral vaginal mucosa resulting in extrusion of vaginal tissues through the vulva.

Pregnancy Loss

Overview

Abortion of all or some of a litter can result from traumatic, infectious, metabolic or degenerative conditions. Early embryonic loss is not usually recognized because resorption occurs. Mid-gestational fetal loss, from 21-30 days gestation, can be recognized with US (Figure 315-5). Late gestational loss (>40 days) usually causes recognizable abortion. Infectious causes of resorption in the bitch include *Brucella canis, Toxoplasma gondii, Neospora caninum,* canine herpesvirus-1, canine minute virus, also known as canine parvovirus type 1, *Cryptosporidium canis* or any ascending opportunistic bacteria.[1,2] Infectious causes of resorption/abortion in the queen are usually viral: leukemia virus, panleukopenia virus, herpesvirus and immunodeficiency virus. Resorption/abortion can also be due to protozoal *Toxoplasma gondii* or several bacteria: *Streptococcus* spp., *Escherichia coli, Campylobacter* spp. and *Salmonella* spp.[2,3]

FIGURE 315-5 Ultrasonographic image of a mid-gestational normal canine fetus (left), and fetal resorption (right). The resorption has no recognizable fetal structures or membranes and lacks allantoic fluid.

Brucellosis (see ch. 213)

Canine brucellosis uncommonly causes abortion/resorption, which can occur early (before day 20) in gestation resulting in fetal resorption or more commonly (75%) later in gestation (generally 45-59 days) resulting in abortion. Any bitch with unexplained pregnancy loss should be screened for *Brucella.* Serology, blood or tissue culture, histology and polymerase chain reaction (PCR) techniques are appropriate for the diagnosis. A positive serologic evaluation is detectable in most infected dogs within 8-12 weeks. Since incubation ranges from 2-12 weeks, there is a window of time in which an infected individual can elude diagnosis serologically. The correct interpretation of serologic results is critical to making an accurate diagnosis. Screening serology is sensitive but not specific: a high rate of false positives occurs because surface antigens of *B. canis* cross-react strongly with antibodies to several non-pathogenic bacterial species. There can be as many as 50-60% false positives because of crossreacting *Bordetella* spp., *Pseudomonas* spp., *Moraxella* spp., and *B. ovis* antibodies. False negatives are rare unless testing is performed early in the infection. Confirmatory testing is needed because of the high incidence of false positives. For this reason, testing is recommended at least 1 month prior to a planned breeding, enabling more accurate testing if the initial screening test is positive. A false negative can occur if a recently infected dog or bitch is less than 8 weeks post infective exposure and the titer has actually not yet become positive. Otherwise, a negative test is usually indicative of a truly negative dog. Infected dogs and bitches should be removed from breeding programs and quarantined. Eradication of the disease in kennel situations has not been successful without removal (culling) of all infected (current or historically) dogs.

Canine Herpesvirus (see ch. 228)

Clinical signs of canine herpesvirus 1 infection in adult dogs are mild and suspicion of a kennel infection often begins with neonatal deaths and/or illness in pups. Problems are dependent on stage of pregnancy when infection occurs. Infection in early stages causes fetal death and mummification; in mid-pregnancy it may result in abortion; and in later stages, premature birth. In naturally occurring disease, pups are usually born apparently healthy but become ill and die during the first several weeks postpartum. Normally, immunity in the bitch develops and even those who have lost a litter because of herpesvirus infection can later give birth to normal litters.[4,5] Until recently, treatment of canine herpesvirus infection in neonates has been unrewarding and recovery may be associated with cardiac or neurologic damage. Treatment with immune serum from affected dams is ineffective in infected puppies. Acyclovir is an antiviral agent with

activity against a variety of viruses including herpes simplex. Its use in veterinary medicine is not well established and it should be used only in situations where indicated and with caution. Safety and effectiveness in humans less than two weeks of age is not established. The dosage (20 mg/kg PO q 6 h × 7 days) is extrapolated from human use. Canine herpesvirus vaccination may be available but indications and efficacy remain unsubstantiated.

Infections in Cats

Appropriate viral screening in catteries should reduce the incidence of viral associated pregnancy loss. Abortion in herpesvirus infected queens is related to systemic disease rather than a direct impact on the reproductive tract. Feline panleukopenia infection during early pregnancy causes subfertility and resorption; infection in mid-pregnancy is typically associated with abortion or fetal mummification. The classic feline panleukopenia-associated neonatal cerebellar hypoplasia (see ch. 225) manifests clinically as tremors and incoordination in neonates and is associated with late pregnancy infection. Feline leukemia and/or immunodeficiency virus-infected queens exhibit subfertility, arrested fetal development, abortion, stillbirths and/or low birth weight kittens. *Toxoplasma gondii*-infected queens, especially if immunocompromised, can produce stillbirths or low birth weight kittens.

Late Term Gestational Loss

Late term gestational loss can occur as a result of pre-term or premature labor. Both hypoluteoidism and inappropriate uterine activity accompanied by cervical changes have been implicated in the pathophysiology of preterm birth in dogs and cats. Premature labor is defined as uterine activity and cervical changes leading to the loss of pregnancy via resorption or abortion before term, for which no metabolic, infectious, congenital, traumatic or toxic cause is identified. Premature labor is associated with progesterone levels <2 ng/mL and is often a retrospective diagnosis after thorough evaluation of the dam and fetuses has been performed because of pregnancy loss. This evaluation should include metabolic screening of the dam for systemic and infectious diseases. Histopathology and culture of expelled fetuses and placentae should be done. Kennel/cattery nutrition, medications and environmental factors should be assessed. Dams experiencing premature myometrial activity in one pregnancy may or may not have issues in subsequent pregnancies.

Pre-Term Birth

Overview of the Human Experience

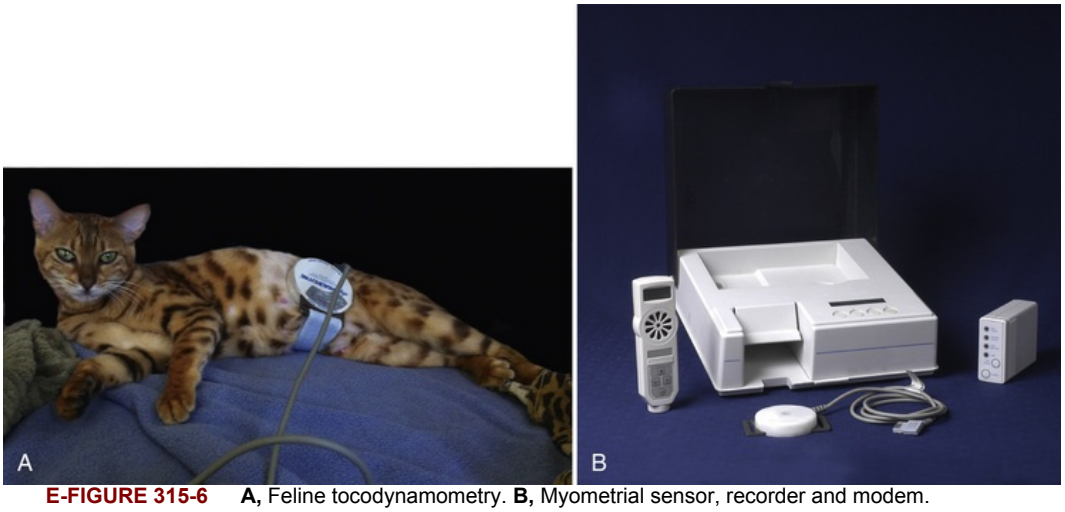
In women, preterm birth occurs in 10-12% of human pregnancies, but it accounts for 80% of fetal morbidity and mortality. The diagnosis of preterm labor requires evaluation of uterine contractility by tocodynamometry, fetal fibronectin, and measuring transvaginal cervical length with US. Together, these parameters have high negative predictive value. Women having preterm delivery are at risk for this same issue with subsequent pregnancies. Antibiotics, hydration, and rest do not have benefit. If intervention is indicated, tocolytic agents have been advocated. Contraindications to tocolytics include severe preeclampsia, placental abruption, intrauterine infection, lethal congenital or chromosomal abnormalities, advanced cervical dilation, and evidence of fetal compromise or placental insufficiency. Tocolytic agents inhibit myometrial contractions and include beta mimetics (terbutaline, ritodrine), magnesium sulfate, calcium channel blockers and prostaglandin synthetase inhibitors (indomethacin, ketorolac, sulindac).

Clinical trials in people given prophylactic progestational compounds have not consistently helped. Based on meta-analysis, prevention of preterm delivery or the prevention of recurrent miscarriage appears to be based on use of the natural metabolite of progesterone, 17 alpha-hydroxyprogesterone caproate (17P). Maintenance of canine or feline pregnancy requires serum progesterone levels >1-2 ng/mL and during normal pregnancy they are 15 to 90 ng/mL, declining gradually during the latter half of gestation, and then abruptly decreasing to basal concentrations at term (usually the day before or the day of parturition). Progesterone promotes the development of endometrial glandular tissue, inhibits myometrial contractility (causes relaxation of myometrial smooth muscle), blocks the action of oxytocin, inhibits formation of gap junctions and inhibits leukocyte function *in utero*. In several species, changes in progesterone or in progesterone : estrogen ratios in placenta, decidua or fetal membranes are important for initiating labor. Progesterone antagonists administered at term can result in an increased rate of spontaneous abortion.

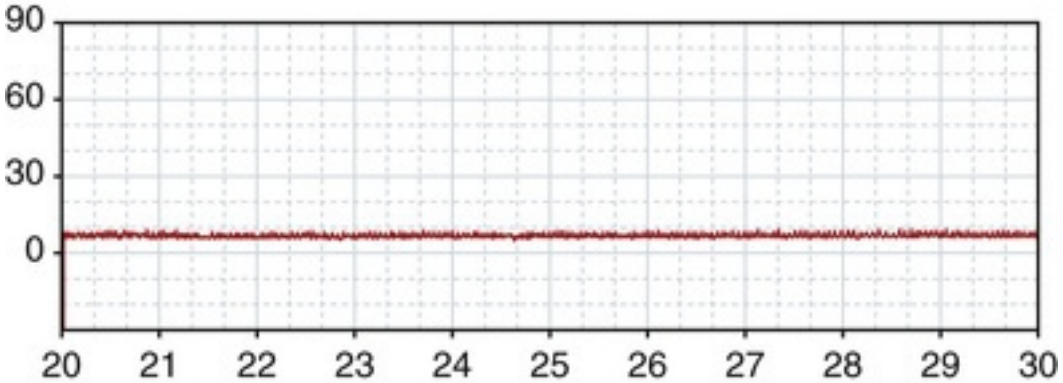
Hypoluteoidism in Dogs and Cats

In the bitch, ovarian corpora lutea are the sole source of progesterone. In queens, placental progesterone production occurs in the latter half of gestation. Canine luteal function is autonomous early in pregnancy but supported by luteotrophic hormones (LH and prolactin) after the second week of gestation. Hypoluteoidism, primary luteal failure occurring before term gestation, has not been a documented cause of late term abortion in bitches, but induction of abortion requires reducing plasma progesterone levels <2 ng/mL. The diagnosis of gestational loss caused by premature luteolysis is difficult, requiring documentation of inadequate plasma progesterone levels prior to abortion for which no other cause is found. Measurement of precise progesterone levels, especially in the critical 1-3 ng/mL range, is not accurate using currently available rapid in-house ELISA kits. For low concentrations, use of commercial laboratories is needed. A few laboratories provide rapid (<8 h) turnaround, facilitating the diagnosis.

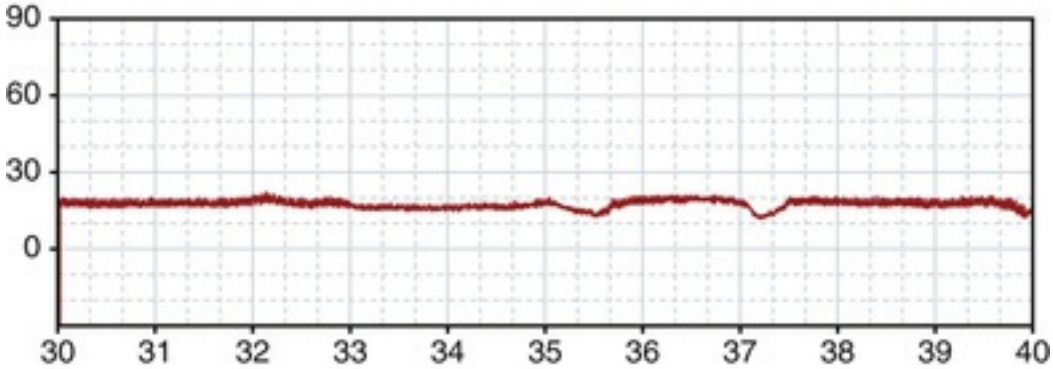
Progesterone levels diminish in response to fetal death; thus, documentation of a low progesterone level after an abortion does not establish a diagnosis of hypoluteiodism. Giving progesterone to maintain pregnancy in dams with primary fetal abnormalities, placentitis, or intrauterine infection can cause continued fetal growth with the possibility of dystocia and sepsis. Administration of too much progesterone to maintain pregnancy in a dam not actually requiring therapy can delay parturition, impact lactation, endanger the lives of bitch and fetuses, and can masculinize female fetuses. Dams with documented low progesterone levels and historical late term loss of pregnancy with no apparent pathology can also be evaluated for premature myometrial activity midgestation, using tocodynamometry (E-Figures 315-6, 315-7, and 315-8). Elaboration of prostaglandins from the endometrium and placenta in association with premature myometrial activity can result secondarily in luteolysis.



E-FIGURE 315-6 **A,** Feline tocodynamometry. **B,** Myometrial sensor, recorder and modem.



E-FIGURE 315-7 Tocodynamometry: normal quiescent uterus. X axis: time in minutes. Y axis: strength of contraction in mm Hg.



E-FIGURE 315-8 Tocodynamometry: uterine irritability mid-gestation. X axis: time in minutes. Y axis: strength of contraction in mm Hg.

Premature uterine activity endangering fetal survival has been identified before complete luteolysis occurs and intervention is indicated if the pregnancy is normal otherwise.[6] Tocolytic agents, alone or in combination with progesterone, decrease myometrial activity. Terbutaline (Brethine, Ciba Geigy; 0.03 mg/kg PO q 8 h) has been used to suppress uterine contractility in bitches and queens with historical preterm loss of otherwise normal pregnancies. Ideally, the dosage is titrated to effect using tocodynamometry and is discontinued 24 hours before term. Progesterone supplementation is only advised late in gestation if progesterone is <2-3 ng/mL to avoid teratogenic consequences (E-Figure 315-9). Serum progesterone can be monitored only when supplemented with the natural product (progesterone in oil, 2 mg/kg IM q 72 h). Altrenogest (Regumate, Merck Animal Health), a synthetic progestagen used in mares, is dosed orally at 0.09 mg/kg q 24 h. Both forms of supplementation must be discontinued in a timely fashion to avoid interfering with normal parturition. Usually, oral synthetic products are stopped within 24 hours of the due date and the injectable depot form 72 hours before. This protocol requires accurate prior ovulation timing (parturition expected to occur 64-66 days from the LH surge or initial rise in progesterone, or 56-58 days from the first day of cytologic diestrus). Less accurate identification of gestational length can be attempted with breeding dates (58-72 days from the first breeding), radiography, or US. Bitches and queens successfully managed for uterine irritability or preterm labor frequently have uterine inertia and require cesarean section.

E-FIGURE 315-9 Anomalous vulva (preputial in orientation) in a female puppy whose dam was treated mid-gestation with Altrenogest.

Metabolic Conditions

General Observations

Blood volume increases by 40% during pregnancy, providing adequate reserve to restore blood and fluid lost at parturition. Increases in plasma volume cause hemodilution, and the expected hematocrit is usually 30% to 35% at term. Increased cardiac output is caused by enhanced heart rate and stroke volume. Lung functional residual capacity is decreased by cranial displacement of the diaphragm by the gravid uterus. Oxygen consumption during pregnancy increases by 20%. Pregnant dogs may have delayed gastric emptying, displacement of the stomach, and increased risk of gastroesophageal reflux. Acromegalic signs can occur in the bitch secondary to progesterone-induced excesses in growth hormone (GH) secretion.[7] Gestational diabetes mellitus is rare in the bitch or queen and when present, is attributed to the anti-insulin effects of progesterone (mediated by increased levels of growth hormone; see ch. 304 and 305). Large fetuses that predispose to dystocia can result because of their enhanced insulin in response to maternal hyperglycemia. However, it is not common for diabetic dogs to carry a litter to term.

Pregnancy Toxemia

Pregnancy toxemia in the bitch occurs as a result of altered carbohydrate metabolism in late gestation resulting in ketonuria without glycosuria or hyperglycemia. This is most commonly due to poor nutrition (lack of nutrition or decreased appetite due to another issue) during the last half of gestation. Hepatic lipidosis can occur (see ch. 285). An improved plane of nutrition can resolve the condition, but termination of the pregnancy may be indicated in severe cases.

Eclampsia and Hypocalcemia (see ch. 146)

Definition

Puerperal tetany or eclampsia, life-threatening hypocalcemia, occurs most commonly in dogs during the first 4 weeks postpartum, but can occur in the last few weeks of gestation and is seen in queens. The condition is

caused by depletion of ionized calcium (iCa) in the extracellular compartment due to improper perinatal nutrition, inappropriate Ca supplementation, or serious losses into milk.[8,9] Small dams with large litters are at increased risk. Excessive prenatal Ca supplementation increases risk of eclampsia by suppressing parathyroid hormone release, interfering with normal mechanisms to mobilize Ca and utilize dietary Ca.

Prophylaxis

A balanced growth commercial (puppy/kitten) diet without additional vitamin or mineral supplementation should be given during the second half of gestation and throughout lactation. Cottage cheese and similar products should be avoided. They disrupt normal dietary Ca-phosphorus-magnesium balance. Metabolic conditions which favor protein binding of serum Ca and promote or exacerbate hypocalcemia include alkalosis from prolonged hyperpnea during labor. Hypoglycemia and hyperthermia may also occur.

Signs and Treatment

Signs preceding the development of tonic-clonic muscle contractions (not actually seizures) include behavioral changes, salivation, facial or distal extremity pruritus, stiff gait, limb pain, ataxia, hyperthermia, and tachycardia. Therapeutic intervention, initiated immediately upon recognizing signs of tetany without waiting for biochemical confirmation, include immediate slow IV infusion of 10% Ca gluconate (1-20 mL [0.5 mL/kg]) given to effect (see ch. 298). Cardiac monitoring for bradycardia and arrhythmias should accompany administration, and if seen, warrants temporary discontinuation of treatment and a slower subsequent rate. Mannitol may be indicated for cerebral inflammation and swelling. Corticosteroids are undesirable because they promote calciuria, decrease intestinal Ca absorption and impair mobilization from bone. Hypoglycemia should be corrected if present. Resolving the hypocalcemia usually resolves hyperthermia as well. Once acute neurologic signs are controlled, the volume of Ca gluconate given IV should be given SC, diluted 50% with saline. This can be repeated q 6-8 h until the dam is stable and able to take oral supplementation. Efforts to diminish lactation losses from the dam and improve her plane of nutrition are indicated. If response to therapy has been prompt, nursing can be gradually reinstituted until the neonates can be safely weaned, usually at a slightly early age (3 weeks). Concurrent supplementation with commercial bitch/queen milk replacement is encouraged. Administration of Ca throughout lactation, but not gestation, may be attempted in dams with a history of recurrent eclampsia (Ca carbonate 500-4000 mg/dam/day PO, divided).

Dystocia

Goals in Diagnosis and Management

Veterinary involvement in canine and feline obstetrics has several goals: to increase live births (minimizing stillbirths resulting from the difficulties in the birth process), to minimize morbidity and mortality in the dam, and to promote increased survival of neonates during the first week of life. Neonatal survival is directly related to the quality of labor. Dystocia (see ch. 146) is defined as difficulty in the normal vaginal delivery of a neonate from the uterus and various criteria are applied to identify this condition (Box 315-1 and Figure 315-10). Dystocia must be diagnosed in a timely fashion for medical or surgical intervention to improve outcome. Cause of dystocia must be identified to guide therapeutic decisions.

Box 315-1

Clues to Recognize Dystocia

Failure to initiate stage I labor at term (prolonged gestation)
- >72 days from first breeding
- >64-66 days from date of LH surge or initial rise in progesterone (1.5-2.5 ng/mL)
- >56-58 days from day 1 diestrus (first day vaginal cytology is <50% superficial cells; bitch usually non-receptive to male on that date)

Failure to enter stage I >24 h after temperature drop <99° F (<37.2° C) or when progesterone <2.0 ng/mL

Failure to proceed to stage II after 24 h in stage I

Failure to deliver all in timely manner (6-8 h); strong abdominal contractions for >1h without delivery (cannot evaluate uterine contractions without tocodynamometry); weak abdominal contractions >4-6 h

Fetal or maternal distress (stillbirths, difficult to resuscitate neonates, exhausted/weak, painful or shocky

bitch)
Copious vaginal hemorrhage
Uteroverdin without immediate delivery, indicating placental separation
Irreversible history of dystocia (chondrodystrophic breeds, pelvic abnormalities, vaginal strictures, masses or hyperplasia)
Radiographic abnormalities: obstruction, malposition, intrauterine/fetal gas suggesting fetal death, oversized fetus(es)
Persistent fetal bradycardia (HR <170-200 bpm)

From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction*, ed 3, St Louis, 2003, Saunders.

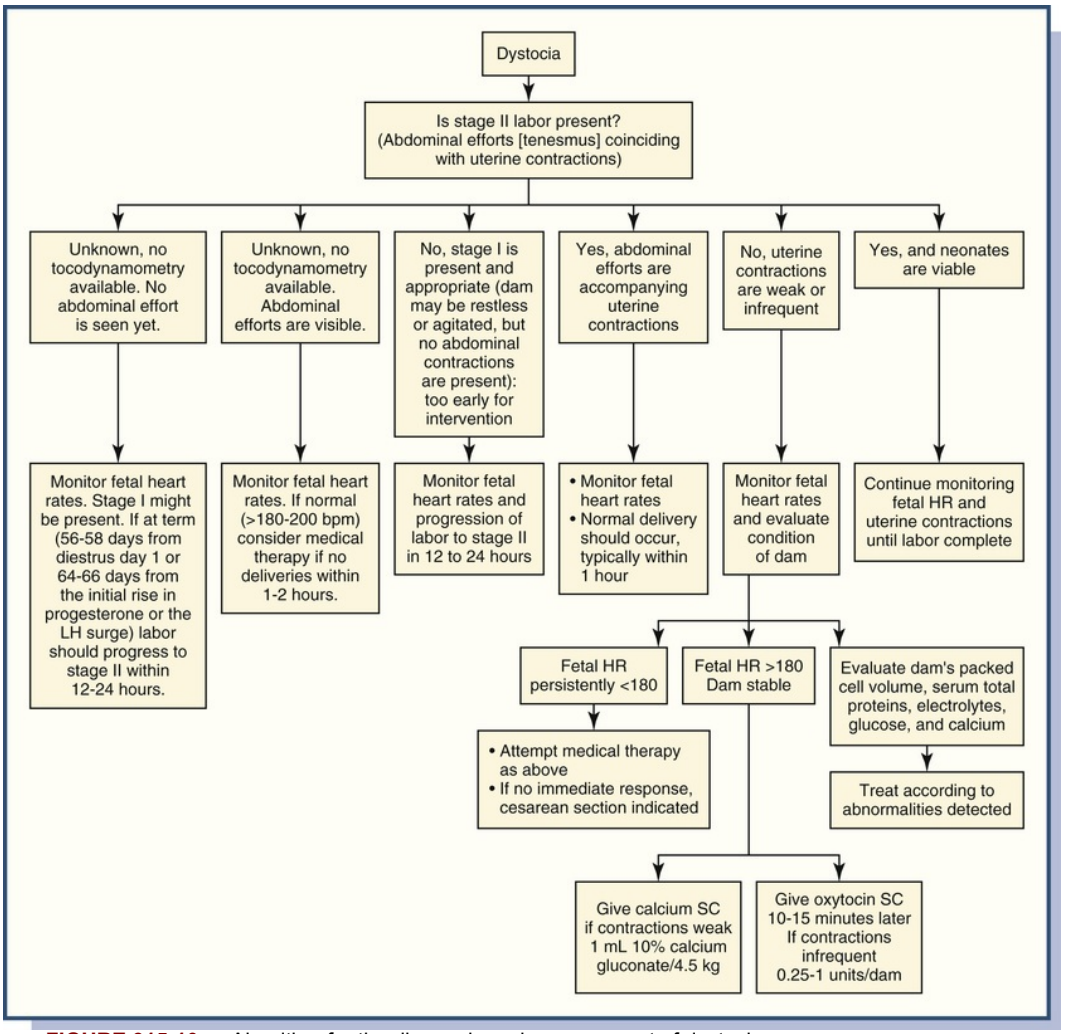


FIGURE 315-10 Algorithm for the diagnosis and management of dystocia.

Normal Parturition

Gestation

Clinicians are commonly asked if a bitch or queen is at term of pregnancy and if she is ready to deliver a litter, and then to intervene if labor has not begun. Accurate determination of gestational length is difficult if numerous copulations occurred and ovulation timing was not performed. Prolonged gestation is a form of dystocia. Gestation in the bitch is more challenging to calculate than in cats, because bitches are spontaneous ovulators. Normal gestation in the bitch is 56 to 58 days from the first day of diestrus (detected by serial vaginal cytologies, defined as the first day that cytology returns to ≤50% cornified/superficial cells; see ch.

119), 64 to 66 days from the initial rise in progesterone from baseline (generally >2 ng/mL), or 58 to 72 days from first breeding. Predicting gestational length without prior ovulation timing is difficult because of the potential disparity between estrual behavior and the actual time of conception in bitches, and the length of time semen remains viable within the reproductive tract of the bitch (>7 days).

Breeding dates do not correlate closely with whelping dates. Additionally, clinical signs of term pregnancy are not specific: radiographic appearance of fetal skeletal mineralization varies at term, fetal size varies with breed and litter size, and the characteristic drop in body temperature (typically <99° F [<37.2° C]) varies and may not be detected in all bitches. Breed, parity and litter size can also influence gestational length.[10] Because the queen is an induced ovulator (ovulation follows coitus by 24-36 hours), gestational length can be predicted more accurately from breeding dates, assuming that mating took place over a limited number days. Gestation duration in queens ranges from 52-74 days (mean 65-66 days), as measured from the first to last day of breeding. Because of poor outcomes with delivery of premature puppies and kittens, intervention is best delayed until stage I labor has begun, or prolonged gestation confirmed (see Figure 315-10).

Labor and Delivery

Bitches typically enter stage I labor within 24 hours of a decline in serum progesterone <2-5 ng/mL due to prostaglandin release and is commonly associated with a transient drop in body temperature (<99° F; <37.2° C). Queens typically enter stage I labor 24 hours after serum progesterone levels fall to <2 ng/mL. Monitoring serial progesterone levels for impending labor is problematic because in-house kits for quick results are inherently less accurate between 2-5 ng/mL and because a rapid decline in progesterone levels can occur over a period of a few hours. Commercial laboratories offering quantitative progesterone by chemiluminescence typically have a 12 to 24 hour turnaround time, not rapid enough to enable decisions about immediate need for obstetrical intervention.

Stage I labor in the bitch normally lasts from 12 to 24 hours, during which time the uterus has myometrial contractions of increasing frequency and strength, causing cervical dilation. Abdominal effort (visible external contractions) is not usually evident during stage I labor, but bitches may exhibit changes in disposition and behavior, becoming reclusive, restless, nesting intermittently, often refusing to eat and sometimes vomiting. Panting and trembling may occur. Vaginal discharge should be clear and watery. Normal stage II labor in the bitch begins when external abdominal efforts can be seen. Myometrial contractions culminate in the delivery of a neonate. Presentation of the fetus at the cervix triggers the Ferguson reflex, promoting the release of endogenous oxytocin from the hypothalamus. Typically, labor does not last longer than 1-2 hours between puppies, although great variation exists. The entire delivery can take between 1 to >24 hours, but usually less. Vaginal discharge can be clear, serous to hemorrhagic, or green (uteroverdin). Typically bitches continue to nest between deliveries, and may nurse and groom neonates intermittently. Anorexia, panting and trembling are common. Stage III labor is defined as the delivery of the placenta. Bitches typically vacillate between stages II and III of labor until all pups are delivered. Stages of labor in the queen are similarly defined. Stage I labor in the queen is reported to last 4-24 hours and stages II and III from 2 to 72 hours, although complete delivery of neonates within 24 hours is expected with normal queening.

Causes of Dystocia

Maternal Factors

Uterine inertia is the most common cause of dystocia. Primary uterine inertia results in the failure of delivery of any neonates at term and its causes are multifactorial, including genetic components and metabolic defects at the cellular level.[11] An intrinsic failure to establish a functional, progressive level of myometrial contractility occurs. Secondary uterine inertia is the cessation of labor after one or more neonates have been delivered, but not the entire litter. It can result from metabolic, anatomic (obstructive), or genetic causes. Birth canal abnormalities such as vaginal strictures, stenosis from previous pelvic trauma, stenosis in particular breeds, and intravaginal or intrauterine masses can cause obstructive dystocia. In most cases, canal abnormalities can be detected in the prebreeding examination and resolved or avoided by elective cesarean section (C-section). Causes of compromise rendering the dam unable to complete delivery include hypocalcemia (see ch. 69), hypoglycemia (see ch. 61), systemic inflammatory reaction (see ch. 132), sepsis (see ch. 132), and hypotension (due to hemorrhage or shock; see ch. 159).

Fetal Factors

Fetal factors contributing to dystocia most commonly involve mismatch of fetal and maternal size, fetal

anomalies and fetal malposition and/or malposture. Prolonged gestation with small litter size can cause dystocia due to an oversized fetus(es). Fetal anomalies such as hydrocephalus and anasarca similarly can cause dystocia. Fetal malposition (ventrum of fetus proximal to the dam's dorsum) and fetal malposture (flexed neck and scapulohumeral joints most commonly) promote dystocia as the fetus cannot transverse the birth canal smoothly.

Diagnosis (see Figure 315-10 and Box 315-1)

Overview

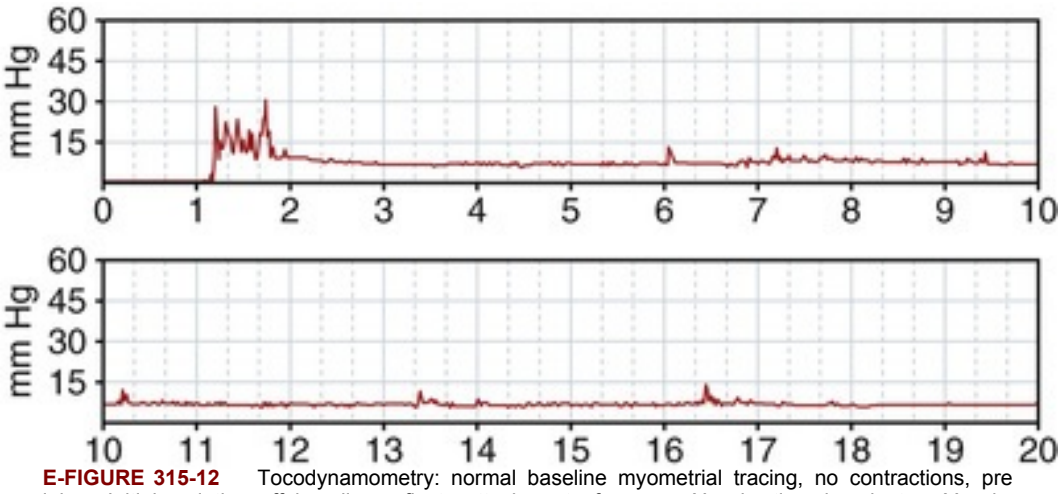
The clinician must quickly obtain a careful reproductive history detailing breeding dates, any ovulation timing performed, historical and recent labor, as well as a general medical history. Physical examination should address the general status of the patient, as well as include a digital and/or vaginoscopic pelvic exam for patency of the birth canal, evaluation of litter and fetal size (radiography most useful), assessment of fetal viability (Doppler or real time ultrasound ideally) and uterine activity (tocodynamometry most useful).

Fetal and Uterine Monitoring

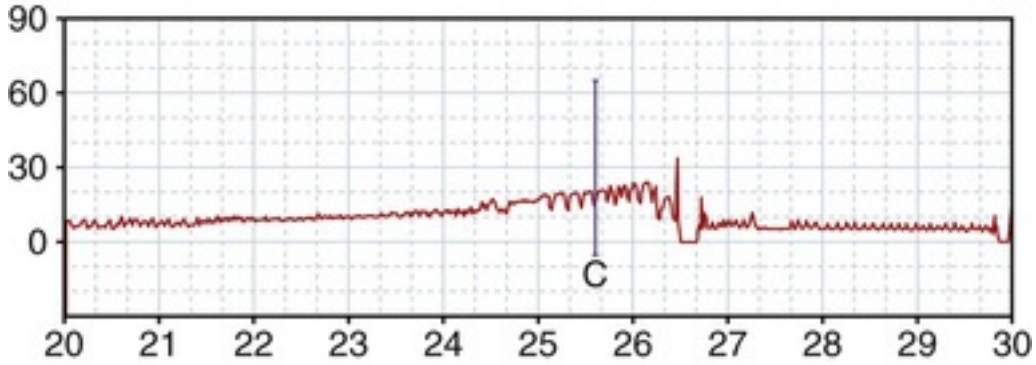
Current approaches to veterinary obstetrical monitoring involve the use of external monitoring devices using tocodynamometry (Healthdyne Inc., Marietta, GA, USA) and a hand-held Doppler (Sonicaid, Oxford Instruments, England) to detect and record uterine activity and fetal heart rates. These devices can be used either in the home or at the veterinary clinic. Their use requires that the hair coat be lightly clipped caudal to the ribcage and over the gravid area of the lateral flanks to allow proper contact of the uterine sensor and fetal Doppler. The uterine sensor detects changes in intrauterine and intra-amniotic pressures. The sensor, strapped over the clipped area of the bitch's/queen's caudolateral abdomen using an elasticized strap, is usually well tolerated. The sensor's recorder is worn in a small backpack placed over the caudal shoulder area. Bitches/queens should be at rest in the whelping/queening box or in a crate or cage during the monitoring sessions (E-Figures 315-6 and 315-11). Fetal Doppler monitoring is performed bilaterally with a hand-held unit with bitches/queens in lateral recumbency, using acoustic coupling gel. Directing the Doppler perpendicularly over a fetus results in a characteristic amplification of the fetal heart sounds, distinct from maternal arterial or cardiac sounds, which enables determination of fetal heart rates. Interpretation of the contractile pattern in strips produced by the uterine monitor requires training and experience. Data are transferred by modem to trained obstetrical personnel who subsequently consult with the attending veterinary clinician and client. Recordings are made twice daily, each an hour long when home monitoring is performed, then intermittently on bitches or queens at home as indicated during active labor, or on site in the veterinary clinic for shorter periods of time (minimally 20 minutes) when patients are being evaluated for suspected dystocia.

E-FIGURE 315-11 Chihuahua bitch undergoing tocodynamometry during evaluation for dystocia.

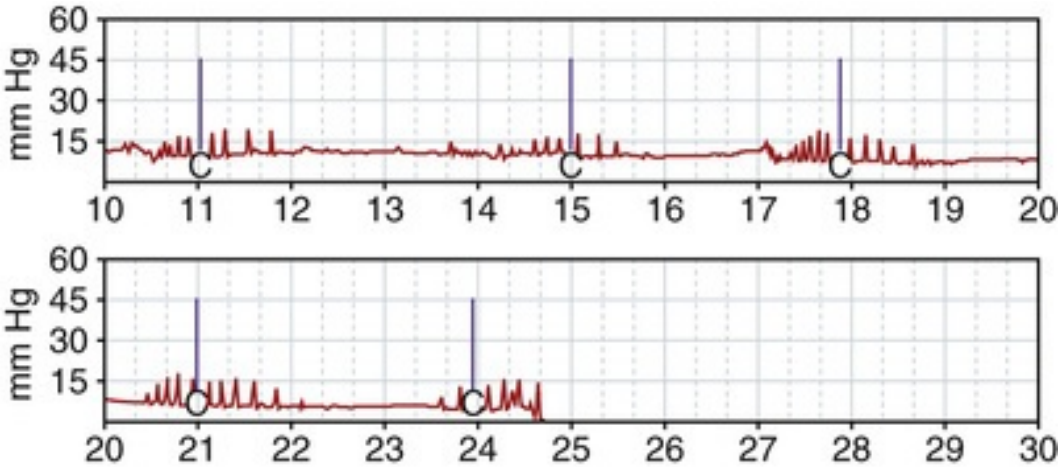
The canine and feline uterus each has a characteristic pattern of contractility, varying in frequency and strength before and during the different stages of labor. Late in gestation, the uterus may contract once or twice an hour before actual stage I labor is initiated. Thus, normal sessions can show no activity (E-Figure 315-12). During stage I and II labor, uterine contractions vary in frequency from 0 to 12 per hour, and in strength from 15 to 40 mm Hg, with spikes up to 60 mm Hg (E-Figure 315-13). Contractions during active labor can last 2 to 5 minutes in duration. Recognizable patterns exist during pre-labor and active (stages I-III) labor. Aberrations in uterine contractility can be detected during monitoring. Uterine inertia can be determined even when external, abdominal efforts are seen (E-Figure 315-14). Abnormal, dysfunctional labor patterns can be weak or prolonged, and often are associated with fetal distress (E-Figure 315-15). Completion of labor can be evaluated via tocodynamometry.



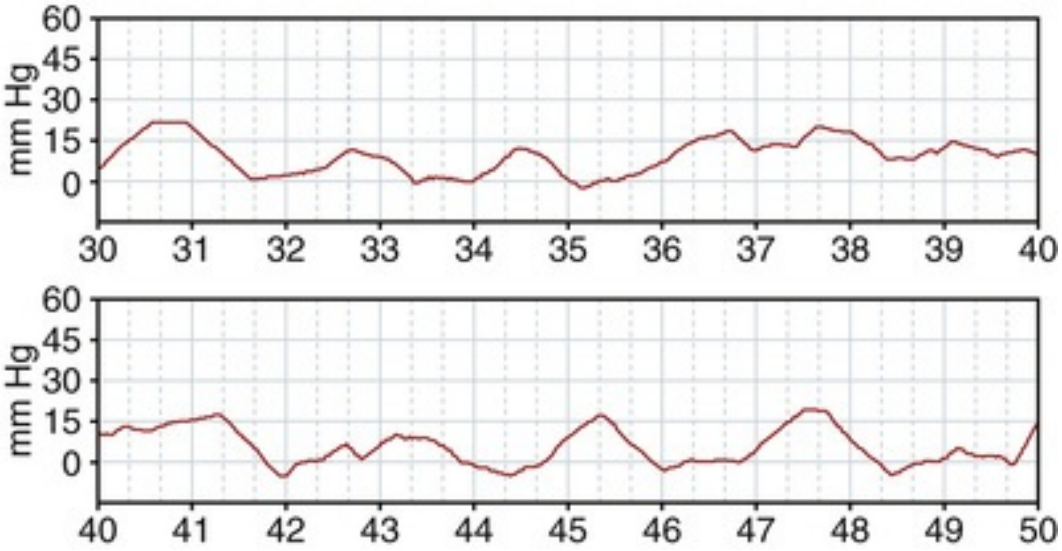
E-FIGURE 315-12 Tocodynamometry: normal baseline myometrial tracing, no contractions, pre labor. Initial variation off baseline reflects attachment of sensor. X axis: time in minutes. Y axis: strength of contraction in mm Hg.



E-FIGURE 315-13 Tocodynamometry: Early active labor, stage II, uterine contractions and abdominal pushing. X axis: time in minutes. Y axis: strength of contraction in mm Hg. *C,* Contraction.



E-FIGURE 315-14 Tocodynamometry: abdominal pushing with uterine inertia. X axis: time in minutes. Y axis: strength of contraction in mm Hg. Vertical spikes (c) indicate abdominal efforts.



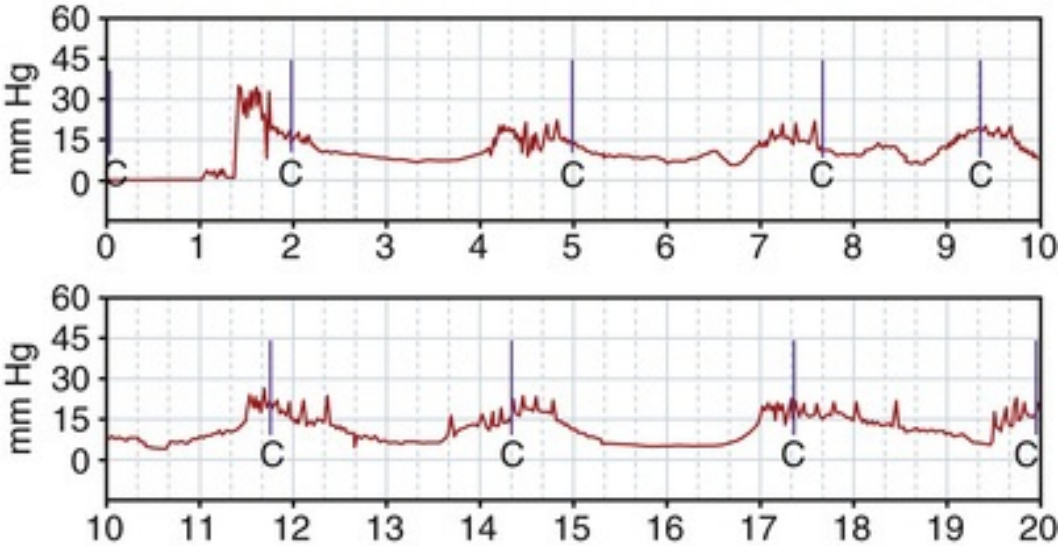
E-FIGURE 315-15 Tocodynamometry: Obstructive pattern. X axis: time in minutes. Y axis: strength of contraction in mm Hg.

Fetal Distress via Monitors

The presence of fetal distress is detected by sustained heart rate deceleration. Normal canine and feline fetal heart rates at term are from 170 to 230 beats per minute (bpm) or at least 4× the maternal heart rate. In the periparturient period, fetal cardiac output is mainly dependent on rate as the right ventricle is relatively stiff (low compliance) and the autonomic nervous system is immature (minimal inotropic response to catecholamines). Decelerations associated with uterine contractions suggest mismatch in size between the fetus and dam or fetal malposition. Transient normal accelerations occur with fetal movement. Fetal heart rates ≤150 to 160 bpm indicate stress, rates ≤130 bpm are associated with poor survival if not delivered within 30-60 minutes. Fetal heart rates ≤100 bpm indicate need for immediate delivery of neonates (medical or surgical). The use of uterine and fetal monitors allows the veterinary clinician to detect and monitor labor, as well as manage labor medically or surgically with insight. At one dog breeding facility, stillbirth rate declined from 9.2% to 2.5% with use of uterine and fetal monitoring.

Medical Therapy for Dystocia

Medical therapy for dystocia, administration of Ca gluconate and oxytocin, can be directed and tailored based on the results of monitoring (see ch. 146). Generally, giving Ca increases strength of myometrial contractions, while oxytocin increases their frequency (E-Figure 315-16). Ca is given before oxytocin in most cases, improving contraction strength before increasing frequency. Ca gluconate (10% solution with 0.465 mEq Ca/mL; 1 mL/5.5 kg SC [Fujisawa Inc., USA]) is given as indicated, noting the strength of uterine contractions, usually every 4-6 hours. Oxytocin (10 USP units/mL; American Pharmaceutical Partners Inc., Los Angeles, California, USA) is effective starting with 0.25 units SC or IM to a maximum of 2 units per bitch or queen. High dosages of oxytocin, or IV boluses, can cause tetanic, ineffective uterine contractions that can further compromise fetal oxygen supply by placental compression. The frequency of oxytocin administration is dictated by the labor pattern and it is generally given about q 30-60 minutes. Additionally, the action of oxytocin appears to be improved when given 15 minutes after Ca. Most bitches/queens are eucalcemic, suggesting that the benefit of Ca is at a cellular or subcellular level.



E-FIGURE 315-16 Same bitch as in E-Figure 315-13, treated with 6 mL 10% calcium gluconate SC and 0.5 USP unit oxytocin IM. Abdominal pushing evident in conjunction with uterine contractions. Neonate was delivered in 26 minutes.

Surgical Therapy (Cesarean Section [C-Section])

Indications

Surgery is indicated if a bitch or queen fails to respond to medical management or if fetal distress is evidenced despite adequate to increased uterine contractility (suggesting mismatch of maternal birth canal to fetal size, fetal malposition or malposture incompatible with vaginal delivery), or if aberrant contractile patterns are noted by uterine monitoring. Well-orchestrated C-sections are the result of established and coordinated anesthetic and neonatal resuscitative protocols together with optimal preoperative preparation of the dam. It should always be remembered that the dam may be debilitated and require careful anesthetic management, there may be little time for routine pre-anesthetic preparation, and she may have been fed recently. Minimally, the hematocrit, total solids, serum Ca and glucose levels should be evaluated preoperatively. IV fluid support is indicated (5-10 mL/kg/h; see ch. 129).

Pre-Anesthesic and Anesthetic Agents

Spinal blocking protocols are described in ch. 146. Atropine is not advised for premedication because it crosses the placenta, blocks the adaptive bradycardic fetal response to hypoxemia, and relaxes the lower esophageal sphincter, making maternal aspiration more likely. However, the use of an anticholinergic is indicated for the dam because of the anticipated vagal stimulation during uterine manipulation. Glycopyrrolate (0.01-0.02 mg/kg SC) does not cross the placenta and is preferred. Most dams do not need preanesthetic tranquilization, which has a depressant effect on fetuses. Phenothiazine tranquilizers are transported rapidly across the placenta. Alpha 2-adrenoreceptor agonists (dexmedetomidine, xylazine) and opiates are contraindicated because of their severe cardiorespiratory depressant effects. If tranquilization is necessary with an intractable dam, narcotic sedatives are preferable as their effects can be reversed (naloxone 1-10 mcg/kg IV or IM) during neonatal resuscitation (see Video 146-1). Metoclopramide (0.1-0.2 mg/kg) can be administered SC or IM prior to induction of anesthesia, reducing risk of vomiting. Pre-oxygenation by mask (5-10 minutes) is always indicated (see ch. 131). Initial preparation of the abdomen can be started during this time. For induction of anesthesia, dissociative agents such as ketamine and the barbiturates are best avoided because they can profoundly depress fetuses. Propofol (6 mg/kg IV to effect) appears to be most useful; its rapid redistribution limits fetal issues after delivery. Alfaxalone (Alfaxan, Jurox) 1.5-4.5 mg/kg IV (canine) and 2.2-9.7 mg/kg IV (feline) has been used as an induction agent for C-sections, but fetal and neonatal depression occur and studies in pregnant or lactating dams are needed. Mask induction causes more maternal and fetal hypoxemia than propofol.

For maintenance of anesthesia, volatile agents are preferable, especially those with low partition coefficients (isoflurane and sevoflurane). These agents show rapid uptake, quick elimination, and may have better cardiovascular margins of safety than more soluble agents (halothane). Nitrous oxide may be used to reduce

the dose of other anesthetic agents, it is transferred rapidly across the placenta and, although it has minimal effects upon the fetus *in utero*, it may result in significant diffusion hypoxia after delivery. Using a local anesthetic (bupivacaine 2 mg/kg) line block in the skin and SC tissues prior to incising permits a more rapid entry to the abdomen while the dam is making the transition from propofol induction to inhalant maintenance, and helps with postoperative discomfort.

Surgery/Ovariohysterectomy (OVH)

OVH at the time of C-section is an option for surgeon and owner, but results in longer anesthetic time, delays neonatal nursing, and increases the chance of maternal blood loss. OVH should be postponed if reasonable. There is some belief that estrogen acts in a permissive fashion for prolactin receptors in the mammary glands, making ovary removal undesirable. If uterine viability is questionable, OVH should be performed. In the normal dam, the uterus will begin to involute shortly after removal of the fetuses, but if this is not the case oxytocin may be administered (0.25-1.0 units per dam) to facilitate involution, help slow any bleeding, and promote milk letdown. Elective C-sections are common in people (>50% of deliveries in the USA). Breeders may request elective C-section when apprehensive about the whelping process. There are pros and cons to consider when counseling clients about elective C-sections. Indications for elective C-section include singleton litter, oversized fetuses, brachycephalic or hydrocephalic breed, or historical inability to whelp vaginally (E-Boxes 315-2 and 315-3). 60% of bitches undergoing C-section can whelp vaginally on subsequent pregnancies.

E-Box 315-2

Positive Considerations for an Elective Cesarean Section

- More predictable outcome in *most* cases
- Scheduled, not emergency time frame
- Single method of delivery
- Sometimes more cost-effective
- Proactive pre-operative management
- Proactive pain management
- Increased veterinary involvement in delivery
- Promotes ovulation timing for gestational aging to select date of cesarean
- Avoids complications of unrecognized dystocia
- Immediate veterinary evaluation of neonates
- Avoids visit to emergency clinic unfamiliar with client and bitch
- Staff enthusiasm

E-Box 315-3

Negative Considerations for an Elective Cesarean Section

- Anesthetic risks
- Surgical risks
- Invasiveness
- Drug delivery to neonates
- Expense
- Bypasses exposure to normal protective vaginal flora (increase in neonatal pathogens)
- Exposure to infectious disease in veterinary clinic
- Loss of selection for natural whelping
- Maternal stress
- Maternal surgical pain
- Maternal drug delivery
- Delayed or abnormal maternal behavior

- Requires neonatal resuscitation

Post-Surgery

Discomfort should be anticipated in the dam, and once the fetuses are removed, narcotic analgesia should be administered to her. Postoperatively, nonsteroidal anti-inflammatories are not advisable due to their uncertain metabolism by the nursing neonates with immature renal and hepatic metabolism. Narcotic analgesia is preferable. Oral narcotics such as tramadol, 10 mg/kg/day PO in divided doses, provide excellent analgesia for nursing bitches with minimal neonatal sedation. In all cases, clients should be advised to closely monitor bitches postoperatively until normal maternal behavior emerges. Post C-section, bitches can be clumsy, inattentive, and even aggressive to their puppies. The normal mechanisms of maternal bonding have been bypassed by surgery and neonatal care is usually fine with time.

Immediate Postpartum Period

Normally, dams remain close to their offspring during the first 2 weeks postpartum, leaving the whelping/queening box briefly, if at all, to eat and eliminate. They should be alert and content to remain with their offspring. Some protective dams may show aggression to housemate animals or people initially. Such behavior tends to dissipate after 1-2 weeks of lactation. Lactation is likely the greatest nutritional and caloric demand of the female's life. Weight loss and dehydration should be avoided because of danger to the dam and because lactation will be negatively impacted. Food and water must be made readily available. Sometimes both food and water need to be placed in the nest box of a nervous dam. Partial anorexia can be exhibited during the last weeks of gestation and in the immediate postpartum period, but appetite should return and increase as lactation progresses. Poor appetite during the last weeks of gestation can be due to displacement or compression of organs (stomach) by the gravid uterus. Early postpartum partial anorexia has been noted after consumption of placentae, causing digestive upset. Diarrhea can be secondary to the bitch being given more food and/or richer food than usual. Also, bacterial overgrowth secondary to carbohydrate malassimilation may occur. Marked postpartum effluvium is normal in bitches, usually occurring 4-6 weeks after whelping and sparing only the head. This is usually more marked than that which occurs in conjunction with the typical estrous cycle. Owners should be assured that is not problematic, despite being noted to happen in conjunction with the weight loss typically associated with lactation.

The body temperature of the dam may be mildly elevated (<103.0° F [<39.4° C]) in the immediate postpartum period, reflecting normal inflammation associated with parturition. It should return to normal levels within 24-48 hours. If a C-section took place, differentiating normal post-surgical inflammation from fever associated with illness may be difficult. Physical examination and a complete blood count may help. Normal postpartum lochia is brick-red in color, non-odorous, and diminishes over several days to weeks (uterine involution and repair progress for up to 16 weeks in bitches). The mammary glands should not be painful, hot, erythematous, or hard. They should be symmetric and moderately firm. Normal milk is gray to white in color and of watery consistency.

Inappropriate Maternal Behavior

Appropriate maternal behavior is critical to neonatal survival and includes attentiveness, protection, facilitation of nursing, herding neonates, and grooming. Although maternal behavior is instinctual, it can be negatively influenced by anesthetic drugs, pain, stress, and human interference. Maternal bonding is pheromone-mediated and initiated at parturition. Whelping and queening should take place in quiet, familiar surroundings with minimal human interference, yet adequate supervision. Dams with good maternal instincts exhibit caution when entering or moving about the nest box so as not to traumatize neonates by stepping or lying on them. A guardrail along the inside of the whelping box can help prevent inadvertent smothering of puppies.

The neuroendocrine reflex regulating mammary gland myoepithelial cell contraction and subsequent milk ejection is mediated by oxytocin and activated by neonatal suckling. During stress, epinephrine induces vasoconstriction, blocking the entry of oxytocin into the mammary gland and preventing milk letdown. A nervous, agitated dam will likely have poor milk availability. Dopamine antagonist tranquilizers, with minimal prolactin interference (acepromazine 0.01-0.02 mg/kg PO q 6-24 h) can be given at the lowest effective dosage to minimize neonatal sedation. This may improve maternal behavior and milk availability in nervous dams. Piling of littermates near their dam facilitates the maintenance of appropriate body

temperature (neonates cannot thermoregulate/shiver until up to 4 weeks of age) and makes nursing readily available. Normal maternal behavior includes gentle retrieval of neonates who become dispersed and isolated across the nest box. Grooming of the neonates immediately following parturition stimulates their cardiovascular and pulmonary functions and removes amniotic fluids. Dams demonstrating little interest in resuscitating neonates can have poor maternal behavior throughout the postnatal period. Later, maternal grooming stimulates reflex neonatal urination and defecation as well as keeping neonatal coats clean and dry. Occasionally, excessive protective behavior or fear-induced maternal aggression can occur. Mild tranquilization of the dam can help, but neonatal drug administration via the milk can be problematic. Benzodiazepines, GABA synergists, are superior to phenothiazines for fear-induced aggression (diazepam 0.55-2.2 mg/kg PO q 8-12 h).

Uterine Disorders

Uterine Prolapse and Rupture

Complete or partial prolapse of the uterus is uncommon in the bitch and rare in queens (Figure 315-17). Diagnosis is based on palpation of a firm tubular mass protruding from the vulva postpartum and an inability to identify the uterus with abdominal US. Vaginal hyperplasia and prolapse should be ruled out by physical examination, vaginoscopy, or contrast radiography (see ch. 146). Prolapsed tissues can be macerated and/or infected from exposure and contamination. The size of most bitches and queens precludes manual replacement; laparotomy and OVH are usually indicated.

FIGURE 315-17 Feline uterine prolapse associated with dystocia.

Rupture of the uterus occurs most commonly in dogs with quite large litters that can cause stretching and thinning of the uterine wall, especially in multiparous dams with dystocia. Rupture can also occur with inappropriate use of ecbolic agents (Figure 315-18). Immediate laparotomy is indicated to retrieve fetuses, repair or remove the uterus, and culture/lavage the abdominal cavity. The uterus should be carefully examined at any C-section for rupture or fragile areas. Peritonitis (see ch. 279) can result with even small uterine tears. Unilateral hysterectomy can be considered if the damaged area is limited and the dam valuable

to a breeding program.

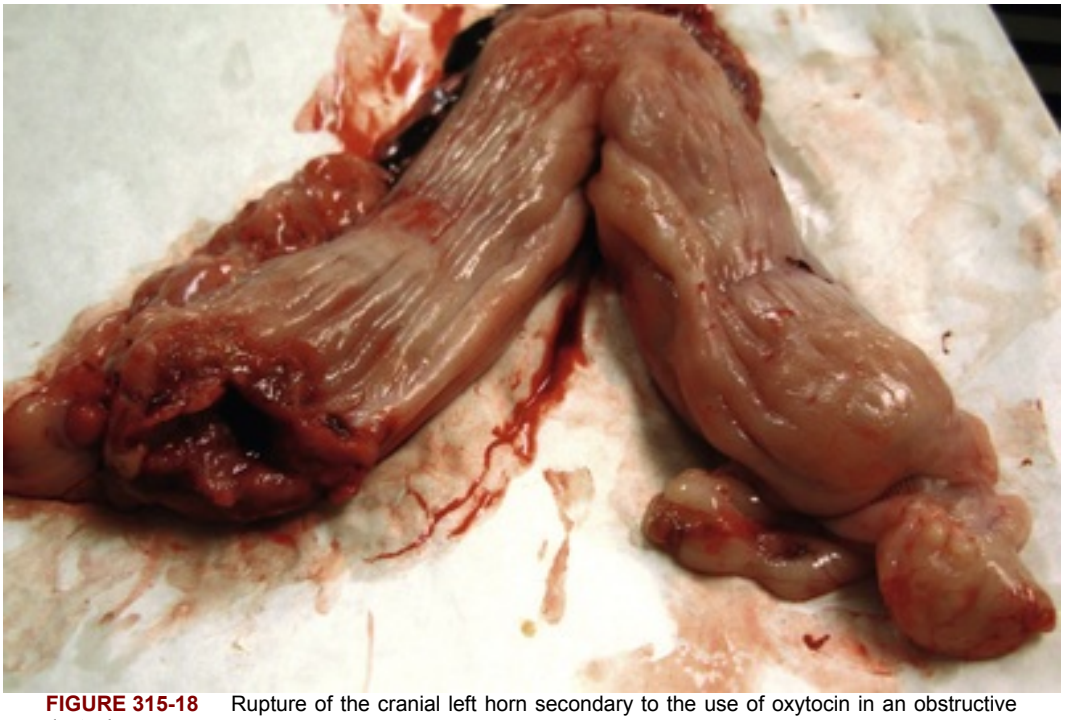


FIGURE 315-18 Rupture of the cranial left horn secondary to the use of oxytocin in an obstructive dystocia.

Subinvolution of the Placental Sites (SIPS)

The persistence of serosanguineous to hemorrhagic vaginal discharge beyond 16 weeks postpartum can indicate SIPS, a condition in which fetal trophoblastic cells persist in the myometrium (they should degenerate), endometrial vessel thrombosis is lacking, normal uterine involution is prevented, and normal interplacental regions exist. Eosinophilic masses of collagen and dilated endometrial glands protrude into the uterine lumen and seep blood. Cause is unknown, blood loss is usually minimal, intrauterine infection is usually not present, and fertility is unaffected. Treatment is generally not necessary, as recovery is spontaneous and symptoms mild.

If vaginal bleeding from SIPS is copious and causing anemia, bleeding disorders (likely defects in the intrinsic pathway or thrombocytopenia/thrombocytopathies), trauma, neoplasia of the genitourinary tract, metritis and proestrus should be ruled out. Vaginal cytology, vaginoscopy, coagulation testing and abdominal US should be considered. The benefit of prostaglandins, oxytocin or other ecbolics is questionable and not proven. The preventative value of mini-dose oxytocin given in the immediate postpartum period is also unproven but probably not harmful. Laparotomy and OVH are curative if blood loss is significant or problematic to an owner. Histologic examination of the uterus is indicated to confirm the diagnosis.

Metritis

Metritis, a serious acute infection of the postpartum endometrium, should be suspected if lethargy, anorexia, decreased lactation, fever, malodorous vaginal discharge, and/or poor mothering are observed. Metritis may be preceded by dystocia, contaminated obstetrical manipulations, retained fetuses, and/or retained placentae. Hematologic and biochemical changes often suggest septicemia, systemic inflammation and endotoxemia. Vaginal cytology shows a hemorrhagic to purulent septic discharge. Abdominal US is excellent for evaluation of the uterine wall and the intrauterine contents for fetal or placental material. Metritis is characterized by an echogenic plicated endometrium with fluid within the uterine lumen (E-Figure 315-19). A guarded cranial vaginal culture will likely be representative of intrauterine flora and should be submitted for both aerobic and anaerobic culture/sensitivity, permitting retrospective assessment of empirically selected antibiotic therapy. Bacterial ascension from the lower genitourinary tract is more common than hematogenous spread.

Escherichia coli is the most common causative organism in bitches and queens.

E-FIGURE 315-19 Sagittal ultrasound image of postpartum metritis; note the echogenic endometrium with plication and fluid within the lumen of the uterine horn.

Therapy consists of IV fluid and electrolyte support, appropriate antibiotics, and uterine evacuation using prostaglandin F_{2alpha} (0.1-0.2 mg/kg SC q 12-24 h) or cloprostenol (1-3 mcg/kg SC q 12-24 h) for 3-5 days or until evacuation of the uterus is complete and the bitch or queen is stable. Cephalexin (10-20 mg/kg PO q 8-12 h) or amoxicillin-clavulanate (14 mg/kg PO q 12 h) are safe for neonates and used pending culture and sensitivities. Many affected dams can be managed on an outpatient basis, permitting neonatal nursing to continue at home. OVH may be indicated if peritonitis occurs and response to medical management is poor. Oxytocin is unlikely to promote effective uterine evacuation when administered >24-48 hours postpartum. Nurslings should be hand reared if the dam is seriously sick. Metritis can become chronic and cause infertility. Retained placentas are usually not problematic and are passed 1-2 days postpartum without complication.

Mammary Disorders: Agalactia, Galactostasis, Mastitis

Agalactia

Agalactia is defined as a failure to provide milk to neonates. Primary agalactia, a lack of mammary development during gestation, results in a failure of milk production, is uncommon, and a defect in the pituitary-ovarian-mammary-gland axis is suspected. Use of progesterone compounds late in gestation can interfere with lactation. Secondary agalactia, a lack of milk availability due to a failure of ejection or letdown, is more common. Mammary development is marked, but milk cannot be readily expressed through the teat sphincter. Production of colostrum in the immediate postpartum period should not be confused with agalactia. Agalactia can occur secondary to premature parturition, stress, malnutrition, debility, pain, metritis, or mastitis. Treatment includes milk supplementation for the neonates, encouraging neonatal suckling, providing optimal nutrition and water to the dam, and resolution of any underlying disease. If detected early, milk letdown can often be induced pharmacologically with mini-dose oxytocin (0.25-1 units, SC q 2 h). Neonates are removed for 10-30 minutes before injection, then encouraged to suckle. The owner can gently "strip" the glands. Metoclopramide (0.1-0.2 mg/kg SC q 12 h) may promote prolactin release. Milk letdown is

usually noted within 24 hours.

Galactostasis

Galactostasis results in engorgement and edema of the mammary glands with discomfort that interferes with further nursing and can be self-perpetuating. It may occur secondary to inverted or imperforate teats, failure to rotate nurslings, litter loss, an unusually small litter, or rarely in pseudocyesis. Encouraging suckling or gently manually evacuating affected glands is advised. If galactostasis occurs during weaning, the use of cabergoline 2.5-5 mcg/kg/day PO for 4-6 days may be helpful.

Mastitis

Mastitis is septic inflammation of one or multiple mammary glands. It can be acute and severe or chronic and low grade. Coliforms, staphylococci, and streptococci are most commonly isolated from both bitches and queens. The source of bacteria is cutaneous, exogenous or hematogenous. Mastitis can be associated with metritis. Mild mammary discomfort and heat, galactostasis, cutaneous inflammation, and a palpable intramammary mass are the earliest signs. The milk may be red or brown due to red blood cells and white blood cells. Some dogs exhibit pain, reluctance to nurse or lie down, anorexia and lethargy. Fever can be marked and may precede other clinical signs. Advanced cases can progress to septic shock with abscessed or necrotic glands. Diagnosis is based on physical examination. Milk cell counts in bitches are not predictive of mastitis. Culture and sensitivity of milk collected aseptically from affected glands allows retrospective evaluation of antibiotic selection.

Therapy should include antibiotics and gentle physical therapy. Analgesics may be indicated; neonates tolerate opioid analgesia in the dam. Cephalexin (10-20 mg/kg PO q 8-12 h) and amoxicillin-clavulanate (14 mg/kg PO q 12 h) are advised and safe for the neonates. Antibiotic therapy may be warranted until weaning and can preclude further nursing if the condition forces use of a drug potentially toxic to neonates. Warm compresses or whirlpool therapy of the affected gland with gentle stripping of milk may help avert abscessation and/or rupture. Severe necrosis warrants mastectomy when the dam is stabilized, and aggressive wound management. Ultrasound can guide management of a developing abscess (E-Figures 315-20 and 315-21). Antiprolactin therapy (cabergoline 1.5-5 mcg/kg/day PO divided q 12 h) may be indicated if severe, to reduce lactation if weaning is timely. Early weaning is not advised as it promotes galactostasis. There is no evidence that nursing from affected glands is problematic for neonates, but they tend to avoid glands if milk is not readily produced. The affected gland should be protected from nestbox-edge trauma or trauma from neonatal claws. Mastitis can recur in subsequent lactations regardless of preventative measures taken; prophylactic antibiotics are not advised; instead, good hygiene and avoidance of galactostasis are indicated.

CHAPTER 316

Pyometra and Cystic Endometrial Hyperplasia

Annika Bergström

Client Information Sheet: Pyometra

Definition

Cystic endometrial hyperplasia (CEH) and pyometra are the most frequent disorders of the uterus in middle-aged and older intact dogs. CEH includes development of pathological cysts and thickening of the endometrium. This is an abnormal response of the canine and feline uterus to repeated long periods of high serum-progesterone concentrations during the luteal phases of their estrous cycle, even though anestrous bitches can be diagnosed with pyometra.[1] Pyometra is a disease characterized by purulent material within the uterus. Bilaterally ovariectomized dogs do not develop pyometra, since ovarian steroids are required. Pyometra is life-threatening, especially in cases where the cervix is closed.

Epidemiology

Due to long periods of high serum progesterone concentration, CEH and pyometra are common in intact bitches. Cats are also affected, but not as frequently as bitches. Pyometra is more frequently diagnosed in certain breeds, such as Rough Collies, Rottweilers, Cavalier King Charles Spaniels, Golden Retrievers and Bernese Mountain Dogs.[2,3] About 15% of all Beagle bitches develop pyometra.[4] In some breeds, the incidence of pyometra by the age of 10 years is as high as 50%. On average, about 25% of all intact bitches develop pyometra by ten years of age.[2] The incidence of CEH is higher in colony-reared than feral cats. The feral cats have a greater number of ovarian interstitial cells but their significance is not known. In cats >5 years of age, the frequency of CEH was about 90% and about 30% of 2-4 year old cats had histologic evidence of CEH.[5] Pyometra is more common in queens >7 years of age. In insured cats, the incidence rate was 17 cats per 10,000 cat years at risk (CYAT) and Sphinx cats ran the highest risk (433/10,000 CYAT). The mortality in this study was about 6%.[6]

Pathophysiology

Hormones Associated with CEH and Pyometra

During the canine estrous cycle, the uterus is under the influence of estrogen relatively briefly, but is under the influence of progesterone for 9-12 weeks following ovulation regardless of pregnancy, resulting in increased endometrial growth, glandular secretions, and inhibition of drainage by stimulating closure of the cervix (see ch. 312). Progesterone also decreases myometrial contractions and inhibits leukocyte activity in the endometrium, increasing risk for bacterial growth.[7] The diestrual period creates an excellent uterine environment for bacteria to thrive.[8] CEH, in which the endometrium becomes thickened due to an increased number of cystic glands, develops after repeated luteal phases and increasing age in all bitches.[1] There are no significant differences in serum hormone concentrations in bitches developing pyometra compared to healthy bitches (see ch. 312). It has therefore been suggested that uterine hormonal receptors may have a role in the pathogenesis of pyometra.[9-11] Studies of uterine estrogen and progesterone receptors in bitches with CEH have provided inconsistent results.[12-14]

Classically, CEH has been considered the predecessor to pyometra. An alternative hypothesis is that a low-grade bacterial infection within the uterus causes endometrial proliferation and CEH. All bitches with CEH

do not develop pyometra and bitches may develop pyometra not preceded by CEH.[15] Clinically healthy bitches can have uterine changes, e.g., those with CEH may accumulate sterile mucoid, serous or hemorrhagic fluid without signs of illness.[16] Pyometra usually develops during diestrus, when the serum progesterone concentration is increased and the ovaries usually have visible *corpora lutea* (Figure 316-1). While less common, pyometra in cats also develops secondary to uterine progesterone sensitization. CEH is not commonly diagnosed in queens. Based on histopathology and hormone analysis, 40-57% of female cats with pyometra or endometritis were in the luteal phase and 43% of female cats with pyometra were in the follicular phase.[17]

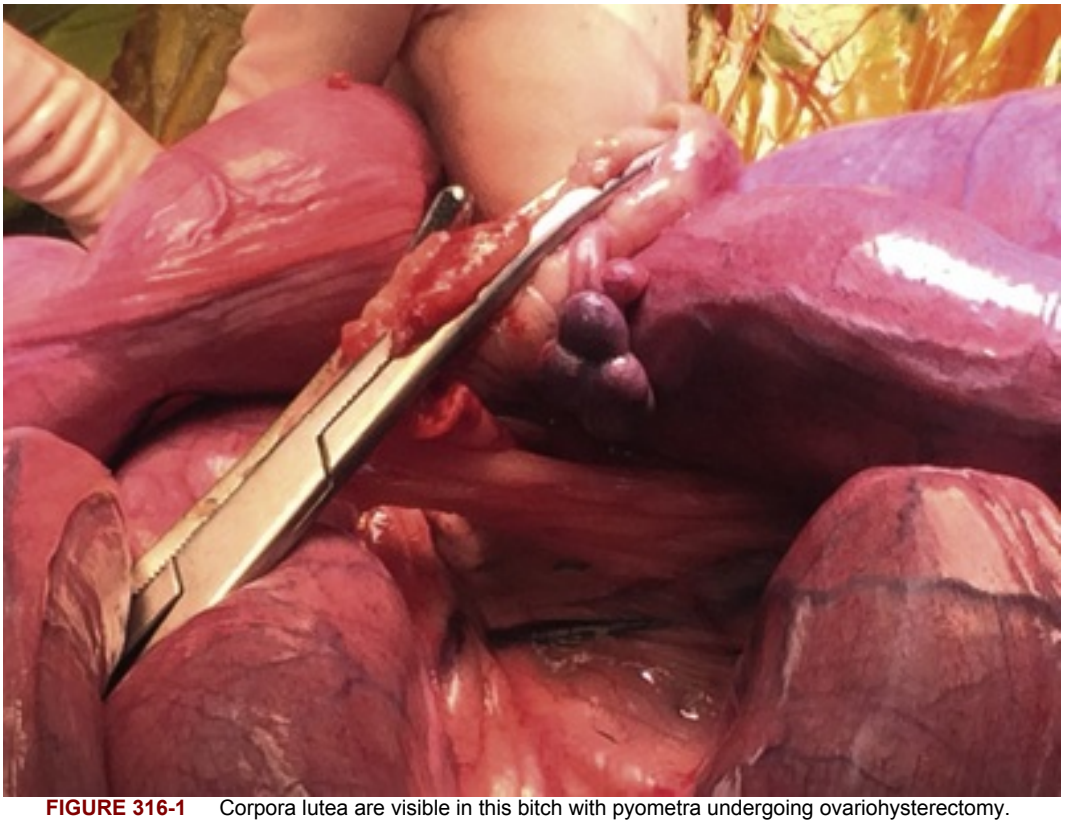

FIGURE 316-1 Corpora lutea are visible in this bitch with pyometra undergoing ovariohysterectomy.

Less commonly, pseudoplacentational endometrial hyperplasia (deciduoma), a form of CEH, has been described.[18,19] Pseudoplacentational endometrial hyperplasia represents luteal phase placentation, similar to the normal histology of the endometrium at placentation sites in normal pregnancy.[19]

Bacteria Associated with Pyometra

During estrus, bacteria from the normal vaginal flora may ascend into the uterus through the open cervix, including *Escherichia coli* (most common), *Streptococcus* spp., *Enterobacter* spp., *Proteus* spp., *Klebsiella* spp. and *Pseudomonas* spp. *E. coli* may adhere to specific receptors in the endometrium and myometrium.[8] Bacterial endotoxins may cause damage to several organs. This is especially true for lipopolysaccharide endotoxin (LPS) from *E. coli*. The polydipsia seen in bitches with pyometra is a compensatory mechanism to replace water lost through the kidneys (see ch. 45). Bacterial endotoxins impair the ability of the loop of Henle to reabsorb sodium and chloride. *E. coli* endotoxins also have the ability to cause tubular insensitivity to antidiuretic hormone (ADH), which causes further loss of urinary concentration ability (see ch. 296).[8]

Cystic Endometrial Hyperplasia (CEH)

The only clinical sign associated with CEH is infertility—there are no other clinical signs. If the CEH progresses into a fluid-filled uterus, the principal sign may be similar to that of a bitch or queen with

pyometra: vaginal discharge. Polyuria, polydipsia and decreased general health may be noted. No medical treatment for CEH has been recognized.

Pyometra

Risk factors for the development of pyometra in dogs and cats include use of progestogens for estrus suppression, or estrogen for estrus induction or pregnancy termination.[3,9,14,20] Estrogen upregulates endometrial progesterone and estrogen receptors.

Clinical Signs and Diagnosis

Timing and Signs

Pyometra in bitches usually develops 4 weeks to 4 months after estrus, during diestrus, when the dominance of progesterone is required to maintain pregnancy.[21] Dogs with pyometra are usually middle-aged or older, but bitches of any age have been diagnosed. In queens, the median age for development of pyometra in one study was 32 months and within 8 weeks after estrus.[22] Pyometra is common and should always be included as a possible diagnosis if an intact female dog or cat is ill. The uterus may be slightly increased in size or severely dilated (Figure 316-2). Differential diagnoses with similar appearance on ultrasound (US) examination are the non-life-threatening hydrometra, mucometra and hemometra.[16]

FIGURE 316-2 A severely enlarged uterus due to pyometra is exteriorized prior to surgical removal. The risk for rupture and septic peritonitis is impendent.

Pyometra usually results in vaginal discharge if the cervix is open, allowing drainage of hemorrhagic, serosanguineous or mucopurulent fluid from the uterus. If the cervix remains closed, there is no vaginal discharge and the uterine contents may increase in volume, resulting in risk for uterine rupture and peritonitis if not recognized and treated in a timely manner. Dogs and cats with closed cervix pyometra are often inappetent, obtunded, lethargic, polyuric, polydipsic, and may have abdominal distention.[21] Fever may be present. Septicemia, toxemia, systemic inflammatory response syndrome (SIRS), DIC, shock and death may occur (see ch. 132, 146, 207, and 279). Potential clinical signs include tachycardia, prolonged capillary

refill time and weak femoral pulses.[16] The rate of SIRS correlates positively with duration of clinical signs, indicating that a delay in treatment leads to rapid progression of clinical illness.[23]

In some pets, uveitis (see ch. 11), joint pain (see ch. 203) and swollen joints may develop secondary to the systemic inflammatory response. Abdominal palpation may reveal an enlarged uterus, but the uterus can be difficult to palpate. Careful palpation is strongly recommended to prevent uterine rupture. Due to severity of inflammation and endotoxemia, some bitches are severely ill despite having a relatively small or slightly distended uterus. Vaginal examination in dogs is recommended to exclude vaginal disease, e.g., neoplasia, as the cause of vaginal discharge. In queens, the most common clinical signs are vaginal discharge, anorexia and lethargy.[24]

Laboratory Testing and Imaging Recommendations

Complete Blood Count (CBC)

Some bitches may have normal blood parameters, depending on severity of disease. Most bitches with pyometra have marked CBC changes that correlate with severe infection and/or chronic inflammation. Normocytic normochromic anemia has been noted in about 70% of dogs with pyometra, likely caused by decreased erythropoiesis.[25] Decreased iron concentrations secondary to chronic inflammation may decrease erythropoiesis. Toxic effects on the bone marrow due to sepsis can further suppress erythropoiesis. A marked increase in total white blood cell count (WBC) is common in pyometra, but significantly less so in bitches with CEH.[26,27] Leukocytosis with severe neutrophilia, left shift, and monocytosis are frequently seen. Bitches with closed cervix pyometra have the highest WBC.[8] In severe illness, endotoxemia may progress to suppress the bone marrow and lead to neutropenia, especially as neutrophils continue to flood the uterus. Predictors of peritonitis in bitches with pyometra are leukopenia, fever and hypothermia. In bitches with leukopenia, the risk for peritonitis is 18 times higher and the hospitalization time is 3.5 times increased.[31]

Serum Biochemistries and Biomarkers

Serum alkaline phosphatase (ALP) activity, globulin and total protein commonly increase in bitches with pyometra. C-reactive protein (CRP) and serum-amyloid A (SAA) may be markers to help distinguish pyometra from CEH.[26] Increases in ALP, bilirubin and cholesterol may be due to intrahepatic cholestasis.[28] Pre-renal azotemia occurs secondary to dehydration and renal azotemia can be due to reversible tubular damage. Serum concentrations of insulin growth factor 1 (IGF-1) and iron are decreased in bitches with pyometra, secondary to the inflammatory response. C-reactive protein and SAA are increased in dogs with pyometra and SAA is likely increased in pyometra cats as well. These biomarkers may be used to identify sepsis in dogs with pyometra, as they are significantly lower in healthy and CEH bitches.[26,29,30]

CRP may also be a useful marker for assessment during the postoperative period as a trend marker for postoperative complications.[29,32,33] Preoperative serum lactate concentration was neither related to systemic inflammatory response syndrome nor to prolonged hospitalization.[34] Repeated measurement of serum lactate may be recommended in severely ill bitches with pyometra to ensure that cellular energy consumption is regained (see ch. 70). Plasma PGF_{2alpha} is increased both in bitches and queens with pyometra, compared to healthy animals.[35,36] The increase in plasma prostaglandins probably originates from endometrial synthesis due to stimulation from bacterial endotoxins.

Imaging

The most commonly used modalities for confirming a diagnosis of pyometra are abdominal ultrasound (US; see ch. 88) or radiology. US is the most sensitive and specific test that may also aid in differentiating pyometra from mucometra. In pyometra, the uterine wall is thickened, the lumen distended with serous to viscous heteroechogenic fluid. In mucometra the uterine fluid is more uniformly hypoechoic. Other diagnostic modalities such as computed tomography and magnetic resonance imaging may be used, but are not usually necessary.

Bacterial Culture

The most common bacteria sampled from a pyometra uterus in dogs and cats are *Escherichia coli*. Bacterial sensitivity to antimicrobials is usually high based on a study where only 10% of *E. coli* from uterine pyometra samples were resistant to amoxicillin.[37] Sampling the cranial vagina with a guarded swab may be useful for

open cervix pyometra treated medically, but vaginal bacteria may differ from those in the uterus. The clinical importance of sampling bacteria from the ovarian bursa is unclear. Samples may be positive in healthy bitches and in bitches with mucometra. Also, only about half of the bacterial samples from the ovarian bursa in bitches with pyometra were the same as those recovered from the uterine pus.[38]

Urinalysis

Urinary tract infection (UTI) may occur simultaneously with pyometra, with identical bacterial isolates (see ch. 330).[39,40] After surgical treatment of pyometra, UTI usually resolves spontaneously. Cystocentesis is not recommended in bitches with pyometra due to the risk of perforating the purulent uterus, but may be performed intra-operatively in a controlled manner. Due to immune complex deposition in the glomeruli, proteinuria may be seen in some bitches, which usually resolves with resolution of the condition.[8] Urine specific gravity may be normal, decreased or increased depending on endotoxemia, hydration status, the effects of *E. coli* interfering with ADH action at the renal tubular level, and presence of UTI.

Treatment

Initial Stabilization

The bitch or queen with pyometra may require life-saving treatment before surgical or medial management, including fluid therapy (see ch. 129) and treatment of acidosis (see ch. 128), electrolyte disturbances (see ch. 67, 68, and 69) and hypoglycemia (see ch. 62). Endotoxemia is approached with aggressive fluid therapy (see ch. 146). Antimicrobial therapy should be directed against *E. coli,* and amoxicillin is effective in 90% of cases (also see ch. 161).[37] If resistance to amoxicillin is noted on sensitivity testing, a different appropriate antibiotic should be chosen. Antimicrobials are not recommended for stable bitches and queens, since the source of the infection is surgically removed (OHE). Since 15% of bitches with pyometra had a positive blood culture, all bitches with clinical signs of septicemia and fever should be treated with antimicrobials perioperatively.[41] In cases with septic peritonitis due to leakage of pus into the abdomen (see ch. 279), antimicrobials are continued for ten days. In others, antimicrobials are not given, or are discontinued after surgery.

Severity of disease correlates with the level of bacterial toxins that cause clinical signs and an essential component of treatment is adequate fluid therapy. If dogs have ventricular tachyarrhythmias, concurrent, inciting abnormalities should be managed and antiarrhythmic treatment may be considered (see ch. 248). In medically treated bitches, antimicrobials are given until the uterus appears normal on US, usually after about 3 weeks. Antimicrobial therapy may aggravate the endotoxemia as LPSs are released when the bacteria die.[42] Close monitoring and sufficient fluid therapy is therefore important.

Medical Management

Background and Case Selection

Surgery is the preferred treatment for pyometra. Medical treatment for pyometra is recommended only in stable brood bitches without signs of sepsis, endotoxemia, hypothermia or fever (Figure 316-3). Also, only dogs without liver or kidney dysfunction should be treated medically. It is extremely important to closely monitor these pets during treatment, as peritonitis or endotoxemia may develop. Bitches with a closed cervix should be treated surgically, despite some recommendations to the contrary.[43,44] Before recommending medical management, one should consider the increased risk for pyometra in the offspring of the bitch being treated. Genetic factors for development of pyometra are likely, as some breeds are known to be more prone to the disease (see above).

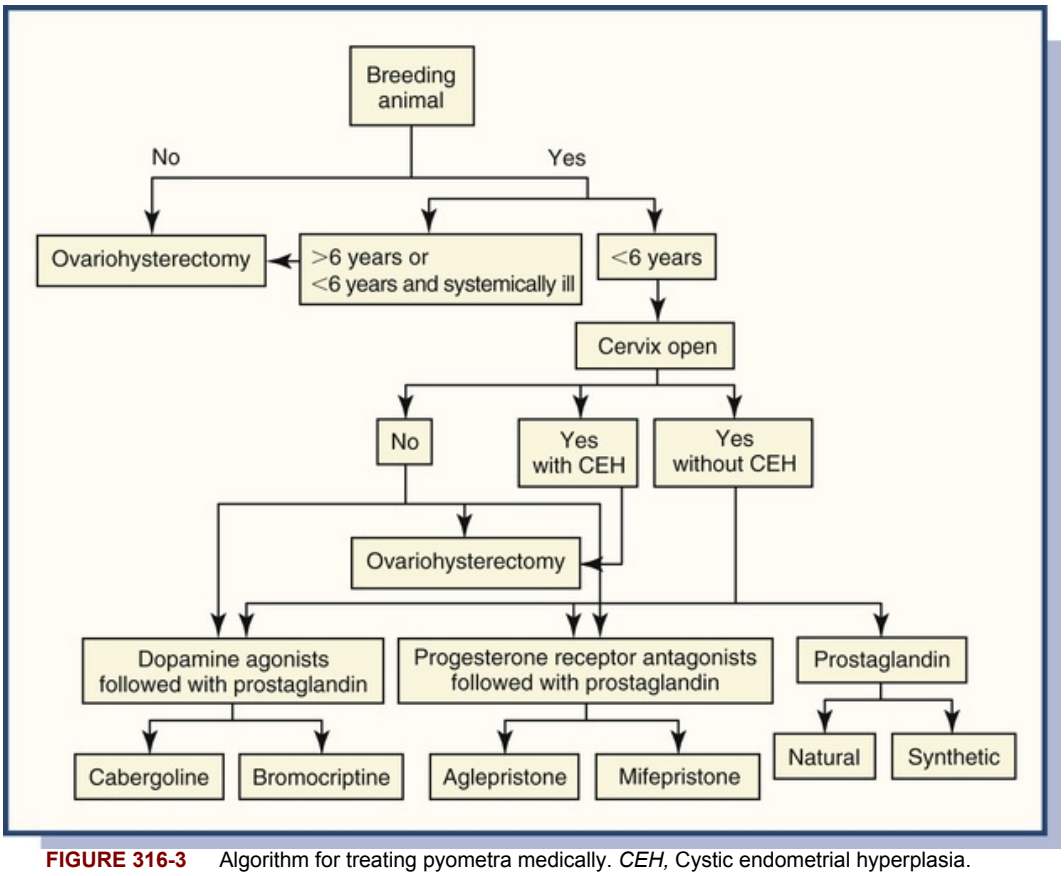

FIGURE 316-3 Algorithm for treating pyometra medically. *CEH,* Cystic endometrial hyperplasia.

Prognosis after medical treatment depends on the presence and severity of metritis, if the cervix was closed or open, and occurrence of cervical or endometrial cysts. Female dogs are more likely to become pregnant after treatment if they are five years old or younger.[44,45] It is important to mate bitches in the first or second estrus after finishing medical treatment. Antimicrobial therapy is given simultaneously and should be based on vaginal culture taken with a guarded swab. US is used to evaluate the effects of medical treatment on a weekly basis (Table 316-1).

TABLE 316-1

Medical Treatment Protocols in Bitches and Queens Diagnosed with Pyometra

MEDICAL TREATMENT	DOSAGE (SC INJECTIONS)	EFFECT	REFERENCE
Natural PGF_{2alpha} (dinoprost)	Day 1: 0.1 mg/kg q 24 h Day 2: 0.2 mg/kg q 24 h Day 3-7: 0.25 mg/kg q 24 h Cat: Day 1-3(5): 0.1 or 0.25 mg/kg q 12 or 24 h	64-100% success, depending on length of treatment Cat: 95% success	8, 22
Synthetic PGF_{2alpha} (cloprostenol)	DAY 1-7: 1-2.5 mcg/kg × 1 Cat: Day 1-3: 5 mcg/kg q 24 h	75-90% success, depending on length of treatment 5/5 cats healthy	63, 64
Progesterone-receptor blocker (aglepristone)	Day 1, 2 & 7/8: 10 mg/kg q 24 h Day 1 & 2, 7 & 8: 10 mg/kg q 24 h Cat: Day 1, 2, 7, 14: 10 mg/kg q 24 h	93% success 10% recurrence 75% success 48% recurrence 9/10 cats healthy	49-51
Combination:	A: Day 1, 2 & 8: 10 mg/kg q 24 h	85% success	43, 52

Aglepristone (A) and cloprostenol (C)	C: Day 3-7: 1 mcg/kg q 24 h C: Days 3, 5, 8, 10, 12: 1 mcg/kg q 24 h Open and closed cervix pyometra	13-20% recurrence at one year	

All injections are given subcutaneously.

Prostaglandins

Prostaglandins stimulate cervical dilatation and increase myometrial activity, which leads to expulsion of uterine content. After giving prostaglandins several times, lysis of corpora lutea follows. Corpora lutea are the sole source of progesterone and as they lyse, progesterone concentrations decline to basal (anestrous) levels (see ch. 312). Synthetic prostaglandins cause fewer side effects but may be less effective than natural prostaglandins.[44] To decrease the side effects of natural prostaglandins, lower dosages may be used and the dosage is increased gradually (see Table 316-1).[46] As many as 5 injections daily may be recommended, depending on the protocol.[1]

Side effects from prostaglandins may be moderate to severe, and include panting, nausea, vomiting, diarrhea and salivation. To reduce the risk of anorexia and nausea, prostaglandins should be given before feeding. There is always a risk for uterine rupture, especially with a closed-cervix pyometra. The medically treated female dog or cat should be kept in the clinic at least 4 hours after treatment, but can stay at home overnight between injections.[8] Recurrence after treatment is common; in one study, 4 of 10 treated dogs developed pyometra after a subsequent estrus.[47] In cats, prostaglandins have been successfully used for treating pyometra and are considered an alternative to surgery. Eighty-one percent of treated cats delivered a litter after successful treatment.[22] Anecdotally, prostaglandin E (misoprostol) administered intra-vaginally has been used for treatment of pyometra in dogs. Prostaglandin E induces cervical relaxation.[48]

Progesterone Receptor-Blocker (Aglepristone)

Aglepristone may open a closed cervix and is used for treatment of unwanted pregnancy in bitches and queens as well as for pyometra in dogs and cats.[49-51] This product is not commercially available in the United States or Canada, but is used in Europe. The side effects are less severe than with prostaglandins and include restlessness, loss of appetite, diarrhea and abdominal cramps. The success rate in dogs is about 75% for long-term recovery and regained fertility; success has been reported in cats as well.[43,49,51] The risk for recurrence of pyometra is higher in bitches with cystic ovaries and/or cystic endometrium.[50] Bitches and queens are usually kept at home between injections.

Combination of Prostaglandins and Progesterone Receptor-Blockers

Combining these drugs decreases side effects and improves results, with 84% of the bitches clinically healthy after treatment using a protocol that included both agents.[52] The prostaglandin is a more effective uterotonic agent, resulting in a faster decrease in luminal diameter and decrease of progesterone compared to if aglepristone is used alone. When cloprostenol is administered together with aglepristone, a low dosage with few or no side effects is used (1 mcg/kg).[44]

Dopamine Agonists (Prostaglandin, Cabergoline)

These agents reduce plasma progesterone concentration quickly due to rapid luteolysis.[53,54] This medically induced luteolysis can be used to induce parturition and to treat pyometra. Effect is expected within 48 hours of initiating treatment that includes prostaglandins, prostaglandins and progesterone receptor-blocker or prostaglandins and dopamine agonists. If the effect of medical treatment is unsuccessful, OHE should be recommended.

Transcervical Drainage

Drainage of a diseased uterus has been performed using catheters placed in the uterine lumen through cervix to vagina.[55] Use of transcervical endoscopic catheterization for diagnosis, artificial insemination, or uterine drainage has been suggested for dogs and cats, but use in pyometra is infrequent.[56-58]

Surgical Management: Ovariohysterectomy (OHE)

Overview

Ovariohysterectomy (OHE) is the recommended treatment for pyometra. After preoperative stabilization, the surgery is performed as soon as the animal is stable. In cases of septicemia due to the infected uterus, surgery must be performed quickly and, therefore, aggressive fluid therapy is required (see ch. 129 and 146). If the uterus is ruptured, the abdomen is lavaged with 200-300 mL/kg of fluid and closed suction drainage is recommended (see ch. 279). Survival after open peritoneal lavage and closed suction drainage is 70% in septic peritonitis in cats and dogs.[59,60] Closed suction drainage is easy to use and does not require repeated anesthesia as is the case with open peritoneal lavage.

Surgical/Anesthetic Complications

Postoperative complications include hemorrhage, peritonitis, wound infections, fistulous tracts and anesthesia-related concerns. In bitches with SIRS and sepsis, ventricular arrhythmias may develop and ECG should be closely monitored in the postoperative period. Postoperative sepsis may develop, and both CRP and IGF-1 may be useful markers to assess in the postoperative period.[29,32]

Ovarian Remnant Syndrome

Ovarian remnant syndrome may occur after OHE and is a result of unsuccessful surgical removal of all ovarian tissue (see ch. 319). If the pet starts to show estrus behavior in spite of OHE, abdominal ultrasound should be performed in search of ovarian tissue. Hormonal assays for estradiol, progesterone, and luteinizing hormone are also recommended, together with vaginal smears to verify presence of cornified cells and thereby confirm remnants of ovarian tissue. The ovarian remnant syndrome may be more common in bitches, as the ovarian tissue is deeper located and more difficult to reach during the surgical procedure in comparison to queens. Ovarian remnant tissue in dogs and cats may be surgically treated by open or laparoscopic surgery.[61]

Uterine Stump Pyometra

Uterine stump pyometra in dogs and cats has a similar clinical appearance as pyometra, except that OHE has been previously performed. Remnant ovarian tissue is commonly seen in the abdomen after surgery in cases of stump pyometra. Ultrasonography may be used for diagnosis, and will reveal fluid filled areas in the cervical region. The treatment is surgical, and includes treatment of the cervical abscess as well as removal of any ovarian tissue remnants.[62]

Prognosis

Dogs and cats with CEH or low-grade pyometra without SIRS or sepsis have good prognosis after OHE. In severely ill animals the diagnosis is more guarded, but with aggressive preoperative fluid therapy and fast surgical intervention, most animals survive. After medical treatment in stable animals without signs of sepsis, endotoxemia, hypothermia or fever, prognosis is good, and chances of regained fertility are considered to be good—especially in younger animals.[1] The risk of recurrence is high after medical treatment, though.

CHAPTER 317

Other Infectious Causes of Infertility and Subfertility in Dogs and Cats

Sophie Alexandra Grundy

Client Information Sheets:
Be Prepared: Reproductive Tract Sample Collection at Home
Pre-Breeding Vaginal Cultures

Introduction

Infectious diseases can usually be identified with culture, polymerase chain reaction (PCR), or histology (see ch. 207). Obstacles to obtaining a definitive diagnosis of reproductive organ infectious disease in clinical practice include lack of sample, cost, and challenging interpretations. Thus, the true impact of infectious disease on canine and feline reproductive performance is difficult to establish. PCR techniques increase availability of cost effective multi-pathogen diagnostic screening, but sample collection, sample site selection, and laboratory quality control each have potential to impact positive and negative predictive values. Results may be confusing since reproductive pathogens may also be considered "normal flora" in healthy pets. Diagnostic panels that combine culture, PCR, and histopathology provide an opportunity to understand the true relationship between infectious disease and reproductive performance in cats and dogs. Client education regarding available testing options and sample requirements is an essential component of the diagnostic process as typically it is clients that have greater access to tissue types such as the placenta, or an aborted fetus.

Sample Collection, Type and Site

There are 4 main categories of infectious reproductive pathogens: bacterial, viral, protozoal, and fungal. Any of these can cause similar "storms" of reproductive failure within a breeding population. All cases of reproductive loss benefit from the collection of samples appropriate for culture, histology, and PCR.[1] PCR, of great diagnostic value for identifying infectious disease, enables rapid identification of pathogens and is highly sensitive. As a result, it is important to consider sample collection protocols. Many reproductive pathogens are environmentally ubiquitous and normally found in oral, genital, urinary, or gastrointestinal flora. Interpretation must be made in the context of environment, sample type, location, and method of collection. All samples for PCR and culture should be collected in as sterile a manner as possible to avoid contamination. Plastic stemmed cotton tipped applicators, gloves, sterile instruments and a clean surface are advised when collecting samples. Samples should be refrigerated until submitted.[2]

Placental tissue can be extremely useful for understanding reproductive concerns in gravid bitches and queens. The placenta may be considered the immune guardian of the developing fetus. When sampling the placenta, a touch slide preparation should be made for prompt *Brucella canis* and *Campylobacter jejuni* screening. Two tissue samples should be collected: one for formalin fixation and one for PCR. If available, samples of fetal kidney, liver, spleen, and lung should also be collected in duplicate: one for formalin fixation and one for PCR. A sample of fetal liver or a swab of the abdomen is ideal for bacterial culture. EDTA whole blood and serum should be collected from the dam, in addition to a vaginal swab for PCR. PCR samples should be kept refrigerated.

When evaluating the male for infectious reproductive pathogens, semen should be cultured and, ideally, the colony count compared to a urethral culture (see ch. 318). Samples of ejaculate may also be submitted for infectious disease screening by PCR. Various combinations of culture, PCR, and histology are available

through private and university laboratories. These panel, or combination test packages offer a cost effective option for multi-pathogen screening.

Pre-Breeding Vaginal Cultures

Normal Flora

It is common to be asked to perform a bacterial culture of the vaginal vault as a pre-breeding screen. There is an incorrect tendency to presume that a positive vaginal culture is abnormal and indicative of an infected and abnormal uterus.[3-11] Some breeders incorrectly believe the normal vaginal canal to be sterile and require a negative pre-breeding culture prior to permitting live cover. However, the normal vaginal canal has aerobic and anaerobic bacterial populations and 60-100% of healthy bitches have positive vaginal cultures.[3-10] Considering anatomical exposure to oral and gastrointestinal bacteria, the common vaginal isolates from bitches include *Enterococcus faecalis, Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pasteurella multocida* and bacteria associated with the skin (*Streptococcus* spp. and *Staphylococci* spp.) (Table 317-1).[3-10] Although bacterial cultures are typically limited to aerobes, anaerobes are also included among normal vaginal flora (*Bacteroides* spp., *Peptostreptococcus* spp., *Clostridium* spp.).[9] Whilst there are slightly different relative frequencies for each isolate, the "normal organisms" are consistent across studies.[3-10] The types of bacteria isolated per healthy bitch are relatively stable during the reproductive cycle, but count and number of isolates tend to increase during proestrus and estrus.[4,5] During proestrus and estrus, it has been shown that the uterine bacterial population reflects the vaginal bacterial population, presumably due to relaxation of the cervix and hormonal changes that decrease uterine immune responses.[4] During diestrus and anestrus, uterine bacterial populations typically clear, making it rare to isolate bacteria during this time.[4,8]

TABLE 317-1

Frequency of Vaginal Bacterial Isolates in Healthy Bitches across Selected Studies, 1978-2012

BACTERIAL ORGANISM	PERCENT POSTIVE BACTERIAL ISOLATES (HEALTHY BITCHES) PER STUDY

**Proteus mirabilis.*

Bacteria in shaded rows indicate that they are more frequently isolated across all studies.

Vaginal Cultures During Proestrus and Estrus

Specific concerns are often raised with respect to positive cultures of *E. coli* or *Streptococcus* spp. as they are commonly associated with pyometra, mastitis, and neonatal septicemia. However, a large majority of vaginal cultures from healthy bitches are positive for *E. coli*.[4,6,8,12] One study associated a positive proestrus *Streptococcus* spp. vaginal culture with a *decreased risk* of uterine infection during diestrus.[5]

With years of literature support, there is no evidence to support routine culture or antibiotic treatment of an asymptomatic bitch with a positive pre-breeding vaginal culture. Future studies quantifying microbial levels of the normal vaginal microbiome may be used to define pathogenic vaginal bacterial populations. Since vaginal cytology is frequently evaluated during proestrus of bitches (see ch. 119 and 312) and often reveals large numbers of bacteria or phagocytized bacteria, caregivers may request treatment of these bacteria. However, no correlations have been made between vaginal bacteria (phagocytized or not), vaginal neutrophils, and fertility in an asymptomatic bitch.[5] Bacteria in the vaginal canal are normal and cytologically observed bacteria are not valid reasons for antimicrobial treatment during proestrus. Caregivers should be informed that most bitches undergoing pre-breeding vaginal cultures are in proestrus or estrus, times when results are *expected* to be positive. While there may be pressure from owners of the bitch or stud dog to treat a bitch with a positive vaginal culture with antibiotics prior to breeding, one should also note the increasing evidence that indiscriminate use of antimicrobials in breeding bitches is correlated with induction of multi-resistant bacteria which can alter vaginal flora and promote growth of pathogenic bacterial populations. This places kennels and neonates at greater risk and does not improve reproductive performance.[13-15] When should a bitch with a positive pre-breeding culture be treated? As a general rule, treatment during proestrus should be considered for a bitch that is exhibiting a clearly abnormal vaginal discharge *and* with significant growth of either a single pure normal bacterial species, or atypical bacterial isolate (see provided Client Information Sheet online).

Vaginal Discharge and Culture

Bacterial cultures of vaginal discharge generally differ from normal flora only with respect to the number of bacteria isolated.[3] In symptomatic dogs or cats, treatment is advised for a single bacterial isolate present in high numbers, typically a 3+ to 4+ on a four-point scale.[3,16] Antimicrobial choice should be made with consideration to sensitivity and minimum inhibitory concentration (MIC).

Mycoplasma and *Ureaplasma*

Positive *Mycoplasma* vaginal cultures are common in bitches and not of clinical significance with respect to fertility. In stud dogs, however, positive *Mycoplasma* culture *may* be associated with infertility if the quantitated culture count of the semen is 2 $\log_{10}$ times greater than that of the urethra.[22*] Many studies evaluating canine vaginal cultures do not comment on *Mycoplasma*. *Mycoplasma* spp. do not grow easily under standard aerobic culture conditions.[4-6,17] When specifically evaluated, positive *Mycoplasma* and *Ureaplasma* vaginal culture rates in the healthy bitch are reported to be as high as 88% and 50%, respectively; *Ureasplasma*, when present, is typically in association with *Mycoplasma*.[18-20] In one study, positive *Ureaplasma* vaginal culture rates were higher in bitches with a vaginal discharge (75%), but there was no significant relationship between *Mycoplasma*, *Ureaplasma*, and fertility.[19] Seventy-two percent to 84% of semen samples from healthy

stud dogs culture positive for *Mycoplasma*.[19] Whilst implicated in some cases of canine orchitis, *Mycoplasma* is not isolated more frequently in infertile dogs.[17,19,21] *Ureaplasma* are generally not present in the prepuce or semen of fertile males, but are found in around 70% of infertile males, typically isolated in association with *Mycoplasma*.[19] For both bitch and stud, *Mycoplasma canis* is the most frequent isolate. In males, *Mycoplasma cynos* is also noted.[19] Females often have multiple species identified.[18-20] Concurrent semen evaluation is advised.

Campylobacter Jejuni

Campylobacter jejuni has been reported in association with abortion in the bitch.[23-25] In all cases, the classic feature is late term abortion or intrauterine fetal death about one week prior to the anticipated whelping date. Bitches may also have a hemorrhagic vaginal discharge.[23-25] Entire litters may be aborted dead, but partial live litter delivery is also reported. As the fetuses are not yet at term, they may be born live, but not viable at less than 61 (females) or 62 (males) days gestation with day 0 defined by the luteinizing hormone surge.[26] An important differential for this clinical presentation is *Brucella canis* (see ch. 213), the major cause of bacterial abortion in the dog. Personal protective equipment should be used when evaluating these cases due to the zoonotic potential of both organisms. Diagnosis is based on either positive bacterial culture, or positive PCR, of the placenta, *and* fetal liver, or lung.[23-25] Successful treatment is rare.

Leptospirosis

Leptospiral organisms induce marked uterine inflammation and abortion is the most common reproductive sign of leptospiral infection in the bitch.[27,28] There is return to fertility after successful treatment. In stud dogs, leptospirosis-induced vasculitis may cause breakdown of the blood testes barrier and any stud dog diagnosed with leptospirosis should have a semen evaluation performed initially at 65 days post recovery to evaluate reproductive potential (see ch. 217).

Other Bacteria

Salmonella and *Listeria* are both reported as a cause of reproductive tract disease in the bitch and queen. *Salmonella* is an uncommon cause of reproductive loss and most often associated with systemic disease.[29] *Listeria* has been reported as a cause of abortion in the literature but is considered an uncommon pathogen.[30] *Bartonella* spp. have been associated with reproductive losses under experimental conditions but this is challenging to prove in clinical cases due to the difficulties isolating the organism (see ch. 215 and 216).[31]

Viral Pathogens

Viral pathogens are an important consideration when evaluating reproductive losses in the bitch and queen as they may cross the placenta, infecting embryo or fetus, in addition to debilitating the dam.[32] Many viral infections can be confirmed by PCR on tissue samples in combination with histology. For an in-depth discussion of the major viral pathogens, the reader is referred to the individual discussions in the infectious disease section (see ch. 222-225 and 229).

Although herpesvirus (see ch. 227 and 228) is reviewed, it is worth highlighting that the reproductive impact of canine herpesvirus (CHV) is extremely difficult to define as a result of its latency, poor immunogenicity, short-lived antibody production, and transient viral excretion.[33] Reproductive hormone fluctuations appear to alter viral reactivation, but it is not clear how this impacts the course of clinical disease.[33,34] Indeed, given that there is no difference in antibody titers between healthy bitches and those with reproductive abnormalities, in addition to zero recovery rates from vaginal PCR in kennels with endemic disease, reproductive loss due to CHV is extremely difficult to document unless associated with neonatal loss.[33-35] Vaccination when available is advised 10 days after mating and again 6 weeks later as it is thought that higher antibody titers in diestrus may protect against reproductive failure.[33,36] Successful medical management of neonatal CHV using acyclovir is described (see ch. 162).[37]

Protozoal Pathogens

Toxoplasma may be associated with reproductive loss in the queen mainly due to systemic effects of disease in the dam.[12] Transplacental transmission of *Neospora* is known to occur in the bitch but the impact of this organism on reproductive performance is unclear.[12] A single case report of *Leishmania*-associated abortion is reported in the literature.[38] The reader is referred to ch. 221 for an in-depth discussion of protozoal disease.

CHAPTER 318

Breeding Soundness Examination and Disorders of Reproduction in Male Dogs

Gary C.W. England, Lúcia Daniel Machado da Silva

Client Information Sheet: Semen Collection and Evaluation in the Dog

Breeding Soundness Examination

Overview

Breeding soundness examination (BSE) is commonly performed to assess fertility in young dogs prior to breeding, monitor fertility during breeding careers, ensure fertility in an aging animal, investigate possible infertility, monitor recovery after reproductive disease, and as part of a semen preservation and artificial insemination program. Performing a BSE may also be important prior to purchase.

Behavior and Health

Veterinarians commonly focus upon the reproductive tract when undertaking a BSE. Further assessment of general health and temperament should be included. One may recommend genetic or other screening tests. This requires knowledge of many relevant behavioral problems and conditions which can be reviewed elsewhere in this textbook or through helpful websites, such as the Canine Health Information Center (www.caninehealthinfo.org), a centralized canine health database sponsored by the Orthopedic Foundation for Animals.

Examination of the External and Internal Genitalia

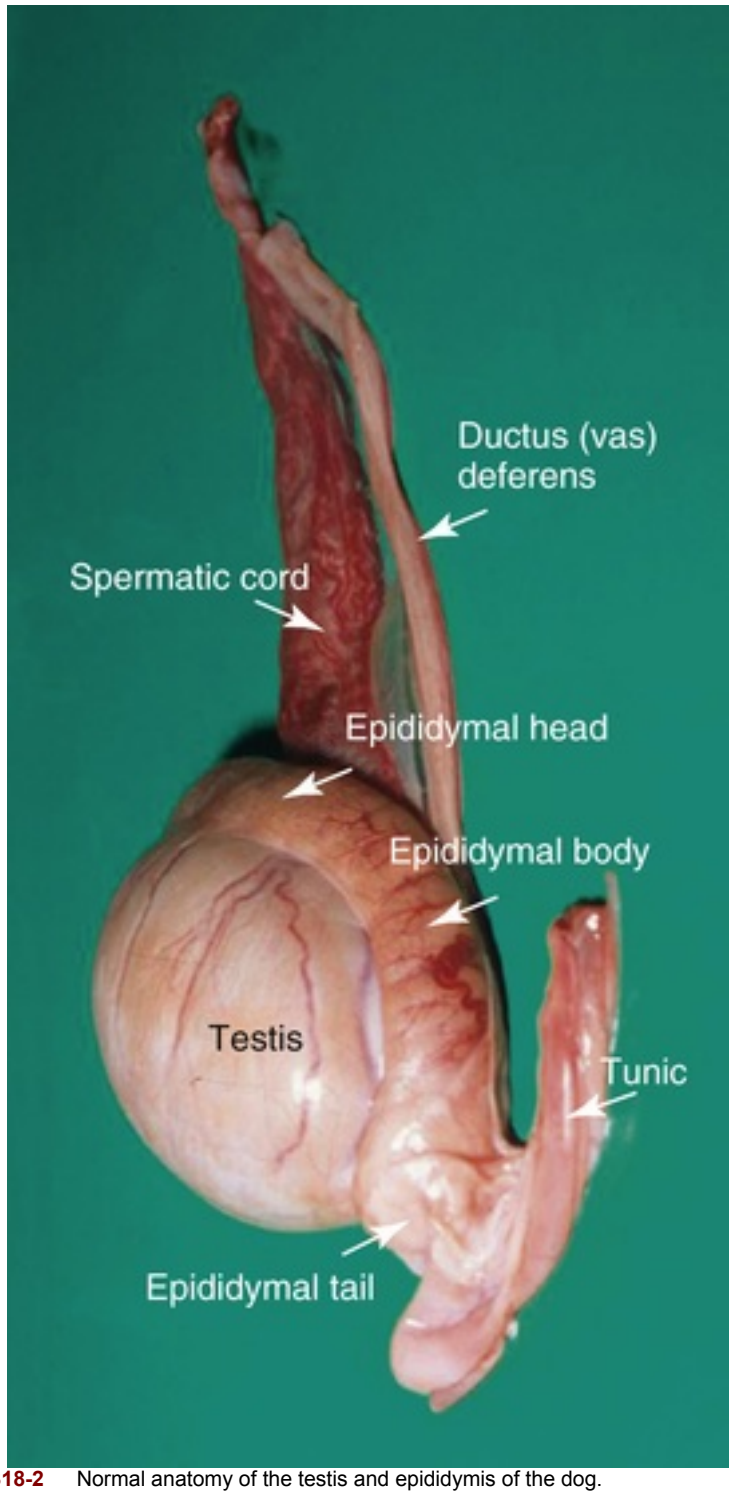
The Penis

The penis and prepuce should be examined to ensure suitability for normal breeding and absence of disease. Examination is best performed prior to the introduction of the teaser bitch. Small volumes of mucopurulent preputial discharge is common and normal (E-Figure 318-1). The prepuce should cover the length of the penis and the penis should be relatively easy to protrude from the prepuce; in experienced dogs this may initiate ejaculation and should be anticipated so that semen can be collected if this occurs. The penile skin should be smooth, with an absence of vesicular or papular lesions. However, raised lymphoid nodules at the base of the penis are common and normal, especially when there is preputial discharge. The *os penis* can be palpated through the prepuce and should be smooth and not painful. The urethra can be palpated caudally along the perineum to the anus.

E-FIGURE 318-1 A small volume of mucoid to mucopurulent preputial discharge is common and normal in dogs.

The Scrotum and Testes

Scrotal skin should have no lesions. Thickened skin or evidence of scarring may indicate a previous scrotal (testicular) insult. The neck of the scrotum should be palpated to allow identification of the vas deferens and to confirm absence of inguinal hernia. The testes are positioned almost horizontally, and one may be positioned slightly cranial. They should be freely mobile within the scrotum, similar in size, and firm but not hard. Testis size is related to body mass; for example, each testis in a 15 kg healthy dog is about 3.0 × 2.0 × 1.5 cm. The body of the epididymis runs along the dorsal surface of the testis and the tail of the epididymis is at the caudal pole (E-Figure 318-2).



E-FIGURE 318-2 Normal anatomy of the testis and epididymis of the dog.

The Prostate

The prostate gland is the sole accessory gland. If normal, it can be readily palpated per rectum as symmetrical and divided into 2 lobes (each about 2 cm in diameter) by a central longitudinal groove. The prostate should be firm in texture, non-painful and freely moveable within the pelvis.

Assessment of Libido

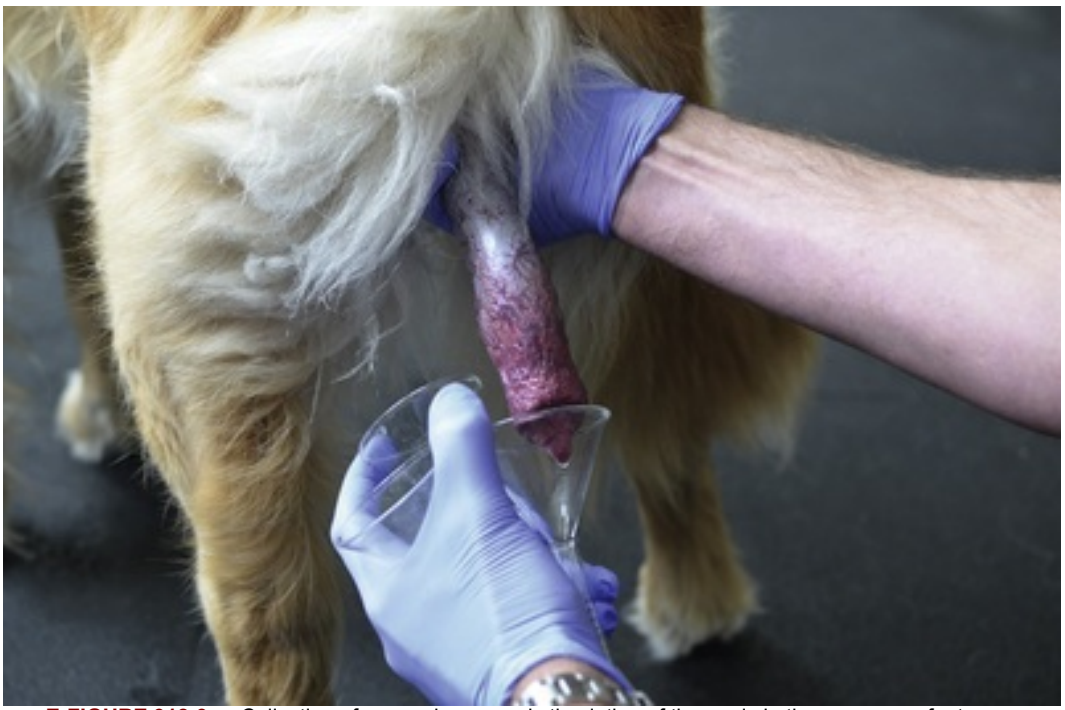
Male behavior when introduced to a female in estrus and breeding is frequently overlooked in a BSE. This can

provide useful information regarding "infertility" caused by behavior issues, negative previous experiences, or pain at coitus. Healthy dogs and bitches exhibit play behavior when first introduced, occasionally including mounting of the female. At this time the dog may ejaculate a small volume of clear fluid. This is the first fraction of the ejaculate and does not contain sperm. The dog will continue to mount, thrust, and dismount until his position allows the penile tip to enter the vagina. After intromission, the dog will achieve a full erection, continue thrusting movements and the second (sperm rich) fraction of the ejaculate is produced. Once thrusting has subsided the dog will turn through 180° and dismount while the penis does not change position, remaining within the vagina. The dog and bitch now stand tail-to-tail (this is called the copulatory tie) while the third (prostatic) fraction is ejaculated. Ties last an average of 20 minutes but vary considerably between dogs and can be as short as 5 minutes or more than 60 minutes.

Semen Collection and Evaluation

Collecting the Ejaculate

Semen collection is straightforward; samples can be collected by manual stimulation of the penis with or without an estrous teaser bitch (Video 318-1). The dog will first achieve a partial erection and then show thrusting movements during which time the first and second fractions of the ejaculate are produced. As thrusting ceases the second (sperm rich) fraction of the ejaculate continues to be produced briefly. Then the dog will lift one hind-leg (as in the copulatory tie) and it is necessary to turn the penis so that the tip faces in a caudal direction between the hind limbs while the third (prostatic) fraction is produced. The three fractions can be collected separately using clear plastic funnels directed into separate tubes (E-Figure 318-3). Since many materials are toxic to canine sperm, all tubes, syringes and pipettes should be carefully tested prior to routine use. Collection equipment should be clean and dry. After collecting semen, samples should be kept warm since cooling can reduce motility and give a false impression of poor semen quality. There are a number of aspects to semen evaluation as detailed below.



E-FIGURE 318-3 Collection of semen by manual stimulation of the penis in the presence of a teaser bitch. The three fractions of the ejaculate are collected into separate test tubes by non-toxic glass funnels.

Ejaculate Volume, Color, Concentration and Total Sperm Count

Volume is measured using a graduated test tube or by pipetting. It is important to have an accurate measurement of second fraction volume to enable calculation of the total sperm output. In a medium-sized

dog the fractional volumes are approximately 0.5-2 mL (first fraction; usually clear and transparent), 0.5-1.5 mL (second fraction; usually white or creamy in color), and 15-20 mL (third fraction; usually clear and transparent), although commonly the entire third fraction is not collected (Figure 318-4). Cytological examination of centrifuged and stained smears may help establish the nature of any contamination.

FIGURE 318-4 The fractions of the canine ejaculate. The first fraction (left) originates from the prostate gland and contains no sperm, the second fraction (middle) is sperm rich, and the third fraction (right) is again prostatic in origin and sperm free.

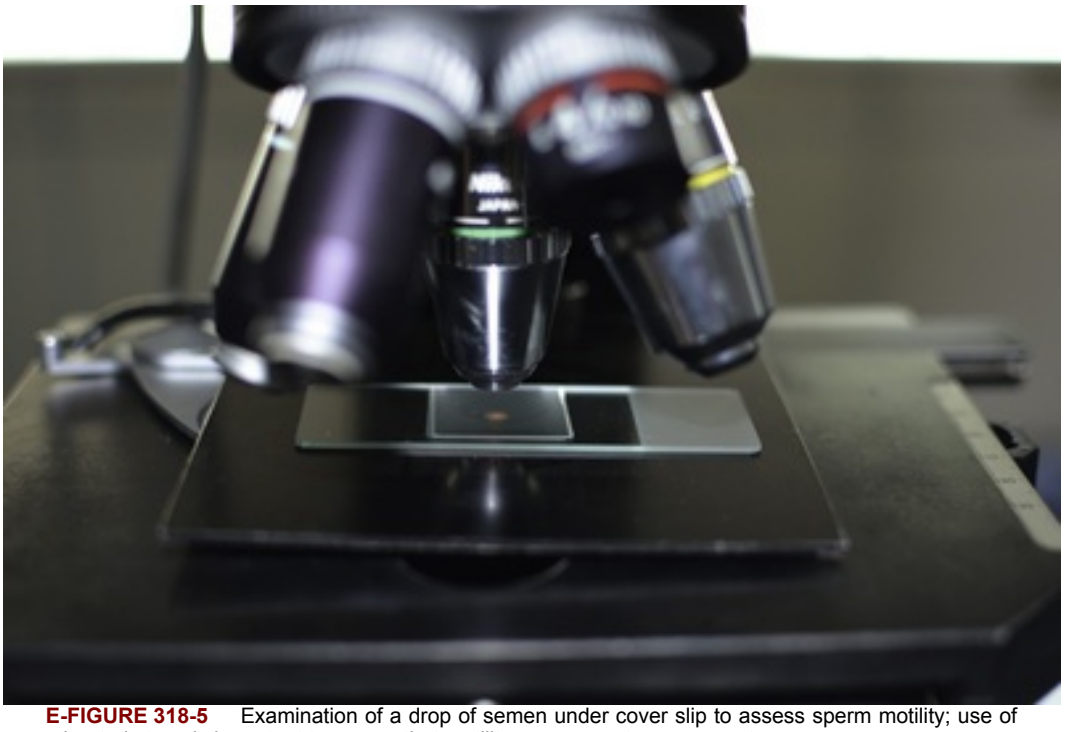
It is common to measure semen concentration using a hemocytometer. A small volume of the second fraction is diluted at a standard rate to enable sperm counting. Distilled water with detergent is often used as a diluent to kill sperm and prevent clumping. Diluted sperm are placed into the chamber and the number of sperm counted; the dilution factor is then used to calculate the initial sperm concentration. However, the total spermatozoal output is a more useful measure than concentration. Total sperm output (TSO) is the total number of sperm within the ejaculate and is calculated by multiplying the second fraction volume by the sperm concentration. TSO is more meaningful than concentration or volume. Normal dogs produce 300-1000 $\times 10^6$ spermatozoa within each ejaculate. Since there is a pool of sperm stored within the epididymides, some of which are removed at each ejaculation, the number of sperm found within a given ejaculate is determined by the number of sperm stored and the frequency of ejaculations (frequent ejaculation will deplete the epididymal reservoir). If collected daily for 4 to 5 days, the number of sperm present in ejaculates is indicative of the daily sperm production. In normal dogs a good correlation exists between daily sperm production and both the volume of the testes and the width of the scrotum.

Sperm Motility

Sperm motility is commonly evaluated subjectively, although in referral centers there is increasing use of computer image analysis. For subjective examination, a drop of semen is placed onto a warmed microscope slide, covered with a cover slip and maintained at 30-35° C (E-Figure 318-5). Evaluation at low temperatures may give erroneous results. Motility decreases over time when the slide is left on the microscope stage (probably due to the effect of light and cooling). Samples should therefore be assessed quickly. Subjectively, the percentage of sperm within each of the following five categories are noted:

- Category O: non-motile spermatozoa
- Category I: spermatozoa which are motile but are not progressive
- Category II: spermatozoa which are motile but poorly progressive

- Category III: spermatozoa which are motile but moderately progressive
- Category IV: spermatozoa which are motile, rapidly progressive and swimming in a forward direction

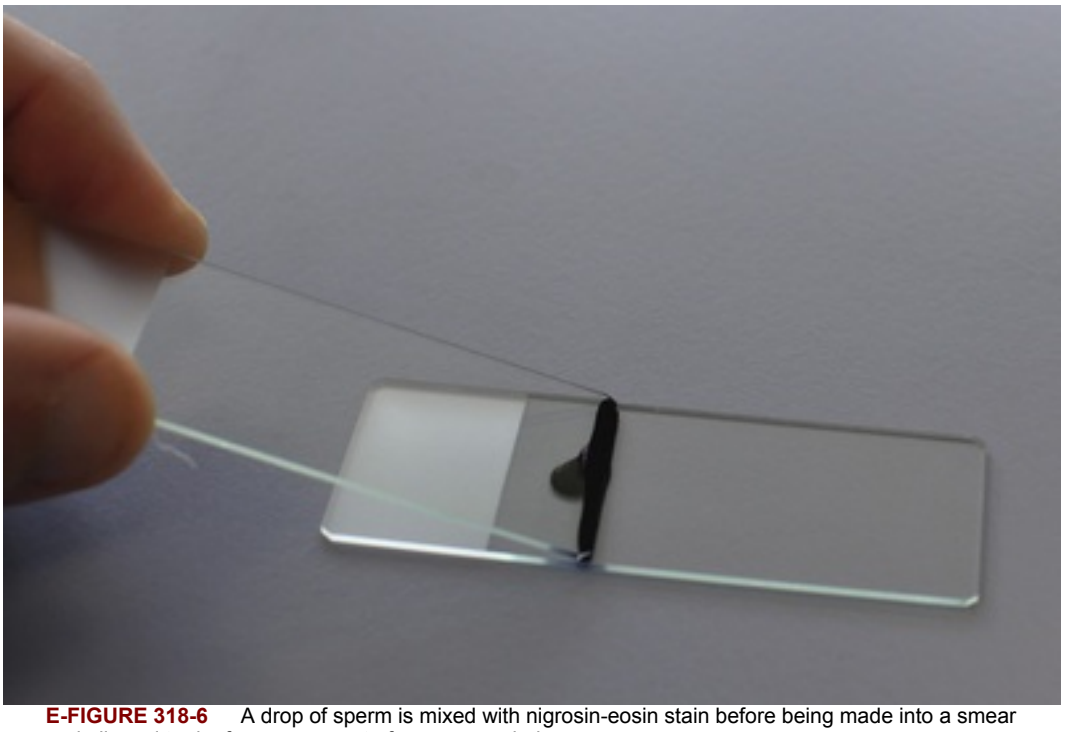


E-FIGURE 318-5 Examination of a drop of semen under cover slip to assess sperm motility; use of a heated stage is important to ensure that motility assessments are accurate.

Using these criteria normal dogs have more than 70% spermatozoa with Category IV motility and 90% total motility (sum of Category I-IV).

Sperm Morphology

A simple method for assessing sperm morphology and membrane integrity is use of eosin combined with the background stain, nigrosin. Semen is mixed 1:5 on a volume basis with the nigrosin/eosin stain and then a drop is transferred to a slide, a smear is made and allowed to dry (E-Figure 318-6). Spermatozoa are silhouetted against the purple-blue nigrosin; white sperm are classified as live (these sperm have intact membranes which prevent the eosin from penetrating into the sperm) and pink sperm are classified as dead. Smears should be examined at ×100 magnification under oil immersion and at least 100 sperm classified according to their staining characteristics and morphology. Most fertile dogs will have more than 60% live and morphologically normal sperm.



E-FIGURE 318-6 A drop of sperm is mixed with nigrosin-eosin stain before being made into a smear and allowed to dry for assessment of sperm morphology.

Normal sperm have a typical appearance (Figure 318-7) and there are a variety of methods used for classification of abnormal sperm. It has been common to classify according to whether abnormalities occurred during (a) spermatogenesis (primary abnormalities), (b) the epididymal phase of development (secondary abnormalities), or (c) collection and processing (tertiary abnormalities). However, a recently proposed system describes sperm as being compensable (abnormalities which render the sperm unable to reach the egg) or non-compensable. The term compensable indicates that the abnormality does not prevent normal sperm from fertilizing an egg; as long as there are sufficient normal sperm, the abnormal sperm can be compensated for. Compensable abnormalities include substantially misshapen heads, tail defects, immature and immobile sperm. Other sperm abnormalities are described as non-compensable since these sperm can reach the oocyte and trigger oocyte depolarization, but then there is either failure of fertilization or later failure of the embryo. In this manner these sperm effectively block other normal sperm from achieving normal fertilization. Large numbers of normal sperm cannot compensate for the abnormal sperm present. Sperm with subtly misshapen heads or nuclear vacuoles are typical of non-compensable abnormalities. Other classification systems use terminology that describes the overall changes in semen quality; for example, oligozoospermia is the term used to describe an ejaculate that contains low numbers of morphologically normal sperm. This type of system may then be subdivided with descriptions of the predominant abnormality (such as acrosome, neck, mid-piece, tail) with a consideration of their significance. This method may not be applicable when there are multiple abnormal forms rather than one or two predominant types.

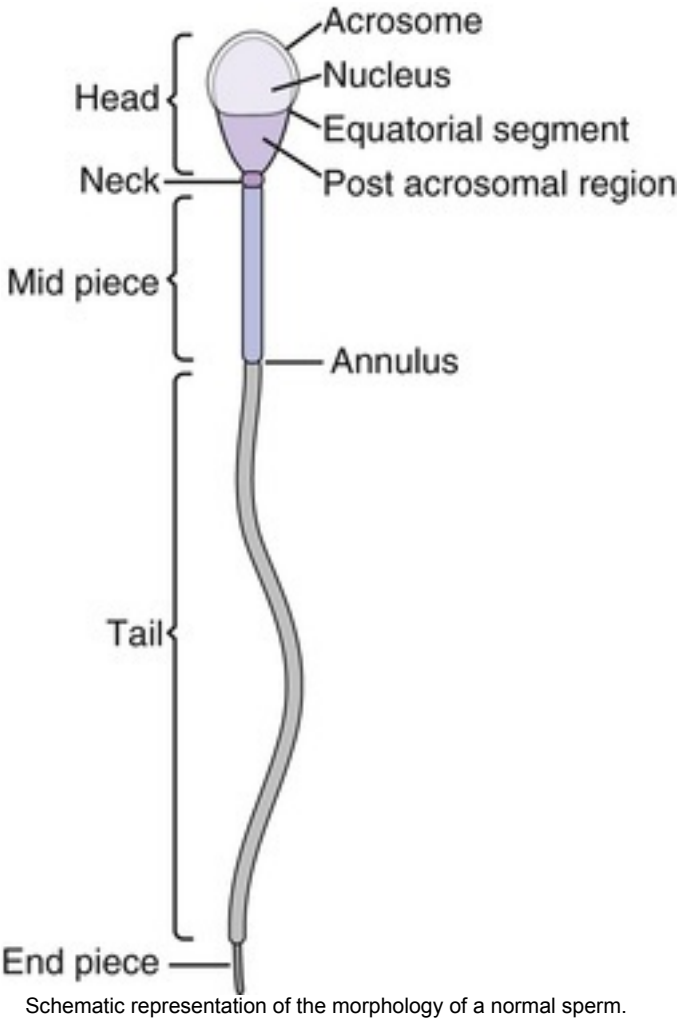


FIGURE 318-7 Schematic representation of the morphology of a normal sperm.

Other Cells in Ejaculates

Ejaculates should be checked for non-sperm cells. Common hematology stains can be used either on air-dried smears or samples concentrated by centrifugation, aiding in detection of prostatic conditions. This may also help confirm azoospermia when spermatogenic cells may be found. Medium neutrophil numbers are common, usually originating from the prepuce (Figure 318-8).

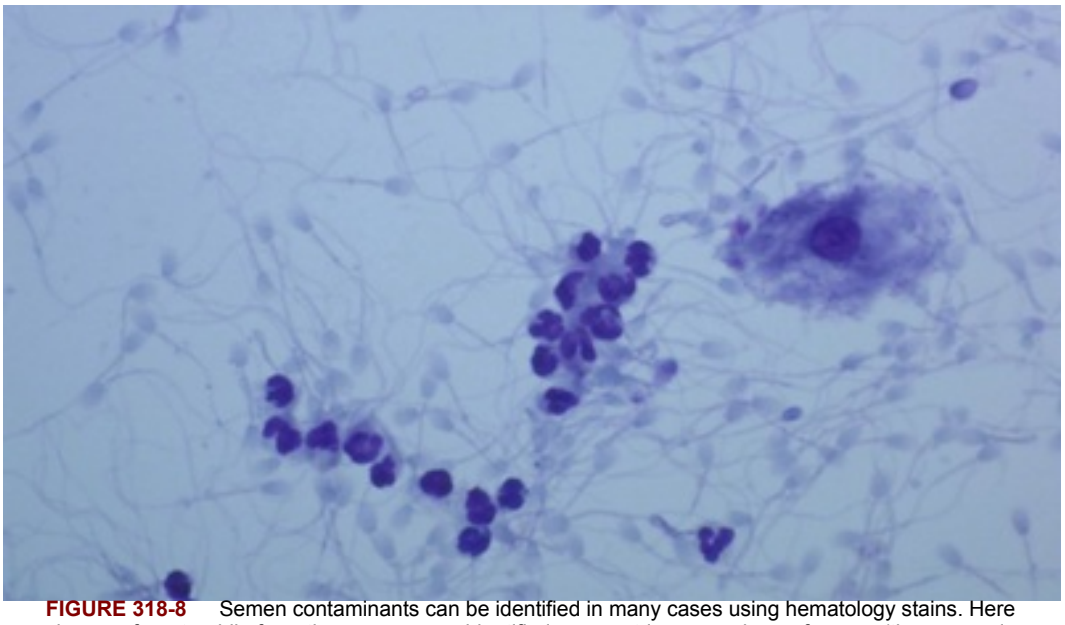

FIGURE 318-8 Semen contaminants can be identified in many cases using hematology stains. Here clumps of neutrophils from the prepuce are identified amongst large numbers of sperm (the sperm do not stain well using the hematology stain).

The Hypo-Osmotic Swelling Test

The hypo-osmotic swelling test is considered by some to be a test of functional sperm membrane integrity. Normal sperm, exposed to a hypo-osmotic medium, absorb water and develop coiled/bent tails. In this manner, simply counting the percentage of sperm with bent tails when exposed to hypo-osmotic medium can be considered to be a marker of membrane function. Most normal samples have more than 70% of sperm with bent tails using this method.

Sperm-Oocyte Binding or Penetration Assay

These tests assess binding or penetration of oocytes by sperm. A pre-determined number of sperm are incubated with homologous oocytes or hamster oocytes (which allow most sperm to penetrate), and the numbers of oocytes bound or penetrated after a specific time are counted. This provides assessment of sperm ability to acrosome react, change their motility characteristics (become hyperactivated) and bind to/penetrate oocytes.

Sample Archive

After semen samples are evaluated, it is prudent to archive a portion for comparison with future evaluations. Samples can be preserved by 1:1 dilution with buffered formal saline followed by storage in a sealed vial. This enables samples to be stored at room temperature for many years without substantial changes in sperm morphology or staining characteristics.

Predicting Fertility

Overview

It is difficult to precisely predict fertility because of the wide range in seminal characteristics seen in fertile animals. Broad normal ranges have been defined (Table 318-1) and semen within these limits are considered likely to be fertile, as long as libido and copulatory ability are normal. In many dogs, one or more assessments may be borderline. If an ill-at-ease dog produces a poor sample, repeat examination is indicated since there may have been incomplete ejaculation. If samples are just outside the normal range the dog may still have normal fertility if the mating regime is adjusted (e.g., mating more frequently in the window shortly after ovulation). When a sample contains no sperm (is azoospermic), a second sample should be collected or an attempt made to establish whether ejaculation did indeed occur by measurement of alkaline phosphatase concentration.

TABLE 318-1

Seminal Characteristics from Fertile Dogs

	PROGRESSIVE, CATEGORY IV, MOTILITY (%)	SPERM-RICH SECOND FRACTION VOLUME (mL)	SECOND FRACTION SPERM CONCENTRATION ($\times 10^6$/mL)	TOTAL SPERM OUTPUT ($\times 10^6$)	LIVE NORMAL SPERM (%)
Mean	82	1.2	330	410	74
Range	40-95	0.3-3.3	50-820	36-1980	50-92

Semen Alkaline Phosphatase Concentration

Large quantities of alkaline phosphatase (AP), produced by the epididymis, are present in normal ejaculates (>5,000 IU/L). Azoospermic samples with increased AP concentrations (5,000-20,000 IU/L) are truly azoospermic, whereas those with low AP concentrations (<5,000 IU/L) either had incomplete ejaculation, retrograde ejaculation, or have an epididymal or vas deferens obstruction. If no sperm are seen on repeated collection, the urine should be assessed for sperm and, if positive, a diagnosis of retroejaculation considered.

Ultrasound (US) Examination of the Reproductive Tract

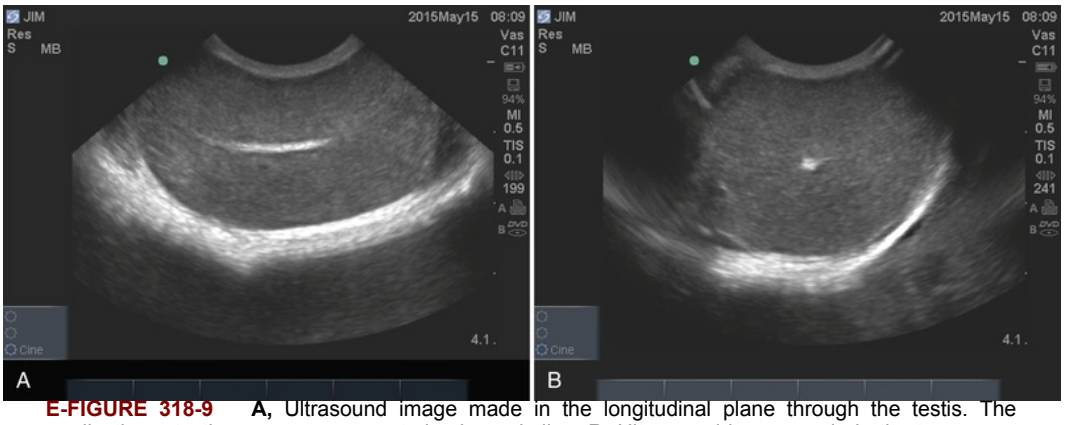
Overview

US examination of the reproductive tract should be a routine component of the BSE. Use of color Doppler and pulsed Doppler US can be used to assess testicular and prostatic blood flow. A small number of studies have described contrast-enhanced US for detection of reproductive tract disorders.

Scrotal Ultrasound

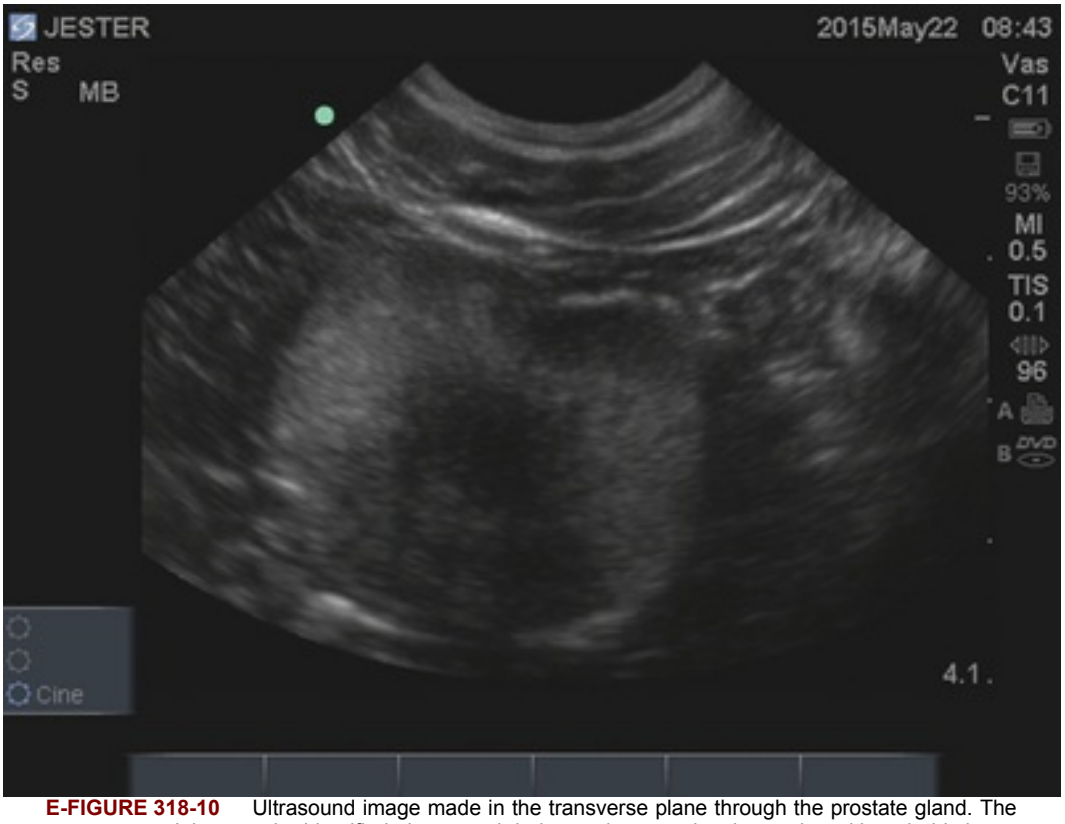
Examination of the scrotum can be undertaken with high frequency linear or sector transducers after application of copious amounts of US gel. It is prudent not to clip the scrotal hair as this often results in irritation and secondary self-trauma following incessant licking. Examination of the neck of the scrotum may be undertaken to rule out scrotal hernia. The testes and epididymides are usually examined in sagittal, transverse and frontal (dorsal) planes. The epididymides are most easily identified using the longitudinal plane with the transducer placed on the ventral surface of the testes; in this manner, the tubular longitudinal section of the epididymal body and triangular appearance of the epididymal tail can easily be identified on the far (dorsal) surface of the testis.

Normal testicular parenchyma is relatively hypoechoic with regular diffuse echogenic stippling, which represents an extension of the fibrous mediastinum responsible for supporting the parenchyma. The mediastinum itself appears as a linear echo extending from the cranial to the caudal pole when imaged in the longitudinal plane and an approximate 2 mm circular echo when imaged in the transverse plane (E-Figure 318-9, *A* and *B*). Acoustic shadowing is common distal to the mediastinum testis. The testis is bordered by the combined testicular and vaginal tunics which appear as a single echogenic line, unless there is a hydrocele and fluid which creates 2 lines. The epididymis is hypoechoic and stippled when compared with testicular parenchyma. Testes which appear more heterogeneous are often associated with poor semen quality, as are those which appear overall to be more hypoechoic or hyperechoic. US can be used to accurately measure testicular size and to calculate testicular volume. There is usually good relationship between testicular volume and body size and a general relationship between testicular size and semen quality. Pulsed Doppler US has been used to measure testicular artery blood flow. Differences have been identified comparing pre-pubertal and pubertal dogs as well as fertile and infertile dogs. Color Doppler may also aid in identifying increased perfusion associated with pathological conditions. Similarly, contrast-enhanced US (a technique where microbubbles are injected into a vessel) may be used to accurately document vascular perfusion and to highlight lesions.



E-FIGURE 318-9 **A,** Ultrasound image made in the longitudinal plane through the testis. The mediastinum testis appears as a central echogenic line. **B,** Ultrasound image made in the transverse plane through the testis. The mediastinum testis appears as a central echogenic spot.

The Prostate (E-Figure 318-10; See Ch. 337)



E-FIGURE 318-10 Ultrasound image made in the transverse plane through the prostate gland. The two separate lobes can be identified; the central darker region contains the urethra although this is not clearly demarcated in this image.

Endocrine Assessment

Assessing circulating reproductive hormones are of limited value. Administration of exogenous gonadotropin-releasing hormone stimulates increases in luteinizing hormone (LH) within 30 minutes and increases in testosterone within 60 minutes. Administration of exogenous human chorionic gonadotropic (hCG; LH-like activity) results in testosterone increases. Such tests have been employed to detect presence of testicular tissue and are not used for subtle changes in pituitary or testicular function. Basal hormone

concentrations in dogs vary considerably throughout the day. Plasma testosterone concentrations in healthy intact dogs are usually >4.0 ng/mL (14.0 nmol/L) and castrated dogs have testosterone concentrations <2.0 ng/mL (7.0 nmol/L). Dogs with impaired spermatogenesis usually have normal results, as do dogs that are bilaterally cryptorchid. Both LH and follicle stimulating hormone (FSH) concentrations vary markedly throughout the day and there is limited information on normal values and how they change in various conditions. LH and FSH concentrations may be increased in dogs with impaired spermatogenesis, but results do fluctuate.

Bacterial Infection Screening

Owners and breeders may have concerns regarding routine screening of both sires and dams for bacterial venereal pathogens. In countries where *Brucella canis* is endemic, screening for this organism is crucial prior to breeding (see ch. 213). It is particularly important that females be screened, since they may harbor the organism with few clinical signs. The history may reveal previous acute infection that caused orchitis or epididymitis that cause systemic signs of illness, pain, discharge and loss of libido. Chronic infection may lead to testicular degeneration, although in some dogs fertility is restored after the acute phase of infection. Multiple sperm abnormalities and sperm agglutination may be detected. *Brucella canis* may be isolated from semen of infected dogs.

Apart from *Brucella canis* there is no evidence that other bacteria are venereal pathogens in dogs. All dogs have a resident commensal microflora and these bacteria may change. Commonly isolated bacteria include hemolytic streptococci, other streptococci, staphylococci, *Escherichia coli*, and others. Most dogs have a mixed flora with 2-5 different species present. Routine screening is unnecessary and use of antibiotics for commensal bacteria does not meet current best practice guidelines.

Virus Screening

Stud dogs may become infected with canine herpesvirus and, with reactivation, small red raised, sometimes ulcerated, lesions on the penis and inner surface of the prepuce may be noted. Virus may be detected by PCR offered by many commercial laboratories. Canine herpesvirus vaccine does not appear to protect dogs from infection or to reduce viral recrudescence (see ch. 228).

Karyotype

Gross abnormalities of underdevelopment of genitalia may be indicative of genetic issues that can be identified with chromosome studies on EDTA blood that can be cultured and examined. Normal dogs have 78 chromosomes: 38 pairs of acrocentric autosomes and 2 metacentric sex chromosomes.

Testicular Fine Needle Aspiration (FNA) and Biopsy

Testicular FNA may be useful if there are gross testicular abnormalities or if a focal lesion has been seen with US (see ch. 87 and 93). US guidance is particularly useful for precise sampling. The dog should be sedated before placing a 20G needle, attached to a syringe, into the region of interest. Biopsy allows evaluation of spermatogenesis and detection of inflammatory or neoplastic cells. However, biopsy is invasive and can itself cause severe testicular changes. It is not recommended.

Additional Prostatic Evaluations

Additional methods for examination of the prostate include cytology of prostatic fluid, FNA, and biopsy (see ch. 111). The first and third fractions of canine ejaculate are primarily prostatic and can be collected by manual stimulation. Each phase of the ejaculate can be collected separately, cultured and evaluated cytologically. If an ejaculate cannot be obtained, prostatic fluid can be obtained by massaging the prostate transrectally while simultaneously flushing the prostatic urethra with 5-10 mL of saline. One can simply place a urethral catheter to the level of the prostate gland and apply suction to retrieve cells for cytologic examination. FNA of the prostate can be done via a transabdominal approach, especially if the gland is large. If the prostate remains within the pelvic canal, a perineal approach is required (see ch. 337). Either technique can be assisted by the use of US guidance. Canine prostate-specific esterase (CPSE) is a serine protease found in normal prostate epithelial cells, prostatic fluid, and in serum or plasma. CPSE concentrations are higher in older dogs and may be a marker of benign prostatic hyperplasia (BPH). BPH is a normal aging change in the

dog and frequently is associated with no clinical signs.

Puberty, Fertility, and Clinical Disorders

Overview

Plasma testosterone concentrations reach adult concentrations with maturation of Leydig cells after about 5 months of age. Large breeds typically demonstrate secondary sexual characteristics later than small breeds. Medium-sized males reach puberty at 10 to 12 months and can ejaculate normal sperm. Total sperm numbers in the ejaculate increase and plateau at about 2 years of age. About 80-90% of breedings of normal fertile males and females result in pregnancy. Veterinary opinion may be sought for males failing to sire litters with two or more healthy bitches. If a dog is used infrequently, there may be long periods before recognizing a possible problem. It is wise to consider routine BSE every 12 months.

Poor Libido, Failure to Achieve an Erection or Intromission

Poor libido is an uncommon cause of infertility in dogs seen most commonly in older males or those with hypogonadism. Poor libido is not associated with low testosterone in the absence of obvious testicular disease. Exogenous testosterone supplementation is not recommended to improve libido in dogs, since this can suppress pituitary function and decrease semen quality. Common causes of apparent poor libido include male inexperience, poor breeding management, or having the female brought to the male at an inappropriate time. Some dogs may have been previously reprimanded when they have shown interest in bitches and this has resulted in a psychological barrier to the normal expression of male sexual behavior. Some dogs benefit from being allowed to mate an experienced and quiet bitch.

Rarely, dogs have failure of erection separate from poor libido or disinterest in females and are reluctant to mate. In these dogs even manual stimulation of the penis fails to stimulate an erection. Previous trauma (fracture of the *os penis*) can cause failure of the corpus cavernosum to fill with blood, resulting in partial or complete erectile failure. Abnormalities may be detected by observing the penis when attempting to collect semen. Off-license treatment with sildenafil has not been useful. Sometimes it is best to collect semen for artificial insemination of the bitch. Failure to achieve normal intromission may be the result of abnormalities of the penis or sheath, the result of disease that causes pain and thus prevents intromission, or abnormality of the caudal female reproductive tract that prevents intromission.

Penile, Preputial and Related Abnormalities

Persistent Penile Frenulum

Failure of rupture of the penile frenulum at puberty may result in a ventral deviation of the penis during erection and failure to breed. In some dogs, traction on the frenulum causes pain or tearing and bleeding of the penile skin. Persistent frenulum can be detected by inspection of the penis. The frenulum (which is normally avascular) can be incised to enable an effective cure. Since this may be an inherited trait, it should be considered before breeding such males.

Fractured *Os Penis*

Traumatic fracture of the *os penis* usually causes acute swelling, urethral hemorrhage and dysuria. Following healing there may be residual pain, deviation of the penis, or abnormalities of erection. Each can result in inability to achieve normal intromission. Some of these males never achieve normal coitus and breeding has to be assisted by the use of semen collection and artificial insemination.

Lymphoid Hyperplasia

Small, 1 to 2 mm diameter raised lymphoid nodules are commonly present on the caudal glans in the region of the preputial reflection at the base of the penis and are especially common in dogs with a muco-purulent preputial discharge. This discharge is usually normal and associated with commensal bacterial growth within the prepuce. Occasionally these lymph nodules can be numerous or particularly protuberant and traumatized when the prepuce is retracted at the time of mating or semen collection. Extensive lymphoid hyperplasia may cause pain and bleeding at coitus but usually they do not prevent breeding.

Penile Neoplasms

Tumors of the penis are rare. Squamous cell carcinomas are most common; they spread locally and metastasize to the inguinal lymph nodes. Hemorrhage from an ulcerated neoplasm may be the first clinical sign, although usually there is frequent penile licking. When lesions are large they may prevent normal intromission. Radical surgical resection is warranted in the absence of metastases. Transmissible venereal tumor (TVT; see ch. 351) is a consideration, but a mass is not always present. Diagnosis of TVT is important as transmission of cells from the infected individual seeds the genital mucosa of the recipient. In the early stage, small tumors do not prevent breeding. Animals should not be used for breeding if any active tumor tissue is present. Spread to the oral or nasal cavity is common due to licking. Most dogs are cured with chemotherapy.

Phimosis

An abnormally small preputial orifice may occur either congenitally or result from trauma or inflammation. A narrow stream of urine during micturition and urine pooling within the prepuce can result and cause balanoposthitis. Affected dogs are not able to copulate and show signs of pain during erection and intromission. Surgical enlargement of the orifice is usually curative.

Musculoskeletal Pain Preventing Intromission

Some dogs may be unable to breed due to musculoskeletal pain due to spine or orthopedic issues (see ch. 353). In non-hereditary disease, males may breed after being given anti-inflammatory agents, but others may require semen collection and artificial insemination.

Female Causes of Failure of Intromission

Various abnormalities within the bitch's caudal reproductive tract may prevent intromission. Careful examination of the bitch for the presence of vulvar hypoplasia, vaginal strictures or vaginal hyperplasia should be routinely assessed prior to mating. Detection of these problems is important since if attempted mating causes either the dog or the bitch to suffer pain, this can result in psychological problems that inhibit future breeding.

Failure to Produce an Ejaculate

Retrograde Ejaculation

Retrograde ejaculation, rare in dogs, is usually a neurological condition causing deposition of sperm into the bladder rather than the emission of semen. In most afflicted dogs, no ejaculate is seen although some produce small volumes of the second ejaculate fraction. Lavage of the bladder with physiological saline after mating may be diagnostic. Some dogs with retrograde ejaculation can be managed by preventing urination prior to mating or semen collection and others respond to sympathomimetic agents (phenylpropanolamine). In unresponsive dogs, the bladder can be emptied of urine, partially filled with saline before being stimulated, and the bladder lavaged afterward. Sperm collected in this manner can be used for artificial insemination.

Tubular Obstruction

Obstruction of the tubular genital tract can result in absence of sperm from the ejaculate, although in most cases the condition is unilateral and results in low numbers of ejaculated sperm rather than a complete absence. If bilateral, there is usually an obvious lesion of the scrotum, testes or epididymides, and it is rare for a dog to present solely with obstructive azoospermia. Potential causes include acute inflammation, sperm granuloma, neoplasia, previous vasectomy and segmental aplasia. With bilateral lesions, ejaculates are azoospermic, urine contains no sperm, and concentrations of alkaline phosphatase are low.

Failure to Ejaculate

Failure to ejaculate can be the result of psychological issues similar to those reported in poor libido and most common in young dogs, inexperienced dogs, or dogs who experienced pain during previous matings. These dogs often fail to thrust forward during intromission, exhibit lack of excitement, and they may fail to develop a complete erection (the copulatory tie is usually absent). Patience and use of an experienced bitch may overcome these issues. Teasing the dog for a time before mating may increase excitement and help overcome the problem.

Poor Semen Quality

Overview

One of the most important aspects of investigating male infertility is the performance of a detailed semen evaluation, since certain characteristics of semen quality are predictive of fertilizing ability. As discussed, it is possible to classify semen abnormalities according to their origin, whether they are compensable or not, or using terminology that describes the overall changes in semen quality.

Hemospermia

Blood or red-coloration to ejaculates is relatively common in dogs. Usually, blood is noted in the prostatic fractions (first or third) of the ejaculate. Occasionally, red blood cells are identified microscopically when not seen grossly. Since the prostate is the sole male dog accessory gland, bleeding or discoloration is nearly always associated with prostatic disease, commonly BPH. Presence of blood warrants further prostatic evaluation (see ch. 337). If contamination of the second fraction is significant and semen is to be used for artificial insemination, one may centrifuge the semen, remove the fluid containing erythrocytes and re-suspend the sperm in a semen extender.

Urospermia

The first fraction of the ejaculate flushes the urethra of urine, cellular debris, and is voided before intromission. It is common, therefore, to find urine in the first fraction and, if allowed to mix with the second fraction, may have a toxic effect. Contamination of the second fraction with first fraction should be avoided and if it occurs, semen should be diluted with an extender, centrifuged, supernatant removed, and the sperm re-suspended in fresh extender.

Azoospermia

Overview

Apparently normal ejaculate containing no sperm is azoospermia. There are various explanations. Diagnosis often requires biochemical and cytological examination of the ejaculate, US examinations and testicular fine needle aspiration (Figure 318-11). Common causes include acquired gonadal dysfunction, incomplete ejaculation, lack of emission (see above), and congenital gonadal dysfunction.

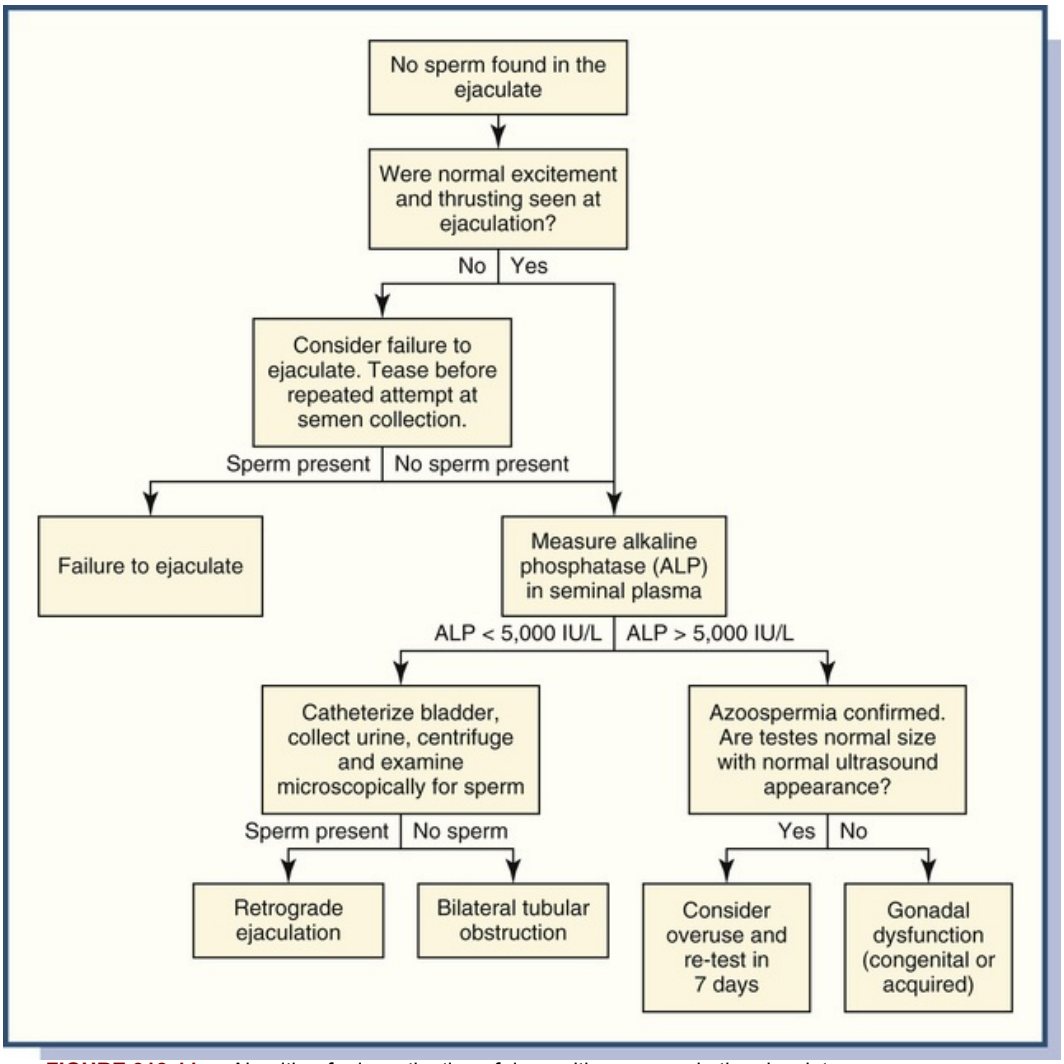


FIGURE 318-11 Algorithm for investigation of dogs with no sperm in the ejaculate.

Acquired Gonadal Dysfunction

Acquired gonadal dysfunction accounts for >55% of "infertile" males. The condition may be called spermatogenic arrest or testicular degeneration. Many of these dogs were previously fertile, but developed decreased fertility (both the percentage of bitches pregnant and a decrease in litter size) before developing azoospermia. In some breeds (Labrador Retriever, Welsh Springer Spaniel) the problem occurs within specific genetic lines and may have an immune-mediated etiology. In the Beagle, a relationship between focal degenerative orchitis and thyroiditis has been established. In many, unrecognized exposure to toxins or use of drugs that cause azoospermia will lead to testicular degeneration. Most azoospermic dogs have normal ejaculate alkaline phosphatase concentrations, confirming ejaculation in the absence of sperm. There are often changes in testicular size, calcification or fibrosis noted on US of testicular parenchyma. FNA and cytology may be useful. In the majority the prognosis for fertility is hopeless. However, azoospermia is reversible following sexual rest in a minority of dogs. The etiology is not understood, although these dogs do not have small testes or US evidence of disease. It is plausible that incomplete ejaculation has occurred. These dogs should be re-examined after a period of sexual rest before diagnosing irreversible azoospermia.

Incomplete Ejaculation

Nervous inexperienced males commonly have an incomplete ejaculation or failure of ejaculation. Diagnosis depends on age, breeding history, observation of a mating, collection of a semen sample and detection of low concentrations of alkaline phosphatase concentration. Examination of urine after centrifugation can be useful for distinguishing these two conditions, since dogs without obstruction may have sperm present within the

bladder, but not the pathological condition of retrograde ejaculation. This is a common observation in normal dogs. Incomplete ejaculation can be treated by changing breeding practices to increase the dog's experience and by teasing the dog for an extended time prior to breeding. Allowing the dog to breed an experienced bitch may improve performance.

Congenital Gonadal Dysfunction

Congenital gonadal dysfunction is usually seen in dogs that are phenotypically male but with chromosomal abnormalities (XXY or XX-male syndromes). Such dogs usually have an absence of spermatogenesis and, as such, are relatively easy to diagnose since there is usually testicular hypoplasia on examination. Testes are palpably small and soft. They are usually hyperechoic on US.

Lack of Emission

Both retrograde ejaculation and tubular obstruction (if bilateral) can result in azoospermia as discussed.

Oligozoospermia

Definition

Oligozoospermia is the term used to describe ejaculates containing low numbers of morphologically normal sperm. It is uncommon in dogs and may occur as a result of incomplete ejaculation, overuse, or retrograde ejaculation.

Incomplete Ejaculation

Incomplete ejaculation caused by inexperience or a previously painful mating is probably the most common cause of oligozoospermia. In these cases there may be a low number of normal sperm within the ejaculate. The condition can be diagnosed and managed as described above.

Overuse

Often, older dogs may have oligozoospermia if frequently used in breeding. It is likely that daily sperm production is low and that frequent ejaculation depletes the extragonadal sperm reserve. Sexual rest may allow the reserves to increase to appropriate numbers. Semen quality of dogs begins to decline at about 7 years of age. Careful management of the time of mating is required in older dogs to ensure that appropriate numbers of sperm are available for fertilization.

Retrograde Ejaculation

In retrograde ejaculation, a small volume of the second ejaculate fraction may be collected and found to contain low numbers of normal sperm. This is uncommon and in most cases there is a complete absence of sperm and the condition can be diagnosed and treated as previously discussed.

Teratozoospermia

Teratozoospermia is the presence of sperm with abnormal morphology. In many cases, such morphological abnormalities result in impaired motility such that teratozoospermia and asthenozoospermia occur concurrently. There is little information about specific sperm abnormalities and fertility in dogs. Large numbers of sperm with abnormal midpieces, head-base/midpiece abnormalities and midpiece swellings have been related to infertility in dogs. Sperm with midpiece defects and deformed acrosomes are also associated with experimental *Brucella canis* infection. There is no direct link explaining why these sperm abnormalities cause infertility. In dogs, this is not especially important as long as the abnormalities associated with infertility are recognized. In some dogs, several abnormalities may be seen. In general, when >40% of sperm are morphologically abnormal there is a decline in fertility. Cause of teratozoospermia is not often determined. Many dogs are in early stages of testicular degeneration after an insult and later are azoospermic. Repeated semen evaluation after about 2 months should allow the progression of the disease process to be established. In some cases, teratozoospermia is seen in older dogs as a result of senile degenerative changes within the testes.

Asthenozoospermia

Asthenozoospermia refers to normal sperm morphology but reduced motility. As previously described, careful assessment of motility is necessary to ensure detection. Cooled semen samples often have sperm with reduced motility. Other recognized causes include immune-mediated disease and contamination of the ejaculate. The latter is not an infertility condition.

Agglutination of Sperm

Antisperm antibodies can cause agglutination and poor motility. Although the cause of such antibody production is usually not known, it has been demonstrated in experimental infection with *Brucella canis*. In most dogs the prognosis for fertility is guarded.

Contamination of the Ejaculate

Contamination of ejaculate with toxic compounds (water, urine, certain plastics, some lubricants, residue from sterilizing agents, and latex artificial vagina liners) can all reduce motility or produce immotile sperm without obvious morphological changes. Careful evaluation of semen collection methods and handling should be undertaken.

Normospermia

There are many dogs who appear infertile despite having normal semen quality. In many, there are anatomical, physical or psychological problems that prevent normal courtship, intromission and ejaculation. Some suggest that a positive semen culture and/or changes in pH, biochemistry or cellularity of the prostatic fluid or seminal plasma can influence fertility. In general, however, when there are such changes in the ejaculate, there are also secondary changes in sperm morphology that influence fertility.

CHAPTER 319

Reproductive Disorders in the Neutered Male or Female Dog

Autumn P. Davidson

Client Information Sheets:
Stump Pyometra
Canine Pseudopregnancy
Puppy Vaginitis
Stopping Signs of Heat
Septate Vaginal Strictures
Priapism
Ovarian Remnant Syndrome

Introduction

Medical disorders of the reproductive tract are not limited to "intact" male and female dogs. Genitourinary disorders occur in neutered dogs of both genders and several medical conditions can be traced to the presence of gonadal remnants after an incomplete neutering procedure. The benefits of neutering pet dogs are well documented. Identification and proper management of neutering-related disorders is important in veterinary medicine.

Urinary Incontinence in the Ovariectomized Bitch

Urinary incontinence is a common and predictable complication of ovariectomy in the bitch (see ch. 333). Urinary incontinence in older neutered dogs is less common and usually related to a myelopathy rather than hypogonadism. Urethral sphincter incompetence resulting in urinary incontinence occurs most commonly in larger (>20 kg) ovariectomized bitches over 8 years of age; the time of ovariectomy is not implicated unless the dog was <12 weeks.[1] Important rule-outs include overflow incontinence due to isosthenuria or hyposthenuria (see ch. 45), urinary tract infection (see ch. 330), undiagnosed ectopia, behavioral or submissive urination, and genitourinary tract inflammatory or neoplastic disorders (see ch. 351). Quantitative urethral pressure profiling is a "gold standard" for diagnosing urethral disorders, but is not commonly available (see ch. 335). Urinary incontinence is problematic for house dogs and it increases the incidence of urinary tract infection (UTI) caused by ascending bacteria.

Once diagnosed, usually by a process of elimination, therapy for urethral sphincter incompetence-associated urinary incontinence involves either estrogen replacement (estrogens sensitize the urethral sphincter alpha1-adrenoreceptors to norepinephrine), phenylpropanolamine (a sympathomimetic which improves urethral tone via the alpha1-adrenoreceptors), or combining the two, since their effects are synergistic (see ch. 333).[1] For dogs failing medical management, endoscopic periurethral collagen implantation can improve the condition for weeks to months but availability is limited. Surgical options include colposuspension, urethral infolding, trans-obturator vaginal taping and urethral hydraulic occluder placement (see ch. 124); all have shown benefit in small numbers of cases (see ch. 335).

Chronic Vestibulovaginitis

History

Bitches with chronic vestibulovaginitis may have a purulent or mucoid-to-hemorrhagic vulvar discharge (see

ch. 44) and, usually, signs of discomfort (licking, scooting, and pollakiuria). Perivulvar and vulvar dermatitis is frequently present and can be severe. The condition is seen in ovariectomized bitches of any age, months to years post-neutering. The history usually includes multiple therapeutic efforts without resolution, although transient improvements can occur. The duration is usually from weeks to months, but sometimes lasts years.

Etiology

The etiology of chronic vestibulovaginitis is multifactorial. The primary cause may be masked and/or exacerbated by common therapies: long-term antimicrobial use, self-mutilation, and douching. Vaginal mucosal biopsy frequently shows nonspecific lymphoplasmacytic inflammation, but sometimes the inflammation is suppurative (neutrophilic) or eosinophilic. Vaginal cultures can show overgrowth of an atypical, often resistant bacterial species (pure Gram-negative cultures, *Pseudomonas* spp.), especially if antibiotics have been used extensively. Occasionally, a yeast overgrowth is identified. Primary bacterial vestibulovaginitis is rare. Vaginal strictures are commonly identified but rarely contributory, and usually represent misinterpretation of the normal narrowing at the vestibulovaginal junction in a maiden bitch. True circumferential vaginal strictures are cranial to the urethral papilla and thus do not contribute to urine pooling. Septate dorsoventral vaginal anomalies are also usually positioned cranial to the urethral papilla. Both can interfere with copulation or whelping, but are unlikely to contribute to vestibulovaginitis in the ovariectomized bitch. Neither previous juvenile ("puppy") vaginitis nor ovariectomy prior to the first estrous cycle predisposes an adult to chronic vestibulovaginitis.[2] Many are classified as idiopathic (E-Box 319-1).

E-Box 319-1

Common Etiologies of Chronic Vestibulovaginitis

1. Extensive perivulvar dermatitis associated with redundant dorsal and lateral vulvar folds
2. Granulomatous uterine stump (rule out stump pyometra/ovarian remnant)
3. Vaginal foreign bodies (foxtails, bone fragments)
4. Chronic urinary tract infection with urethritis/vestibulitis/vulvitis
5. Urinary bladder, urethral, vaginal or vestibular neoplasia
6. Os clitoris, clitoral hyperplasia
7. Significant vaginal stricture occluding the vault
8. Vaginal hemorrhage associated with vascular anomalies or bleeding disorders

Clinical Evaluation

Physical Examination (PE), Laboratory Testing, Imaging

PE of the vulvovaginal area without sedation/analgesia may be precluded due to pain or fear. A minimum data base including a complete blood count (CBC), serum chemistries, urinalysis (UA, preferably acquired by cystocentesis) and urine culture are advised. Radiography (vaginogram/urethrogram/cystogram/IVP) and/or ultrasound (US) of the entire genitourinary tract can be helpful in identifying abnormalities and for eliminating differentials (see ch. 88). US is preferred as it does not require anesthesia and evaluation of the entire abdomen can be performed with particular focus on the genitourinary tract, including the former ovarian sites and the uterine stump (Figure 319-1).[3]

FIGURE 319-1 Transverse ultrasound image of an abnormal ovarian stump; arrow indicates an echogenic foreign body (grass awn).

Endoscopic Examination

When abnormalities are not identified with US (i.e., uterine stump granuloma, chronic cystitis, urolithiasis, trigonal lesions), thorough vaginal examination under adequate (heavy) sedation or anesthesia should be considered (see ch. 44 and 119). Endoscopic equipment allowing evaluation of the entire vaginal vault should be used. A rigid cystourethroscope with saline infusion is optimal. Otoscopes and vaginal speculums do not permit adequate evaluation of the entire vaginal vault. Pediatric proctoscopes lack the sensitive optics of cystourethroscopes. Vaginoscopic evaluation should include visualization of the external vulva, clitoral fossa, vestibule, urethral papilla ± urethra/urinary bladder, vestibulovaginal junction, vagina and caudal cervix (see ch. 108 and 119).[4] Appearance and health of the mucosa throughout the tract, presence of masses, foreign bodies, and source of any discharge should be determined. If a vaginal stricture or marked narrowing of the vestibulovaginal junction is identified, it is important to note if vaginal inflammation secondary to retention of secretions is present cranial to the stricture. If the cranial vagina is normal, the stricture or narrowing is likely not contributory to vestibular-vaginitis (Figures 319-2 to 319-4).

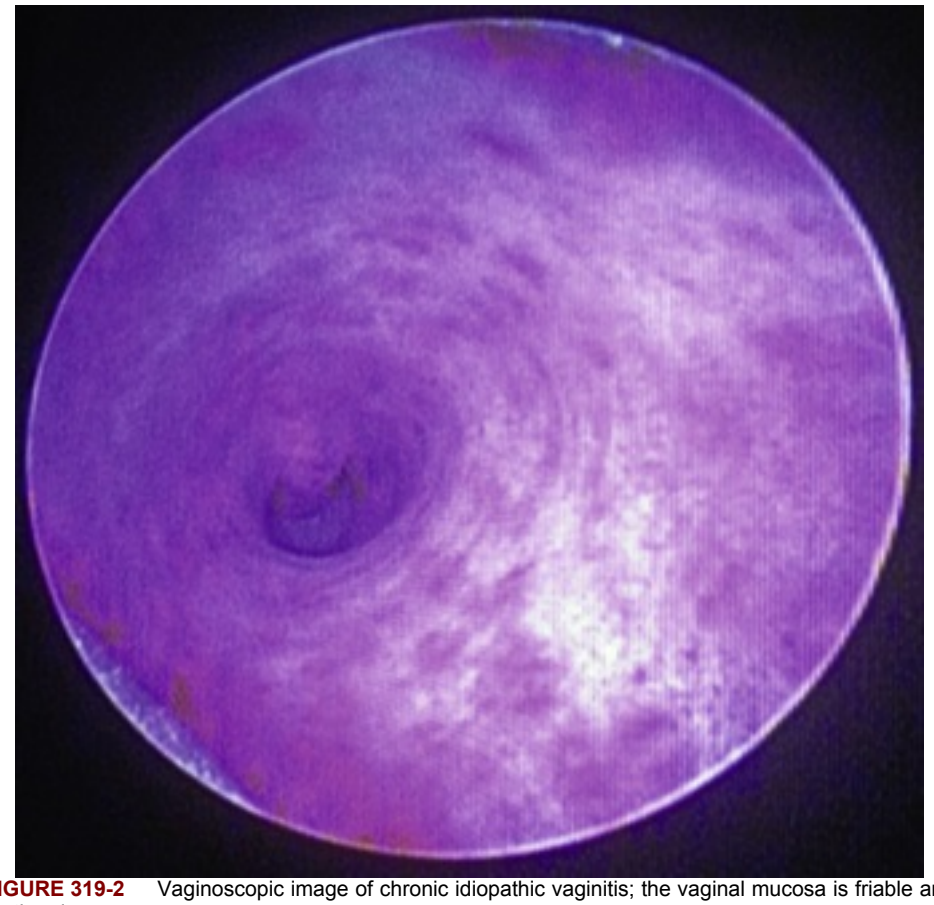

FIGURE 319-2 Vaginoscopic image of chronic idiopathic vaginitis; the vaginal mucosa is friable and erythemic.

FIGURE 319-3 Vaginoscopic image of lymphoid follicles in the vaginal mucosa.

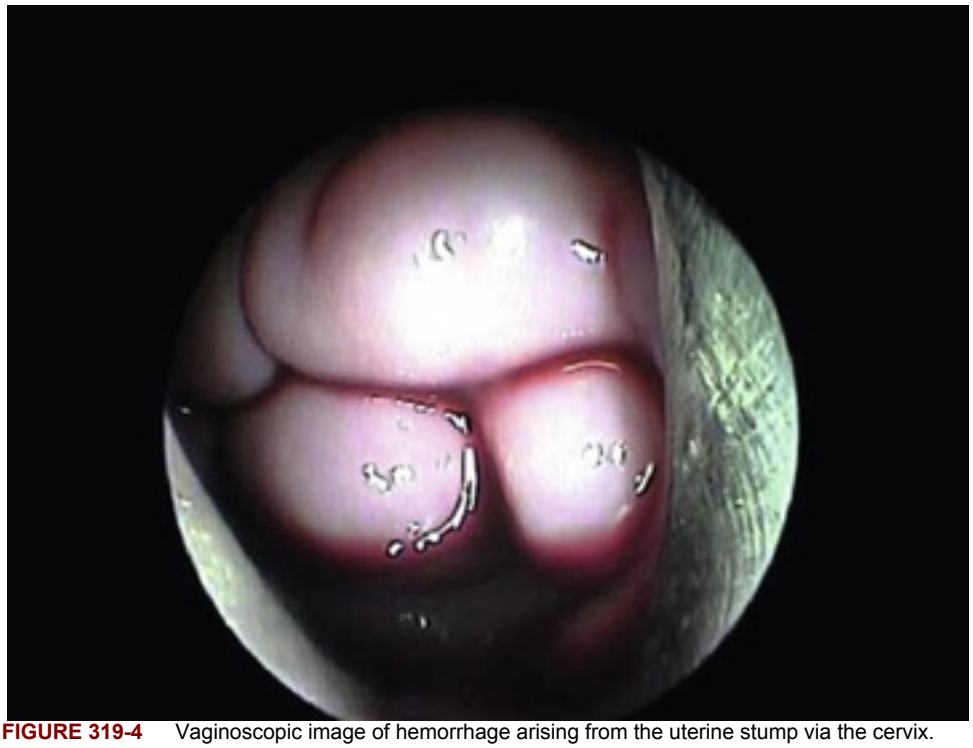

FIGURE 319-4 Vaginoscopic image of hemorrhage arising from the uterine stump via the cervix.

Cytology, Biopsy, Culture

Cytology of vulvar discharge, vaginal mucosal cytology, aerobic guarded vaginal cultures and pinch biopsy of affected vaginal mucosa may be helpful in better understanding this condition (see ch. 119). Interpretation of vaginal cultures should take into consideration previous antimicrobial therapies that could impact normal vaginal flora (mixed gram negative and positive bacteria including *Mycoplasma* spp.). Identification of any contributory anatomic abnormality is important (significant strictures, mass lesions, redundant dorsal or lateral vulvar folds, anomalous ureteral anatomy). It is helpful to have evaluated the bitch in a normal standing position to accurately assess external anatomy (vulvar folds?), after urination, and again after recumbency (urine pooling and scalding?). This complete examination often can only take place after a bitch is sedated or anesthetized (Figures 319-5 and 319-6). The presence of urine pooling in the vaginal vault during anesthesia can be misleading. Presence of redundant vulvar folds can be difficult to visualize if the bitch is positioned sternally or dorsally.

FIGURE 319-5 Redundant dorsal and lateral vulvar folds in a bitch with chronic vaginitis.

FIGURE 319-6 Marked perivulvar dermatitis made visible by retraction of the redundant folds in the same dog as seen in Figure 319-5.

Treatment

General Guidelines

Most dogs are managed by discontinuing any topical irrigations/douching, prevention of self-mutilation with Elizabethan collars and initiation of antimicrobial therapy only when indicated by proper interpretation of culture and sensitivity testing. Antimicrobial therapy should be limited to dogs with pathogens that have displaced normal flora (e.g., *Pseudomonas* spp.). Analgesia and anti-inflammatory therapy are indicated in most cases. NSAIDS are superior to corticosteroids because the latter increases risk of UTI. Narcotics such as tramadol (2-5 mg/kg PO q 8 h) and gabapentin (10-60 mg/kg divided PO q 8-12 h) can be beneficial for adequate analgesia.

Specific Conditions

If a specific cause of chronic vaginitis is identified, resolution can be straightforward. The identification and removal of foreign bodies should be curative (Figure 319-7). Surgical correction with careful post-operative prevention of self-mutilation is indicated if anatomic abnormalities (redundant dorsal or lateral vulvar folds, significant vaginal stricture, granulomatous uterine stump) have contributed to or caused the condition (Figure 319-8).[5-7] Appropriate management of chronic urinary tract infection, if identified, should resolve associated vaginitis. Surgery and/or chemotherapy may be indicated for urogenital masses or neoplasia (Figure 319-9).

FIGURE 319-8 Post-vulvaplasty/episioplasty correction of redundant perivulvar folds.

FIGURE 319-9 Clitoral hyperplasia contributing to chronic vulvitis/vaginitis.

Idiopathic

The condition is idiopathic if no anatomic, foreign body, infectious, granulomatous or neoplastic cause can be discerned. Oral estrogen replacement therapy is often helpful in establishing normal mucosal integrity and eventual normalization of the vaginal vault. Idiopathic vaginitis in ovariectomized bitches is similar to post-menopausal estrogen-deplete vaginitis in women. Women improve with intravaginal estrogen application,

which is difficult in the dog.[8] Oral estrogen (Estriol, Incurin, Merck or compounded diethylstilbestrol, DES) is advised; the dose is empiric and usually the same as used for urinary incontinence due to urethral sphincter incompetence (Estriol 0.5-2 mg/bitch PO q 24-48+ h; DES 0.20-1 mg/bitch PO q 48-72 h). Several weeks of therapy are required before improvement is recognized. Side effects are uncommon: overdosage results in signs of proestrus/estrus (attracting male dogs, vulvar swelling); myelosuppression is highly unlikely if the recommended dosage is followed. Analgesics and anti-inflammatories should be continued until an estrogen effect with relief is established. Vaginal cytology or vaginoscopy (see ch. 119) can confirm estrogen effect (Figure 319-10 and Video 319-1).

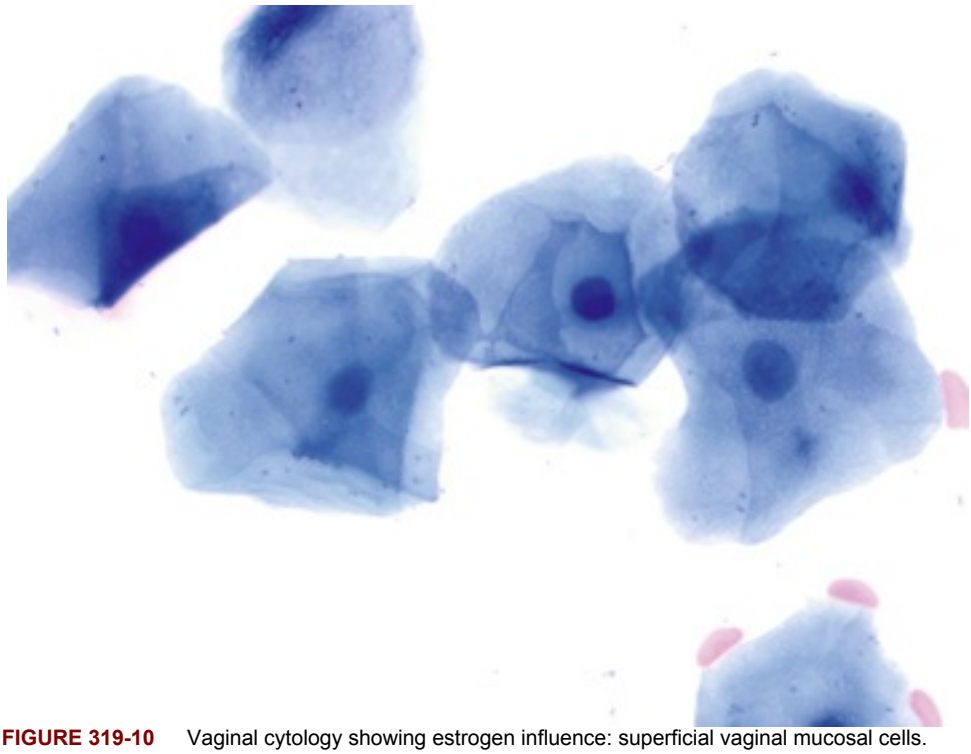

FIGURE 319-10 Vaginal cytology showing estrogen influence: superficial vaginal mucosal cells.

Estrogen Toxicosis in the Ovariectomized Bitch

Signs and Sources of Estrogen

Hyperestrogenism causes behavioral and/or physical signs of estrus in a bitch. Sources of estrogen in a spayed bitch are limited. Endogenous estrogen sources include functional residual ovarian tissue (ovarian remnant syndrome) or adrenal gland disease. Exogenous estrogen most commonly results from consumption of human hormone replacement transdermal products, but it can also occur with overdosage of veterinary prescribed estrogen for urinary incontinence. Excess estrogen in a neutered bitch causes attraction of male dogs, swelling of the vulva, mucoid to sanguineous vulvar discharge, passive interaction with male dogs, flagging, and sometimes copulation. Sanguineous discharge associated with estrogen is of uterine origin, indicating presence of a uterus or uterine stump. Chronic excess estrogen can cause symmetric alopecia, gynecomastia, and/or lactation.

Ovarian Remnant Syndrome (ORS)

Etiology

ORS is reported to be responsible for about 17% of complications post-ovariectomy/-ovariohysterectomy because both ovaries were not completely removed. There is no correlation with age at surgery, difficulty of surgery, obesity of the dog, or experience of the surgeon. The presence of anatomically abnormal ovarian tissue (fragmentation into the broad ligament) is possible but quite uncommon. A “supernumerary ovary” is

extremely rare. Experimentally, functionality can return to ovarian tissue removed from its vascular supply and replaced into or onto the lateral abdominal wall. No breed predisposition or geographic distribution has been reported for this condition.[9]

Signs

The signs of an estrous cycle usually occur months to years after ovariectomy/ovariohysterectomy, but can begin within days. Signs of proestrus last an average of 9 days. Signs of estrus last an average of 9 days; if ovulation occurs, diestrus (progesterone influence) follows and lasts 45-60 days. The average interval between signs of estrous cycles is 7 months (see ch. 312). Of note, the signs are usually cyclical or periodic (about every 5-8 months) rather than constant if a functional ovarian remnant is present. Stump pyometra causing a purulent vulvar discharge can develop when a bitch is under progesterone influence (see ch. 142 and 316). Constant signs of estrogen effect suggest an exogenous source, usually a transdermal human hormone product. Remnant ovarian disease (follicular cyst, functional neoplasia), or rarely, adrenal gland disease, are other possibilities.[10] The clinician must consider multiple differentials (E-Box 319-2).

E-Box 319-2

Differential Diagnoses for Hyperestrogenism

1. Ovarian remnant syndrome
2. Inadvertent exposure to human transdermal hormone replacement product
3. Excessive estrogen administration (for urinary incontinence or idiopathic vaginitis)
4. Ovarian remnant follicular cyst formation or malignant transformation
5. Excessive phytoestrogen ingestion (e.g., flaxseed)
6. Adrenal gland disease

Testing and Diagnosis *(Figure 319-11)*

A minimum database including a CBC, biochemistry panel and UA with culture should be performed, but are usually unremarkable. Evidence of chronic blood loss anemia may be noted if vaginal hemorrhage is profound, but is uncommon. Chronic blood loss has been seen in dogs with ovarian neoplasia, follicular cysts, bleeding disorder, or other systemic disease. Pancytopenia is possible from estrogen toxicosis (see ch. 52 and 54). Vaginal cytology will identify estrogen effect: vaginal mucosal cornification is a bioassay for elevated plasma estradiol concentrations (see Figure 319-10; see ch. 119). A serum progesterone concentration >2 ng/mL (measured 1-3 weeks after behavioral estrus) is consistent with functional luteal tissue and consistent with ORS. GnRH (50 mcg IM), hCG (400 IU IV) or hCG (1,000 IU: 1/2 IV, 1/2 IM) can be used to induce ovulation or luteinization for diagnostic purposes, but this is rarely informative due to the refractory nature of ovarian remnants. The test with either drug involves assessing serum progesterone concentration 2-3 weeks after dosing. A positive anti-mullerian hormone (AMH) result, now commercially available (MOFA), in a bitch > 6 months of age (post-pubertal) supports presence of ovarian tissue.[11] It is the screening test of choice. Exogenous estrogen exposure will not affect AMH results, permitting differentiation of ovarian remnant from exogenous estrogen toxicity. Luteinizing hormone assay (Witness LH, Zoetis) results are increased (>1 ng/mL) in ovariectomized bitches due to lack of negative pituitary feedback. However, when a positive result is obtained, a repeat test is advised in 24 hours to rule out detection of the 12-24 hour LH surge in an intact, estrual bitch (she should have representative vaginal cytology; see ch. 119 and 312). If results are positive several days apart, complete gonadectomy is supported. A negative test (<1 ng/L) is found with intact bitches unless performed at the moment of the LH surge during proestrus.[12] Exogenous estrogen exposure in a gonadectomized dog can cause the LH to become negative misleadingly.

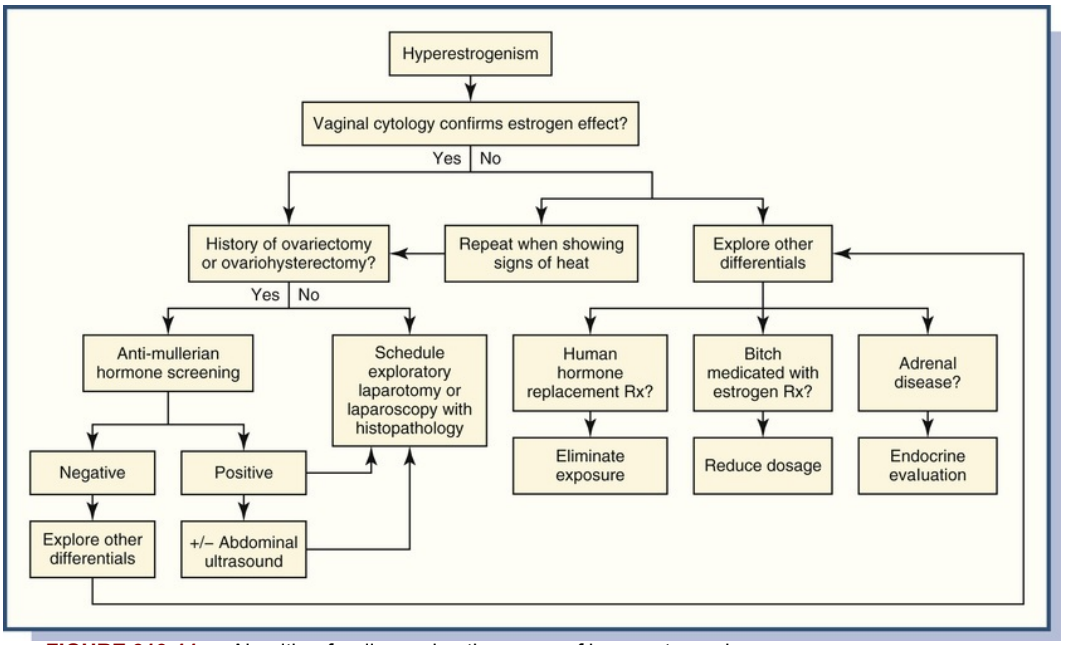

FIGURE 319-11 Algorithm for diagnosing the cause of hyperestrogenism.

US can be used to support a diagnosis of ovarian remnant syndrome initially suspected on history, clinical signs, vaginal cytology and a positive AMH (see ch. 88). Imaging should begin in a sagittal plane slightly caudolateral to the kidneys (where remnant ovarian tissue is expected). Remnant ovarian tissue may be visible only during the follicular phase (anechoic, cystic structures) or luteal phase (hypoechoic or isoechoic cystic structures) (Figure 319-12, Videos 319-2 and 319-3). Ectopic ovarian tissue can be difficult to locate and image with US and requires expertise. When positive, one can have added confidence in proposing laparotomy. The adrenal glands should be evaluated at the same time for size and shape (see ch. 308).[3]

FIGURE 319-12 Sagittal ultrasonographic image of an ovarian remnant showing a discrete hypoechoic follicular structure (cursors).

Surgical Treatment

Exploratory laparotomy with the goal of removing residual ovarian tissue confirms and resolves the problem. Identification of residual ovarian tissue is facilitated by the presence of active follicles or resultant corpora lutea; the clinician should schedule the surgical procedure when clinical signs are present. Because the uterus has been removed in part or whole, the usual concerns about performing surgery in an estrual bitch are lessened. All visible ovarian tissue should be removed and evaluated histologically. If no visible ovarian tissue is identified, all residual tissue at the ovarian pedicles should be resected and submitted for histology. Histopathology is important if neoplastic transformation has occurred. A stump granuloma or pyometra should be removed. Removal of functional luteal tissue may induce transient signs of pseudopregnancy in bitches post-operatively due to resultant increases in prolactin (see ch. 315). If profound, anti-prolactin therapy (cabergoline; Galastop 2.5 mcg/kg PO q 24 h for 4-6 days) can be given. Successful removal of remnant ovarian tissue should result in cessation of clinical signs of estrus, even if ovarian disease is present.

Medical Treatment

Medical therapy is often requested by clients not eager to pursue a second surgical procedure. Progestational or androgenic compounds used to suppress follicular ovarian activity are not recommended because of undesirable side effects (mammary neoplasia, diabetes mellitus, undesirable behavior). Immunocontraception or GnRH agonist administration will offer a viable alternative to laparotomy when perfected and commercially available in the United States. In dogs being given or consuming estrogen, successfully avoiding all estrogen exposure should lead to resolution of clinical signs in 2-4 weeks (Figure 319-13).[13] Owners are commonly unaware that medication in transdermal products is active after consumption by pets.

FIGURE 319-13 Vulvar enlargement in a 12-week-old mixed breed ovariectomized puppy resulting from exposure to an owner's transdermal hormone replacement therapy.

Prostatic Adenocarcinoma

Overview

Prostatic adenocarcinoma is a disease of male dogs usually neutered and older than 10 years of age (see ch. 337 and 351). It carries a poor prognosis. Prostatic adenocarcinoma originates from the glandular portion of the prostate; other prostatic tumor types include fibrosarcoma, leiomyosarcoma, transitional cell carcinoma (TCC) and squamous cell carcinoma. TCC and prostatic adenocarcinoma (ACA) are the most common

primary prostatic malignancies. TCC originates from the transitional epithelium extending from the bladder into the prostate or from the uroepithelium of the prostatic urethra. Most prostatic adenocarcinomas do not express androgen receptors and do not appear influenced by androgens. In contrast, castration (especially <1 year of age) appears to be a risk factor for its development. Previous benign prostatic hyperplasia is not a risk factor for prostatic neoplasia.[14,15]

Clinical Findings and Testing

Stranguria, dysuria, tenesmus, small stools, lumbar pain and gait abnormalities are common clinical signs. Tumors are often detected after metastatic spread as clinical signs occur late and early screening is unavailable. On rectal examination, a large (especially since the dog is neutered), asymmetrical, irregular painful prostate can be identified. Commonly, affected dogs have abdominal pain, lumbosacral pain, and/or sublumbar lymphadenopathy. Anorexia and associated weight loss reduce body condition. CBC and chemistry panel findings reflect chronic disease and inflammation. Post-renal azotemia can occur if the mass is obstructive, causing hydroureter and hydronephrosis. An elevation of alkaline phosphatase occurs in ≈50% of dogs, perhaps associated with axial bone metastasis. Hematuria, pyuria, bacteruria and atypical transitional cells may be noted on urinalysis (see ch. 72). UTI is a common comorbidity (see ch. 330). Malignant transitional cells appear similar to reactive transitional cells making biopsy important. Thoracic radiographs are indicated to screen for pulmonary metastasis. Lumbar spinal radiographs can show vertebral metastasis. Mineralization in the enlarged prostate and/or sublumbar lymphadenomegaly is suggestive of malignant disease.

Abdominal US is a valuable diagnostic tool, permitting evaluation of the prostatic parenchyma, regional lymphatics, extension into the urinary bladder, urethral or trigonal obstruction and presence of hydroureter and hydronephrosis. Focal or multifocal hyperechoic prostatic parenchyma with asymmetry, irregular capsule outline, and mineralization are common. Cavitary regions due to necrosis and hemorrhage may be present and sublumbar lymphadenomegaly can be marked (Figure 319-14).[16] US and US-guided fine needle aspirate (FNA) or biopsy (see ch. 89 and 93) are useful, but risk of tumor seeding makes open biopsy preferable. Histopathology (rather than cytology) is usually required to differentiate tumor type.

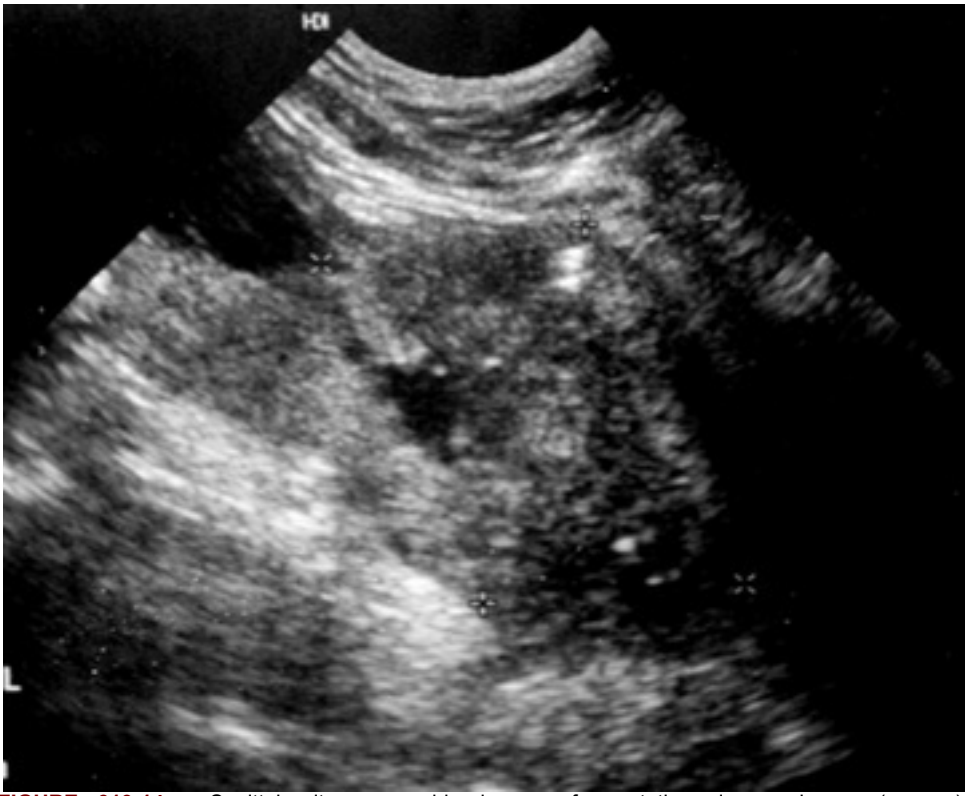

FIGURE 319-14 Sagittal ultrasonographic image of prostatic adenocarcinoma (cursors); mineralization is evident.

Treatment (see ch. 337 and 351)

Therapy with NSAIDs often in combination with oral analgesics can prolong life. Chemotherapy (carboplatin, cisplatin, doxorubicin, gemcitabine) can improve signs, but cure is unlikely. Prostatectomy can prolong life if the cancer is confined within the prostatic capsule, but there is a high complication rate (incontinence, urethral stenosis). Palliative radiation and/or urethral stenting offer short-term relief. Stool softeners are indicated with tenesmus. IV bisphosphonates such as pamidronate (0.65-2 mg/kg IV, slow infusion with 0.9% NaCl over 2 h) can help with pain relief from skeletal metastases.

Squamous Prostatic Metaplasia

Squamous prostatic metaplasia occurs as a consequence of hyperestrogenism, either of endogenous (functional Sertoli cell tumor, adrenal gland dysfunction) or exogenous (therapy for benign prostatic hyperplasia inadvertent consumption of owner transdermal hormone medication) origin. Prostatic epithelial squamous metaplasia is accompanied by secretory stasis and the potential for intraprostatic cysts. The prostate gland is usually large for a neutered dog and firm on palpation. Compression of the urethra and colon can cause dysuria and tenesmus. Other physical findings typical of hyperestrogenism can be present: attractiveness to males, gynecomastia, symmetric alopecia, hyperpigmentation, and a pendulous prepuce. Presence of an abdominal (cryptorchid) testis should be ruled out with US if both testes are not palpable. Estrogen toxicosis to the bone marrow can cause pale mucous membranes (anemia; see ch. 52), petechiation or hemorrhage (thrombocytopenia; see ch. 54), and fever (secondary to neutropenia). A careful history should be taken concerning possible exposure to human transdermal hormone medications or past purposeful therapy with estrogen for prostatomegaly.

A CBC, serum chemistry panel and UA/culture should be assessed for myelotoxicosis and general health. Changes are variable, depending on exposure duration, dose, and time between insult and testing. In the initial 2-3 weeks, either thrombocytopenia or thrombocytosis may be noted with progressive anemia and leukocytosis (WBC count may exceed 100,000/mcL). After 3 weeks, pancytopenia and aplastic anemia may be noted. Hematuria may occur due to thrombocytopenia or prostatic bleeding. Squamous epithelial cells exhibiting estrogen influence can be seen in the urine or recognized in samples from the preputial mucosa.

In a neutered dog with no scrotal testes, abdominal US should be performed to screen for a malignant-transformed cryptorchid testis or an unusually enlarged, hyperechoic, cavitary prostate. Assessing serum luteinizing hormone (LH, Zoetis) concentrations may indicate presence of testicular tissue, if low. If an abdominal testis with a parenchymal mass or an enlarged prostate is discovered with US, FNA or biopsy samples may provide cytologic evidence of functional testicular neoplasia or prostatic epithelial squamous metaplasia (see ch. 89 and 93). Therapy is dictated by the clinical findings, but discontinuing exogenous estrogen exposure or therapy is important. Castration should be recommended if cryptorchid. Concurrent prostatic infection or abscessation can be present and should be treated appropriately (see ch. 337).

Priapism

Definition and Etiology

Priapism is a persistent penile erection without sexual stimulation categorized as either nonischemic (arterial, high flow) or ischemic (veno-occlusive, low flow) and occurs most commonly in neutered dogs (Figure 319-15). Ischemic priapism is quite painful and considered an emergency, as rapid necrosis can result. Either form can result in significant trauma to the penile tissues (see ch. 146).[17] Castration of a dog with priapism is not helpful as the condition is not mediated by testosterone. Priapism should be differentiated from paraphimosis, which occurs more commonly in intact male dogs after semen collection or masturbation and results from constriction of the erect penis by the preputial opening (Figure 319-16). Priapism should also be differentiated from other causes of penile swelling, such as a hematoma, trauma or mass lesions (Figures 319-17 and 319-18). Penile hematomas usually form as a result of trauma or bleeding disorders. Simple visual inspection and palpation of the penis are usually sufficient to differentiate the conditions, but US and/or color-flow Doppler examination may further help differentiate these disorders from priapism (Figure 319-19). US of the perineum and the entire penile shaft may aid in identifying neoplasia, os penis fracture, hematoma, or thromboemboli (Videos 319-4 and 319-5).

FIGURE 319-15 Priapism in a neutered Boston Terrier; note the bulbus glandis is inside the prepuce.

FIGURE 319-16 Paraphimosis following semen collection; note the bulbus glandis is outside the prepuce.

FIGURE 319-17 Ruptured tunica albuginea causing a mass effect in the canine penis.

FIGURE 319-18 Lymphoma, involving the canine penile mucosa, causing a mass effect.

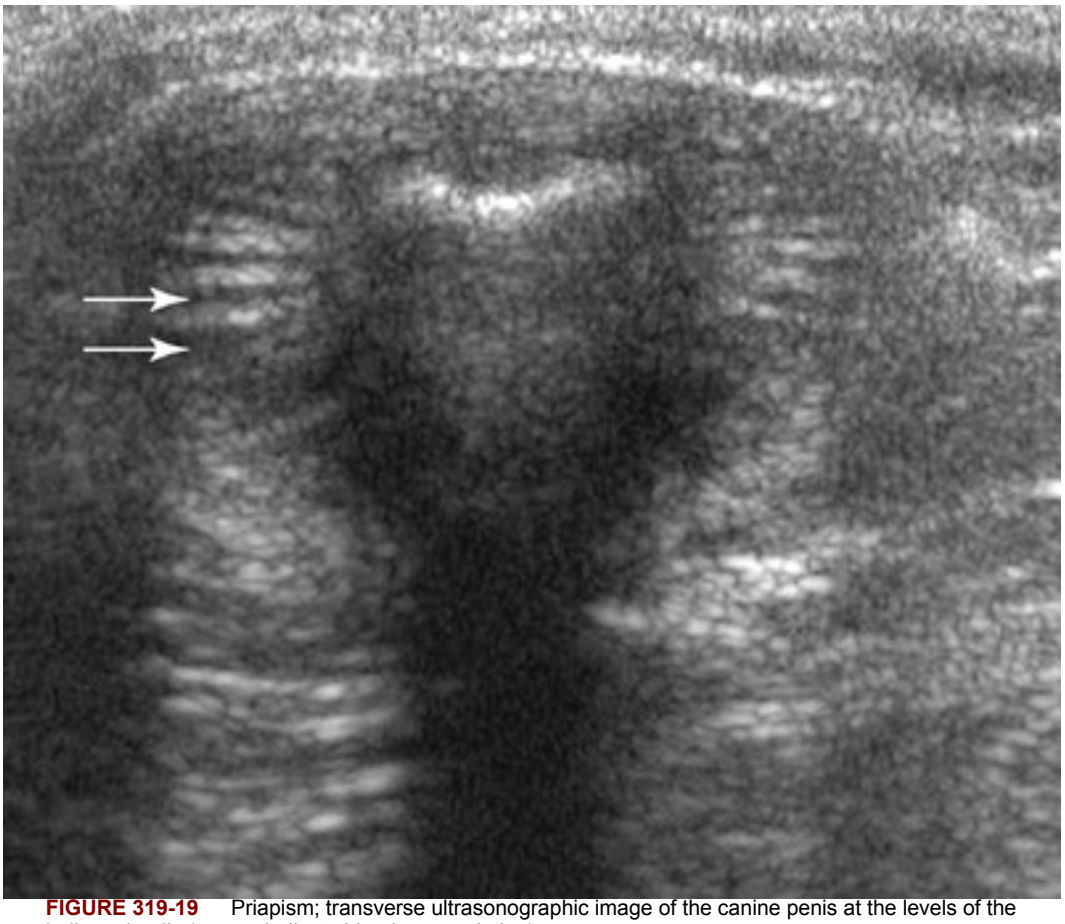

FIGURE 319-19 Priapism; transverse ultrasonographic image of the canine penis at the levels of the bulbus glandis (arrows indicate blood accumulation).

The canine erection is mediated through the pelvic nerve, which arises primarily from the first and second sacral nerves (S1-S2) and is composed of parasympathetic nerve fibers. Pelvic nerve stimulation causes erection by increasing penile blood pressure, partially inhibiting venous drainage, and dilating penile arteries. The pudendal nerve, which arises from the sacral nerves S1-S3, is involved as well, by stimulating contraction of the extrinsic penile muscles. The hypogastric nerve, a sympathetic nerve originating from the lumbar L1-L4 spinal cord segments, may also have a regulatory role. The hypogastric nerve is responsible for prostatic fluid secretion and ejaculation. Sympathetic chain fiber stimulation increases arterial resistance, decreases corpus cavernosal pressure, decreases venous resistance and inhibits erections. The sympathetic inhibition of the erectile process is mediated by the alpha-1 adrenergic system.[18] True priapism (either form) can be associated with vascular disorders (efferent or afferent), neuropathy, or a myelopathy (lumbosacral). One hypothesis on the pathophysiology of priapism suggests dyssynergic neurostimulation of inflow and outflow penile blood vessels causing vasospasms or smooth muscle spasms. This dysregulation may occur at the level of the penis, the CNS (spinal cord), or in the peripheral nervous system.

Diagnosis and Treatment

Distinguishing ischemic (proceeds to gangrene) from non-ischemic priapism is important, as is identifying and treating the underlying cause. If determined to be ischemic, prompt aspiration of the corpora cavernosa under sedation or anesthesia with or without irrigation should be done (see ch. 146). Intracavernosal injections of phenylephrine should be considered, but they carry some risk as appropriate dosages in dogs and cats have not been determined. Therefore, starting with low dosages (1-3 mcg/kg) and cardiovascular monitoring is important. Providing lubrication is important to limit tissue damage secondary to exposure and excoriation. An Elizabethan collar is indicated. If intracavernosal drainage and injections are not successful or significant tissue damage has occurred, penile amputation and perineal urethrostomy may be necessary.

Nonischemic priapism can resolve spontaneously, but can take hours to days. Thus conservative therapy using analgesia, protecting penile integrity with lubrication, and use of an Elizabethan collar are

recommended. Sedation with a phenothiazine drug can be helpful. Several systemic medications are of potential benefit, although little controlled data exist regarding efficacy. Gabapentin (10-60 mg/kg PO daily, divided q 8-12 h), terbutaline (1.25-5 mg/dog PO q 8-12 h) or ephedrine (1-2.5 mg/kg PO q 12 h) should be tried. Incrementally increasing dosage is advised. If detumescence is not achieved after several days of treatment with one drug then switching to another may be successful.

CHAPTER 320

Pediatric Care during the Postpartum Period

Margret L. Casal

Definitions

The "postpartum period" in women is defined as the first 6 to 8 weeks that follow giving birth. During this time, the uterus returns to its normal non-pregnant size. This is also the time period during which most neonatal deaths occur.[1,2] In veterinary medicine, the postpartum period has been described as about 2 (discharge of lochia) to 8 weeks (the time it takes the uterus to return to its normal size macroscopically).[3-6] The focus of this chapter is the most critical time period for neonates: the first 2 to 3 weeks of life.

Pre-Partum

Raising healthy neonates begins before they are born. Physical examination of dam and sire should be performed and is an opportunity to identify possible infectious or genetic issues (see ch. 2). Genetic screening can be considered in purebreds (see ch. 3 and 4). Bitch and stud should be screened for *Brucella* (see ch. 213) and queen and tom for feline leukemia virus (see ch. 223) and feline immunodeficiency (see ch. 222). Fecal examinations should be performed (see ch. 81) and both sire and dam should be current on parasite control (see ch. 163) and vaccines (see ch. 208). The dam's diet should be adjusted to meet demands of pregnancy and her body weight monitored since mortality rates are higher in litters from under- or overweight queens and bitches (ch. 315). Raw foods during pregnancy are not recommended because of possible exposure to bacteria (e.g., *Salmonella* spp.) or parasites (e.g., *Toxoplasma gondii*) (see ch. 192).[7,8] Most commercial diets are adequate and can be supplemented with puppy or kitten food during the last trimester. Adding vitamins or other supplements is not necessary and may be detrimental. Excessive vitamin A, for example, can cause midline defects in fetuses. Modified live vaccines administered during pregnancy may also cause fetal defects or cause active disease. Fenbendazole is safe for deworming bitches during pregnancy to reduce transplacental transmission of *Toxocara canis* and pyrantel pamoate for queens to decrease shedding of *Toxascaris leonina*.

The Immediate Post-Partum Period

Stress should be minimized by providing a whelping/queening room with a clean dry box and by reducing human and animal traffic to avoid introduction of infectious diseases. The queening or whelping box should be made of a material that can easily be sanitized, such as stainless steel or plastic. Bedding should be washable (blankets, towels) or disposable (newspapers, diapers). Other materials that might be needed include species-appropriate milk replacer, feeding tubes, a gram scale, digital thermometers that can measure as low as 32°C (89.5°F), warm water bottles/gloves or heating blankets, stethoscope, fluid bags (Ringer's or 0.9% NaCl), a fluid line, needles, syringes, shoe covers, and hand sanitizer (see ch. 171). Heating devices should be used cautiously, as neonates may not be able to escape if the temperature is too high. Shoe covers and hand sanitizers are used to minimize chance of disease transmission in kennels or catteries.

The ambient temperature for neonates should be relatively high (29.5-32.2°C; 85-90°F), as neonates cannot regulate their body temperature. During the first week of life, the temperature should be adjusted to 24-26.7°C (75-80°F) for haired breeds of dogs and cats. Hairless breeds (e.g., Mexican Hairless dogs, Sphinx cats) may require slightly higher ambient temperatures. Low body temperature interferes with cellular immune function. Maintaining proper ambient temperatures decreases morbidity. To prevent dry skin, the humidity levels should be about kept at 55-65%; higher humidity is conducive to infectious diseases. Cattery and kennel staff should care for the youngest animals first to decrease transmission of infectious disease to this most vulnerable subpopulation.

Assessment and Care of Neonates

Overview

Each neonate should be examined once the entire litter has been delivered, including testing of basic reflexes (righting, rooting, suckling, lumbar reflex), checking for cleft palate, umbilical hernia, open fontanelle, atresia ani, symmetry, muscle tone, and for any other gross congenital defects. The neonates should be identified individually, and all findings recorded in their respective charts. Body weights should be recorded daily for the first three weeks of life, as decreased weight gain, lack of weight gain or weight loss can be the first sign of illness. Daily observation and quick physical examinations are important for recognizing emerging signs of illness, such as sepsis, infection behind closed eyelids, diarrhea, change in mentation, dehydration, and hypothermia. Other than injury resulting from trauma, it is often difficult to determine cause of illness in neonates. Most exhibit weight loss, hypothermia, hypoglycemia, and/or dehydration. Injuries may result from accidentally being crushed by the dam, overzealous grooming by the dam or human, or being bitten by the dam or another animal. Wounds are treated accordingly and antibiotics that are safe for the age group (penicillins, cephalosporins) are administered.[9]

Hydration

Body water content is increased in neonates (≈80%) and they are unable to concentrate urine. Dehydration is always a concern to avoid. Autoregulation of renal blood flow, not yet developed, results in decreased glomerular filtration rate. Compensatory mechanisms such as increasing the heart rate and cardiac contractility in response to dehydration are limited in neonates. Their high metabolic rates and insensible losses (evaporation and respiration) contribute to fluid needs and dehydration can develop rapidly. Even mild dehydration can compromise health and needs to be treated immediately. Checking moisture of the oral mucous membranes allows for better assessment of hydration than skin tenting, which occurs later in neonates than in adults. Clinical signs include tacky to dry mucous membranes (5-7% dehydration), very dry mucous membranes plus a noticeable decrease in skin elasticity (10% dehydration) and circulatory collapse (upwards of 12% dehydration). Diarrhea, vomiting, inappetence, starvation, and neglect are the most common causes for dehydration.

In mild cases, fluids can be administered SC, where absorption is slow and less likely to overload the system. Ideally, fluids are administered IV via the jugular or cephalic vein (see ch. 129). In the absence of IV access, intraosseous (IO) catheters can be placed in the femur or humerus using an 18 to 22G needle or a 20G × 3.75 cm spinal needle (see ch. 77). At the site of placement, a small amount (less than 0.5 mL) of lidocaine is injected infiltrating the cutaneous, subcutaneous, and periosteal tissues. The area should be aseptically prepared. Access to the marrow space is gained through the trochanteric fossa for the femur or through the greater tubercle for the humerus. Maintenance fluid requirements are high at 80-100 mL/kg/day (3-4 mL/kg/h), yet total volumes administered are small, and volume overload occurs quickly due to the neonate's inability to process fluids quickly.

In moderate to severe dehydration or shock, 30-40 mL/kg of isotonic crystalloids can be given as a bolus over 5-10 minutes. Before administration, fluids should be warm, but not higher than 1°C (2.2°F) above body temperature. Fluid lines can be run through a warm water bath or under a heating blanket to keep them from cooling. Once stabilized, neonates can be maintained at 6 mL/kg/h with 50% of the deficit added over 6 hours (deficit = BW × % dehydrated) for rehydration. The lungs should be ausculted often to ensure that volume overload does not occur.

Hypothermia

Neonates are not able to regulate body temperature. Hypothermia can be serious and caused by maternal neglect or decreased metabolism for a variety of reasons.[10] Whatever the cause, it needs to be addressed immediately after obtaining samples for diagnostics. Hypothermia results in decreased gut motility, which can ultimately lead to ileus. Tube feeding or force-feeding neonates can cause aspiration followed by pneumonia or bloat resulting in increased intrathoracic pressure and labored breathing. Neonates in pain or who have difficulty breathing often swallow air and worsen bloat. This vicious circle can result in circulatory distress and death. Also, cellular immune function is inhibited by hypothermia, increasing susceptibility to infection.

Hypothermia in a neonatal puppy or kitten is defined as body temperatures dropping below 34.4°C (94°F) at birth, below 35.6°C (96°F) at 1-3 days of age, or below 37.2°C (99°F) at one week of age. Chilled neonates

with body temperatures above 31.1°C (88°F) may show restlessness, continuous crying, red mucous membranes, and skin that is cool to the touch. Muscle tone may be acceptable but respiratory rates will be above 40/minute and the heart rates above 200/minute. At body temperatures in the range of 29.4°C (85°F), neonates appear lethargic and uncoordinated but will respond to stimuli. Moisture and small bubbles of saliva are seen at the lip commissures. Heart rates drop to less than 50/minute and respiratory rates will be between 20 and 25/minute. Abdominal sounds will be absent and metabolism will be greatly decreased, resulting in hypoglycemia. Neonates with a body temperature under 21°C (70°F) may be comatose but treatment should be attempted if extreme methods of arousal produce a response.

Affected neonates should be kept dry, hydrated, and slowly warmed as described by not increasing temperature more 1°C (2.2°F) per hour. If the neonate is premature (and/or of low birth weight), humidity and temperature may be briefly raised to 85-90% and 29.5-32.2°C (85-90°F), respectively. The higher temperature and humidity will help to maintain neonatal core body temperature, hydration, and metabolism. Overheating should be avoided and the neonate's body position changed frequently to reduce vomiting and thus aspiration. Oxygen cages and human neonatal incubators provide oxygen and warm air to safely and quickly rewarm neonates.

In severe hypothermia, warm fluids can be administered IV or by intraosseous catheter. If warmed too quickly, neonates can suffer heat prostration. Clinical signs include increased respiratory rate and effort, cyanosis, diarrhea, and ultimately seizures. Life-threatening conditions often result if the body temperature is raised at more than 2°C (4.5°F) per hour. Overheating can be corrected with cool air and lukewarm water baths. However, delayed organ failure and death still may occur despite initial positive response. Skin burns can occur if neonates cannot escape a heat source. Treatment consists of local application of petroleum jelly to prevent drying, IV crystalloids, and systemic or oral antibiotics. Burn wounds require a large amount of energy for healing and thus, caloric supplementation at 2-4 times maintenance should be provided.

Hypoglycemia

Defined as a serum glucose <30 mg/dL (some suggest <75 mg/dL), hypoglycemia is the most common cause of neonatal seizures. Other clinical signs include tremors, crying, irritability, dullness, lethargy, coma, and stupor. Common causes for hypoglycemia in neonates are starvation, neglect, inborn errors of metabolism such as glycogen storage disease, portosystemic shunts, and hypopituitarism. Therapy consists of administering dextrose IV at 0.5-1 g/kg as a 2.5-5% dextrose solution in lactated Ringer's or normal saline. The osmolality of higher dextrose solutions (>5%) can be caustic and cause phlebitis. If needed, dextrose can be applied directly to oral mucous membranes. Regulatory mechanisms are not fully developed in neonates; thus, blood glucose levels should be closely monitored during therapy to avoid hypo- or hyperglycemia. However, no more than 5% of an ill neonate's blood volume should be removed each week, i.e., no more than 0.5 mL blood/100g body weight. Blood taken must be carefully limited.

Feeding

If a neonate is not gaining or maintaining body weight, supplementation may be required (see ch. 171).[10] Neonatal puppies and kittens should be able to ingest daily requirements for both calories and fluid in four to five feedings. Puppies are expected to gain approximately 2.2 grams per kilogram of the anticipated adult weight per week. Kittens are usually born at 80-120 grams and should gain 70-100 grams per week. However, it is common for neonates to lose or maintain weight during the first day or two of life. As long as they are vigorous and nursing, no treatment is required. Only species-appropriate milk replacement should be used. The most common problems with supplementation are over- or underfeeding. Overfeeding milk replacers almost always results in diarrhea and underfeeding may result in dehydration and insufficient weight gain. Homemade formulas and many commercial milk replacers that contain cow's milk may be deficient in growth factors, amino acids and other essential nutrients. The caloric density of the formula is often high but the fluid content low. Therefore, the fluid needs may not be fulfilled despite energy requirements being met. Diluting the formula to meet caloric and fluid requirements can resolve the issue if multiple feedings per day are possible. If necessary, the milk can be of high caloric density and SC fluids can be given. Neonates should be encouraged to urinate and defecate after each feeding by stimulating the anogenital area with a moist cotton ball. At this time, lack of anal patency or diarrhea might be noted. Highly concentrated urine may be indicative of dehydration. Also, constipation may be noted, suggesting inappropriately prepared milk replacer or hypothyroidism in kittens.

During their first three weeks of life, neonates should be weighed daily to be certain of weight gain.

Neonates should never be supplemented if their body temperature is below 35.6°C (96°F), as the intestinal tract slows and aspiration may occur. Feeding can be initiated if intestinal sounds are present. Supplemental feeding can be provided by tube feeding or placing a neonate with a surrogate mother. In the latter case, the neonate may need to be rubbed against the other neonates in the litter (or even their feces) to entice a surrogate mother to adopt and care for an orphan.

Some neonates can be bottle-fed to meet their needs (see ch. 171). For this, the neonate is held upright, allowing placement of the front paws on the bottle or the person's hand. Enough time is allotted for the neonate to swallow and breathe in between sips, otherwise they tend to swallow air or aspirate. Tube feeding is a convenient way to supplement the neonate with nutritional needs, especially if malformations are present or the neonate is weak.[10] Exact amounts can be fed and it is less time consuming when multiple neonates need to be supplemented. Depending on neonatal size, a 5 or 8 F plastic feeding tube can be used for tube feeding. To determine length of tubing needed and to have the tip of the tube rest just past the lower esophageal sphincter, the feeding tube is placed along the side of the neonate from the tip of the nose to the last rib. A mark is made at three quarters of the measured length from the tip of the feeding tube and this will indicate the portion of the feeding tube to be placed. Correct placement of the tube is indicated by negative pressure when pulling back on the plunger of the syringe, vocalization by the neonate, and the fact that the neonate swallowed the tube. Feeding should occur at the dosage and rate indicated on the milk replacer packaging. Sometimes it may need to be diluted. Caloric and fluid content of canine, feline, bovine and caprine milk are indicated in Table 320-1.

TABLE 320-1

Nutrient Content of Milk from Different Species

	BITCH'S MILK	QUEEN'S MILK	COW'S MILK	GOAT'S MILK
Fluid content (%)	77.3	79.0	87.7	87.0
Fat (%)	9.5	8.5	3.6	4.1
Protein (%)	7.5	7.5	3.3	3.6
Lactose (%)	3.3	4.0	4.7	4.0
ME kcal/100 mL milk	146	121	64	69

Note the differences in metabolizable energy (ME) between the different species. When mixing cow or goat's milk as a milk replacer for neonates, it is important to be aware that in order to cover the energy requirements, the lactose concentrations will be far too high and cause diarrhea. Commercial milk replacers are a better choice.

Fading Puppy Syndrome

The fading puppy or kitten syndrome is not a diagnosis but rather a clinical condition characterized by anorexia, lethargy, emaciation, birth defects, and death.[11] Neonates may be too weak at birth to nurse, resulting in dehydration, hypothermia, hypoglycemia, and death within hours to days.[12] Diagnosing the underlying cause begins with a thorough history (see ch. 1), including information on the queen or bitch, the environment, ingestion of colostrum, milk replacers and any medications given.[13] After thorough physical examination (see ch. 2), decisions regarding need for blood and urine testing can be made. Patients may require stabilization before complete physical examination and diagnostics are pursued. Results from blood work, urinalyses, and/or radiographs should be compared with age-matched normal controls if possible. In neonates suspected of having congenital or genetic disease, careful review of the pedigree and a detailed history on previous litters can prove helpful.[14] It may be necessary to euthanize the sickest neonate in the litter and submit it necropsy to better understand the cause of illness, if multiple neonates are affected in a litter.[15]

CHAPTER 321

Clinical Approach and Laboratory Evaluation of Renal Disease

Harriet M. Syme, Rosanne Jepson

Introduction

The function of the kidneys is to regulate the volume and composition of extracellular fluid by the formation of urine. This is achieved by formation of an ultrafiltrate of plasma by the passage of solutes, small proteins and other non-cellular constituents of the blood across the glomerular filtration barrier. The volume of ultrafiltrate formed is primarily determined by the number of functioning nephrons but is also affected by the hydrostatic pressure within the glomerular capillary tuft. Following filtration, the composition of this fluid is altered according to the physiological needs of the animal by the secretion and reabsorption of solutes and water as it passes along the nephron. In a healthy animal, under normal physiological conditions, less than 1% of the fluid that is filtered by the glomerulus will eventually be excreted as urine.

Kidney disease can influence these processes in a number of different ways. Most frequently kidney disease is diagnosed when glomerular filtration rate (GFR) is decreased (usually recognized as azotemia), in a patient with either chronic kidney disease (CKD) or acute kidney injury (AKI). These syndromes are discussed in detail in ch. 324 and 322, respectively. Kidney disease may also be recognized when a patient develops proteinuria due to damage to the glomerular filtration barrier (see ch. 325). Renal tubular defects may result in altered urine (and as a consequence plasma) composition (see ch. 326), or urolithiasis (see ch. 331 and 332). In addition, the kidney has a number of endocrine functions and is integral in the maintenance of blood pressure (see ch. 157).

Clinical Approach

Investigation of a patient for renal disease may be initiated by the presenting clinical problems (polyuria/polydipsia, signs relating to uremia, abnormal renal palpation, edema or ascites) or after performing routine blood work and urinalysis in a patient with nonspecific presenting signs (depression and anorexia, for example) or in which "wellness" screening tests are performed.

History

Owners of patients with CKD will usually report that their animal is drinking and/or urinating more than normal. Polydipsia has been defined as an intake of >100 mL/kg/day in dogs (and perhaps half this amount in cats) but even if this threshold is not exceeded, an increase in reported thirst may still be significant. The volume of urine that is produced is rarely quantified but owners may notice that this is increased, or that the urine is more dilute than normal. It is important to differentiate polyuria from pollakiuria (with small volume), dysuria, and urinary incontinence, which are generally referable to problems of the lower urinary tract rather than the kidneys. However, it is quite common for disease to co-exist in the lower and upper urinary tract (for example polyuria will exacerbate urinary incontinence, pyelonephritis usually results from ascending urinary tract infections and obstructive lesions may result in post-renal azotemia) so these problems may also be of relevance. There are a great number of potential causes of polyuria and polydipsia (see ch. 45) of which renal disease is just one, and a careful complete medical history should be obtained as much to try to exclude some of these differential diagnoses as to try to confirm that renal disease is present. Reduction in appetite or weight loss may be reported in patients with renal disease but also occurs with many other diseases. Signs referable to systemic hypertension (hyphema, mydriasis, blindness) may be reported by the owners of cats with CKD, but are much less common presenting signs in dogs.[1-3]

The history in patients with AKI may be very nonspecific (lethargy, inappetence) but is typically of short

duration. In some instances, patients will have a long history relating to a medical condition that predisposed them to the development of AKI, and this chronicity can cause confusion in differentiating acute from chronic disease. Occasionally patients with AKI will have a history of known toxin ingestion or of prescribed, potentially nephrotoxic, medications.

Physical Examination

A complete physical examination should be performed in all patients with kidney disease (see ch. 2). The kidneys should be assessed for their size and contour and whether palpation of them elicits signs of discomfort. The kidneys of cats are easily palpated but in dogs they are often difficult to identify conclusively. The size of the bladder may be important; a large bladder in a patient that urinated recently suggests polyuria, bladder turgidity may indicate obstruction, and an empty bladder in a patient that hasn't urinated recently may indicate oliguria.

Hydration status may be abnormal in patients with renal disease with dehydration and/or hypovolemia sometimes occurring as a consequence of polyuria or contributing to the development of AKI. Edema and/or ascites are features of nephrotic syndrome but also can develop as a consequence of overhydration in patients that are oligo-anuric. Cats are particularly vulnerable to the development of pleural effusion with overhydration and may become dyspneic.

Patients with chronic disease may be in poor body condition. When CKD occurs in young, growing animals, deformity of the maxilla and mandible ("rubber jaw" due to fibrous osteodystrophy) may be present although this presentation is uncommon. Older animals occasionally suffer pathological fractures due to CKD-mineral and bone disorder (MBD). Mucous membranes may be pale in patients with CKD due to anemia. Uremic ulceration of the oral mucosa (Figure 321-1) and tongue tip necrosis can be present if azotemia is severe but does not differentiate between acute and chronic renal disease.

FIGURE 321-1 Uremic ulcers at the labial commissure in a cat with AKI. These ulcers healed when the cat's azotemia, which occurred as a result of lily ingestion, improved. (Picture courtesy Helen Wilson.)

Blood pressure measurement should be performed in all patients with renal disease (see ch. 99). Fundic examination should ideally be performed in all patients but particularly in any dog or cat with systolic pressure greater than 160 mm Hg (see ch. 11).

Differentiation of Acute and Chronic Disease

Chronic kidney disease (CKD) is usually defined as a problem that has been present for a prescribed period of time (typically 2-3 months or longer); however, conceptually it may be more useful to consider CKD as a condition characterized by a permanent loss of functioning nephrons. The condition is irreversible without any possibility of true recovery although the remaining nephrons may hypertrophy and hyperfiltrate. It is therefore vital to differentiate patients with CKD from those with AKI, in which recovery is possible (see ch. 322), since the management of these two groups of patients is very different.

Differentiation of acute and chronic disease is often easily done based on the patient's history and physical examination findings. A longstanding history of polyuria and polydipsia is usually present in dogs and cats with CKD although occasionally their owners do not recognize this. Weight loss due to a poor appetite may be a feature of the patient's history, or poor body or coat condition evident on physical examination, if the disease has been chronic. These features are not, however, invariably present and may sometimes have alternative causes if the patient has more than one disease.

Renal size and shape may provide valuable clues to whether the azotemia is acute (normal or enlarged size, normal shape, occasionally abnormally turgid feeling) or chronic (small and/or irregular in shape). Renal palpation is usually much more informative in cats than it is in dogs. Diagnostic imaging can be used to provide further information. This allows a more objective assessment of renal size and contour, together with evaluation for mineralization and loss of internal architecture, changes consistent with chronicity.

Non-regenerative anemia may be present in patients with CKD (see ch. 199). The causes are multifactorial but relative erythropoietin deficiency is thought to be the most important. Anemia may also occur in patients with AKI for a number of reasons; for example, patients with overhydration, leptospirosis or hypoadrenocorticism may be anemic. Additionally, hemorrhage or hemolysis resulting in hypoxia/hypotension may serve as an inciting cause for AKI. Documentation of anemia should not, therefore, be considered to indicate invariably that azotemia is chronic in nature, and particularly if the anemia is regenerative (see ch. 198) then alternative causes for anemia and possible AKI should be sought.

Hyperkalemia is most often associated with AKI and particularly with post-renal causes of azotemia. Hyperkalemia may, however, occasionally develop in dogs with CKD that are eating renal diets especially if they are concurrently treated with angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers.[4] Complete urinalysis is mandatory in the investigation of azotemia and may provide valuable clues to its underlying cause (see ch. 72); for example, pyuria, bacteriuria and white cell casts would be consistent with pyelonephritis, calcium oxalate monohydrate crystals suggest ethylene glycol poisoning, and glucosuria indicates proximal tubular dysfunction. However, pyelonephritis and proximal tubular dysfunction can be either acute or chronic in nature. Large numbers of granular casts, and renal epithelial tubular cell casts, are indicative of acute tubular necrosis.

In a small proportion of cases with newly documented azotemia, it remains unclear after careful review of the history and physical examination, ultrasonographic examination of the kidneys, and routine hematology, biochemistry and urinalysis whether the problem is acute or chronic in nature. This scenario may occur when a patient displays no evidence of chronic disease but its azotemia does not improve substantially with appropriate supportive management for presumed AKI. Additional tests that may be useful in differentiation of acute and chronic disease in these select cases include radiographing the mandible/maxilla to look for loss of the lamina dura around the teeth[5,6]; ultrasound examination of the parathyroid glands to detect hypertrophy consistent with chronic stimulation[7]; and, in theory at least, measurement of carbamylated hemoglobin (which is reflective of the prevailing urea concentration), although tests for this are not currently commercially available.[8,9] Renal biopsy (discussed below) is also occasionally used to differentiate acute and chronic disease.

Differentiation of Pre-Renal, Renal, and Post-Renal Azotemia

The distinction between pre-renal and renal causes of azotemia is most often made on the basis of measurement of urine specific gravity (USG). If the USG is greater than 1.030 in a dog, or 1.035 in a cat, then the azotemia is considered to be pre-renal in origin. However, certain caveats to these rules should be noted. Cats with chronic kidney disease (CKD) will sometimes retain significant urine concentrating ability (>1.035 or even 1.040) even once azotemic. Concentrated urine has been documented in cats following 7/8ths nephrectomy.[10] Dogs and cats with primary glomerular disease also sometimes retain concentrating ability even once they have developed azotemia. Conversely, it is important to consider that the patient will only be able to concentrate urine in the face of pre-renal azotemia if tubular/collecting duct mechanisms for doing so

are intact. If there is a lack of medullary hypertonicity (for example in a patient with hypoadrenocorticism, or eating a very protein-restricted diet) or interference with tubular (patients receiving diuretics) or collecting duct (patients with primary or secondary causes of diabetes insipidus) function then creation of concentrated urine will not be possible, even when azotemia is pre-renal. In these patients, the pre-renal nature of the azotemia is confirmed by administering intravenous fluids (or reducing the dose of diuretics) and documenting its resolution.

Post-renal azotemia is usually suspected on the basis of the patient's history and physical examination, with signs referable to lower urinary tract obstruction or rupture (see ch. 150 and 335). Diagnostic imaging may also be informative, particularly in patients with partial obstruction, or unilateral ureteral obstruction where clinical signs are less obviously indicative of the problem. If fluid is present in either the retroperitoneal or peritoneal cavity, then a sample should be collected for analysis; creatinine concentration in the fluid greater than twice that in the blood is consistent with urinary tract rupture. Urine is a chemical irritant so non-septic, neutrophilic inflammation is common but the amount of associated hemorrhage and inflammation is variable.[11]

Assessing Disease Severity

The International Renal Interest Society (IRIS) has developed a staging scheme for CKD, which was subsequently endorsed by the Society for Nephrology and Urology in 2006, and is now in widespread use (see ch. 324). More recently a grading system for AKI has been developed (see Table 322-1).

Laboratory Diagnostics

Evaluation of Renal Function

Glomerular Filtration Rate

Direct assessment of glomerular filtration rate (GFR) is the gold standard for assessing the filtration and excretion function of the kidney.[12-14]

Global GFR is the sum total of single nephron GFRs from both kidneys. Key factors determining GFR include oncotic and hydrostatic pressure of plasma and ultrafiltrate within the Bowman's space in addition to the capillary surface area for filtration and capillary permeability, which is given the term ultrafiltration coefficient. GFR can therefore be defined as $Kf[(P_{GC}-P_b)-(pi_{GC}-pi_b)]$ (Kf, ultrafiltration coefficient; P_{GC}, hydrostatic glomerular capillary hydrostatic pressure; P_b, hydrostatic pressure in Bowman's space; pi_{GC}, oncotic pressure in glomerular capillaries; pi_b, oncotic pressure in Bowman's space).

Evaluation of GFR may be of benefit in a number of key situations including evaluation of renal function in patients suspected to have non-azotemic kidney disease (e.g., non-azotemic patient presenting with polyuria and polydipsia or persistently low urine specific gravity), where the clinician wishes to exclude renal disease as an underlying cause for the presenting signs. GFR may be useful as a screening tool for patients where incipient renal disease is anticipated (e.g., breeds with known juvenile or adult onset nephropathies) or in patients undergoing administration of potentially nephrotoxic medications where detection of reducing renal function might lead to altered therapeutic approach. GFR measurement may also have utility in patients with renal disease where an estimation of renal function reduction is needed in order to adjust dosing of medications undergoing renal excretion. There is currently no evidence to support the routine use of GFR assessment in patients with azotemic CKD, where creatinine is an appropriate surrogate marker of renal function.

Several methodologies have been evaluated and validated in both dogs and cats for direct assessment of GFR including assessment of urinary and plasma clearance. Markers of GFR must have a number of key characteristics: They must be freely filtered at the glomerulus, not circulate bound to plasma proteins, not undergo reabsorption or be secreted by the tubules, and must not themselves alter GFR or be toxic to the kidneys.

GFR measurements, irrespective of methodology, require standardization prior to interpretation particularly considering the potential effects of body weight, breed, sex and age. The most commonly used standardization is for GFR to be expressed in terms of body weight, although this assumes that the relationship between body weight and GFR is linear. Although exact values will vary depending on the methodology used, and direct comparisons should only be made between identical methods, GFR is typically 3.5-4.5 mL/min/kg for dogs and 2.5-3.5 mL/min/kg for cats. However, due to metabolic scaling, body weight may not be an appropriate standard, particularly in dogs <10 kg or >50 kg. Whilst alternative parameters for

standardization such as body surface area (BSA) and extracellular fluid volume (ECFV)[15,16] may seem appealing, the optimal formula for calculation of body surface area is yet to be determined.[17] Studies in dogs suggest that standardization to BSA may be preferable to body weight.[18-23] GFR, as assessed by endogenous creatinine clearance, has previously been documented to be higher in both puppies and kittens.[24-26] In male dogs creatinine is actively secreted in small amounts by the renal tubule, potentially overestimating GFR when assessed by creatinine clearance.[27]

Renal or Urinary Clearance

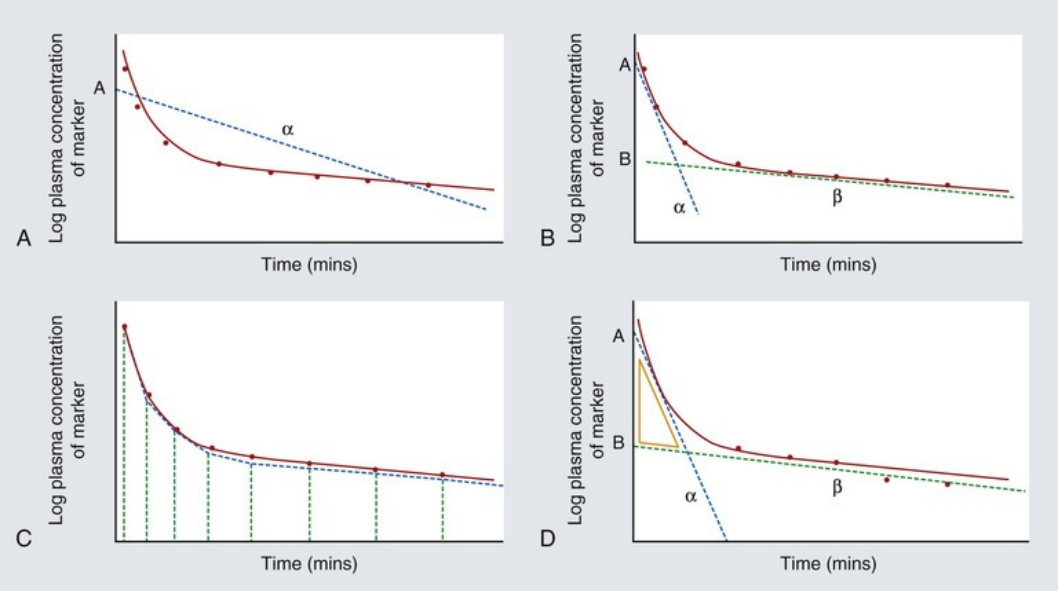
Renal or urinary clearance relates to the rate at which a filtered substance is cleared from a given volume of plasma by the kidneys into the urine, providing information about the amount of marker appearing in the urine per unit of time. Assessment of urinary clearance requires that the amount of substance, either exogenous or endogenous, is assayed both in the plasma and in the urine (see ch. 73) over a given time period. Urinary clearance is calculated using the following formula: C = (Uv × Uc)/Pc where C = clearance (mL/minute), Uv is urine flow rate (mL/minute), Uc is concentration of the solute in urine and Pc is the concentration of the solute in plasma. Urinary clearance necessitates placement of a urinary catheter (see ch. 105), and repeated and complete bladder emptying typically over a 12-24 hour urine collection period, although shorter sampling/collection protocols have been described.[28-30] All urine must be collected over the timed period of the study as failure to do so will lead to an underestimation of GFR. Urinary clearance of inulin has been considered the gold-standard method of estimating GFR but limited availability of inulin and of laboratories performing inulin quantification, and the relative difficulty of performing complete urine collection mean this method is rarely used clinically.[28,30-37] Alternative methodologies utilize either endogenous or exogenous creatinine or iohexol renal clearance.[29,38]

Endogenous urinary creatinine clearance assesses GFR by quantifying creatinine concentrations in blood and urine.[31-33,39] Methodologies utilizing creatinine quantification measured by the Jaffe method are subject to issues relating to non-creatinine chromogens whereby these give falsely increased results.[40] The effect of this is greatest when the non-creatinine chromogens make up a greater proportion of the result (i.e., when patient creatinine concentration is within reference interval). This effect is not identified when enzymatic methodologies are used for creatinine quantification. In order to minimize the effect of non-creatinine chromogens, exogenous renal creatinine clearance methodologies were developed with a goal of increasing creatinine concentrations to the point that non-creatinine chromogens reflect only a small proportion of the total creatinine measured in a patient.[32-34,38,41-44]

Plasma Clearance

Plasma clearance is a more frequently used methodology in clinical practice as it avoids the requirement for urine collection. Timed samples must be obtained accurately to avoid errors in calculation of the AUC. Markers of plasma clearance which have been used include inulin, exogenous creatinine, iohexol and radiolabeled markers such as [^{125}I] sodium iodohippurate, ^{51}Cr-ethylenediaminetetraacetic acid (EDTA), and ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA). Although urinary clearance of inulin is considered to be the gold standard, plasma clearance of inulin is not recommended since up to 40% of inulin is excreted via non-renal routes in the dog.[32] Extra-renal clearance of inulin has not been studied in the cat.

GFR determined by plasma clearance is calculated using the equation C_{plasma} = D/AUC where D = dose of the substance administered and AUC is the area under the plasma concentration versus time curve (also see ch. 160). The AUC is determined by obtaining the plasma concentration of the substance at multiple timed intervals over a pre-determined period of time. A number of different pharmacokinetic models can be used to determine the AUC depending on the analyte and sampling frequency. One-compartment, two-compartment, multi-compartment and non-compartmental pharmacokinetic models have previously been used for estimation of the AUC in veterinary GFR studies (E-Figure 321-2). The number of compartments or the model used impact the calculation of the AUC and therefore the resulting GFR calculated.[45] Multiple sampling protocols may be less than ideal, particularly in small or anemic patients. Therefore, numerous studies have recently focused on the validation of limited sampling or single sample protocols, which provide an easier approach to assessment of GFR by plasma clearance in the clinic.



E-FIGURE 321-2 Models used for calculation of GFR from plasma clearance. **A, One-compartment models** consider the patient as a single compartment and assume immediate distribution of the substance used as the marker of GFR throughout the body and that the marker is excreted from that compartment only. The plasma concentration of the chosen marker (dots) is plotted against time. A linear slope is constructed (dashed line) and area under the slope is calculated by dividing the zero time intercept (A) by the slope of the exponential (alpha). Clearance of the marker is determined by dividing the dose of marker by the area under the curve. Using this model, the plasma concentration of the marker immediately after injection exceeds that estimated by the one-compartment model which may lead to overestimation of GFR. **B,** The **two-compartment model** assumes that the marker is initially distributed from the vasculature (central compartment) to the extracellular fluid volume (ECFV; peripheral component). A subsequent second elimination phase from the body allows slow redistribution of the marker back to the plasma from the interstitial fluid as the marker undergoes renal clearance. The log plasma concentration of the chosen marker (dots) is plotted against time. The area under the curve is calculated from two straight lines (dashed lines) representing an initial steep redistribution (alpha) from plasma to ECFV and the second terminal elimination (renal clearance) phase (beta). The area under the curve is calculated using the following equation: [A/ alpha + B/ beta], where A and B represent the zero time intercepts of the first (distribution) and second (elimination) phase, respectively, and alpha and beta represent the slope of their respective exponentials. **Multi-compartmental models** are similar to the two-compartment model except that each component is resolved to a series of straight lines providing a theoretically more accurate representation of the area under the curve but with the limitation that a more frequent sampling protocol would be required. **C,** In a **non-compartmental model** the area under the curve is calculated by adding the area of trapezoids defined by the curve. Unlike compartmental models, a non-compartmental model is free from assumptions regarding the redistribution and elimination phases. Errors in GFR calculation from this approach may arise because the terminal phase of elimination from the last sample to the time of theoretical zero must be estimated and also when early ending of plasma sampling means that a greater proportion of the curve must be estimated. **D, Slope-intercept technique for estimation of GFR.** The slope-intercept technique can be used for estimation of GFR using a limited number of samples (red dots) from only the elimination phase. Exclusion of the distribution phase will lead to an overestimation of GFR (orange triangle) as the area under the curve will be under-estimated. This overestimation will be proportionally larger for patients with near normal GFR compared to patients with low GFR as the distribution phase in such patients contributes to a greater extent of the overall area under the curve. A correction formula is applied to adjust for this.

Single sample methods for GFR estimation have also been evaluated both in dogs[22,23,74] and cats[22,23,72] using linear regression or non-linear regression approaches to determine the best single sample timing from multi-sample methods.[79] True assessment of GFR using a single sample method requires that the volume of distribution is known and that the sample is collected at a time point when there is complete mixing of the marker through the volume of distribution.[79-82] Such an approach has recently been evaluated in the cat and suggests that optimal sampling time is 180 minutes after iohexol marker administration.[83] Although this will be applicable for the majority of cats where GFR measurement is clinically required (i.e., cats with near normal GFR), timing of sampling would need to be delayed for any cat anticipated to have low GFR.[83]

Plasma Exogenous Creatinine Clearance

Creatinine is produced from breakdown of creatinine phosphate within muscle tissue with minimal impact

from protein intake.[39] It is freely filtered at the glomerulus and does not undergo reabsorption. In male dogs there may be a small amount of tubular secretion, which can lead to overestimation of GFR.[46] Exogenous creatinine has been used as a plasma marker of filtration although lack of availability of a medical grade creatinine product can limit utility outside a research setting. Exogenous creatinine plasma clearance has been used in both dogs[32,41,47,48] and cats[49-54] for assessment of GFR. Creatinine has a larger volume of distribution than other markers and this therefore leads to a longer test time being required.[32,55] This can also result in a larger extrapolated region in the AUC calculation than for other markers and particularly for patients with reduced renal function this may lead to inaccuracies in GFR estimation. In dogs, extra-renal clearance of creatinine has also been identified which may falsely increase GFR assessment, although this association has not been explored in the cat.[56]

Radiocontrast Agents

Both iohexol and gadolinium have been evaluated as markers of filtration although iohexol is the most frequently used marker.[57,58] Iohexol is a non-ionic iodinated, water soluble, low osmolar contrast agent, which can be used as a marker for plasma clearance. Contrast agents such as iohexol have been associated with AKI in human patients but such an association has not been reported in veterinary medicine and use of iohexol is therefore widely considered safe in veterinary patients. Iohexol remains within the extracellular space, does not undergo significant metabolism and protein binding is negligible. It is a stable molecule such that samples can be readily transported to the laboratory without concern regarding degradation. Several methods have been used for quantification of iohexol but most recent studies use high performance liquid chromatography (HPLC) or high performance capillary electrophoresis (HPCE) technologies.[42,59-61] Iohexol exists as two isomers, endo- and exo-iohexol, that can be quantified separately if HPLC methodologies are used.[62] The predominant isomer quantitatively is known to be exo-iohexol. In cats, several studies have suggested differential excretion of endo- and exo-iohexol, suggesting that there may be inaccuracies if only total-iohexol plasma clearance of GFR is evaluated.[50,63] However, a recent study by Finch and colleagues did not demonstrate a difference in clearance of the two isomers and similar findings have been demonstrated in dogs.[45,64,65] There was also no significant conversion of one isomer to the other after administration.[45] Evaluation of total iohexol for plasma iohexol clearance is therefore preferred.

Plasma iohexol clearance has been widely used in both the dog[23,42,60,61,65-68] and the cat.[19,23,43,49-52,54,69-71] Studies evaluating plasma iohexol clearance have mainly been compared to exogenous or endogenous clearance of creatinine rather than inulin. Although some differences exist depending on the model used for calculation of AUC, plasma clearance of iohexol performs well in comparison to renal clearance of exogenous creatinine.[42,60] Plasma iohexol clearance is currently the most frequently used methodology for assessment of GFR in clinical practice.

Radioisotopes

Radiolabeled markers such as [^{131}I] sodium iodohippurate [^{125}I] sodium iothalamate, ^{51}Cr-ethylenediaminetetraacetic acid (EDTA), and ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA) are freely filtered at the glomerulus and do not undergo reabsorption or secretion in the tubules and have therefore been used for assessment of GFR via both plasma and renal clearance.[44,50,72-75] Use of older radiolabeled markers such as [^{131}I] sodium iodohippurate [^{125}I] sodium iothalamate has largely been superseded by those with a shorter half-life such as ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA; 6 hours) meaning that patients are cleared of radioactivity within a 24-48 hour period. Limitations of using radiolabelled markers for plasma or renal clearance include the availability of laboratories for measuring such markers, difficulties associated with transportation of samples and appropriate facilities in which to conduct nuclear medicine and to hospitalize the patient post-procedure.

Limited Sampling Protocols

In an attempt to simplify the assessment of GFR for clinical patients where repeated sampling is not feasible, limited sampling protocols have been developed. Using a two-compartmental model (see E-Figure 321-2), a minimum of four samples is required to generate the biexponential curve. However, in order to minimize the number of samples required, an estimation of GFR may be made by using only the elimination phase and excluding the distribution phase that is assumed to be independent of renal clearance. The methodology used to estimate GFR from a limited number of samples using only the elimination phase is the **slope-intercept**

technique (see E-Figure 321-2).[23,54,66] A correction formula is subsequently applied to obtain the corrected slope-intercept clearance. Several formulae have been used in humans[76-78] and dogs[18] and more recently a feline specific formula has been evaluated.[14,45]

Alternative Methodologies for GFR Assessment

- **Radioisotope markers:** One of the primary advantages to evaluating a radiolabeled marker is the potential to perform renal scintigraphy using a gamma camera. This allows assessment of both global and individual kidney GFR by measuring the percentage dose update of the marker by each kidney separately. However, difficulties associated with renal scintigraphy include the experience of personnel in defining the area of interest, requirement for sedation/general anesthesia, adjusting for kidney depth, availability of appropriate facilities for scintigraphy and hospitalization facilities post-procedure. Several studies have evaluated nuclear scintigraphic determination of GFR in dogs and cats using ^{51}Cr-EDTA and ^{99m}Tc-DTPA.[31,35,75]
- **Computed tomography:** Computed tomography has been used in conjunction with iohexol administration to provide both global and individual kidney estimation of renal uptake in a similar manner to scintigraphy.[84-91] Due to the ease of performing such studies and the relatively wide availability of computed tomography, further studies evaluating this approach are warranted.
- **Fluorescent-labeled markers:** Sinistrin is a polyfructran, which has been evaluated as a potential marker for plasma clearance.[92] A preliminary study has evaluated fluorescence-labeled sinistrin as a transcutaneous marker of GFR that holds promise for the future as a non-invasive methodology.[93] A further study has evaluated fiberoptic radiometric fluorescence as a method for GFR.[94]
- **Estimated GFR:** In human medicine GFR is routinely estimated from plasma creatinine concentration or cystatin C (estimated GFR; eGFR) using equations which take into consideration other factors such as age, gender, race, and measurements of body size that reflect muscle mass.[95-97] Such equations appear to offer advantages in terms of assessment of renal function when compared to plasma creatinine or cystatin C concentrations alone. To date only one study has attempted to formulate such an equation for cats but the eGFR did not offer substantial benefit over the use of plasma creatinine as an estimate of GFR.[98]

Surrogate Plasma/Serum Markers of Glomerular Filtration Rate

For most clinical patients initial assessment of renal function will be made using a surrogate marker of GFR, most commonly urea and creatinine quantification.

Urea

Urea is produced from ammonia derived from amino acids as part of the ornithine cycle within the liver. Amino acids used in the production of urea can originate either from endogenous or exogenous protein sources. Urea is filtered at the glomerulus but undergoes passive reabsorption within the tubules. The degree of reabsorption increases with slower tubular flow rates, which are typically identified in patients that are either hypovolemic or dehydrated. Plasma/serum urea concentration is commonly reported as blood urea nitrogen (BUN) in the United States and urea elsewhere in the world, which has great potential for confusion since two conversion steps are required, first from BUN to urea, and then from traditional (mg/dL) to SI (mmol/L) units.

One of the main limitations of urea as a marker of renal function is that production and excretion are not constant and can be influenced by a number of factors. It is widely recommended that both dogs and cats have food withheld for a minimum of 8-12 hours before assessment of urea concentrations to avoid the effects of dietary protein ingestion on urea concentrations. Conditions associated with increased protein catabolism (e.g., fever, burns, infection, starvation, hyperthyroidism) increase urea.[99] In particular, upper gastrointestinal hemorrhage is an important cause of elevated urea concentrations and urea : creatinine ratio in dogs and cats.[100] Conversely, reduced hepatic function, portosystemic shunting, and low protein diets may contribute to reduced urea concentrations. In-house reagent test strips are available for rapid and inexpensive assessment of urea and have demonstrated good sensitivity and specificity in dogs and cats.[101]

Creatinine

Creatinine is the most widely used surrogate marker of GFR in clinical practice.[102] It is produced from dehydration of creatine and dephosphorylation of phosphocreatine in muscle. Provided muscle mass remains stable, creatinine is produced at a constant daily rate. However, creatinine concentrations are affected by lean

body mass and as such, young animals and those with poor muscle mass will have proportionally lower plasma/serum creatinine concentrations than mature or well-muscled individuals.[103] Studies suggest that plasma creatinine concentrations increase gradually over the first year of life in dogs but then remain stable or increase moderately up until 8-10 years of age[102] whilst in kittens creatinine concentrations are relatively high at birth but are similar or lower than in adults by 8 weeks of age.[104] Greyhounds have been documented to have higher creatinine concentrations than other breeds, likely as a consequence of their muscling.[105] In cats, breed-related differences have been reported and in particular the Birman has been reported to have high plasma creatinine concentrations.[106-108] There is no apparent effect of sex on plasma creatinine in either the cat or the dog. Creatinine is freely filtered at the glomerulus. It is very weakly secreted in renal tubules in dogs, especially males, but this is of negligible clinical significance even in a patient with reduced renal function.[32,41,46,109]

Serum concentrations of creatinine are reported to be 5-10 micromol/L (0.05-0.1 mg/dL) higher than in plasma. Creatinine is less influenced by recent protein ingestion than urea. However, studies evaluating the effect of feeding on creatinine concentrations have been variable, with those reporting feeding of raw or cooked meat indicating increases for up to 12 hours post-prandially, whilst other studies indicate a decrease or no change after feeding of commercial foods.[110-112] It is nevertheless preferred to evaluate creatinine in a patient that has been fasted for 8-12 hours.

Creatinine concentrations in the laboratory are usually measured either by the nonspecific Jaffe method (based on the formation of a yellow-orange chromogen when creatinine is mixed with picrate ion in alkaline conditions) or by specific enzymatic techniques. Non-creatinine chromogens may interfere with measurement of creatinine when using the Jaffe reaction.[113,114] However, the relative degree of interference decreases in patients with kidney disease as true creatinine concentration increases. Enzymatic methods are not affected by non-creatinine chromogens but may be influenced by hyperbilirubinemia.[113] The laboratory reference intervals reported can vary widely and it is therefore important to always compare results with the relevant reference interval and ideally for comparative samples from the same patient to be analyzed either at the same laboratory or using the same in-house analyzer.[115]

Creatinine has an exponential relationship with GFR (Figure 321-3).[116] This means that in patients with a near normal GFR, creatinine is an insensitive marker of renal function, as change in GFR results in only a relatively small increase in plasma creatinine concentration. The relationship between creatinine and GFR is only valid in patients where renal function is in a steady state. The magnitude of alteration in creatinine and urea concentrations cannot be used to determine whether azotemia is pre-renal, renal or post-renal in origin nor the potential for reversibility of the azotemia.

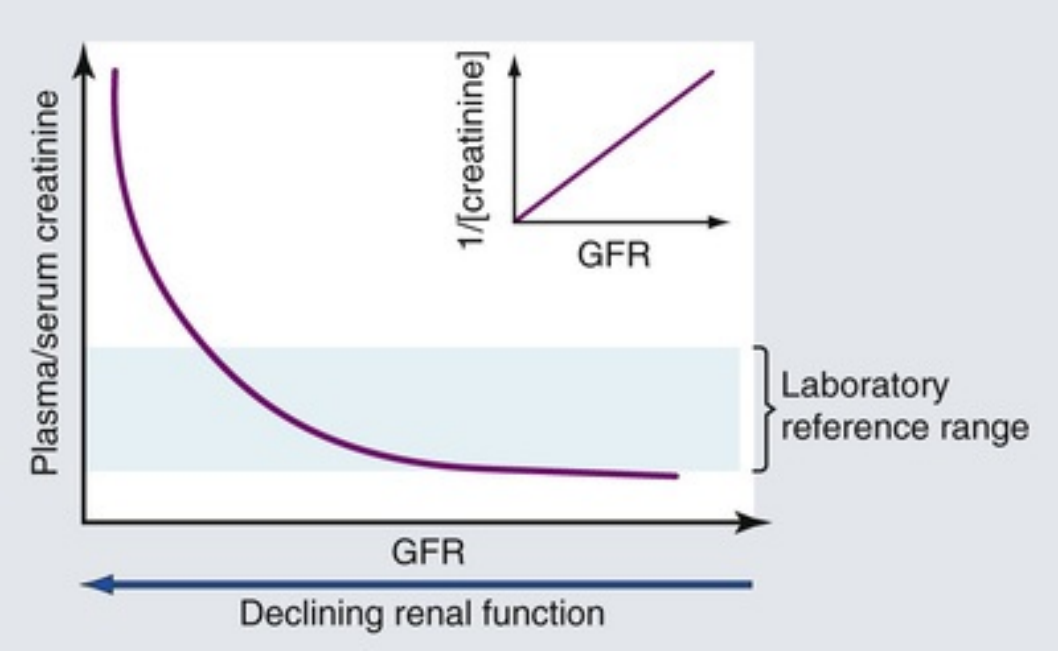


FIGURE 321-3 Creatinine demonstrates an exponential relationship with GFR (purple line) when

plotted directly, while the relationship between the reciprocal of creatinine plotted against GFR approximates a straight line (inset).

Symmetric Dimethylarginine

Symmetric dimethylarginine (SDMA) is a dimethylated derivative of arginine produced from intranuclear methylation of L-arginine residues by protein-arginine methyltransferase along with its stereoisomer asymmetric dimethylarginine (ADMA). SDMA is primarily excreted via renal filtration, indicating that it has characteristics required for an endogenous marker of renal function.[117] Plasma SDMA has been demonstrated to correlate well with plasma creatinine concentration.[118,119] In azotemic and non-azotemic cats, a linear relationship has been demonstrated between the reciprocal of SDMA (1/SDMA) and GFR assessed by plasma iohexol clearance performing in a similar manner to the reciprocal of creatinine (1/creatinine).[120] Studies suggest that SDMA concentrations are less influenced by body muscle mass than plasma creatinine.[103,119,121] Preliminary studies suggest that SDMA may be a more sensitive marker of early decline in renal function in cats.[122] Assessment of SDMA does not appear to be affected by feeding a renal diet supplemented with both fish oil or L-carnitine in the dog.[121] However, further work is still required to determine the effect of concurrent disease on this novel marker. Historically, assessment of SDMA has been limited by requirement for quantification by liquid chromatography mass spectrometry. However, development of a commercially available immunoassay has recently made this marker widely available as a clinical diagnostic test (see also ch. 324).[123]

Cystatin C

Cystatin C is a low molecular weight (13 kilodalton [kDa]) protein which acts as a proteinase inhibitor and which is produced at a constant rate because it is encoded by an intracellular housekeeping gene.[124,125] Cystatin C is not bound to plasma proteins and is freely filtered at the glomerulus.[126] However, cystatin C, unlike other markers, is reabsorbed by megalin-mediated endocytosis within the proximal tubules and is catabolized.[126-128] No tubular secretion of cystatin C occurs and in human medicine, it has been proposed as a more sensitive marker of GFR than plasma creatinine concentration.[129] In addition, as urinary cystatin C is typically very low, the presence of an increased concentration of urinary cystatin C may indicate tubular dysfunction.[130] Numerous studies have evaluated the potential use of cystatin C in dogs and cats. However, to date these studies have not demonstrated consistent superiority over creatinine and confounding factors may limit the utility of this marker in practice.[124] Indeed two recent studies indicate that serum cystatin C is not a useful marker for identification of reduced renal function in the cat.[124a,124b]

Fully automated particle-enhanced turbidimetric immunoassay (PETIA) has been used for quantification of cystatin C in both urine and serum/plasma from dogs[131-134] whilst a particle-enhanced nephelometric immunoassay (PENIA) has been validated in cats.[135,136] Both methodologies are dependent on cross-reactivity between serum cystatin C and polyclonal rabbit anti-human cystatin C antibodies. However, direct comparison of the PETIA and PENIA methodologies with simultaneous GFR assessment remains to be performed to determine which methodology is superior.[137] One study has identified an effect of age and body weight on serum cystatin C in dogs,[138] although other studies have not confirmed this finding.[134] Of concern, plasma cystatin C decreased significantly 1 hour post-prandially.[138] This decrease persisted for up to 9 hours before returning to baseline and based on this data a minimum period of 12 hours fasting would be advocated prior to assessing cystatin C in dogs. Whether this change in cystatin C reflects alteration in GFR after feeding remains to be determined. The most recent validation study in cats by Ghys and colleagues suggested that there was no influence of age, sex or breed.[136] Recently, feline specific recombinant cystatin C monoclonal antibodies have been developed which may lead to the development of a feline specific assay in the future.[139]

In human medicine, a number of concurrent conditions may influence serum cystatin C concentrations including thyroid function, neoplastic disease, asthma and inflammation.[140] Serum cystatin C concentrations may be increased and decreased in hyper- and hypothyroidism, respectively, relating to the stimulatory effect of thyroid hormones and also TGF-beta on cystatin C production.[141] Decreased regulation by cystatins is responsible for increased activity of cysteine protease in neoplastic cells and individuals with carcinomas and leukemia have been shown to have significantly higher cystatin C concentrations pre- versus post-treatment,

although not all studies have shown this association with malignancy.[142,143]

Studies have indicated that serum cystatin C concentrations are significantly higher in dogs with CKD than control dogs.[138,144] However, overlap existed between groups in the studies. A study using a renal mass reduction model identified that the correlation between the reciprocal of cystatin C was superior to the reciprocal of creatinine when compared with GFR initially when GFR was very low (0.5 ± 0.15 mL/min/kg) but that after 10 weeks when GFR increased (1.00 ± 0.27 mL/kg/min) there was no apparent difference between the two parameters.[133] Studies have indicated that cystatin C may have a higher sensitivity (76%) when compared to creatinine (65%) for the detection of a decreased GFR as measured by exogenous creatinine clearance, although specificity for both markers was similar (cystatin C 87% and creatinine 91%).[134] In cats, serum cystatin C has been shown to be significantly higher with CKD than in control cats, although there was overlap between groups.[135] Few studies have evaluated urinary cystatin C but those performed in both dogs[131] and cats indicate that urine cystatin C concentrations are higher in patients with CKD than controls.[135]

To date, few studies have evaluated the potential confounding factors relating to cystatin C quantification in veterinary patients. The study by Almy and colleagues revealed that cystatin C was not a good marker of pre-renal azotemia in an experimental study where dogs were administered furosemide.[133] Studies support that cystatin C may be elevated in patients with leishmaniasis when creatinine concentrations were not correspondingly elevated.[145] In dogs, preliminary studies suggest that cystatin C may decrease with weight loss.[146] In cats, the effect of diabetes mellitus has been evaluated and appears to have no impact on cystatin C measurement, but a preliminary study evaluating hyperthyroidism suggested that this may impact on measurement as in human studies.[147,148] Two recent studies have demonstrated that serum cystatin C is not a reliable indicator of renal function in cats and that this marker fails to identify azotaemic cats with CKD.[124a,124b] Further study is warranted to fully determine the effect of concurrent disease before the utility of cystatin C can be determined for dogs.

Evaluation of Proteinuria

Proteinuria is the term used to describe the presence of increased amounts of protein within the urine. Providing pre-renal (e.g., Bence Jones proteins) and post-renal (lower urinary tract inflammation) causes of proteinuria can be excluded, the proteinuria can be considered to be renal in origin. The glomerular filtration barrier composed of the glomerular capillary endothelium, basement membrane and epithelial podocytes limits the passage of medium and high molecular weight proteins from the blood to the glomerular filtrate with albumin (69 kDa) and larger proteins typically being retained. Proteins that do undergo filtration, in health, are effectively reabsorbed via megalin- and cubulin-mediated endocytosis within the proximal tubular cells such that the magnitude of proteinuria is typically low. Proteinuria can originate either from change in structure or function of the glomerular filtration barrier, glomerular proteinuria, or can be due to reduced capacity of the proximal tubular cells to reabsorb proteins—tubular proteinuria. Proteinuria should be evaluated in all patients with CKD as part of the IRIS staging scheme (see ch. 324). In other patients, proteinuria may be investigated when a positive result is obtained on a urine dipstick or protein-losing nephropathy is a clinical differential in a patient presenting with cavitary effusion or peripheral edema suggestive of nephrotic syndrome or hypoalbuminemia, especially when globulin concentration is normal. Numerous methodologies are available for the assessment of proteinuria.

Colorimetric Biochemical Reagent Urine Dipstick

Urine dipsticks are the most frequently used screening test for the detection of proteinuria. They typically have a higher sensitivity for albuminuria than other urinary proteins with a lower limit of detection of 30 mg/dL. In general, these dipsticks have reasonable sensitivity (>80%), but very poor specificity, particularly in cats.[149,150] False negative results may occur with Bence Jones proteinuria, dilute or acidic urine. False positive results are reported more commonly in cats and may be the consequence of alkaline or highly concentrated urine, pyuria/hematuria or not reading at the correct time interval.[149,151,152] Given the limitations of this test, in any patient for which there is concern regarding the presence of proteinuria, further assessment with a urine protein to creatinine ratio (UPC) is warranted.

Sulfosalicylic Acid Test

The sulfosalicylic acid (SSA) test is performed in some diagnostic laboratories as a confirmatory test with a reported limit of detection of 5 mg/dL.[151,153] Unlike urine dipsticks, the SSA test can detect globulins and Bence Jones proteins within urine.

False positive results may occur in patients that have received radiocontrast agents, cephalosporins, and penicillins, and protein content may be overestimated if urine samples are turbid and not centrifuged prior to evaluation.[153] Sensitivity and specificity to detect microalbuminuria (1 mg/dL) compared to a species-specific ELISA are only moderate (cat sensitivity 58%, specificity 25%; dog sensitivity 73.3%, specificity 63.9%).[149] In a study evaluating 237 cats with CKD the SSA test (positive results >5 mg/dL) had a 63% sensitivity and 96% specificity for the detection of microalbuminuria.[150]

Microalbuminuria

Microalbuminuria is defined as a concentration of albumin that is >1 mg/dL but below that typically detectable by urine dipsticks, <30 mg/dL.[151] Microalbuminuria can be measured either by species-specific point-of-care semi-quantitative tests or by species-specific ELISA techniques. Similar to urine protein concentrations, urine albumin when quantified should be standardized either to urine creatinine concentration to give a urine albumin to creatinine ratio or to a urine specific gravity of 1.010. Screening for microalbuminuria can be considered in patients where there is concern for a false negative result on a routine urine dipstick, where low level proteinuria may be predictive of the onset of hereditary glomerular disease, in geriatric patients where a more sensitive screening test is desired, or for monitoring of known microalbuminuria. The interpretation of microalbuminuria is important as the presence of microalbuminuria may be affected by post-renal causes. However, the effect of hematuria and pyuria on microalbuminuria is variable. Studies suggest that microalbuminuria concentrations are unlikely to exceed 1 mg/dL until urine is grossly hematuric (>250 red blood cells/hpf) and that in a group of 70 urine samples with pyuria (>5 white blood cells/hpf) 67% had negligible urine albumin concentrations.[154] Any positive result should be repeated after 7-14 days to ensure that this is a true and persistent finding. Discordant results suggest that the first was likely to be a transient phenomenon but if both are positive then this is support for continued monitoring or assessment of UPC.

Urine Protein to Creatinine Ratio

Urine protein to creatinine ratios are the most commonly used method for quantifying proteinuria. A UPC >0.4 in the cat and >0.5 in the dog corresponds to urine albumin concentrations >30 mg/dL and is considered abnormal if this is a persistent finding (≥3 occasions ≥2 weeks apart).[155] UPC >2.0 are strongly suggestive of underlying glomerular disease although other etiologies cannot be excluded without renal biopsy.[155-157] Studies have demonstrated that spot UPC correlates well with 24-hour urine protein quantification, negating the requirement for 24-hour urine collection in clinical patients.[158-160] UPC ≥0.2 in both the dog and the cat has a good level of specificity for detection of microalbuminuria (>1 mg/dL) being 98.6% and 90.8%, respectively. However, the sensitivity for UPC to detect low level microalbuminuria is not as good, being 47.9% in the dog and 32.7% in the cat.[149] However, a further feline study suggested that UPC performed well with sensitivity 84.6% and specificity 81.8% when compared to a positive result on a semi-quantitative microalbuminuria dipstick.[150]

Recent studies support that there is little difference in UPC result obtained from a free catch urine sample, mid-stream compression sample versus cystocentesis.[161,162] However, one study has shown that in dogs, UPC values obtained in a hospitalized environment may be higher than at home.[163] Studies suggest that UPC is unlikely to be influenced by hematuria unless gross hematuria (>250 red blood cells/hpf) is identified and that the effect of pyuria is likely to be minimal in most patients.[154] There appeared to be little inter-laboratory variability when assessing UPC with three different methodologies and reagents.[164] However, considerable day-to-day individual variability was reported in a study that evaluated dogs with X-linked hereditary nephropathy. This study supported that UPC must change by 35% for patients with UPC ≈12 and by 80% for patients with UPC ≈0.5 for this to reflect a true change in UPC rather than day-to-day variability.[165] Furthermore, whilst one sample may be sufficient for evaluation of UPC in dogs with UPC <4.0, for patients that are more markedly proteinuric (UPC >4.0) then >2 samples should be evaluated and averaged to give a true representation of that patient's magnitude of proteinuria.[165] Pooling an equivolume of urine from three samples is a more cost effective and comparable way to evaluate proteinuria in patients with UPC >4.0.[166]

Renal Biopsy

Renal biopsy is most often performed in patients where there is a high index of suspicion for primary glomerular disease. Current International Renal Interest Society guidelines suggest that renal biopsy is considered for patients with persistent substantial proteinuria (UPC >3.5), in patients where proteinuria is unresponsive to anti-proteinuric therapy, or the patient is demonstrating a progressive increase in proteinuria or decline in renal function despite instituting standard therapy for proteinuria (see ch. 325). Renal biopsy may also be considered if the clinician is contemplating the use of immunosuppressive therapy in a patient with suspected primary glomerular disease in order to determine the presence of immune complex glomerulonephritis. In certain circumstances renal biopsy may be considered in patients with AKI, particularly if there is concern regarding an acute glomerulonephritis or where a client may be considering the merit of continuing with long-term dialysis and would benefit from knowledge regarding whether there is evidence of a regenerative response within the remaining renal parenchyma. However, in most situations, renal biopsy would not lead to definitive identification of the etiology of AKI.

A comprehensive diagnostic investigation should always be performed prior to performing renal biopsy in order to evaluate for any underlying disease process contributing to the patient's proteinuria (e.g., neoplastic or infectious disease etiology), to document that the proteinuria is a persistent finding, and to ensure that it cannot be attributed to either pre- or post-renal origins (see ch. 325).[157] Key considerations for patients undergoing renal biopsy should include control of systemic hypertension when present (see ch. 99 and 157), discontinuation of anti-thrombotic therapy a minimum of 72 hours prior to renal biopsy procedure and assessment of hemostasis (platelet count, activated partial thromboplastin time, prothrombin time, thromboelastography, buccal mucosal bleeding time [see ch. 80], blood typing). Contraindications for renal biopsy include IRIS stage 4 CKD where the degree of severity of underlying renal disease is unlikely to be reversible irrespective of renal biopsy findings, patients with primary tubulointerstitial disease where there is no index of suspicion for glomerular disease that could be responsive to immunosuppressive therapy, evidence of hydronephrosis, pyelonephritis, hemostatic disorders and renal abscessation. There is also little purpose in performing a renal biopsy in a patient where there is a high index of suspicion for either amyloidosis or a hereditary nephropathy given that, to date, there is no evidence that such patients will respond to immunosuppressive agents.

Several methods are available for renal biopsy including ultrasound-guided Tru-Cut (see ch. 89), laparoscopic biopsy (see ch. 91), keyhole surgical and full exploratory laparotomy with either Tru-Cut or surgical wedge biopsy.[167-169] Irrespective of the technique used, it is important to ensure that the biopsy is obtained from cortical tissue only (Figure 321-4). This ensures not only that the area of interest is available for examination (i.e., glomeruli that are located within the cortex), but also reduces the risk of substantial hemorrhage, which may occur if the corticomedullary junction is crossed due to the location of the arcuate arteries within this region. In particular, caution should be exercised when using a Tru-Cut biopsy device in conjunction with either a keyhole or full exploratory surgical approach to ensure that the device remains within the cortical tissue. The number of glomeruli obtained has been documented to be significantly higher when a 14-gauge Tru-Cut device is used compared to 18-gauge whether performed laparoscopically or with ultrasound guidance with increased crush artifact evident on 18-gauge biopsy samples.[170] However, in most patients an 18-gauge Tru-Cut biopsy device will obtain a satisfactory sample although in large patients use of a 16-gauge device may be preferable.[168] A minimum of two 10-mm length cores of cortical tissue should be obtained. In the event that the core of renal tissue is shorter than 10 mm or there is concern for substantial crush artifact, then a third sample should be obtained.[168] Irrespective of the methodology, providing the operator is experienced, satisfactory renal biopsies can be obtained in both cats (86.2%) and dogs (87.6%).[171] Samples are more likely to be of satisfactory quality when performed under general anesthesia, which in particular allows control of respiration for patients undergoing ultrasound-guided Tru-Cut renal biopsy, although this procedure is also reportedly performed with success under deep sedation.[168]

After procurement, the renal biopsy sample should be handled carefully to avoid crush or handling artifact, ideally maintaining the samples in physiological saline. Confirmation of glomeruli present within the samples can be performed by examination under 10×-40× magnification.[168] The samples should be carefully divided for evaluation by light microscopy (formalin fixed), transmission electron microscopy (TEM, glutaraldehyde) and immunofluorescence (Michel's medium).[168] Due to the specialist nature of renal biopsy interpretation, samples should be reviewed by a specialist veterinary nephron-pathologist where possible (Box 321-1). Light microscopy should not be restricted to hematoxylin and eosin (H&E) but should also incorporate evaluation with Masson's trichrome (MT) to identify collagen and connective tissue. Periodic acid Schiff hematoxylin (PASH) highlights the junction between tissue compartments (e.g., tubular, Bowman's capsule and capillary basement membrane); Jones methenamine silver (JMS) stains the fine structures of the glomerular basement membrane, which is useful for identifying immune complex deposits; and Congo red (CR) identifies amyloid.[172,173] A recent study indicated that in approximately 27.4% of cases, TEM was required either to confirm or make the diagnosis of immune-complex-mediated glomerulonephritis, which would otherwise have been inappropriately classified on the basis of light microscopy alone.[156] When immune-complex deposits are identified, immunofluorescence can subsequently be used to determine their origin with antibodies directed against IgG, IgA, IgM, C1q, C3, lambda and kappa light chains.[168,172,173]

Studies evaluating the effect of repeated renal biopsy on renal function in healthy dogs and cats have not documented a significant impact on GFR.[174,175] However, complications have been reported to occur in 13.4% of dogs and 18.9% of cats.[171] Factors that have been associated with an increased risk at the time of renal biopsy include patients of small size (<5 kg), severe azotemia (serum creatinine >5 mg/dL) and evidence of disorders of hemostasis.[171] Hemorrhage is reported in 9.9% of dogs and 16.9% of cats and should be treated aggressively when identified. Other complications reported include gross hematuria (4.2% of dogs, 3.1% of cats) although microscopic hematuria may be more common, hydronephrosis (0.4% dogs, 3.1% cats) and death (2.5% dogs and 3.1% cats).[171,176] Linear infarcts are commonly observed after renal biopsy in both dogs and cats.[171]

Renal fine needle aspirates are rarely rewarding in patients where there is a high index of suspicion for primary glomerular disease. However, for underlying inflammatory, primary or metastatic neoplastic disease (e.g., lymphoma), this may be a low-risk alternative to renal biopsy and is reported to provide a cytological diagnosis in 78% of canine renal lymphoma cases.[177]

Assessment of Hypercoagulability in Glomerular Disease

Hypoalbuminemia may be identified in patients with moderate to marked proteinuria and is a component of nephrotic syndrome along with hypercholesterolemia, proteinuria and either cavitary effusion or peripheral edema (see ch. 60). Traditionally the development of a hypercoagulable state in patients with glomerular disease has been attributed to the loss of **antithrombin,** which has a comparable molecular weight to albumin and can therefore be lost via the urine. However, the association between proteinuria and antithrombin concentrations is weak. **Thromboelastography** (TEG) provides a global assessment of coagulation status. Numerous review articles cover the principles of this diagnostic test.[178-180] Dogs with glomerular disease, including those with nephrotic syndrome, have been identified to be hypercoagulable on the basis of thromboelastography.[181,182] An early study suggested that dogs with glomerular disease and protein losing nephropathy had significantly lower antithrombin and significantly higher protein C than dogs with other systemic disease.[181] However, a more recent study evaluating 28 dogs with protein-losing nephropathy (UPC >2.0) showed that although dogs were hypercoagulable according to their TEG parameters, there was no association between TEG, UPC, antithrombin or serum albumin concentrations.[182] This study indicates that neither the magnitude of hypoalbuminemia, antithrombin concentrations nor magnitude of proteinuria can be used as a predictor of risk for thrombotic complications in dogs with glomerular disease or to guide anti-thrombotic therapy. In such patients, a comprehensive assessment of the coagulation system may be required.[182] For information on management of hypercoagulability in glomerular disease, see ch. 196, 197, and 325.[183]

Genetic Testing in Renal Disease

A number of breeds of dogs and cats are known to have genetic mutations that are causative for underlying renal disease (see ch. 328). For some of these conditions, genetic tests are available from commercial laboratories. To date, no hereditary glomerular conditions have been identified which benefit from immunosuppressive therapy and therefore performing an appropriate breed related genetic test might assist in precluding the requirement for renal biopsy. A genetic origin for several tubular disorders (e.g., cystinuria, hyperoxaluria, hyperuricosuria) has been identified and can now be tested for.[184-187] As the field of canine and feline genetics expands and new technologies become more widely available, our understanding of underlying genetic mutations as causes for renal conditions in both dogs and cats is likely to expand.[188]

Urinalysis

Urinalysis (see ch. 72) is an important component of assessing renal function, particularly in terms of urine

concentrating ability, glomerular and tubular function, and the presence of urinary tract infections, which in certain situations may ascend to affect the renal parenchyma and result in pyelonephritis. Biochemical evaluation of renal function should always be performed in conjunction with concurrent urinalysis.

Urine Concentrating Ability

Urine concentrating ability is to some extent species-specific, with, for example, the cat capable of achieving greater urine concentration than the dog. The majority of water is reabsorbed within the proximal tubules, loop of Henle, and early distal convoluted tubule (≈85%). The remainder is reabsorbed in the late distal tubule and collecting ducts under the control of antidiuretic hormone (ADH), otherwise referred to as arginine vasopressin (AVP) and which facilitates the insertion of aquaporin 2 water channels. Release of ADH is controlled both by plasma osmolarity and also by blood volume, giving the capacity to both actively concentrate and dilute urine. ADH driven water reabsorption is dependent on the medullary-concentrating gradient maintained by the countercurrent multiplier system.

Normal urine contains predominantly low molecular weight molecules (e.g., electrolytes and urea). **Urine osmolality** is the concentration of osmotically active molecules dissolved in urine being dependent only on the number of molecules and not related to their molecular size or weight and is reported as osmoles per kg (Osm/kg) (see ch. 73). Urine osmolality (U_{Osm}) is measured in laboratories using freezing depression point osmometers based on the principle that each mole of dissolved solute will depress freezing by 1.86 °C. The relationship between osmolality and specific gravity is considered linear[189] and therefore urine specific gravity measured by hand-held refractometer is more frequently used as an approximation to urine osmolality in clinical practice. The term **isosthenuria** is used to define USG between 1.008-1.015 (urine osmolality 300 mOsm/kg) and indicates that the urine has the same solute concentration as the glomerular filtrate and plasma. The term **hyposthenuria** is used to define USG <1.008 (U_{Osm} <300 mOsm/kg) indicating active tubular dilution whereas **hypersthenuria,** which is an infrequently used term, would imply USG >1.015 (U_{Osm} >300 mOsm/kg). Urine dipsticks are not a reliable methodology for assessment of USG.[190]

Urine specific gravity (USG) is typically evaluated by use of a hand-held refractometer and is defined as the ratio of the weight of a volume of liquid to the weight of an equal volume of distilled water. It is dependent on the number, size and weight of the particles in the urine.[191] Early studies suggest that feline urine has a higher refractive index than human or canine urine and that use of refractometers designed for human use would lead to factitiously high results.[191] This has led to the development of feline specific refractometers or, alternatively, the use of a **feline conversion factor** (0.846 × medical refractometer specific gravity) + 0.154.[191] However, more recent studies call into question this difference between species.[192-194] Studies evaluating both digital and optical analogue refractometers suggest that results are likely to be comparable both in dogs and cats.[194,195]

Other endogenous factors which may influence USG include severe proteinuria or glucosuria, which will result in slight overestimation of USG with every gram of protein per deciliter increasing USG by 0.003-0.005 and every gram of glucose per deciliter increasing USG by 0.004-0.005.[196] Exogenously administered substances that increase USG measurements include colloids, mannitol and iohexol.[197]

In patients with normal renal function, urine concentration is very variable. A patient with normal renal function that is dehydrated or has pre-renal azotemia is anticipated to have maximal urine concentration in order to preserve fluid volume and therefore a USG >1.030 in the dog and >1.035 in the cat.

A recent study showed that when USG was evaluated in 976 healthy cats of variable age from a first-opinion setting, 91% had USG >1.030 and 88% >1.035 on spot assessment.[198] Age has been reported to have an effect on USG with cats >9 years having an increased probability of USG <1.035 and an increased chance of identifying an underlying condition relating to reduced urine concentrating ability.[198,199] Kittens reportedly have urine concentrating ability comparable to adults from 8 weeks of age and puppies do from 4 weeks of age. Dietary moisture intake may affect urine concentrating ability.[200] Studies evaluating the effect of dietary moisture content on USG in cats have been variable with some supporting that feeding a wet diet may contribute to a lower USG[198] whilst others have shown no effect when comparing dry versus moist urinary diets.[201,202]

Water deprivation testing (WDT) is used as a test of tubular response to AVP in patients with polyuria and polydipsia where all differentials have been excluded apart from nephrogenic or central diabetes insipidus and psychogenic polydipsia (see ch. 296).[203] Any patient that is azotemic or has developed a pre-renal

azotemia in the face of inappropriately dilute urine (USG <1.030) has already in effect failed a WDT and should not have further water restriction.

Markers of Tubular Dysfunction/Damage

A number of markers can give information about apparent change or loss of tubular function and may be important in the evaluation of certain acute and chronic kidney diseases.

Glucosuria

Filtered glucose is almost completely reabsorbed within the proximal tubular cells via the SGLT2 (and to a lesser extent SGLT1) transporters and in health should not be identified in the urine of dogs or cats. Glucosuria is identified if the renal threshold and tubular maximum for glucose absorption (180 mg/dL; 10 mmol/L in the dog and 300 mg/dL; 16.6 mmol/L in the cat) is exceeded. Glucosuria is most commonly identified in patients demonstrating concurrent hyperglycemia (see ch. 61); however, primary renal glucosuria in the face of euglycemia indicates alteration in renal tubular function. Renal glucosuria has been identified either as a single or complex renal tubular disorder. In the latter, increased excretion of other molecules (e.g., amino acids, phosphate, bicarbonate and electrolytes) may occur and can be either inherited (e.g., Fanconi syndrome [see ch. 328]) or acquired (see ch. 322 and 326). Glucosuria can be identified using a colorimetric dipstick test based on a glucose oxidase enzymatic reaction. Certain antibiotics such as ciprofloxacin[204,205] when using the glucose oxidase reaction and penicillin and cephalosporins[205,206] when using a copper sulfate based reagent may give false positive results on a urine glucose dipstick test due to sugar reducing properties.

Fractional excretion (FE) of electrolytes is the fraction of the amount of a measured electrolyte that is filtered which is excreted into the urine (see ch. 73). Determination of FE usually requires collection of urine over a protracted period of time (≈24 hours) with the patient ideally placed in a metabolic cage or catheterized to ensure complete urine collection. However, this is largely impractical in the clinical setting and spot assessment FE of electrolytes is therefore more commonly used. Spot evaluation of FE can be calculated using the following formula:

$$\begin{aligned}\%\,\mathrm{FE} = &((\text{Urine concentration of E})\\ &\times(\text{Plasma concentration of creatinine})/\\ &(\text{urine concentration of creatinine})\\ &\times(\text{Plasma concentration of E}))\times 100\end{aligned}$$

Non-protein bound electrolytes are freely filtered at the glomerulus and are then reabsorbed within the tubules. For conserved solutes (e.g., amino acids and glucose) reabsorption within the proximal tubule is virtually complete (>99%) such that fractional excretion in health is <1%. However, for solutes such as sodium and potassium, approximately 2/3 of reabsorption occurs irrespective of body requirements (proximal and distal tubule and loop of Henle) with the remainder being either excreted or reabsorbed depending on homeostatic hormonal regulation (e.g., aldosterone). Similarly, calcium reabsorption (proximal and distal tubules) is tightly regulated by parathyroid hormone and phosphorus reabsorption (proximal and distal tubules) is controlled by the combination of parathyroid hormone and fibroblast growth factor 23/alpha-Klotho complex.[207]

Numerous exogenous and endogenous factors influence the FE of electrolytes, such as age, breed, food intake, dietary composition, exercise, ultrafiltration rate, the individual's solute and volume status, renal function and drug administration.[12, 208] Calculation of FE of electrolytes from a spot sample is at best a crude assessment of 24 hour urinary excretion of electrolytes in dogs and cats as a consequence of the inaccuracies of using creatinine as a marker of GFR, fluctuations in urine electrolyte concentrations due to dietary change, and circadian rhythms.[208-211] No clearly defined reference intervals exist for FE of electrolytes although values considered normal are reported.[208] FE of electrolytes is rarely used clinically in veterinary medicine

due to marked inter- and intra-patient variability (see ch. 73).

For patients where quantification of FE of electrolytes is being considered, it has been suggested that a standardized diet be fed for a minimum of a 1-week period to prevent the effect of dietary fluctuations and that the patient has been normally hydrated for several days.[12] FE of most electrolytes increases as GFR decreases, which limits the value of this test in clinical patients with renal dysfunction.[12,208] This may be the consequence of the compensatory response and hypertrophy of remaining nephrons allowing for enhanced reabsorption despite substantial functional renal mass reduction. Recently however, serial evaluation of FE of sodium has been reported as a potentially prognostic indicator of AKI outcome.[212]

Aminoaciduria occurs when amino acids, which are normally effectively and completely reabsorbed by the proximal tubule cells (>99%), are identified within the urine. This may occur due to excess circulating concentrations of a given amino acid leading to filtrate concentrations that exceed the tubular maximum for reabsorption, through an intrinsic defect in the tubular reabsorptive mechanism, or due to failure of intracellular processing or transport mechanisms on the basolateral surface of the proximal tubular cell. Aminoaciduria may be an isolated finding due to a defect in an individual transport protein, e.g., cystinuria, although other amino acids may be involved (lysine, glycine, ornithine and arginine) and hyperuricosuria, or may be part of a complex renal tubular disorder such as Fanconi's syndrome, which may be inherited (e.g., Basenji) or acquired (e.g., AKI) (see ch. 326). Urine amino acid profiling which may indicate a primary or secondary renal tubular disorder is currently available at the University of Pennsylvania (PennGen).

Acid-Base Evaluation and Urine pH

The kidney is intrinsically involved in acid-base homeostasis with the proximal tubule being responsible for absorption of both hydrogen ions and bicarbonate but the distal tubule being the important location for homeostatic regulation of hydrogen ion secretion and adjustment of urine pH.[207] Evaluation of acid-base status via blood gas analysis (see ch. 128) can be important in the management of patients with both CKD (see ch. 324) and AKI (see ch. 322) where metabolic acidosis may be identified. In addition, renal tubular acidosis is a rare group of disorders that lead to metabolic acidosis where evaluation of both acid-base status and urinary pH are fundamental to achieving a diagnosis (see ch. 326).

Urine pH in both dogs and cats is variable and can be influenced by a number of external and internal factors including diet, medication or underlying acid-base disorders. Urine pH can be assessed either by biochemical reagent dipstick testing or using a calibrated hand-held pH meter. Biochemical reagent dipsticks are routinely used for urine pH assessment in clinical practice although studies have shown that they are accurate to within only ±0.5 pH and therefore where accurate assessment of urine pH is required calibrated pH meters should be used.[213-215]

Markers of Tubular Injury

In recent years there has been considerable interest in the development of novel biomarkers of tubular injury that could be used for the early detection of AKI and/or CKD prior to the onset of overt azotemia. Such biomarkers would offer the opportunity to intervene clinically at an earlier time point and might also show prognostic potential. To date, the majority of these markers is used on an experimental or research basis and are not widely commercially available. Early studies evaluating nephrotoxins (e.g., gentamicin) focused on the role of **urinary enzymes** (e.g., N-acetyl-beta-d-glucosaminidase, gamma-glutamyl-transferase, lactate dehydrogenase, alkaline phosphatase, alanine aminopeptidase and the feline specific enzyme cauxin) which, when released into the urine from their brush border location, indicate regional tubular damage. More recently, studies have explored the use of **low molecular weight proteins** (LMW <35 kDa; e.g., retinol binding protein, $beta_2$-microglobulin, $alpha_1$-microglobulin). These are freely filtered at the glomerulus and reabsorbed via megalin and cubulin mediated endocytosis. Tubular damage reduces the capacity for this reabsorption and hence increased concentrations of LMW proteins are expected in the urine with primary tubular disease. Alternative markers include **tubular proteins** (e.g., neutrophil gelatinase-associated lipocalin [NGAL], kidney injury 1 [KIM1] and clusterin) or **inflammatory markers** (IL-8), which again inform regarding direct tubular damage or the inflammatory processes taking place during renal injury.[216,217] Of these, NGAL has received the most attention as a potential marker of AKI (see ch. 322). More recent studies evaluating CKD in cats have begun to explore urine excretion of **profibrotic markers** such as transforming growth factor-beta[218] and potential **markers of hypoxia** (e.g., vascular endothelial growth factor). For all urinary markers, it is important that the measured concentrations or enzymatic activities are reported in

association with urine creatinine concentrations or standardized urine specific gravity to account for urine volume.

Urinary enzymes are located both on the brush border and in intracellular locations within tubular cells. Being medium to high molecular weight proteins, typically >150 kDa, it is anticipated that enzyme activity identified in the urine is likely to be of renal origin. Knowledge of the location of urinary enzymes within the nephron and alteration in either urine enzyme concentration or activity could therefore be used to indicate either damage or an alteration in activity of cells from that region of the tubule. To date the urine enzymes that have received the most attention are gamma-glutamyl-transferase (GGT), N-acetyl-beta-d-glucosaminidase (NAG) and the feline specific enzyme cauxin, although other tubular enzymes have also been evaluated (e.g., lactate dehydrogenase, alkaline phosphatase and alanine aminopeptidase).[216,217]

Gamma-glutamyl-transferase is a proximal tubular enzyme located on the brush border. It has predominantly been investigated as a marker of acute tubular injury with studies demonstrating increase in urine GGT : creatinine index in experimental gentamicin toxicity studies prior to the onset of azotemia.[219,220] A more recent study has evaluated GGT in healthy, CKD, and AKI dogs and although GGT : creatinine index was significantly higher in dogs with AKI there was significant overlap between groups. Studies suggest that urine pH and also gender in dogs may influence GGT activity and due to inter-individual variability the GGT : creatinine index may be most useful where there is a known risk of inducing AKI (e.g., administration of nephrotoxic drug) and longitudinal monitoring with a rapid turn-around time is available.[221]

N-acetyl-beta-d-glucosaminidase is predominantly a proximal tubular enzyme but for which two isoenzymes exist; NAG-A which is located on the brush border and NAG-B which is an intracellular enzyme. In veterinary studies performed to date, total NAG activity has been assessed in relation to urine creatinine concentrations to give a total NAG index. However, it has been suggested that elevation in individual NAG isoenzyme may differentiate tubular cell damage from altered tubular cell activity (i.e., due to proteinuria) and protein processing by the proximal tubular cells. NAG index has been more extensively studied than other urinary enzymes due to superior stability in urine with storage and has been evaluated in both acute and chronic kidney disease.[221,222] Studies have indicated that NAG index may be significantly higher in dogs with X-linked hereditary nephritis prior to the onset of azotemia although not prior to the onset of proteinuria.[223] However, after the development of azotemia, urine NAG index plateaued, suggesting that subsequent alteration in renal function was not indicated by change in NAG index. Although NAG index was predictive of the development of azotemia in healthy geriatric cats (>9 years), it did not perform as well as other more traditional markers such as UPC.[224] Substantial overlap between healthy and CKD patients has been identified both in dogs and cats, and similar to GGT this inter-individual variability in spot assessment may limit the utility of NAG index as a marker of tubular injury in chronic disease.[222,225]

Cauxin is a feline specific carboxylesterase enzyme which has been localized to the proximal tubular cells involved in the production of the pheromone felinine.[226,227] Early studies suggested via immunohistochemistry that cauxin expression was reduced in cats with advancing CKD.[228] However, a study evaluating the relative concentration of urine cauxin to creatinine ratio in cats with variable renal function suggested no association with creatinine concentration as a marker of azotemia and only a mild association with proteinuria.[229]

Low molecular weight (LMW) proteins (<35 kDa) are freely filtered at the glomerulus and in health should be readily reabsorbed via megalin and cubulin mediated endocytosis within the proximal tubular cells. Tubular injury may result in reduced reabsorption such that increased concentrations of LMW proteins are identified within the urine. Several such proteins have been investigated including retinol binding protein (RBP), $beta_2$-microglobulin and $alpha_1$-microglobulin. Similar to urinary enzymes, it is important that urinary low molecular weight proteins are standardized to urine creatinine concentration in order to compensate for urine volume.

Retinol binding protein is a 21 kDa protein which in the unbound form is freely filtered at the glomerulus and, in health, efficiently and almost completely reabsorbed and catabolized by proximal tubular cells. RBP has been identified in the urine of both dogs and cats.[230,231] In dogs urinary RBP : creatinine ratios have been shown to be elevated with CKD with strong correlation with urea and creatinine.[225] Similar findings have been identified in dogs with X-linked hereditary nephritis where urinary RBP : creatinine ratio showed progressive increase prior to the onset of azotemia and also a continued significant increase with declining renal function.[223] In cats, urine RBP : creatinine ratio has been evaluated in CKD and also as a predictor of azotemia after treatment of hyperthyroidism.[232,233] However, high interindividual variability appears to limit its utility in this species, which may reflect poor specificity of the assay.

Beta$_2$-microglobulin (11.8 kDa) is a LMW protein expressed on all nucleated cells, freely filtered at the glomerulus and reabsorbed within the proximal tubular cells. Beta$_2$-microglobulin has been explored in dogs with X-linked hereditary nephritis. Urine beta$_2$-microglobulin : creatinine ratio was found to be an independent predictor of GFR, increasing prior to the onset of azotemia although not preceding the onset of proteinuria in these dogs. It was also noted to reach a plateau during the later stages of disease, suggesting it may be less useful in chronic disease and after the onset of azotemia in predicting change in renal function.[223] However, the utility of beta$_2$-microglobulin is limited due to poor thermostability and instability at acid pH values.

Proteins of renal origin, which may be released or upregulated and released into urine after tubular or glomerular damage, have also been investigated including neutrophil gelatinase-associated lipocalin (NGAL), kidney injury 1 (KIM1) and clusterin.

Clusterin is a glycoprotein which is upregulated during renal damage although the location of injury leading to increased urine clusterin : creatinine ratio is nonspecific. To date one study has validated an ELISA for quantification of clusterin in canine urine and demonstrated that in dogs with leishmaniasis, urine clusterin : creatinine ratios increased with declining renal function,[234] and a further study has suggested potential in the detection of AKI.[235] To date no published studies have evaluated clusterin in cats.

Kidney injury molecule-1 is a type-1 cell membrane glycoprotein, which is expressed at low levels in the normal kidney. It is considered to be specific for the detection of proximal tubular cell damage in AKI. Expression of KIM1 is upregulated with ischemic or toxic renal injury with the ectodomain being shed into urine and demonstrating stability for subsequent identification and quantification.[236,237] To date, KIM1 has only been evaluated in cats where three expressed gene transcripts have been identified and immunohistochemistry localized expression to the proximal tubular cells. An immunoassay has been validated for urinary quantification of KIM1 and KIM1 was detectable in urine from cats with AKI but not those with CKD.[236] To date, no published studies have evaluated KIM1 in the dog.

Neutrophil gelatinase-associated lipocalin (NGAL) is a 25 kDa protein expressed not only by neutrophils but also by epithelial cells and specifically the proximal tubular cells within the kidney. In human medicine, NGAL may exist as a monomer, dimer or complexed to matrix-metalloproteinase-9 (MMP-9). A recent study has identified these different forms of NGAL in canine urine.[238] A canine specific NGAL ELISA has been developed and validated.[223] Studies have demonstrated that urinary NGAL : creatinine ratio is increased in dogs with both naturally occurring and experimentally induced AKI.[239-241] Furthermore, two studies evaluating urinary NGAL : creatinine have demonstrated that the ratio is significantly higher in dogs with AKI than in CKD or control dogs, although there is overlap between these groups.[241,242] In dogs with X-linked hereditary nephritis, similar to previous biomarkers, urine NGAL : creatinine ratio was significantly increased prior to the onset of azotemia in affected dogs.[223] However, given the expression of NGAL by neutrophils, concern has been raised about the potential impact of urinary tract inflammation and infection on urine NGAL concentrations. Studies have documented that urinary NGAL : creatinine ratio in dogs with urinary tract infections is significantly higher than control dogs and dogs where there was suspicion for a urinary tract infection but culture proved negative. However, urinary NGAL:creatinine ratios in dogs with UTI were significantly lower than in dogs with either CKD or AKI.[238,241,243] There has also been recent interest in evaluation of serum/plasma NGAL concentrations. Studies have shown that serum/plasma NGAL concentration is higher in dogs with CKD than controls, increases with advancing stage of CKD and may be significantly higher in patients with AKI than CKD.[242,244] Further work is needed to determine the effect of concurrent disease on both urine and plasma/serum NGAL and whether differentiation of monomer, dimer or complexed NGAL offers any advantage over total NGAL assessment. To date, poor cross-reactivity between currently available human and canine antibodies with feline NGAL has precluded assessment of this biomarker in cats.

Inflammatory markers may also provide information about both acute and chronic kidney injury with the potential to provide information about the pro-inflammatory state of the kidney (e.g., IL-18), renal hypoxia (e.g., vascular endothelial growth factor [VEGF]) and a pro-fibrotic environment (e.g., transforming growth factor-beta [TGF-beta] and transglutaminase).[245-248] However, to date, only preliminary research orientated studies are available evaluating these molecules in either the dog or cat and further validation is required before any clinical utility can be considered.

Indicators of Renal Disease on Urinalysis

Routine urinalysis consists of evaluation of specific gravity for assessment of urine concentrating ability (see above), biochemical reagent dipstick evaluation (see above for discussion regarding pH, glucosuria and protein evaluation), microscopic sediment examination and urine culture. Collection of urine for analysis is considered in ch. 105. In relation to renal disease specifically, urinalysis is beneficial for detection of reduced urine concentrating ability (see USG above), urinary tract infections and secondary pyelonephritis (see ch. 327), identification of hematuria, which may be renal in origin, indicators of AKI (e.g., cast formation or calcium oxalate monohydrate crystals in patients with ethylene glycol toxicosis) and may give an indication regarding tubular dysfunction either through alteration in pH, presence of glucosuria and proteinuria or through the presence of certain types of crystals on sediment examination (e.g., cystinuria). Urinalysis should ideally always be performed on a fresh sample evaluated at room temperature. Consideration should be given to the methodology used for urine collection when interpreting laboratory findings. The urine should initially be assessed in terms of gross appearance (see ch. 77) including color, odor and turbidity. Readers are directed to numerous comprehensive reviews on performing complete urinalysis and pre-/post-analytical factors that may influence results.[249-251]

Hematuria

Excessive numbers of red blood cells (RBC) in the urine is referred to as hematuria and can be either microscopic (detectable only on dipstick or microscopic examination) or macroscopic (grossly visible). There are numerous potential causes for hematuria originating from the kidney, although lower urinary tract (e.g., urinary tract infection) and systemic causes (e.g., coagulopathy) are more commonly identified and all must be differentiated from hematuria occurring as a consequence of disease occurring in the genital tract (see ch. 47). Low levels of RBC can be identified in normal urine from the dog and cat, with values typically being <5 RBC/hpf on free catch. However, increased numbers may be identified in patients where urine is collected either by catheterization or cystocentesis (<20 RBC/hpf). Occasionally, erythrocyte casts may form and be identified in the urine. When identified, this implies a renal origin of hemorrhage (e.g., idiopathic renal hematuria).

Pyuria

Pyuria refers to the presence of increased white blood cells (WBC) in urine (Figure 321-5) and is most likely to be identified in patients with urinary tract inflammation and infection (see ch. 350) or bacterial infection that has ascended to the kidney resulting in pyelonephritis (see ch. 327). However, the presence of pyuria alone cannot be used to differentiate whether the infection is localized to the lower or upper urinary tract unless cellular casts composed of white blood cells can be identified (Figure 321-6) indicating renal involvement, or the sample has been obtained directly from the renal pelvis by performing pyelocentesis.

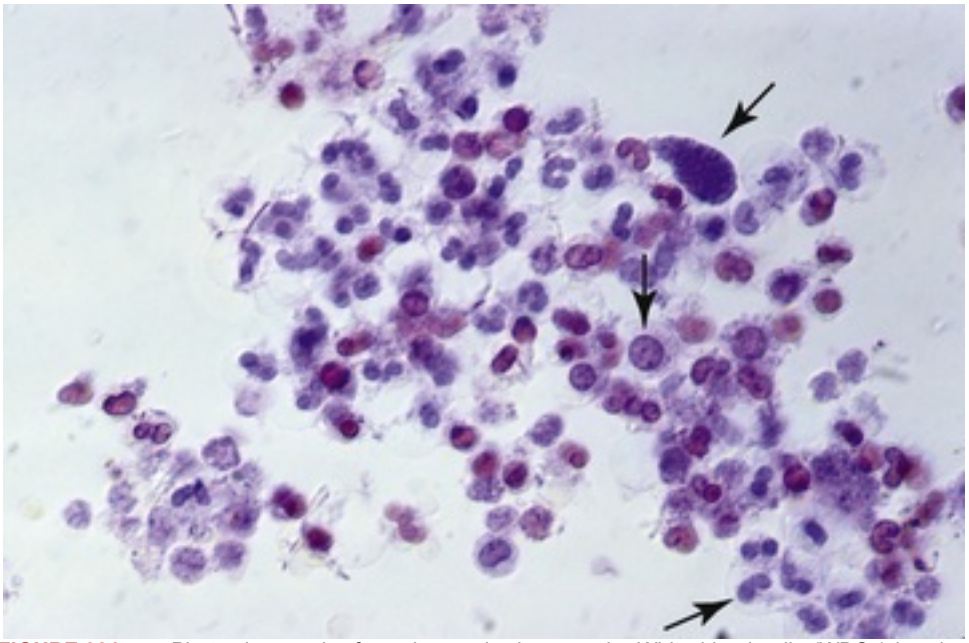

FIGURE 321-5 Photomicrograph of an abnormal urine sample. White blood cells (WBCs) in urine

are subject to degenerative changes that may complicate their identification. They may shrink in concentrated urine or swell in dilute urine. Clumps of WBCs are often associated with infection. Occasional transitional epithelial cells are present in this field (top two arrows) and a neutrophil with a polymorphonuclear nucleus and swollen cytoplasm is also seen (bottom arrow).

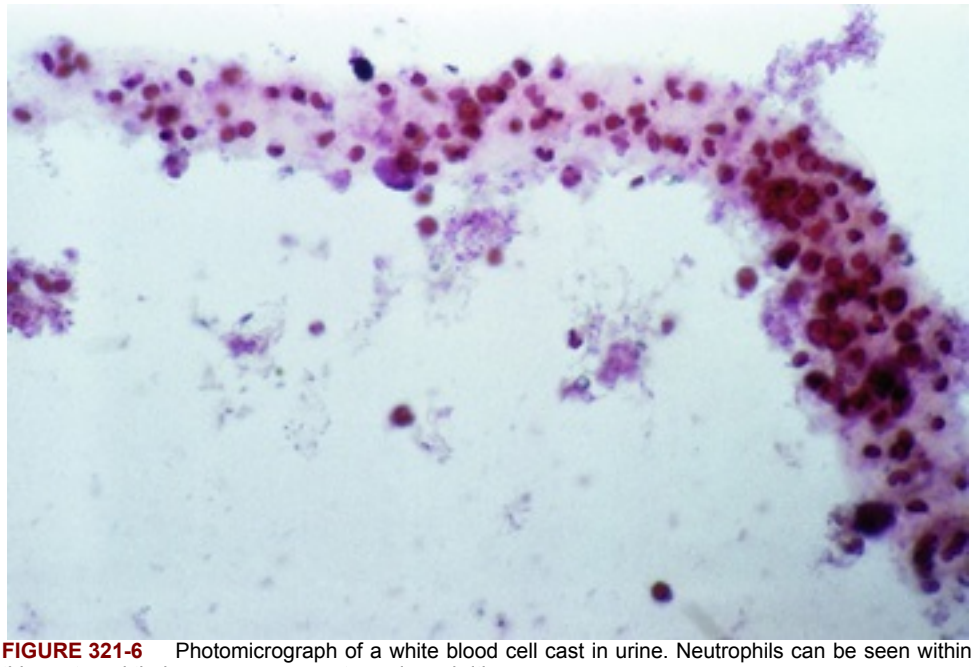

FIGURE 321-6 Photomicrograph of a white blood cell cast in urine. Neutrophils can be seen within this cast, and their presence suggests pyelonephritis.

The leukocyte esterase pad contains indoxyl which is released by esterases from either intact or lysed leukocytes and reacts with diazonium salt to give a blue color after oxidization. This reaction has been shown to be specific for pyuria in canine urine but has a low sensitivity.[252] In the cat, the leukocyte esterase pad is modestly sensitive but nonspecific, likely as a consequence of urinary esterase enzymes.[253] On microscopic sediment examination, the total number of white cells identified is usually low (<3 WBC/hpf cystocentesis, <5 WBC/hpf catheterized, <8 WBC/hpf free catch). Increased WBC count within urine may also be present due to hematuria and the degree of blood contamination and peripheral white cell count may therefore need to be taken into consideration, particularly if gross hematuria is present. The potential for contamination from the genital tract must also be considered depending on the method used for urine collection.

Epithelial Cells

Both squamous and transitional epithelial cells may be identified in urine sediment and low numbers of such cells can be considered normal. Squamous epithelial cells (Figure 321-7) may be noted in higher numbers in both voided and catheterized samples and are of limited clinical significance in relation to renal disease as they are likely to reflect contamination from the urethra or vagina. Transitional epithelial cells are derived from urothelium and may originate from the renal pelvis to the urethra and therefore could reflect damage at the level of the kidney (Figure 321-8). They are variable-sized cells but are typically smaller with tapered ends (caudate cells) when originating from the renal pelvis (Figure 321-9). However, a definitive renal origin can only be determined if epithelial cells form epithelial cellular casts (Figure 321-10) confirming a tubular origin.

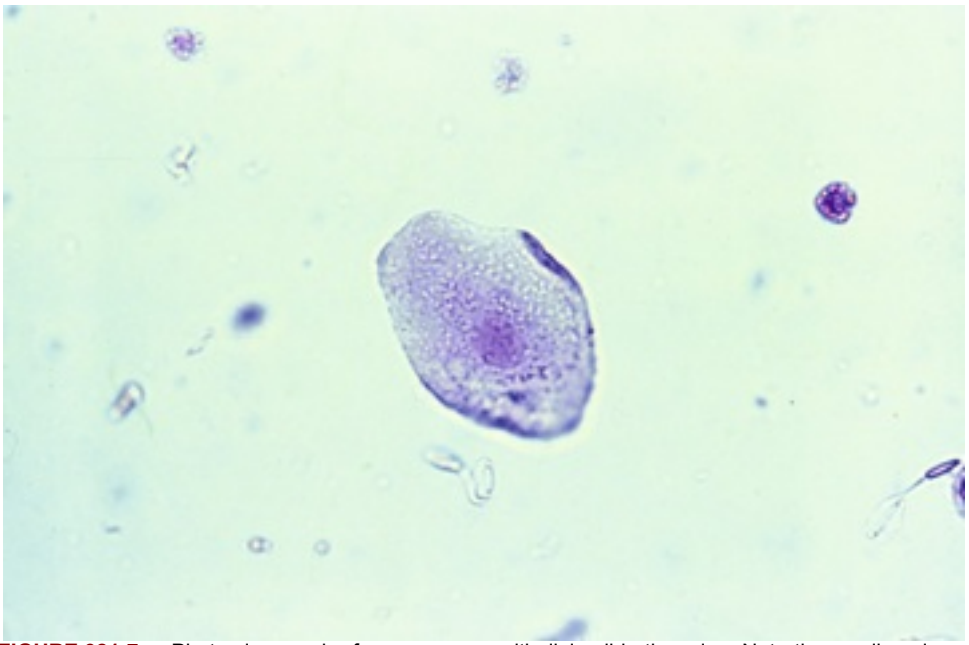

FIGURE 321-7 Photomicrograph of a squamous epithelial cell in the urine. Note the small nucleus, irregular cell shape, and folding of the cytoplasmic margin in some areas.

FIGURE 321-8 Photomicrograph of a raft of transitional epithelial cells in the urine.

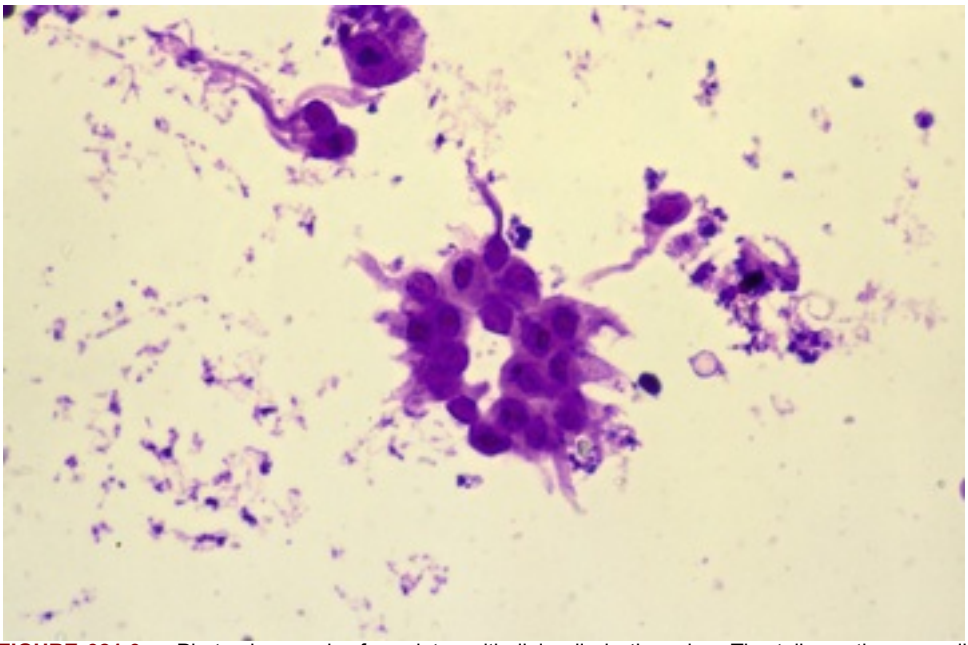

FIGURE 321-9 Photomicrograph of caudate epithelial cells in the urine. The tails on these small epithelial cells suggest that they originated in the renal pelvis.

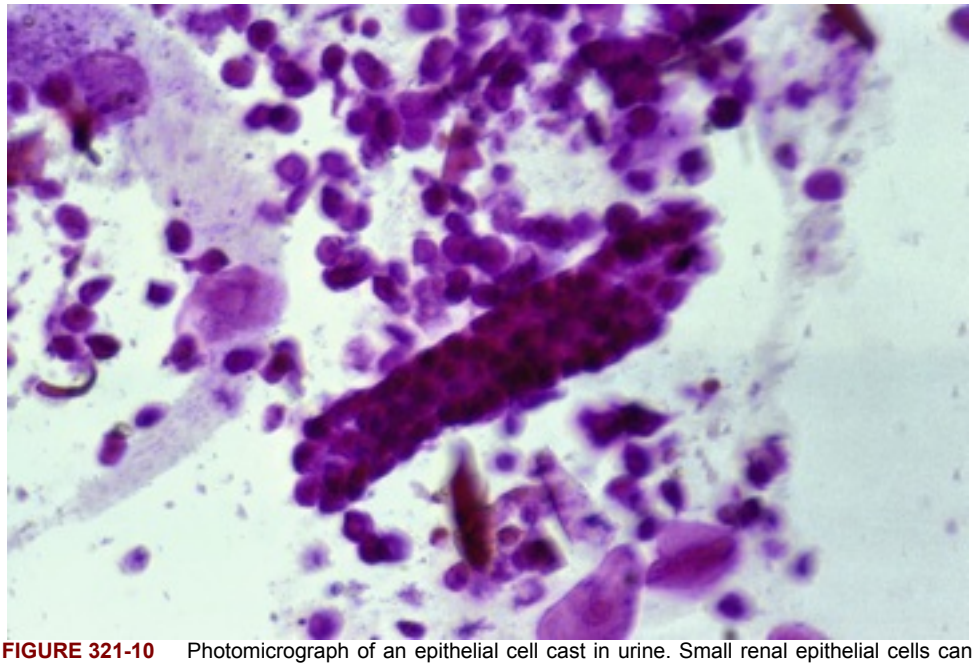

FIGURE 321-10 Photomicrograph of an epithelial cell cast in urine. Small renal epithelial cells can be identified in this cast.

Bacteriuria

Traditionally it has been considered that urine within the bladder is a sterile environment whilst the distal urethra and genital tract may harbor bacteria. However, this is not necessarily the case and subclinical bacteriuria, may occur. Subclinical bacteriuria refers to the identification of bacteria in urine by positive bacterial culture from a cystocentesis sample in the absence of either clinical evidence of a urinary tract infection.[254,255] The prevalence of subclinical bacteriuria in dogs and cats is low in healthy individuals (2-9%)[256-259] but may be higher (up to 30%) in patients with concurrent disease (e.g., hyperthyroidism, diabetes

mellitus and chronic kidney disease).[260-262] Clinicians should therefore consider carefully the method used for sample collection (i.e., cystocentesis, catheterization, voided), concurrent urinalysis findings (e.g., presence of an active sediment), quantitative culture results (expressed in colony forming units/mL urine), as well as a patient's clinical signs before diagnosing a urinary tract infection and administering antimicrobial therapy.[255] Further information regarding the diagnosis and management of lower urinary tract infections and pyelonephritis is provided in ch. 330 and 327, respectively.[263-268]

Crystalluria

In the context of renal disease, crystalluria may provide information about alteration in tubular function. The presence of crystalluria in canine and feline urine is dependent on urine pH, temperature, and length of time between collection and examination and the concentration of solutes that may form crystals. Crystalluria may be identified in the absence of urolithiasis and certain types of crystalluria (struvite, amorphous phosphate, calcium oxalate) may be a normal phenomenon in both dogs and cats. *In vitro* crystalluria formation has been shown to occur in approximately 30% of samples and is more likely to occur with prolonged storage (24 hr >6 h), with refrigeration increasing both the number and size of crystals identified.[269] Equally, urolithiasis may be detected without any evident crystalluria (see ch. 331, 332 and 334).[250]

Cylindruria (Cast Formation)

Casts can be identified in urine sediment examinations as elongated cylindrical structures and the presence of casts immediately implies a renal origin of damage as they are typically formed within the ascending limb of the loop of Henle and the collecting duct where tubular flow rates are slowest. The presence of casts within urine is referred to as cylindruria. Rare hyaline or granular casts may be normal in dogs and cats but the presence of higher numbers or cellular casts is always abnormal and implies tubular renal damage. Casts can be classified as hyaline, granular, waxy, fatty, cellular (epithelial, white blood cell, red blood cell), may contain crystals and/or microorganisms or can be mixed in origin.

Hyaline casts are composed entirely of proteinaceous material (mucoprotein, Tamm-Horsfall protein/uromodulin, albumin) and have a colorless cylindrical appearance (Figure 321-11). Low numbers may be identified in individuals after extreme exercise or with fever but they may be identified more commonly in the urine of patients with marked proteinuria. However, they can be missed if there is a delay in sediment examination being performed or in alkaline or dilute urine due to dissolution. If epithelial cells become entrapped within the mucoprotein then these are referred to as ***epithelial casts*** (see Figure 321-10) where cells are clearly visible and imply the presence of direct tubular cellular damage (e.g., with gentamicin toxicosis). **Granular casts** (Figures 321-12 and 321-13) are identified where there has been partial degradation of the cellular components of a cast and are typically indicative of either an ischemic or nephrotoxic renal tubular insult. **Waxy casts** (Figure 321-14) refer to the situation where complete cellular degradation has occurred leaving a cast that has a smooth, waxy texture. Waxy casts form during protracted periods of tubular stasis, are relatively stable and are described often as convoluted with blunt ends. **Fatty casts** are rarely identified but when present can imply a disorder in lipid metabolism (e.g., diabetes mellitus or nephrotic syndrome). **Erythrocyte casts** indicate marked renal hemorrhage (e.g., post-renal biopsy or idiopathic renal hematuria), whereas **white blood cell casts** (see Figure 321-6) can be identified with marked renal inflammation (e.g., pyelonephritis) or with acute tubular necrosis.

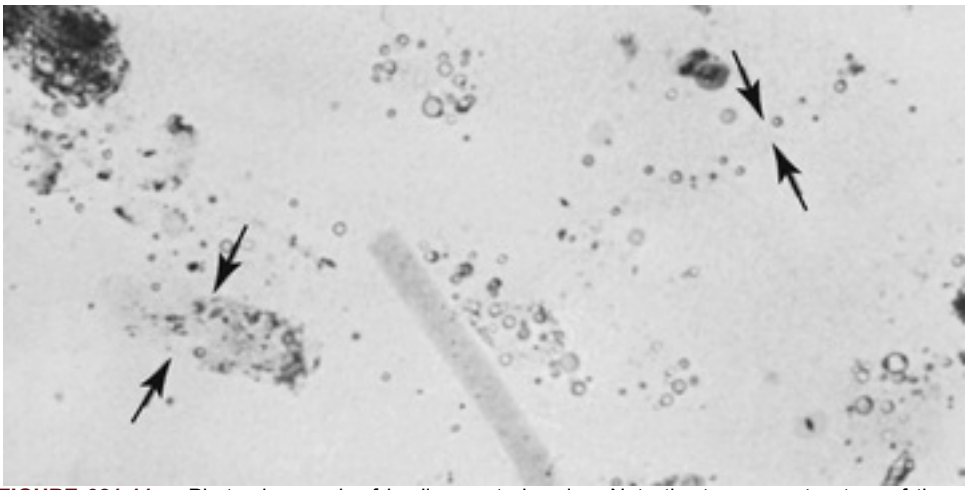

FIGURE 321-11 Photomicrograph of hyaline casts in urine. Note the transparent nature of these casts (between arrows). The casts are easily missed because their optical density is very low, necessitating low illumination for optical visualization. The darker cast in the center of the field is a waxy cast. Many lipid droplets are present in the background.

FIGURE 321-12 Photomicrograph of a finely granular cast in urine.

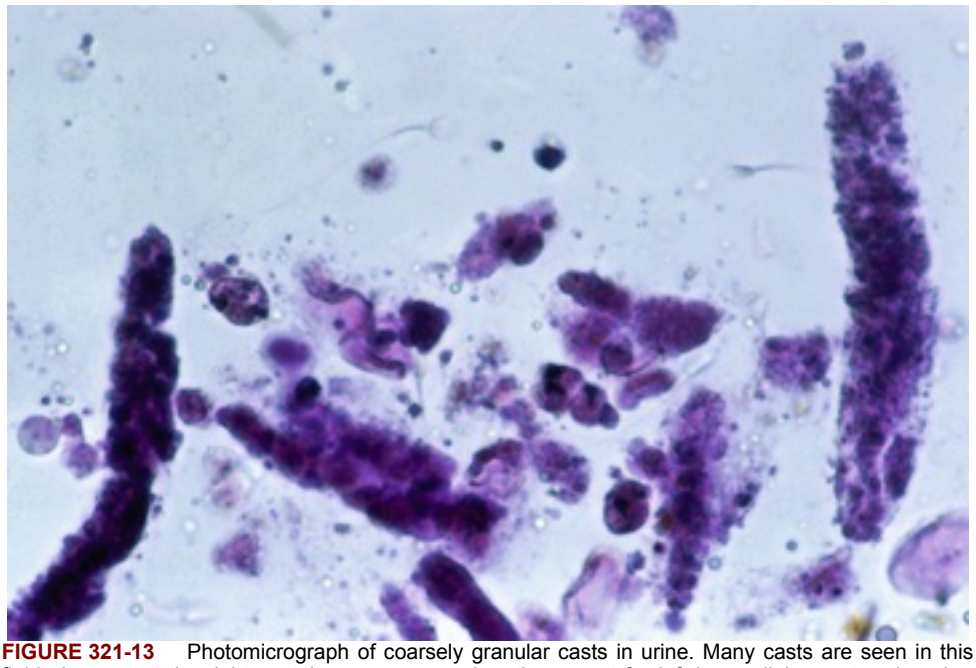

FIGURE 321-13 Photomicrograph of coarsely granular casts in urine. Many casts are seen in this field; the cast at the right contains coarse granules, the one at far left is a cellular cast undergoing degeneration.

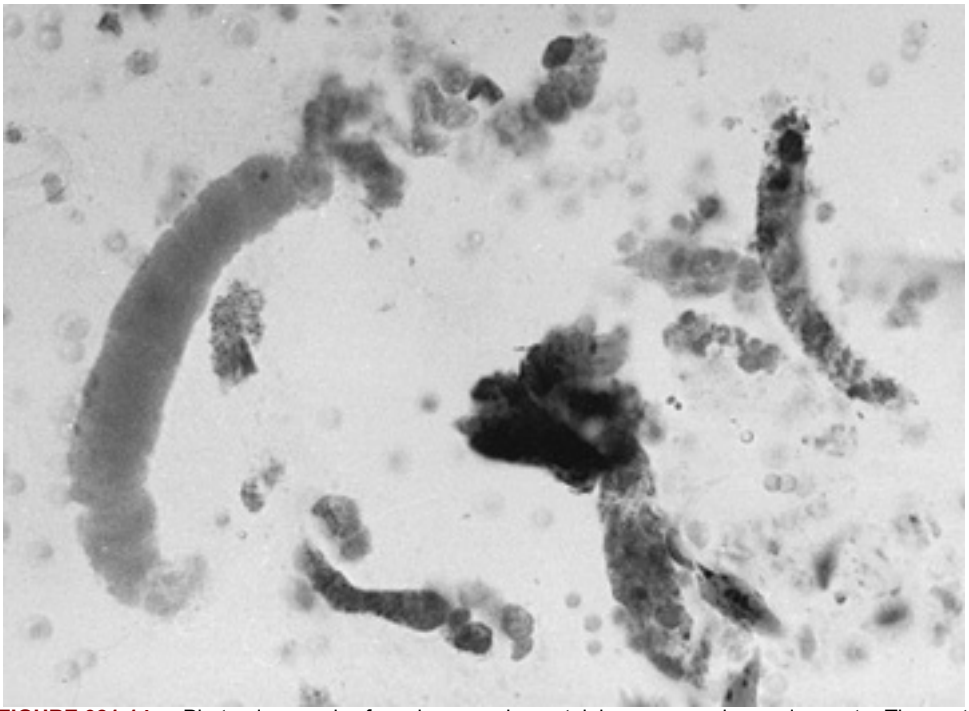

FIGURE 321-14 Photomicrograph of a urine sample containing waxy and granular casts. The cast at the left is waxy, whereas the others are granular. Note that the waxy cast is translucent, whereas hyaline casts are transparent. Waxy casts are brittle and often have cracks or sharply broken ends.

Bilirubinuria

See ch. 53.

Ketonuria

See ch. 142.

Parasites

Rarely, parasitic ova from *Stephanurus dentatus*, *Capillaria plica* (Figure 321-15), *Capillaria felis*, and *Dioctophyma renale* may be identified in urine. Microfilariae of *Dirofilaria immitis* may rarely be observed in canine urine sediment.[250]

FIGURE 321-15 Egg from *Capillaria plica* identified in the urine of a dog presenting with clinical signs of pollakiuria. (Reproduced by kind permission of Alice Hughes.)

Diagnostic Imaging

Diagnostic imaging often forms an integral part of the diagnostic workup of the dog or cat with renal disease. Multiple imaging modalities are available, each with inherent advantages and limitations, which should be considered when devising a diagnostic plan for an individual patient. Details of technique and normal imaging findings are not described in depth; readers are referred to diagnostic imaging texts and appropriate reviews for further information.[270-275]

Radiology and Computed Tomography (CT)

Plain radiographs can be used to provide information about renal size. To account for variation according to body weight, the length of the kidney is typically evaluated as a ratio to the length of the second lumbar vertebrae on a ventrodorsal view; the reference values for the ratio that are most often quoted are 2.5-3.5 for the dog,[276] and 2.4-3.0 for the cat,[277] however, numerous studies have found that the renal size in normal animals may extend beyond these limits so these measurements should be interpreted cautiously.[278,279] Renal volume can be accurately estimated from CT scans using the voxel count method.[280]

Radiographs also provide some information about renal contour. However, ultrasonography and advanced imaging techniques are now usually used in preference to radiography for this assessment, due to the additional information these techniques provide regarding the internal renal architecture. Renal and ureteric calculi are often radiopaque and consequently these may be visible on abdominal radiographs. However, even uroliths of mineral composition that are typically radiopaque (calcium oxalate, struvite and calcium phosphate) may not be visible if the stones are very small, a particular problem with feline ureteral stones (see

ch. 329). Dystrophic mineralization and nephrocalcinosis are sometimes visible radiographically if the changes are extensive but are more often detected with ultrasound.

Excretory urography (intravenous urography) may be performed to provide additional information about the renal collecting system (renal pelvis, ureters, ureterovesicular junction), such as in the work-up of a patient with suspected urinary tract obstruction, rupture or urinary incontinence (see ch. 329). Although excretory urography may also provide information regarding renal number, size, contour and internal architecture, its use has largely been superseded by ultrasonography and other imaging modalities and is rarely used for this primary purpose.

CT imaging of the kidneys may be selected in preference to other imaging modalities when the focus of interest is the renal pelvis and ureter (usually due to concern for ureteral obstruction or ectopia)[281,282] or when a mass is present in, or close to, the kidney.[283-287] The triphasic patterns of contrast uptake and excretion in dogs undergoing CT imaging have been described,[288] as have techniques for CT-angiography for the characterization of vascular anatomy prior to renal donation for transplant.[289,290]

Ultrasonography

Ultrasonography is a useful diagnostic imaging modality in the investigation of kidney disease as it can provide important anatomical information concerning the renal size, shape and internal architecture. It should also be recognized, however, that the appearance of the kidneys can be completely normal, even when significant renal disease is present.

Renal dimensions in the dog are correlated with body weight, although it is actually renal volume that is linearly related to body weight and the relation with renal length (which is what is most often determined clinically) departs from linearity in patients weighing less than 10 kg.[291] Methods for indexing renal length to the aortic diameter,[292] or to the length of the body of L5,[293] have been proposed as alternative methods for evaluating renal size but are not in widespread use. Subjective assessment of renal size is common, but given that the overall variability in renal size is enormous, the validity of this approach seems doubtful. Normal renal size in cats is typically considered to be between 3.0 and 4.5 cm,[294] although it may be greater in male intact cats,[295] and recent studies suggest that renal lengths of up to 5.0 cm are common, even in neutered animals.[296-298] Diffuse renal enlargement with relatively normal internal renal architecture may occur due to compensatory hypertrophy, AKI of various causes, amyloidosis, lymphoma, portosystemic shunts, and acromegaly.[271,299-302] Small kidneys are found with congenital renal hypoplasia or dysplasia, chronic end-stage renal disease of many etiologies, and as a sequela of chronic ureteral obstruction.[271,303-307]

Kidneys are usually less echogenic than the liver and spleen, but their echogenicity may vary with the frequency of the transducer being used.[308] In addition, fat vacuoles in the renal tubular epithelium are thought to affect the echogenicity of feline kidneys, with the result that renal cortical tissue in healthy cats may be isoechoic or hyperechoic to the adjacent hepatic parenchyma.[309] Diffuse increase in cortical echogenicity is a very nonspecific indicator of renal disease, which has been reported in association with glomerulonephritis, pyelonephritis, leptospirosis, acute tubular necrosis, end-stage renal disease, feline infectious peritonitis, nephrocalcinosis, renal lymphoma and other tumors, and ethylene glycol toxicosis.[300,303,310-316] In ethylene glycol toxicosis, the increase in echogenicity is often dramatic, and may suggest the diagnosis, but for the other disorders, the increase in echogenicity is usually non-discriminatory.[275] Changes in echogenicity have been found to be only weakly correlated with histological findings.[317] Increased renal echogenicity is often observed in association with a lack of corticomedullary definition, which is another very nonspecific finding commonly associated with CKD, whatever the underlying etiology. In a study of young dogs with renal dysplasia, loss of corticomedullary definition and increased echogenicity were found to mirror the severity of the renal histopathologic changes, even in the absence of azotemia.[318]

Focal lesions are the easiest to identify with renal ultrasonography. Cystic lesions have round to oval contour, echo-free contents, thin walls and show strong distal acoustic enhancement. Single, simple cysts are usually incidental findings. Multiple small cyst-like lesions may be seen with end-stage kidney disease; if these are due to glomerulocystic lesions they may be confined to the renal cortex,[319] and certain familial diseases may result in cystic lesions at the corticomedullary junction specifically,[320,321] but otherwise cysts may be present in both cortex and medulla. Autosomal dominant polycystic kidney disease (PKD) is commonly found in Persian and related breeds,[322-324] and occasionally in dogs[325-327] resulting in multiple,

variably sized cysts throughout the cortex and medulla (see ch. 328). If cystic lesions have thick or irregular walls, internal septations, or if the contents are not completely anechoic, then other disorders, such as hematomas, abscesses and tumors should be considered in the differential diagnosis.[271,275,286,328-331]

Solid renal masses are commonly neoplastic and may be hypoechoic, isoechoic or hyperechoic to the surrounding renal parenchyma, or may have a mixed pattern.[273,274,300,330,332] The appearance of these lesions is not characteristic of the tumor type and so aspirate or biopsy is required for differentiation. Granulomas, or calcified hematomas or abscesses, are potential differential diagnoses for this type of lesion, but are much less common than tumors. An acute renal infarct may initially appear isoechoic or hypoechoic and could be confused with a mass lesion, but more typically these are diagnosed once they are chronic, resulting in hyperechoic, wedge-shaped lesions that are widest toward the outer surface of the kidney.[273-275]

Fluid surrounding the kidney can be subcapsular or peri-renal and this may be difficult to differentiate. Small volumes of fluid may be accumulations of urine, blood, transudate or exudate and may be seen with urine leakage, AKI, ureteral obstruction, renal abscessation, hemorrhage or neoplasia.[274,275,313,333,334] Presence of a large volume of anechoic fluid is likely to represent a perinephric pseudocyst; these are more common in cats than dogs, usually found in association with CKD, and may be unilateral or bilateral.[335,336] Hypoechoic subcapsular thickening mimicking fluid accumulation is a relatively common appearance of renal lymphoma in cats.[337] Demonstrating blood flow within the subcapsular region using Doppler shows this is cellular accumulation, not fluid.

Sometimes a distinct hyperechoic line is present parallel to the corticomedullary junction: the so-called medullary rim sign. This finding is considered to be a normal variant in cats.[309] Although when first reported this finding was associated with renal disease in dogs,[338-340] it is also considered by many to be a normal variant, particularly when found in the absence of other signs of disease.[341] More recently it has been suggested that the outer medulla may often be relatively hyperechoic in dogs, particularly those of small breeds, and this may be confused with a true medullary rim sign (which is not located directly adjacent to the renal cortex but slightly distanced from it, within the medulla).[342] In addition, a diffuse band of hyperechoic tissue within the inner medulla has been reported in some dogs with acute leptospirosis[313] (Figure 321-16).

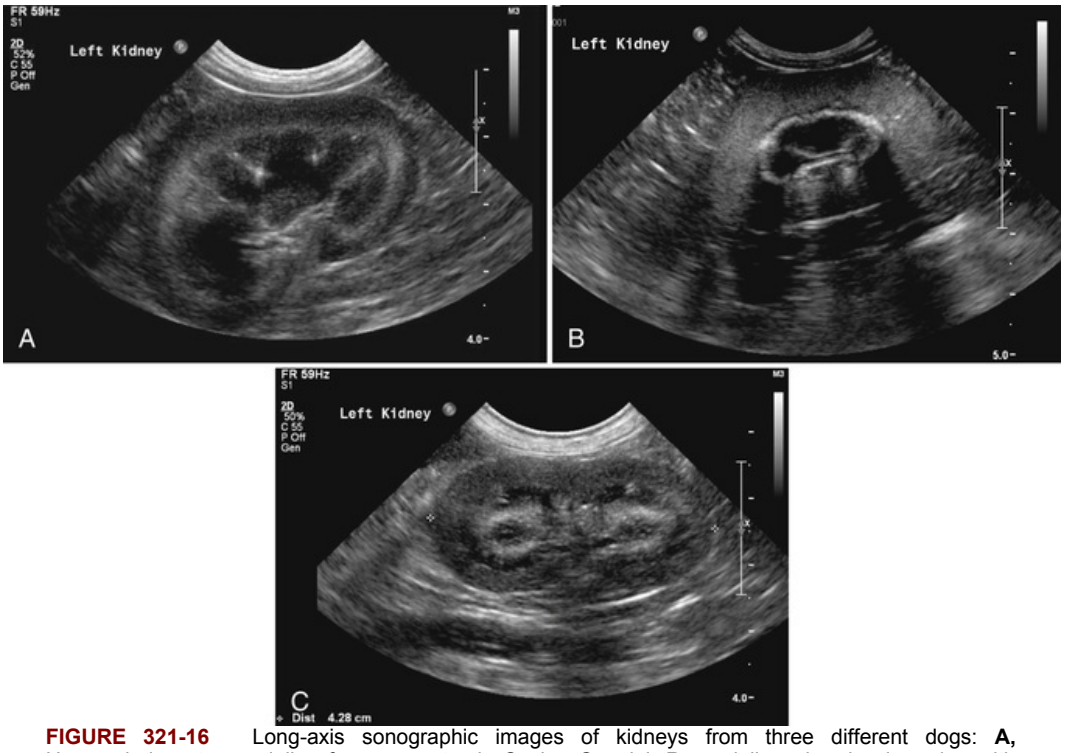

FIGURE 321-16 Long-axis sonographic images of kidneys from three different dogs: **A,** Hyperechoic outer medulla of a non-azotemic Cocker Spaniel; **B,** medullary rim sign in a dog with ethylene glycol poisoning; and **C,** medullary band sign in the inner medulla of a dog with AKI due to leptospirosis. (All images are reproduced from Hart DV, Winter MD, Conway J, et al: Ultrasound appearance of the outer medulla in dogs without renal dysfunction. *Vet Radiol Ultrasound* 54:652-658, 2013.)

In normal dogs and cats, urine cannot be visualized within the renal pelvis; however, current high-resolution ultrasound equipment allows detection of mild pyelectasia during diuresis.[343,344] This may be asymmetric. The differential diagnosis for renal pelvic dilation therefore includes all polyuric renal diseases, as well as obstructive lesions and pyelonephritis.[312,344,345] Sonographic changes are not always present in patients with pyelonephritis; however, changes that have been reported, in addition to pyelectasia, include increased echogenicity of the medulla and/or renal cortex, and hyperechogenicity of the mucosal lining of the renal pelvis.[271,275,312] When the reason for pelvic dilatation is uncertain, ultrasound-guided percutaneous antegrade renal pyelography may be used to definitively identify and characterize ureteral obstruction (see ch. 329).[346,347]

Doppler Assessment of Renal Blood Flow Indices

Pulsed-wave Doppler examination of blood flow in the interlobar or arcuate arteries can be performed as an aid to the detection of increased vascular resistance that may occur due to renal disease or ureteral obstruction. A unitless variable, the resistive index (RI), is most commonly used to quantify this. This is calculated by subtracting the end diastolic velocity from the peak systolic velocity and dividing the result by the peak systolic velocity. Increases in vascular resistance cause an increase in RI because the effect on blood flow in diastole is greater than the effect on blood flow during systole.

In general a value of greater than 0.70 (or sometimes 0.71 in cats, 0.73 in dogs) has been considered to be abnormal in clinical studies.[275,296,348-353] Intrarenal RI is increased in some, but not all, dogs and cats with renal disease. In humans, glomerular disease is thought to be less likely to result in increases in RI, and this seems to also be true in dogs and cats.[354,355] In AKI swelling of the interstitial tissues may increase resistance to renal blood flow. Increased RI has been documented in some dogs and cats with azotemic-AKI, and may decrease with recovery of the patient.[354,356,357] Sensitivity of RI for detection of AKI may depend on the nature of the injury.[349] RI may also increase in some dogs and cats with CKD.[354,355,357,358]

RI has been proposed as an aid in differentiating obstructive from non-obstructive renal disease.[354,359] Obstruction typically causes an increase in RI in the affected kidney but varies with the completeness and chronicity of the obstruction. Sensitivity of the test can be increased by not only considering the absolute value for RI but also comparing measurements from obstructive and non-obstructive kidneys.[360,361] Inducing diuresis may accentuate this difference, improving the sensitivity of RI for detection of obstruction, but results with this technique have been inconsistent.[360-362] RI has been proposed as a means to detect acute allograft rejection[356]; however, it has not been found to be clinically useful in cats following renal transplant.[363]

In clinical practice, there are many limitations to the interpretation of Doppler blood flow indices. Sedation and anesthesia have been found to have variable effect on RI,[348,350,364,365] and it is also increased by a variety of non-renal disorders including hepatic disease,[366] hyperadrenocorticism, diabetes mellitus,[367] anemia,[368] mitral valve disease[369] and babesiosis.[370]

Contrast-Enhanced Ultrasound

The assessment of renal perfusion potentially can be enhanced by use of ultrasound contrast agents; these are inert microbubbles, administered as intravenous boluses, that are small enough to pass through the microcirculation and transiently enhance the echogenicity of blood. Enhancement of echogenicity of the cortex is more marked, and occurs sooner, than enhancement of the medulla.[371] The risk of renal injury with use of these contrast agents is minimal.[372] Perfusion patterns in the kidneys of normal dogs[373-375] and cats[371,376] have been described.

In humans, contrast-enhanced ultrasound has been used to detect a wide range of renal conditions. It has particular indications for detection of parenchymal lesions in acute pyelonephritis,[377] evaluation of renal allografts[378] and in the differentiation of tumors from benign anatomical variants and cystic lesions.[379,380] In veterinary patients, the use of contrast-enhanced ultrasound to image focal renal lesions[330] and to diagnose renal hemorrhage in a case of renal rupture[381] has been described. It has also been employed in experimental canine studies demonstrating its potential as a noninvasive tool for the detection of conditions where renal perfusion may be altered, either focally or globally.[382,383]

Renal Scintigraphy

The radioisotope most frequently employed in dogs and cats is ^{99m}Tc-DTPA, which can be used in the estimation of GFR as described above. Injection of furosemide immediately after the initial scan can provide additional information regarding the patency of the ureters because ^{99m}Tc-DTPA is rapidly cleared from the kidneys by the diuretic if no obstruction is present.[384,385] Other scintigraphic techniques that have been occasionally described in dogs and cats include ^{99m}Tc-mercaptoacetyltriglycine (MAG-3) and ^{99m}Tc-dimercaptosuccinic acid (DMSA) scintigraphy.[386-389] Concentration of ^{99m}Tc-MAG-3 and ^{99m}Tc-DMSA within renal tissue predominantly occurs due to proximal tubular uptake of these isotopes, not glomerular filtration. ^{99m}Tc-MAG-3 scans are performed dynamically and provide an assessment of renal blood (plasma) flow and ^{99m}Tc-DMSA scans are static and provide superior images for the assessment of differential renal function. In one study in dogs these techniques were found to be more sensitive for detection of gentamicin-induced nephrotoxicosis than measurement of GFR.[387] In humans these techniques are used to detect areas of decreased isotope uptake due to conditions such as acute pyelonephritis, infarction and renal scarring.[390,391]

CHAPTER 322

Acute Kidney Injury

Cathy E. Langston

Client Information Sheet: Acute Kidney Injury

Introduction

The kidneys are at high risk for ischemic and nephrotoxic insult due to a variety of factors, including the kidney's high proportion of cardiac output (20%) in comparison to total body weight (0.5%), high metabolic demand, and potential for nephrotoxin concentration in tubular epithelial cells.[1,2] Acute kidney injury (AKI) accounts for 1% to 4% of hospital admissions, complicates an estimated 7% to 36% of inpatient episodes in people, and complicates sepsis at an even higher rate (47%).[3-9] The incidence of naturally acquired AKI in pets is unknown, but its effects can be devastating. AKI developed in 15% to 22% of hospitalized dogs and cats, specifically 12% of dogs with abdominal sepsis in one study, and even minor renal injury increases mortality in people and animals.[10-14] In several studies of nonrenal disease, increased blood urea nitrogen (BUN) or serum creatinine concentrations were inconsistently associated with mortality.[15-20]

Definition and Grading Aki

Classic versus More Sensitive

AKI has classically been defined as an increase in serum creatinine above the upper limit of the reference range, in the absence of chronicity.[21-23] This definition is sensitive but not specific. AKI is not only a rapid decline in renal function, but is often associated with retention of uremic wastes, deranged fluid status, electrolyte imbalances and acid-base disorders. An increase of >0.3 mg/dL or >25% increase from baseline creatinine are two of many AKI definitions used in people to detect subtle renal injury.[24,25] Because creatinine is poorly correlated with glomerular filtration rate (GFR) at low levels of dysfunction, such changes in creatinine may represent a dramatic decrease in renal function but still remain within the reference range (see ch. 62). Such increases may not fit the classic definition, but they do represent AKI, in which even mild changes have prognostic implications.[13]

Grading AKI

Various grading schemes have been applied to AKI in people and animals. In a retrospective study of dogs in intensive care, developing even a low level of AKI (increase in creatinine of ≥0.3 mg/dL or 1.5-2 times baseline creatinine) was associated with higher mortality than no AKI (58% vs. 16%).[10] In another study of hospitalized and out-patient dogs and cats, dogs but not cats who remained nonazotemic with an increase in creatinine of ≥0.3 mg/dL had three times higher 90-day mortality compared to those in which the creatinine did not change.[11] In both dogs and cats that developed azotemic AKI, mortality was 3 times higher at 30 and 90 days, compared to no AKI.[11] Because of inconsistencies in defining AKI, a grading scheme was adopted by the International Renal Interest Society (IRIS) in which separate criteria are based on changes in creatinine, preexisting renal disease and urine output (Table 322-1).[26]

TABLE 322-1

IRIS Classification Scheme for Acute Kidney Injury[200]

AKI GRADE	BLOOD CREATININE (MG/DL)	CLINICAL DESCRIPTION
Grade I	<1.6	Nonazotemic AKI: a. Documented AKI: (Historical, clinical, laboratory, or imaging evidence of AKI, clinical oliguria/anuria, volume responsiveness*) … and/or b. Progressive nonazotemic increase in blood creatinine; ≥0.3 mg/dL (≥26.4 mcmol/L) within 48 h c. Measured oliguria (<1 mL/kg/h) or anuria over 6 h
Grade II	1.7-2.5	Mild AKI: a. Documented AKI and static or progressive azotemia b. Progressive azotemic increase in blood creatinine; ≥0.3 mg/dL (≥26.4 mcmol/L) within 48 h, or volume responsiveness* c. Measured oliguria (<1 mL/kg/h) or anuria over 6 h
Grade III	2.6-5.0	Moderate to severe AKI: a. Documented AKI and increasing severities of azotemia and functional renal failure
Grade IV	5.1-10.0	
Grade V	>10.0	

*Volume responsive is an increase in urine production to >1 mL/kg/h over 6 hours and/or decrease in serum creatinine to baseline over 48 hours.

AKI, Acute kidney injury; *IRIS*, International Renal Interest Society.

Etiology

Categories

The causes of AKI have, classically, been subdivided into: hemodynamic (prerenal), intrinsic renal, and postrenal causes (Figure 322-1). Conceptually, each category is distinct, but may overlap in an individual, which complicates distinguishing the role of each. Persistent extrinsic renal damage can lead to intrinsic renal damage, because they are different points on a continuum. The term *acute uremia* encompasses biochemical changes induced by all categories. In people, it is estimated that 20% to 80% of acute uremias have hemodynamic causes, 5% to15% have postrenal causes, and 10% to 45% are the result of intrinsic renal failure. The most common intrinsic causes are ischemic and nephrotoxins, with lower incidences of large vessel, microvasculature, glomerular, or acute tubulointerstitium disease.[27-29] In people, acute uremia on hospital admission is due to hemodynamic causes in 70% of cases, is the result of a single condition without other organ involvement, and generally carries a good prognosis. Acute uremia that develops in hospital is generally caused by multiple insults, has multiple organ system involvement, is associated with hemodynamic causes in 40% of cases, and generally has a worse prognosis.[6,30,31]

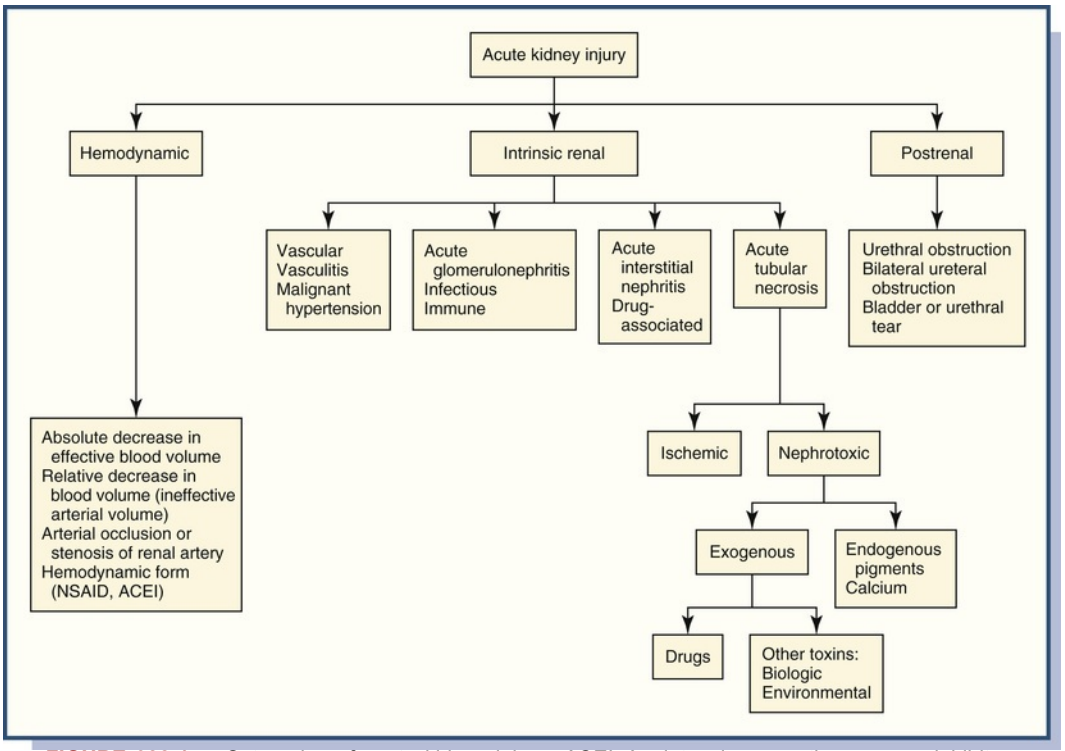

FIGURE 322-1 Categories of acute kidney injury. *ACEI*, Angiotensin-converting enzyme inhibitor; *NSAID*, nonsteroidal anti-inflammatory drug.

Volume-Responsive Azotemia (Hemodynamic Azotemia)

Insufficient delivery of blood to functional kidneys may impair clearance of solutes and uremic toxins. While this condition is typically called prerenal azotemia, different terminologies have been suggested to help clarify the cause of this phenomenon, including hemodynamic azotemia, transient azotemia, and volume-responsive azotemia.[32-36] Any process that decreases renal blood flow, including dehydration, hypovolemia, hypotension, decreased effective circulating volume (i.e., cardiac failure, hepatic cirrhosis, nephrotic syndrome), anesthesia, hypoadrenocorticism, trauma, surgery, shock (hypovolemic, hemorrhagic, hypotensive, septic), heatstroke, hypoalbuminemia, or renal hypoperfusion (i.e., secondary to nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme [ACE] inhibitors) can contribute to this functional disturbance.

Hemodynamic azotemia is characterized by increased BUN and creatinine concentrations in conjunction with a concentrated urine specific gravity. The fractional excretion of sodium (Na) in the urine is usually low, except in Na-avid states such as congestive heart failure, liver failure, and nephrotic syndrome (see ch. 73).[37] Hemodynamic azotemia is characterized by rapid reversal when the underlying condition is corrected (i.e., replacing fluid deficits and maintaining mean arterial blood pressure above 80 mm Hg).[36,38,39] If these hemodynamic factors are not addressed rapidly, the patient may progress to a volume-nonresponsive state. In one study on people, transient azotemia that resolved within one day doubled the odds ratio of mortality compared to no azotemia. Perhaps hemodynamic azotemia should be renamed transient AKI.[33-35] While many pets with poor renal perfusion (e.g., dehydration, hypotension) respond to IV fluids, some do not (e.g., congestive heart failure, sepsis).[36] Although reduced renal blood flow and ischemia have been considered major contributors to the pathogenesis of AKI, renal hypoperfusion alone (80% reduction of renal blood flow for 2 hours) did not induce sustained AKI.[40] Local and systemic inflammatory responses, changes in intrarenal blood flow distribution, microcirculatory dysfunction, and glomerular hemodynamics contribute to renal dysfunction.[41] These factors are not corrected with fluid therapy.

Intrinsic Renal Failure

Contributors

Intrinsic renal failure may follow damage to any section of the kidney: glomeruli, tubules, interstitium, or vessels. Most commonly, intrinsic renal failure follows ischemic or toxic tubular damage (Table 322-2). Ischemia, usually due to hypoperfusion, is the most common cause of intrinsic renal failure in people.[30,42] Together, hemodynamic and intrinsic renal causes account for 70% to 75% of AKI.[6,43] Prolonged obstruction (>1 week) can also lead to intrinsic renal failure.[39] Multiple factors may be present and it may be difficult to determine the relative contribution of each. Specific contributors to intrinsic renal failure from ischemia include progression of hemodynamic azotemia, hypotension, hypovolemia, circulatory collapse, excessive renal vasoconstriction, or renal vascular disease (thrombosis, disseminated intravascular coagulation, or stenosis), extensive cutaneous burns, and transfusion reactions. A variety of infectious diseases can lead to AKI. Bacterial pyelonephritis is usually caused by ascending infection from the lower urinary tract, but infection may be hematogenous in origin (see ch. 327). Most urinary tract infections (UTIs; 74%) are caused by Gram-negative organisms.[44,45] *Escherichia coli* is most common and accounts for 37% to 45% of UTIs while Gram-positive organisms account for 25% to 30%.[44,45] Predisposing conditions for the development of pyelonephritis include bacterial endocarditis, discospondylitis, and pyometra.[44]

TABLE 322-2

Causes of Intrinsic Acute Renal Failure

ISCHEMIC EVENTS	PRIMARY RENAL DISEASES	SECONDARY DISEASES WITH RENAL MANIFESTATION	NEPHROTOXINS
Shock (hypovolemic, hemorrhagic, hypotensive, septic) Decreased cardiac output (congestive heart failure, arrhythmias, cardiac arrest, cardiac tamponade) Deep anesthesia/extensive surgery Trauma Hyperthermia/hypothermia Extensive cutaneous burns Transfusion reaction Renal vessel thrombosis/DIC Hyperviscosity/polycythemia NSAIDs	Infectious (pyelonephritis, leptospirosis, borreliosis) Immune-mediated (acute glomerulonephritis, SLE, renal transplant rejection, vasculitis) Neoplasia (lymphoma)	Infectious (feline infectious peritonitis, babesiosis, leishmaniasis, bacterial endocarditis) Systemic inflammatory response syndrome, sepsis, multiple organ failure, disseminated intravascular coagulopathy Pancreatitis Hepatorenal syndrome Malignant hypertension	Exogenous toxins Drugs Endogenous toxins

DIC, Disseminated intravascular coagulation; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *SLE*, systemic lupus erythematosus.

Leptospirosis

Leptospirosis (see ch. 217) is caused by multiple serovars of *Leptospira interrogans* or by *Leptospira kirschneri* serovar grippotyphosa. It is a filamentous, motile bacterium. Each serovar is maintained by one or more natural hosts. Clinically important serovars and their normal hosts in North America include canicola (dog), icterohaemorrhagiae (rat), grippotyphosa (vole, raccoon, skunk, opossum), pomona (cow, pig, skunk, opossum), hardjo (cow), and bratislava (rat, pig, potentially horse). Host-adapted species do not usually develop disease from the serovar they carry, but infection in an incidental host can cause severe disease. The primary method of transmission is via water contaminated with urine, although urine-contaminated soil, bedding, and food are also routes of exposure. Organisms can penetrate mucous membranes, wet or macerated skin, or intact skin. Exposure to urine, blood, or saliva can also transmit disease. The organism prefers a warm, moist, alkaline environment, and is more likely to be present in stagnant or slow-moving water. An increase in incidence is common following periods of flooding. Peak incidence in dogs is from July to November.[46-50] Adult large-breed male dogs with access to outdoors are more likely to contract leptospirosis, although one recent study found that smaller dogs (<7 kg) had the highest prevalence, perhaps because this group was less often vaccinated.[46-48,51-53] Small intestinal intussusception has been noted in puppies and adult dogs with leptospirosis-induced AKI.[54] Although cats have traditionally been thought to be resistant to leptospirosis, cats with kidney disease were more likely to be seropositive than cats without

kidney disease.[55] A rapidly progressive AKI with nephrotic syndrome has been recognized in dogs with positive serology for *Borrelia burgdorferi.* Despite aggressive therapy, many patients fail to respond.

Nephrotoxins

There is a wide range of nephrotoxic causes of AKI (Table 322-3; see ch. 152-156). The most common causes of nephrotoxicosis in dogs are ethylene glycol, nonsteroidal anti-inflammatory drugs (NSAIDs), cholecalciferol, and aminoglycosides.[56] The most common causes in cats are ethylene glycol, cholecalciferol, and lilies.[56] Increased use of NSAIDs for perioperative pain management may increase the incidence of AKI. Primary acute renal diseases include immune, neoplastic, or degenerative conditions. Systemic diseases may cause AKI by affecting renal hemodynamics or creating a systemic inflammatory response. Systemic diseases associated with AKI include feline infectious peritonitis, pancreatitis, sepsis, systemic inflammatory response syndrome, multiple organ failure, disseminated intravascular coagulation, hemolytic anemia, hyperthermia, heart failure, and hyperviscosity.

TABLE 322-3

Nephrotoxins[56,201]

CLASS OF AGENT	EXAMPLES
Antibacterials	Aminoglycosides, cephalosporins (cephaloridine, cefazolin, cephalothin), penicillins, sulfonamides, fluoroquinolones, tetracyclines, vancomycin, carbapenems, aztreonam, rifampin, nafcillin, polymyxin
Antiprotozoals	Trimethoprim-sulfamethoxazole, sulfadiazine, thiacetarsamide, pentamidine, dapsone
Antifungals	Amphotericin B
Antivirals	Acyclovir, foscarnet
Chemotherapeutics	Cis- or carboplatin, doxorubicin, azathioprine, methotrexate
Immunosuppressives	Cyclosporine, interleukin-2
Nonsteroidal anti-inflammatories	All
Angiotensin-converting enzyme inhibitors	All
Diuretics	All
Radiocontrast agents	
Misc. therapeutics	Allopurinol, cimetidine, apomorphine, Dextran 40, penicillamine, EDTA, streptokinase, methoxyflurane, tricyclic antidepressants, lipid-lowering agents, calcium antagonists, vitamin D_3 analogs (psoriasis medications), lithium, phosphorus-containing urinary acidifiers
Heavy metals	Mercury, uranium, lead, bismuth salts, chromium, arsenic, gold, cadmium, thallium, copper, silver, nickel, antimony
Organic compounds	Ethylene glycol, chloroform, pesticides, herbicides, solvents, carbon tetrachloride and other chlorinated hydrocarbons
Miscellaneous toxins	Gallium nitrate, bisphosphonates, mushrooms, grapes, raisins, snake venom, bee venom, lilies, vitamin D_3–containing rodenticides, sodium fluoride, superphosphate fertilizer
Endogenous toxins	Hemoglobin, myoglobin

Postrenal AKI

Postrenal azotemia is caused by urine leakage within tissue or urinary obstruction. Obstructions may occur in the urethra, both ureters, or one ureter with a solitary functional kidney (see ch. 329-332 and 335). Urinary obstruction decreases renal clearance by a combination of neurohumoral events and increased back-pressure in the kidney. An increase in pressure in the collecting system after obstruction disrupts the balance of

hydrostatic and oncotic pressures and decreases GFR. Azotemia is rapidly reversed by relieving obstruction, although long-standing obstruction may lead to intrinsic renal failure. Ureterolithiasis in cats is increasing in frequency, commonly seen as acute severe uremia in what was an apparently healthy cat.[57] Azotemia secondary to leakage is rapidly reversed by providing drainage of urine out of the body, either a peritoneal catheter for uroabdomen or urinary diversion (i.e., urethral catheter or stent extending above and below a rupture site). Urine is caustic and inflammatory. It can lead to sterile peritonitis (see ch. 143). Urine leakage into the abdomen in a pet with a UTI can lead to a septic peritonitis, a surgical emergency (see ch. 279).

The Four Phases of AKI

AKI begins without clinical signs as an ischemic or nephrotoxic insult and continues until there is a definable change in renal function (increase in BUN or creatinine; decreased urine output). The length of time necessary to see changes is variable, depending on the insult's nature and severity.[58] During this stage, early intervention may prevent progression. The second stage is an extension of the first, with continuing hypoxia and inflammatory responses propagating kidney damage.[59] Cortical structures (proximal tubule and loop of Henle) are predisposed to toxic and ischemic damage because they receive 90% of renal blood flow and are highly metabolic. Hypoxia leads to a decrease in ATP which, in turn, impairs the Na^+K^+ pump with subsequent cellular swelling and death.[60] After tubular cell injury, there is loss of the brush border of apical and basal cell surfaces, likely caused by increase in cytosolic calcium (Ca).[61] The sublethal injury may progress to cell death. Intervention may not be successful in this phase.

Phase 3 is the maintenance phase, generally lasting 1 to 3 weeks.[58] Urine output may be increased or decreased and it resembles the ultrafiltrate, with little modification by tubular processes. In this stage, a critical amount of irreversible damage has occurred. The fourth, recovery phase, is heralded by an increase in urine output that may or may not be accompanied by a decrease in urine Na because the proximal tubules and ascending limbs of the loops of Henle have reductions in the number of Na transporters and aquaporin-2 proteins.[58,62] During this period, extreme Na losses lead to volume depletion that can delay or interrupt renal recovery. Regeneration and repair of the renal tissue may take weeks to months.

Cellular Mechanisms of the Pathophysiology of AKI

See E-Box 322-1.

E-Box 322-1

Cellular Mechanisms of the Pathophysiology of AKI

Although acute intrinsic renal failure is commonly called acute tubular necrosis, histologically, necrosis is not prominent. Acute tubular injury is a better description.[61] The two major mechanisms for a reduction in glomerular filtration rate (GFR) associated with ischemic injury are intrarenal vasoconstriction and tubule dysfunction. Although the kidneys receive a large proportion of cardiac output, most blood is delivered to the cortex. The outer medulla exists in a state of chronic oxygen deprivation normally, despite the high metabolic activity of the S3 segment of the proximal tubule and medullary ascending thick loop of Henle because of the activity of the basolateral Na^+K^+-ATPase pump.[43] Intrarenal vasoconstriction may be because of an imbalance in endothelin and decreased nitric oxide production caused by sublethal endothelial injury. The tubular dysfunction is characterized by tubular obstruction from detached tubule epithelial cells and debris, and by back-leakage of the tubules.[28]

A variety of factors contribute to the cellular mechanisms of damage. Under conditions of oxygen depletion, adenosine triphosphate (ATP) is converted to adenosine monophosphate (AMP), leading to an energy deficit. Prolonged ischemia causes mitochondrial damage and impairs the ability to regenerate ATP. ATP depletion reduces activity of the Na^+K^+-ATPase pump, with resultant disruption of Na^+ and K^+ concentration gradient. This allows cell swelling, which causes tubule obstruction and vascular congestion. Mannitol may alleviate these problems, probably by hemodynamic alterations, osmotic diuresis, and scavenging of hydroxyl ions. The role of increased intracellular free calcium is still uncertain. When the intracellular calcium concentration is abnormally high, which occurs in energy-

depleted states because of lack of activity of intracellular calcium pumps, the mitochondria uptake calcium, leading to mitochondrial swelling and uncoupling of oxidative phosphorylation. Calcium channel blockers, especially diltiazem and verapamil, ameliorate acute kidney injury (AKI) if given to human kidney transplant donor and recipient. The effect is not clearly a result of reducing cytosolic calcium. These drugs improved renal hemodynamics and stabilized cell membranes. Other factors that contribute to renal ischemic damage on a cellular basis are reperfusion injury, oxidant injury, intracellular acidosis, phospholipase activation, and protease activation.[28]

The actin cytoskeleton plays important role in renal cell function and energy depletion causes cytoskeletal injury.[28,61] The normal reabsorption and unidirectional transport of sodium depends on cell polarity. With ATP depletion, disruption of actin cytoskeleton impairs the fence function of junctional complexes which prevent migration of certain cell membrane structures. This allows epithelial cells to lose polarity in proximal tubules, although it is a reversible change. Sodium/potassium pumps remain functional but are redistributed from basolateral to apical membrane. Disruption of the actin core bundle damages the structural integrity of microvilli, causing them to slough and leads to tubular obstruction with fragments of brush border in more distal segments. Normally, the actin cytoskeleton is important in limiting paracellular reabsorption at junction complex. Ischemia increases permeability of tight junctions. The resultant back-leakage of glomerular filtrate decreases GFR (despite only subtle histologic changes).

Disrupted cell-substrate attachment from damage to the cytoskeleton and integrin (molecules that mediate cell-cell adhesion) leads to denudement of cells from basement membrane. This allows back-leakage of glomerular filtrate, loss of tight junction complex function, and frank cell necrosis. Adhesion of detached renal epithelial cells to sublethally injured cells still attached to basement membrane causes aggregation of detached cells within lumen, leading to cast formation and tubule obstruction.

Renal recovery depends on recovery of sublethally injured cells with realignment of polarity, migration of viable cells, removal of necrotic cells and intratubular casts, and regeneration of renal cells. Normally quiescent renal tubule cells enter a growth cycle and proliferate to complete the recovery process.[28,61]

Diagnosis

Clinical Presentation

Animals with AKI usually have <1 week of anorexia, lethargy, nausea or vomiting, diarrhea, polyuria/polydipsia (PU/PD) or oliguria/anuria, and weakness. Animals with exposure to a nephrotoxin may have no other significant historical findings. Lily ingestion by cats may be associated with vomiting of leaves or other plant parts. Acute central nervous system (CNS) signs may be present early in the course of ethylene glycol toxicosis (see ch. 152) in dogs and cats. Physical examination may reveal variable degrees of hydration, generally good body condition, uremic halitosis or oral ulceration with severe uremia, renal pain (specific or nonspecific abdominal pain), renal enlargement, tachycardia, or bradycardia.

Laboratory Evaluation

Initial clinical evaluation generally includes hematology (complete blood count [CBC]), urinalysis, and serum biochemistries. Abnormalities may include azotemia (elevated BUN, creatinine), increased phosphate, metabolic acidosis, hypocalcemia, and/or hypo- or hyperkalemia. Anemia can follow blood loss, if gastrointestinal (GI) bleeding occurs. Urinalysis may reveal isosthenuria or minimally concentrated urine specific gravity (<1.035), proteinuria, and glucosuria. Casts in the urine sediment (see ch. 72) indicate ongoing renal damage, but are fragile and may disintegrate if evaluation is delayed (as with shipping samples to a laboratory). Red blood cells (RBCs), white blood cells, or bacteria may be present. Calcium oxalate crystals may indicate ethylene glycol toxicosis (see ch. 152). Urine culture may reveal a bacterial (rarely fungal) pyelonephritis as the cause of AKI.

Imaging

Radiographs may demonstrate normal to enlarged kidneys and/or nephroliths/ureteroliths. Abdominal ultrasound may show normal or enlarged kidneys (see ch. 88). With ethylene glycol toxicosis, the kidneys may appear hyperechoic (E-Figure 322-2). Perirenal fluid accumulation can be seen with leptospirosis in dogs, lymphoma in cats, and other conditions. Hydronephrosis may indicate obstruction or pyelonephritis (E-

Figure 322-3). Mild renal pelvic dilation may follow aggressive fluid therapy. Mild ureteral dilation extending only minimally past the renal pelvis supports inflammation associated with pyelonephritis. A dilated ureter may be traced to an obstructing stone (frequently difficult to visualize). Intravenous (IV) or antegrade pyelography or computed tomography (CT) may better demarcate a ureteral obstruction (Figure 322-4).

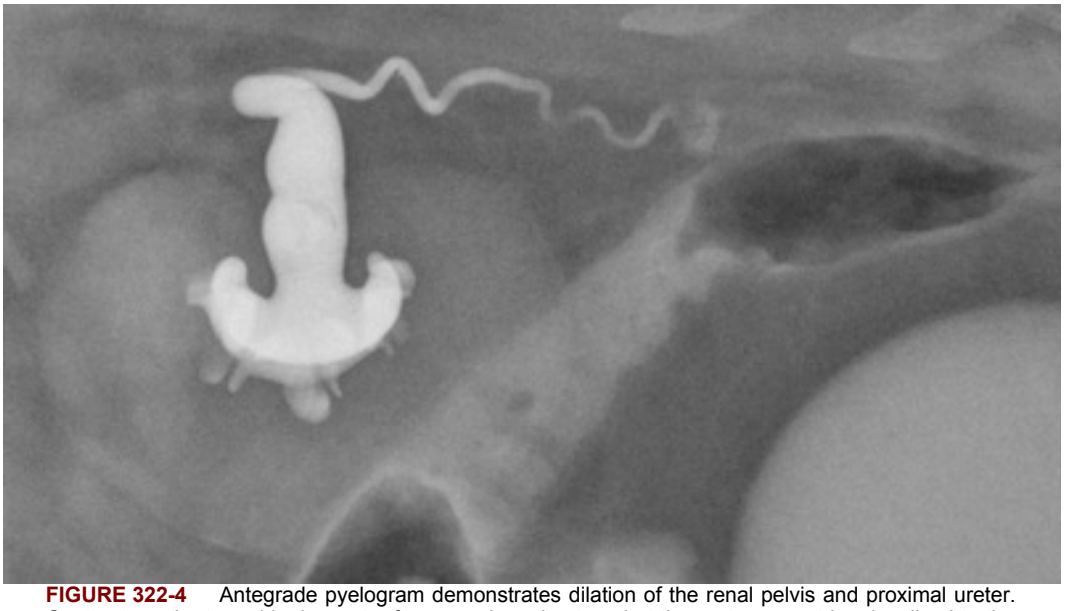

FIGURE 322-4 Antegrade pyelogram demonstrates dilation of the renal pelvis and proximal ureter. Contrast can be traced in the ureter for several centimeters, but the ureter cannot be visualized to the bladder. The bladder contains contrast from the contralateral kidney.

E-FIGURE 322-2 Abdominal sonogram of the right kidney of dog with ethylene glycol intoxication. The renal cortex is hyperechoic in comparison to the liver and the corticomedullary junction is

prominent.

E-FIGURE 322-3 Abdominal sonogram of right kidney of a cat with obstructing ureterolith. Note the marked hydronephrosis. *RT KID*, Right kidney.

Renal Fine Needle Aspirate (FNA) and Biopsy

Fine-Needle Aspirate (FNA)

Renal FNA (see ch. 89 and 93) may be helpful in establishing a diagnosis of renal lymphoma. FNA, using a 22- or 25-gauge needle, with or without ultrasound guidance, can be performed with heavy sedation. Risk of bleeding is low. Renal lymphoma can be confirmed with cytology, but failure to confirm still leaves it as a possibility. FNA cytology cannot definitively diagnose most other conditions.

Biopsy

Percutaneous ultrasound-guided needle biopsy can be performed after the pet is given a quick-acting injectable anesthetic (see ch. 89). The biopsy needle is directed across the greater curvature of the kidney into the cortex, or through the cortex and medulla into the renal pole. The renal pelvis and major vessels must be avoided. Advantages of this procedure include avoidance of a surgical wound and general anesthesia, but disadvantages include small sample size and inability to control bleeding. Laparoscopic needle biopsy (see ch. 91) or a surgical wedge biopsy through a keyhole incision in the flank usually provides sufficient sample for accurate diagnosis. Renal biopsy may identify a specific diagnosis (i.e., ethylene glycol toxicosis, renal lymphoma, leptospirosis), or it may show acute tubular necrosis—a specific pathologic finding but one caused by many conditions. Risk of bleeding when uremia is severe is high because of the thrombocytopathy (see ch. 197).

Specific Tests of Renal Function

Serum Creatinine and GFR

Serum creatinine is probably one of the most commonly used measures of renal function in clinical medicine but is an insensitive marker for mild renal dysfunction (see ch. 62, 321, and 324). Only small changes in serum creatinine occur despite large decreases in GFR when renal function is close to the normal, whereas small changes in GFR lead to large changes in serum creatinine when function is severely compromised (Figure 322-5). In people, equations factoring in different variables (i.e., age, gender, ethnicity) have been developed to estimate GFR from serum creatinine, to avoid the encumbrance of measuring GFR, but similar equations have not been considered useful in veterinary medicine. Normal values for GFR in dogs vary by size and breed.[63,64] There are useful methods of measuring GFR, including plasma clearance (iohexol, exogenous creatinine), urine clearance (endogenous or exogenous creatinine), or renal scintigraphy. GFR is rarely measured in pets with AKI because of risk, cost, or promptness of getting results, or because the GFR is not in a steady state in patients with AKI.

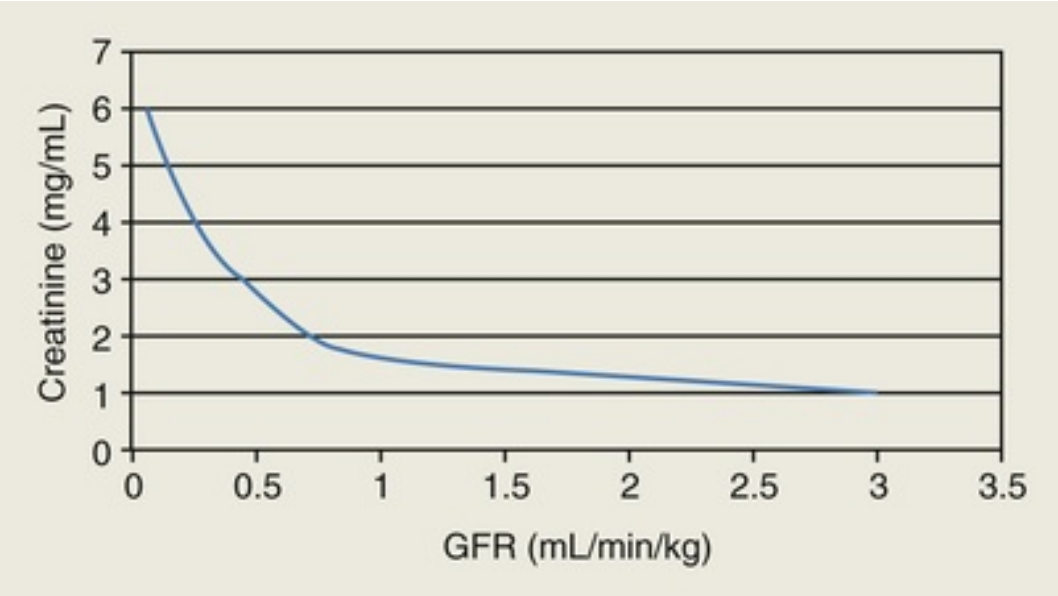

FIGURE 322-5 Glomerular filtration rate (GFR) and serum creatinine concentration.

Fractional Excretion of Sodium (FE_{Na})

FE_{Na} (see ch. 73) can be used to help differentiate hemodynamic from intrinsic renal azotemia and is calculated from the equation:

$$FE_{Na} = [(\text{Urine Na} \times \text{plasma creatinine}) / (\text{plasma Na} \times \text{urine creatinine})] \times 100$$

With hemodynamic azotemia and volume depletion, the kidneys conserve Na effectively, resulting in a fractional excretion <1%. With intrinsic renal damage, the FE_{Na} will be higher. Results are difficult to evaluate with concurrent diseases that may impair urine concentrating ability, or diuretic use. Fractional reabsorption of urea has been evaluated to help distinguish hemodynamic from intrinsic renal azotemia but lacks specificity.[65,66]

Biomarkers

Biomarkers of renal function more sensitive than creatinine are being sought.[67] Ideally, a panel of biomarkers would be able to detect kidney dysfunction much earlier (when interventions are more likely to be effective), distinguish acute from chronic disease, give some indication of the duration and severity, and be prognostic.

Cystatin C correlates to GFR better than serum creatinine in dogs, and will probably rise before creatinine in early renal disease.[68] However, cystatin C has not yet been evaluated in dogs with AKI. Gamma-glutamyl transpeptidase (GGT) and N-acetyl-beta-D-glucosaminidase (NAG) are urine biomarkers of tubular (or interstitial) damage and are elevated in early kidney disease (see ch. 321).[69] Neutrophil gelatinase-associated lipocalin increases before creatinine in AKI and seems useful in differentiating acute from chronic kidney disease (CKD).[70-73] Fibroblast growth factor 23 and symmetric dimethylarginine (SDMA) are also being evaluated as early markers of renal disease (see ch. 324).

Tests for Specific Diseases

Specific diagnostic tests are available for certain causes of AKI. Rapid ethylene glycol testing may be performed with a commercially available in-house test kit (EGT Test Kit, PRN Pharmacal, Pensacola, FL; see ch. 152). False-positive results are possible if drugs containing propylene glycol (e.g., etomidate, diazepam, activated charcoal) have been administered. False-negative results are possible with cats because of the lower limit of detection of test kit (50 mg/dL). Determination of blood concentrations of certain drugs is available to determine if a toxic concentration is present and to monitor response to therapy. Leptospirosis (see ch. 217), Lyme disease (see ch. 211), Rocky Mountain spotted fever (*Rickettsia rickettsii* infection; see ch. 218) can cause oliguric renal failure. Signs of vasculitis, polyarthritis, meningitis, and mild thrombocytopenia are likely as AKI develops. *Ehrlichia canis* can produce a similar spectrum of clinical signs, although renal lesions are more likely to be glomerular damage with proteinuria rather than AKI.

Risk Factors for AKI

Hospital Acquired

AKI developing prior to veterinary examination is generally owing to a single cause (i.e., ingestion of nephrotoxin by previously healthy pet). Multiple risk factors increase risk of AKI. In pets with preexisting risk factors, careful attention to avoiding or minimizing other risks is prudent (Box 322-2). In a retrospective study of 29 dogs with hospital-acquired AKI, 72% were exposed to a nephrotoxin, 69% were >7 years of age, 41% had chronic heart disease (see ch. 357), 35% had preexisting renal disease, 31% had neoplasia, 28% had fever, and 14% had undergone anesthesia.[22] This study did not include data on hydration status, so the contribution of hemodynamic effects cannot be determined. Volume depletion is a significant predisposing factor for developing hospital-acquired AKI.[1,37] Volume depletion exacerbates renal hypoperfusion and increases risk of postoperative AKI.[74] Because the three major physiologic determinants of renal blood flow are cardiac output, intravascular volume, and renal perfusion pressure, attention to all are necessary, although AKI can develop even if all of these parameters are normal.[75,76] If hypotension is present and the pet is euvolemic, pressor agents may be needed, but there is risk of their causing intrarenal vasoconstriction.[1,77]

Box 322-2

Risk Factors for Hospital-Acquired AKI[1,22,60,199]

Clinical Conditions

- Hypoperfusion
  - Volume depletion
  - Hypoalbuminemia or decreased COP
  - Decreased cardiac output
  - Systemic hypotension
  - Increased blood viscosity
- Electrolyte abnormalities
- Acidosis
- Systemic hypertension
- Fever
- Sepsis
- Anesthesia

Surgery
Shock
Multiple organ failure
Gastric torsion
Nephrotoxic drugs, especially:
Radiocontrast media (potentiated by hyponatremia)
NSAIDs (potentiated by anesthesia, sodium or volume depletion, sepsis, CHF, nephrotic syndrome, hepatic disease)
Nephrotoxic drug combinations (aminoglycosides + furosemide, ACEI + diuretic)

Preexisting Diseases

Renal insufficiency
Pancreatitis
Hepatic insufficiency
Diabetes mellitus
Cardiovascular disease
Multiple myeloma
Trauma
Extensive burns
Increasing age
Vasculitis
Fever
Neoplasia

ACEI, Angiotensin-converting enzyme inhibitor; *CHF,* congestive heart failure; *COP,* colloid osmotic pressure; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

Sepsis (see ch. 132)

In people with sepsis, norepinephrine was shown to be more efficacious at improving blood pressure, causing diuresis, and lowering mortality when compared with high-dose dopamine.[77,78] Arginine vasopressin, a potent pressor agent, is recommended for patients who are hypotensive despite norepinephrine.[77] Vasopressin causes more efferent arteriolar constriction whereas norepinephrine has more effect on the afferent arteriole. Vasopressin was more effective in reducing progression of AKI when compared with norepinephrine in patients with septic shock.[79] Maintenance of adequate cardiac output and prevention of peripheral vasoconstriction has been shown to decrease risk of AKI.[80] In high-risk patients, avoid use of any potentially nephrotoxic drugs. Anesthesia protocols should focus on avoiding hypotension and maintaining normal blood volume and pressure. Electrolyte disorders have been shown to increase risk of AKI. Low Na potentiates radiocontrast-media–induced AKI in dogs. Hypokalemia, metabolic acidosis, hypocalcemia, and hypomagnesemia enhance gentamicin's nephrotoxicity.[1] Strict control of hyperglycemia with insulin therapy decreases AKI in critically ill nondiabetic people.[75,81]

Aminoglycosides

Aminoglycosides are commonly associated with nephrotoxicosis in dogs and cats because they are not metabolized, are a low molecular weight, and are water soluble (see ch. 161). These factors lead to their almost exclusive excretion in urine.[82] They easily ionize to cationic complexes that bind to anionic sites on epithelial cells of the proximal tubule, are then internalized by pinocytosis, which leads to renal cortical concentrations 10 times that of the plasma and can cause renal tubular damage.[82] Factors that increase the risk of toxicosis include prolonged use (>5 days), elevated trough levels (>2 mcg/mL for gentamicin and tobramycin, >5 mcg/mL for amikacin), preexisting renal disease, dehydration, hypokalemia, hypocalcemia, hypomagnesemia, metabolic acidosis, age, concurrent nephrotoxic drug administration, diuretic administration, and antiprostaglandin therapy.[1,83]

Aminoglycoside toxicosis can be reduced by less frequent dosing.[1] Efficacy of aminoglycosides is determined by peak concentration (6 to 10 mcg/mL for gentamicin, 25 to 30 mcg/mL for amikacin), but toxicosis is closely correlated to trough concentrations.[83] Dosing once daily instead of three times daily can

achieve therapeutic blood levels, result in lower but still effective trough levels, and decrease the incidence of AKI from 24% to 5%.[74,83-85] Daily monitoring of fresh urine sediments for protein or casts can give an indication of renal damage prior to the onset of azotemia (see ch. 72). If a pet is azotemic before therapy, an alternative drug regime should be chosen or the dosing interval prolonged by a factor related to the serum creatinine (i.e., if serum creatinine is 4 mg/dL, increase interval from 8 hours ×4 to 32 hours), if the drug must be used.[82]

Other Antibiotics

Giving expired tetracyclines can cause a Fanconi-like syndrome (glucosuria, aminoaciduria, hyperphosphatemia) due to accumulation of metabolites in mitochondria that interfere with proximal tubular oxidative enzymes.[2] Penicillins are not directly nephrotoxic, but they may induce a hypersensitivity reaction because the penicillin derivative may act as a hapten.[83] Sulfonamides act by causing intratubular crystals, exacerbated by renal damage, lower urine output, and higher urine acidity.[83]

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs inhibit the cyclooxygenase (COX) enzyme, which acts on arachidonic acid to form prostaglandins (see ch. 164). NSAIDs have a low potential for nephrotoxicosis in healthy postoperative patients.[84,86] Renal function is more dependent on prostaglandin synthesis in situations when blood flow may be decreased, such as during anesthesia, surgery, Na or volume depletion, hypotension, sepsis, congestive heart failure, nephrotic syndrome, hepatic disease, preexisting renal disease, old age, or concomitant drug therapy (especially other NSAIDs). This is because the predominant prostaglandin in the kidneys causes afferent arteriolar dilation, which maintains renal blood flow and counteracts the effects of systemic vasoconstriction.[87] By blocking prostaglandin production, NSAIDs carry a higher risk for toxicosis in these settings.[1,87]

The two isoforms of cyclooxygenase are COX-1 and COX-2. COX-1 isoforms are constitutively expressed throughout the body and are responsible for generating prostaglandins involved in routine physiologic functions. COX-2 enzymes are rapidly induced at sites of inflammation. Selective COX-2 inhibitors should have good clinical effect with fewer adverse GI effects than nonselective COX inhibitors. However, COX-2 can be constitutively expressed in kidneys, and expression can be upregulated by a number of situations that lead to decreased actual or effective circulating volume.[88] COX-2 selective NSAIDs appear to be no safer for kidneys than nonselective NSAIDs.[86,88] Perioperative NSAID use in cats has been associated with AKI even when doses were within the recommended range.[89] The prognosis for NSAID toxicosis is favorable if recognized early.[56,87]

Nephrotoxic substances should be avoided if possible in patients with risk factors for AKI.[80] Diuretics should be avoided if hemodynamic azotemia is present.[80] Less nephrotoxic drugs should be used preferentially, such as lipid emulsified or liposomal amphotericin B instead of regular amphotericin B, or carboplatin instead of cisplatin.[84,90-96] If the nephrotoxic drug must be given, modest volume expansion may decrease nephrotoxicosis in select cases, including the use of radiocontrast agents, amphotericin, cisplatin, and drugs that induce crystalluria.[84,97-99] Volume expansion and natriuresis help prevent AKI in some cases.[1]

Monitoring

Overview and Hydration

Any critically ill pet is at risk for developing AKI and appropriate parameters should be monitored. Those with additional specific risk factors may require specific monitoring. Monitoring may allow for optimization of hemodynamic parameters, surveillance for common uremic complications, and evaluating response to therapy.[100] Frequency of monitoring depends on severity of disease.

Monitoring hydration status is a key ongoing process to appropriate fluid therapy plans (see ch. 129). Readily available accurate tools to assess blood volume are not yet feasible in veterinary practice, but blood volume can be measured using indicator dilution techniques, radioactive tracers, bioimpedance spectroscopy, or other methods. Despite a lack of precise objective data, there are many ways to estimate hydration. Diminished skin turgor may indicate dehydration (5% of body weight or greater), recent weight loss, or loss

of elasticity because of aging. Dry mucous membranes or sunken eyes also suggest dehydration, although uremic pets may have xerostomia. Overhydration may cause moist mucous membranes, increased skin elasticity (heavy or gelatinous), shivering, nausea, vomiting, restlessness, serous nasal discharge, chemosis, tachypnea, cough, dyspnea, pulmonary crackles and edema, pleural effusion, ascites, diarrhea, or subcutaneous (SC) edema (especially intermandibular space and hock joints).[39,101] However, pets with low colloid osmotic pressure (i.e., hypoalbuminemia) or alterations in vascular permeability may appear overhydrated based on skin turgor assessment, yet have intravascular volume depletion. Body weight should be measured three to four times a day on the same scale to monitor fluid balance. Changes in body weight during hospitalization primarily reflect changes in body water. A sick animal may lose up to 0.5% to 1% body weight per day because of anorexia; changes in excess of this amount are caused by changes in fluid status.[102]

Blood Pressure, Packed Cell Volume, Total Solids, Central Venous Pressure

Since either hypertension or hypotension can be detrimental to renal function, blood pressure monitoring may be critical (see ch. 157-159). Oscillometric methods or Doppler technology are commonly used indirect measures (see ch. 99). Direct measurement is most accurate for assessing blood pressure, but not often used because it involves arterial cannulation. Blood pressure <80 mm Hg is insufficient for adequate renal perfusion and should be immediately addressed to avoid further renal damage.[39] An increase in blood pressure may indicate a gain of fluid; conversely, a decrease in blood pressure may indicate a net fluid loss. Because of the high percentage of patients with hypertension (80% of dogs with severe AKI, 20% to 30% of dogs and cats with CKD), trends in pressures rather than absolute values are of more utility in assessing changes in hydration status.[39,103-105] Similarly, trends in packed cell volume and total solids may reflect changes in volume in the absence of bleeding or blood transfusion. Since each parameter is impacted by aspects beyond hydration status, these factors must be viewed in aggregate. Central venous pressure measurement via a central IV catheter (see ch. 76) has been advocated to help determine volume status, but does not predict volume-responsiveness since there are myriad factors that impact it.[106,107]

Cardiac Monitoring, Acid-Base, Urine Output

Cardiac output monitoring requires a pulmonary artery catheter, special equipment, and is rarely used.[108] Electrocardiogram (ECG) is the only tool which allows recognition of arrhythmias that can be life threatening due to decreasing cardiac output (see ch. 103). ECG can be used to aid in recognizing conduction disturbances caused by hyperkalemia (see ch. 248). Echocardiography may be used to assess myocardial performance and can provide information about volume status by evaluating chamber volume (see ch. 104). Venous blood gas analysis is useful for determining acid-base status (see ch. 75 and 128). Electrolyte abnormalities are both a risk factor for and an effect of AKI. Therefore, regular electrolyte monitoring is advised. BUN and creatinine concentrations are easily measured, but are insensitive markers of early renal dysfunction, because the GFR must be less than 75% of normal for these values to be elevated.

The importance of monitoring urine output and composition cannot be overemphasized. Urine production in a healthy animal is about 1 to 2 mL/kg/h and a decrease may be an appropriate renal response to hypovolemia or a pathologic change in renal function. AKI may also cause polyuria (>2 mL/kg/h). Methods for determining urine volume include placing an indwelling urinary catheter with a closed collection system, collection of naturally voided urine, metabolic cage, or weighing cage bedding/litter pans (1 mL of urine = 1 g; see ch. 105 and 106). An indwelling catheter is most precise, although technical issues such as urine leakage around the catheter or inadvertent disconnection may cause incorrect measurements. Risk of an iatrogenic UTI can be decreased by careful attention to catheter hygiene, including cleaning the external portions of the catheter with antiseptic multiple times daily and changing the collection bag and tubing daily.[109] Complete collection of voided urine is difficult because of lack of pet cooperation or incontinence. An accurate scale is necessary to measure small volumes of urine in cats and small dogs, but weighing cage bedding or litter pans before and after use may provide an adequate assessment. Fluid losses from vomiting and diarrhea are usually estimated. Other losses (draining ascites or pleural effusion) or nasogastric tube suctioning should be measured. When renal damage has occurred, urine casts may appear before the urea or creatinine levels increase. Therefore, urine sediment should be evaluated daily in animals receiving aminoglycosides or other potential nephrotoxic medications (see ch. 72).

Prevention

Prevention of AKI involves avoiding or ameliorating risk factors while using renoprotective drugs. Radiocontrast agents cause vasoconstriction of the renal circulation.[80] The incidence of contrast-induced nephrotoxicosis is difficult to estimate, but can be as high as 30% in people with preexisting risk factors but less than 10% in people with no risk factors.[110,111] Reports of contrast-induced AKI in dogs are rare.[112] Studies evaluating the incidence of adverse effects of iodinated radiographic contrast agents in dogs and cats did not find postcontrast renal failure, but the small number of pets evaluated and delay between contrast administration and postcontrast evaluation of BUN and creatinine (mean 38 to 60 days for dogs, 3 to 105 days for cats) impair accurate assessment.[113,114] Of 3 cats evaluated within 3 days of receiving an iodinated contrast agent (nonionic), 2 had postcontrast increases in BUN and creatinine, but both were being evaluated for ureteral obstruction and were azotemic prior to contrast administration.[114] Saline diuresis prior to administration decreases toxicity.[80] Recommendations for preventing radiocontrast-induced AKI in acutely ill patients include aggressive, rapid volume expansion prior to performing the radiographic study, avoid mannitol, avoid furosemide, use a low dose of contrast or a nonionic agent.[74,84] Although use of acetylcysteine has not been proven effective, because of its low cost and few side effects, its use could be considered.[74,115]

There is no evidence that prophylactic treatment with furosemide protects against hospital-acquired AKI.[116] Studies have shown deleterious effects of prophylactic loop diuretic administration in patients predisposed to AKI, despite theoretical reasons to use furosemide to prevent AKI.[77,117] Calcium channel blockers have been used to prevent AKI in people receiving transplants, but they do not prevent AKI in the nontransplant setting.[116,118] Fenoldopam, a selective dopaminergic 1 (DA-1) receptor agonist, may dilate renal arteries, inhibit Na^+/K^+-ATPase activity, inhibit angiotensin II, and inhibit antidiuretic hormone.[119] It does not have DA-2, alpha, or beta-adrenergic activity, so it does not cause vasoconstriction, tachycardia, or arrhythmias sometimes seen with dopamine.[58,116] Fenoldopam maintained renal blood flow in an experimental model of hypovolemia in dogs, suggesting that it may have a renoprotective effect in acute ischemic injury.[120,121] In a study of healthy cats, diuretic effect and transiently increased GFR were noted 4 to 6 hours after a 2-hour infusion of fenoldopam. One of 6 cats had a decrease in GFR 2 hours after the infusion.[119] Various other therapeutic agents have been investigated for potential use in AKI, including atrial natriuretic peptide, theophylline, insulin-like growth factors, antibodies to adhesion molecules, scavengers of oxygen free radicals, amino acid infusion, and prostaglandins. None has been proved to be safe or effective for people.[43] In an experimental model of ischemic AKI in rats, a single dose of erythropoietin or darbepoetin administered 6 hours after the ischemic insult significantly inhibited subsequent apoptotic cell death, enhanced tubular epithelial regeneration, minimized the severity of renal dysfunction, and promoted more rapid renal functional recovery, but results of clinical trials are not available.[122]

Treatment

Goals

Treatment goals for the patient with AKI are aimed at limiting further renal damage and enhancing cellular recovery. Strategies for improving renal oxygen delivery, reducing metabolic demand, and maintaining urine output used for preventing AKI are equally important in treatment. Limiting cytotoxic and inflammatory responses and promoting regeneration of tubular cells is desirable.[116] Treatment is most successful during the induction and extension phases, and success diminishes once the maintenance and later phases have been reached. Therefore, prompt recognition of the disease process and institution of specific therapy are important.

Fluid Treatment Strategies

Source of Losses

The most effective therapy of AKI is careful management of fluid balance, which involves thoughtful assessment of hydration, a fluid treatment plan personalized for the specific patient, and repeated and frequent reassessment of fluid and electrolyte balance, with appropriate changes in the treatment plan in response to changes in patient status (see ch. 129). Normal fluid losses consist of insensible and sensible

losses. Insensible losses are not consciously perceived, such as water lost via respiration, stool, or sweating. Sweating is negligible in dogs and cats. There is variation in respiratory fluid loss in dogs (normal: ≈22 mL/kg/day) since they may lose considerable amounts via panting. The major source of sensible fluid loss is urine; others include vomiting, diarrhea, body cavity drainage, burns, etc. In healthy animals, losses are replaced by consumption of water and food, but the ill do not typically consume adequate amounts. With renal disease, urine volume is frequently high, low, or inappropriate.

Traditional Fluid Therapy

Traditionally, one administers IV fluids to correct dehydration and then uses aggressive rates of fluid administration to force diuresis. If azotemia does not resolve, one then increases the fluid rate. However, evidence now implies that this approach may actually worsen kidney function and impair their ability to recover. In a study of dogs undergoing anesthesia and surgery for cranial cruciate repair being given 10 mL/kg/h lactated Ringer's solution (LRS), GFR and urine output did not increase, but body weight increased from a mean of 32.6 kg to a mean of 33.7 kg. These dogs were systemically normal and although some received carprofen, it did not have an effect on renal and fluid parameters.[123] After administration of crystalloid fluid, 80% moves into the interstitium, causing interstitial edema, which leads to impaired oxygen and metabolite diffusion, and may worsen renal and overall outcome.[124,125] The kidneys are physiologically adapted to conserve Na and fluid rather than excrete excesses.[125] In healthy patients, it may take days for that fluid to be excreted.[124,126]

Revised Fluid Therapy Approach

Fluid therapy may be best considered as a three-step process: (1) acute resuscitation to restore effective intravascular volume, organ perfusion and tissue oxygenation, causing a positive fluid balance; (2) maintenance of intravascular volume homeostasis without fluid accumulation; and (3) fluid removal during convalescence to remove hemodynamically unnecessary volume.[127]

Hypovolemic Shock

Some pets with AKI present in hypovolemic shock (see ch. 127), with signs of dull mentation, hypotension (systolic blood pressure <80 mm Hg; see ch. 99 and 159), poor perfusion (cold extremities, pale/grey mucous membranes with slow capillary refill time), hypothermia, or tachycardia.[128] Immediate therapy is necessary to prevent further organ damage with crystalloids given at about 60 to 90 mL/kg for dogs and 45 to 60 mL/kg for cats (see ch. 129). About 25% of that volume is given over 5 to 15 minutes.[129] If hemodynamic parameters do not improve sufficiently with this first dose, a second and equal dose should be given. Aggressive fluid efforts are continued until the patient is hemodynamically sound and has adequate tissue perfusion. In dogs with shock resuscitated to traditional endpoints (heart rate, mean arterial pressure, urine output), 38% had persistent decreased central venous oxygen saturation, suggesting they had occult shock, despite seemingly normal perfusion parameters.[130]

Adequate resuscitation as assessed by achievement of identifiable goals decreases renal morbidity as compared with using standard resuscitation doses in people.[100] Perfusion parameters are targeted to be corrected within 6 hours of goal-directed therapy. With early and aggressive therapy to measurable physiologic endpoints, the volume of fluid administered during this resuscitation phase may be high, but less is given subsequently, such that the total volume administered during hospitalization is the same with goal-directed therapy compared to conventional therapy, but mortality and incidence of AKI are less with goal-directed therapy.[131]

Rehydration

The volume to fluids that need to be administered to correct dehydration is calculated from a formula: body weight (in kg) × estimated % dehydration* = fluid deficit in L. Because dehydration <5% cannot be detected clinically, pets who appear hydrated (but not overhydrated) should receive about 5% of their body weight in fluids over 2 to 4 hours to rapidly reverse any ongoing renal damage from poor perfusion and to quickly assess urine output. Fluids can be administered over a longer time frame if cardiovascular compromise prohibits rapid fluid administration. If a fluid bolus was used for initial resuscitation, that volume is subtracted from the dehydration deficit. Maintaining adequate renal perfusion, by correcting dehydration/volume depletion and restoring blood pressure and cardiac output, are essential.

"Maintenance" Fluid Therapy

Overview

Commonly estimated to be about 66 mL/kg/day, "maintenance" fluid dose presumes "normal" urine output without excessive losses (i.e., vomiting, diarrhea). Urine output in a pet with AKI may or may not be "normal." Even if the urine output is normal (0.5 to 2 mL/kg/h), damaged kidneys may not be able to alter the volume to excrete a fluid load. These patients have relative oliguria. Giving IV fluids in excess of "maintenance" needs has long been advocated as a method of forced diuresis, to promote toxin removal and flush out tubular casts. While of value in certain situations (e.g., radiocontrast nephropathy), this approach is now considered suboptimal.[125] Not only is aggressive fluid therapy not helpful, volume overload has repeatedly been shown to worsen outcome because it does not increase renal oxygen delivery despite improved cardiac output and renal blood flow.[41,132,133] Maintaining optimal hydration while assiduously avoiding overhydration or underhydration is one of the most important and most difficult challenges in treating AKI.

Ins and Outs

The "Ins-and-Outs" method of fluid administration helps maintain an appropriate fluid balance by matching the volume administered to the volume excreted. It is useful for all AKI settings, including anuria/oliguria, relative oliguria, and PU AKI. This method of determining fluid rate does not account for dehydration and should only be used after rehydration is complete. The three components of volume calculation are insensible losses (fluid lost via respiration and normal stool; 22 mL/kg/day), urine losses (calculated by actual measurement), and ongoing losses (i.e., estimated from vomiting, diarrhea, body cavity drainage). If a fluid pump is not available, fluid dosage can be determined by calculating daily insensible fluid needs and dividing by administration interval (i.e., if adjusting fluid rate 4 times a day, dividing daily fluid need by 4); to this volume, the amount of urine produced in the previous 6 hours (or appropriate interval), and a volume estimate of other losses should be added. If a fluid pump is available, daily insensible fluid needs can be calculated and divided by 24 to calculate an hourly rate. To this, the hourly volume of urine output over the previous monitoring interval should be added, plus an estimate of ongoing losses (Box 322-3). Other administered fluids that should be included in calculations include medications, transfusions, and nutrition. Anuric patients should receive fluids to replace insensible losses only. If the patient is overhydrated, the insensible loss should be withheld. Overhydration in an anuric patient or inability to induce diuresis in an oliguric or anuric patient is an indication for dialysis, which is the only other effective therapeutic option (see below and ch. 110).

Box 322-3

Sample Calculations for Ins-and-Outs Fluid Therapy

Sample Calculations without Fluid Pump

4.5 kg cat × 22 mL/kg/day = 100 mL/day
100 mL/day ÷ 4 = 25 mL per 6 hours
30 mL urine output over previous 6 hours
Vomiting about 3 times a day (≈8 mL each time) = 6 mL over 6 hours
25 + 30 + 6 mL = 61 mL to administer over next 6 hours

Sample Calculations with Fluid Pump

4.5 kg × 22 mL/kg/day = 100 mL/day
100 mL/day ÷ 24 = 4 mL/h
30 mL urine output over previous 6 hours ÷ 6 = 5 mL/h
Vomiting about 3 times a day (≈8 mL each time) = 1 mL/h
4 + 5 + 1 = 10 mL/h

When the patient has stabilized and is entering a recovery phase, any accumulated fluid should gradually be removed by decreasing the volume administered to a volume less than that being excreted. If excessive fluid has accumulated, diuretics may hasten fluid removal. Diuretics are ineffective in preventing or treating AKI, and although one study found lower mortality in patients with AKI receiving higher furosemide doses,

this effect was not significant when controlling for fluid balance.[116,117,134-137] In other words, the benefit of furosemide was in controlling the fluid overload associated with worse outcomes.[137] In some pets, profound PU develops during recovery that can lead to dehydration and worsening renal perfusion if the volume of fluids given is inadequate. In those situations, IV fluid therapy is continued until the patient can maintain adequate hydration with enteral (via voluntary intake or feeding tube; see ch. 82) and SC fluids. It can take weeks to regain sufficient urine concentrating ability to wean off IV fluids in more extreme cases.

Fluid Type

Choices

Of the various types of fluid available, a balanced polyionic solution (i.e., LRS, Plasmalyte, Normosol) is appropriate in most situations (see ch. 129). Fluids with chloride concentrations approximating plasma (i.e., LRS, Plasmalyte, at 98-111 mEq/L) are associated with lower incidence of AKI compared to higher chloride concentration fluids (i.e., 0.9% saline, 150 mEq/L), although there was no effect on mortality.[138-140] As a higher concentration of chloride is presented to the distal tubule, the macula densa will induce renal afferent arteriolar vasoconstriction.[141] Physiologic saline (0.9% NaCl) is indicated if hyponatremia is present, but fluids lower in Na are more appropriate if high Na is present (i.e., 0.45% NaCl with 2.5% dextrose, 1/2-strength LRS with 2.5% dextrose). Dextrose 5% in water (D5W) is rarely appropriate as the sole fluid choice, but may be combined with LRS or 0.9% saline to make 1/2- or 3/4-strength Na solutions (25 mL LRS + 25 mL D5W = 50 mL 1/2-strength LRS + 2.5% dextrose).

Colloidal solutions (i.e., hydroxyethyl starch) have been recommended with persistent hypotension or if hypoalbuminemia is present (e.g., protein-losing nephropathy, diseases associated with vasculitis, or severe GI losses or bleeding), at a dosage of 20 mL/kg/day. Despite early reports that colloids could expand the vascular volume with lower doses than crystalloids, recent reports refute this finding. In a large study in human intensive care settings, the hetastarch group received less fluid than the saline group, and had a lower positive fluid balance (921 ± 1069 mL vs. 982 ± 1161 mL, p = 0.03), but the fluid sparing effect was less than predicted.[142,143] Colloids rapidly escape the vascular compartment, as do crystalloids.[132,144] Hetastarch is associated with a higher risk of AKI and mortality in critically ill patients; licensing has been restricted in Europe and the U.S. Food and Drug Administration (FDA) has approved a boxed warning about use in septic patients.[145-149] An alternative to synthetic colloids is human albumin, but this product carries risk of anaphylaxis (see ch. 130).[150,151]

Oliguria and Anuria

Definitions

A decrease in urine production may be due to hemodynamic, intrinsic renal, or postrenal causes. An appropriate renal response to inadequate renal perfusion from hypovolemia or hypotension includes fluid retention with a concomitant decrease in urine volume. Renal perfusion should be optimized before determining whether oliguria is pathologic or physiologic. A volume of fluid equal to 3% to 5% of body weight should be administered to patients that appear normally hydrated because dehydration of less than 5% cannot be detected clinically. In pets that are clearly volume overloaded, this fluid administration is not necessary. Healthy kidneys can autoregulate renal blood flow at perfusion pressures between 80 to 180 mm Hg, but perfusion may be more linear in damaged kidneys.[38,102] The mean arterial pressure should be maintained above 60 to 80 mm Hg, or the systolic pressure above 80 to 100 mm Hg when measured by Doppler technology (see ch. 99). Apparent anuria can be caused by obstruction of the urinary tract or leakage into the peritoneal, retroperitoneal, or SC tissues and must be excluded before determining that a lack of urine is a result of intrinsic renal damage. Anuria is defined as essentially no urine production.[39] Various values have been used to define oliguria, including <0.25 mL/kg/h, <0.5 mL/kg/h, and <1 to 2 mL/kg/h.[39] In a hydrated, well-perfused pet, <1.0 mL/kg/h can be considered absolute oliguria and urine volumes of 1 to 2 mL/kg/h in a pet on aggressive fluid therapy is considered relative oliguria.[39,102] Urine volume above 2 mL/kg/h is considered PU.

Assessing Diuretic Action

There is no evidence that diuretics improve the outcome of AKI. The ability to respond to diuretics may be a marker of less severe renal injury and a better prognosis. In people, increased urine output with diuretic use

delays referral for dialysis, perhaps inappropriately.[135] However, in veterinary medicine, where dialysis is not as readily available to control fluid status, an increase in urine output from diuretic use may allow an increase in the volume of other medications or nutrition, and may be justified even without improvement in renal function. Volume overload has been associated with worse outcome.[152-157]

Mannitol/Glucose

Mannitol is an osmotic diuretic that causes extracellular volume expansion and inhibits renal Na reabsorption by inhibiting renin. Mannitol also increases tubular flow, which may relieve intratubular obstructions from casts and debris. Mannitol decreases vascular resistance and cellular swelling; increases renal blood flow, GFR, and solute excretion; protects from vascular congestion and RBC aggregation; scavenges free radicals; induces intrarenal prostaglandin production and vasodilation; and induces atrial natriuretic peptide release.[39,58,102,158] Mannitol may blunt the influx of Ca into mitochondria of sublethally injured renal cells, thus decreasing the risk of injury progressing to lethal damage. Despite the theoretical advantages, no randomized studies have shown a better clinical response with the use of mannitol and volume expansion than with volume expansion alone in people or healthy cats.[58,159] Mannitol should be administered as a slow IV bolus of 0.25 to 1 g/kg. If urine production increases, it may be administered as a constant rate infusion (CRI) of 1 to 2 mg/kg/min IV or 0.25 to 0.5 g/kg q 4-6 h (see ch. 78).[39] Doses in excess of 2 to 4 g/kg/day may cause AKI. Mannitol should not be given to patients that are dehydrated, because it will further exacerbate intracellular dehydration. Conversely, it is also contraindicated if overhydration is present, and may worsen pulmonary edema. Hypertonic dextrose can be used as an osmotic diuretic, if mannitol is not available. The total daily dose of 22 to 66 mL kg of a 20% dextrose solution should cause hyperglycemia and glucosuria.[160]

Loop Diuretics

Loop diuretics (furosemide) can increase urine flow without increasing GFR.[58,77,84,159,161] Despite the increase in urine output, loop diuretics do not improve outcome, suggesting that those who respond have less severe renal failure, resulting in a better outcome for recovery independent of drug therapy.[58,77,84,161,162] For example, people who could be converted from oliguric to nonoliguric renal failure had better APACHE scores and higher creatinine clearance prior to treatment, suggesting that they had less severe renal injury.[162] Because of the perception that there is a low complication rate associated with the loop diuretics, they are often used despite lack of proven benefit. Loop diuretics inhibit the $Na^{+2}Cl^{-}K^{+}$ pump in the luminal cell membrane of the loop of Henle, decreasing transcellular Na transport. Basal Na^{+}/K^{+}-ATPase activity becomes unnecessary and medullary oxygen consumption decreases, which may protect the kidney from further injury.[162,163] The amount of structural damage to the thick ascending limb of the loop of Henle decreases after furosemide administration when evaluated in isolated perfused kidneys.[163] Loop diuretics also have renal vasodilatory effects.[116]

Despite these theoretical reasons to use loop diuretics, one retrospective study in people showed an increased risk of death or failure of renal recovery in a furosemide treatment group. Potential explanations included detrimental drug effects, delay in recognizing severity of renal failure with subsequent delay in starting dialysis, or preferential use of loop diuretics in patients with a more severe course of disease.[77,135] Loop diuretics may make fluid management easier in people, without changing the outcome.[162] Established indications for use of furosemide in veterinary medicine include treatment of overhydration or hyperkalemia.[39] Furosemide should not be given patients with aminoglycoside-induced AKI.[102]

An increase in urine output should be apparent 20 to 60 minutes after an IV furosemide dose of 2 to 6 mg/kg. Ototoxicosis has been reported at high doses in people, and doses of 10 to 50 mg/kg may cause adverse effects in animals (apathy and anorexia in cats; hypotension, apathy, ataxia in dogs).[102] If there is no response to high doses, therapy should be discontinued. If a response does occur, this dose can be administered every 6 to 8 hours or until volume overload has been corrected. CRI provides more sustained diuresis with a lower cumulative furosemide doses versus repeated bolus infusions.[77] In people, the time to maximal effect with a loading dose and CRI is 1 hour, and without a loading dose is 3 hours. The dosage in people is about 0.01 to 0.15 mg/kg/h with some reports using dosages as high as 0.75 mg/kg/h.[164] In normal dogs, 0.66 mg/kg/h resulted in diuresis, and dosages of 0.25 to 1 mg/kg/h have been used in dogs and cats with naturally occurring renal failure.[39,165,166] Because electrolyte and fluid balance disorders can develop rapidly if diuresis ensues, frequent monitoring is necessary.

Dopamine/Fenoldopam

Dopamine has been shown to make some human oliguric patients nonoliguric, but it does not increase GFR or improve outcome.[58,84,167,168] Because of lack of efficacy and side effects associated with dopamine, it is no longer recommended for treatment of oliguric renal failure, except for pressor control.[39,169] Fenoldopam, a selective DA-1 receptor agonist, increases urine output.[58,116] Its effects on GFR and renal outcome are not known.

Calcium Channel Antagonists

Calcium channel antagonists presumptively reverse renal vasoconstriction by causing predominantly preglomerular vasodilation, inhibit vasoconstriction induced by tubuloglomerular feedback mechanisms, cause natriuresis independent of GFR, and decrease renal damage after transplantation.[170] Although results of one study using diltiazem in addition to standard care in dogs with AKI from leptospirosis were not statistically significant, there was a trend toward increased urine output and more complete resolution of azotemia.[170]

Renal Replacement Therapy

Indications

Renal replacement therapy is used for patients that fail to respond to medical management (Figure 322-6; see ch. 110). The appropriate time to institute dialytic therapy is not clearly established, although intractable hyperkalemia, life-threatening volume overload, or persistent uremic symptoms are uncontroversial (Boxes 322-4 and 322-5). Early institution of dialysis in people may improve outcome compared with starting later in the course of the disease. Starting dialysis at a lower level of overhydration improves outcome in pediatric patients.[103] Renal transplantation is not an emergency procedure (see ch. 323). If a cat with AKI is stabilized but does not recover renal function, transplantation can be considered.

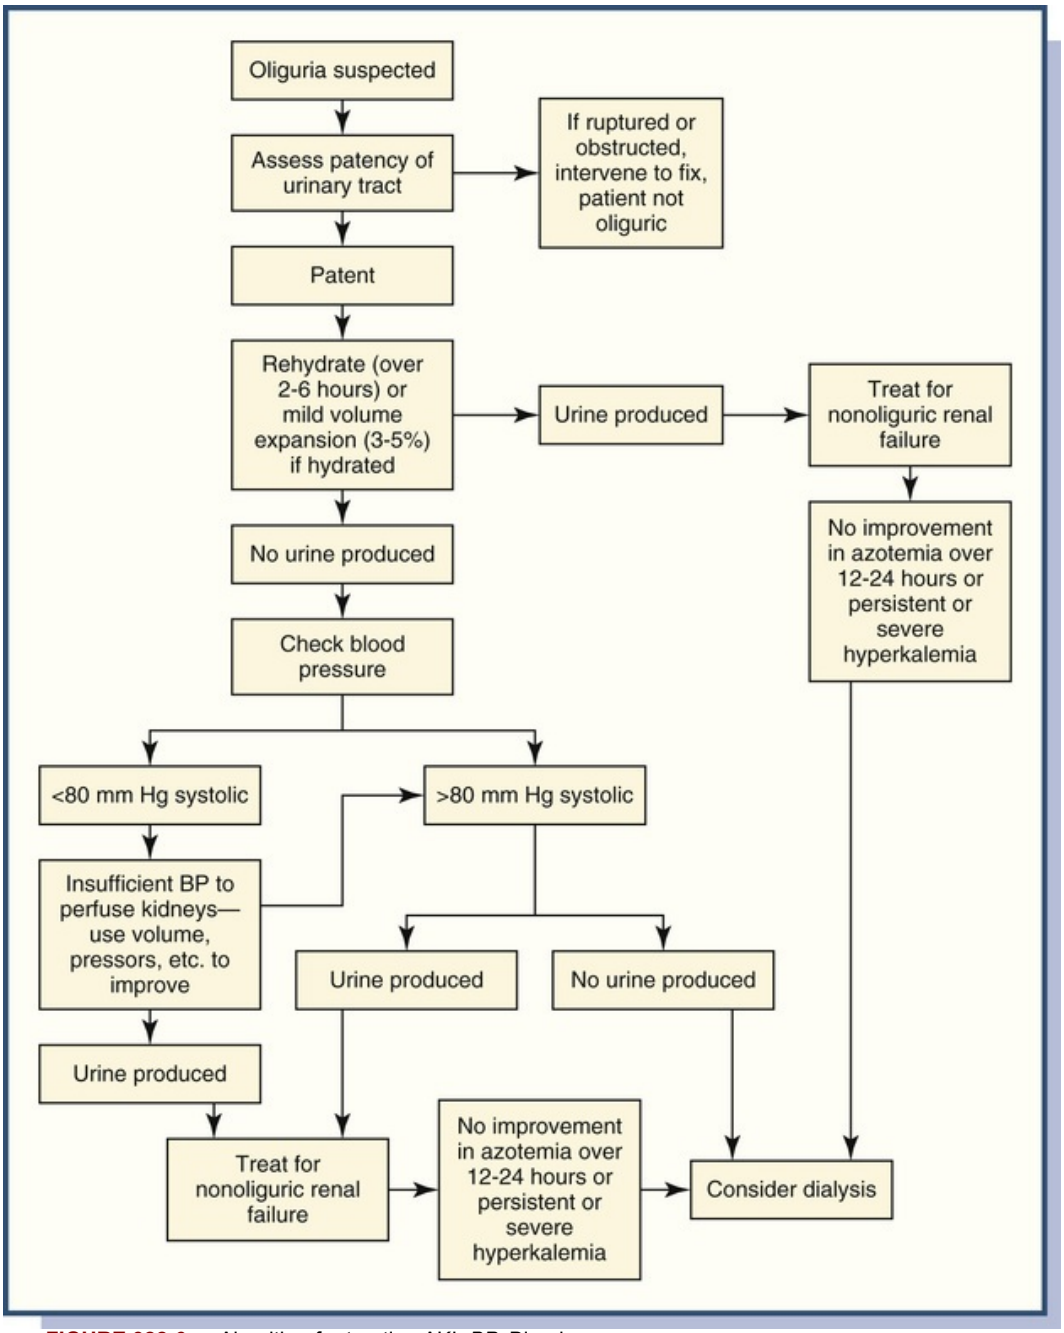

FIGURE 322-6 Algorithm for treating AKI. *BP,* Blood pressure.

Box 322-4

Indications for Renal Replacement Therapy

Inadequate urine production
Life-threatening pulmonary edema or fluid overload
Hyperkalemia or other life-threatening electrolyte or acid-base disturbance
Progressive/unremitting azotemia
Diuretic resistant congestive heart failure or severe overhydration in absence of renal disease
Acute poisoning/drug overdose with substance that can be removed by dialysis

Box 322-5

Patient Characteristics for Renal Replacement Therapy

≥2.5 kg
Systolic blood pressure ≥ 80 mm Hg
Tractable

Peritoneal Dialysis

Peritoneal dialysis is rarely used for AKI in critically ill people, but is more readily available for animals than hemodialysis or hemofiltration.[171] Peritoneal dialysis removes uremic toxins by diffusion from the peritoneal membrane into abdominal infused dialysate and then drained. Necessary supplies are readily available, but the procedure is time-consuming (see ch. 109). Common complications include catheter occlusion and peritonitis. Outcomes similar to hemodialysis have been documented in cats treated with peritoneal dialysis, with 10 out of 22 cats surviving to hospital discharge, but historical outcomes with peritoneal dialysis in dogs are less favorable (26% survival).[172-174]

Extracorporeal Renal Replacement Therapy (ERRT; see ch. 110) (Video 322-1)

ERRT includes intermittent hemodialysis (IHD) and continuous renal replacement therapy (CRRT). ERRT removes uremic toxins from the bloodstream by diffusion and/or convection. During treatment, patient blood is continuously carried to the dialyzer through disposable tubing (extracorporeal circuit) and then returned. The dialyzer, or artificial kidney, contains a porous membrane whose size and charge determine which particles are filtered. Small- to middle-sized molecules in high concentration, such as urea and creatinine, diffuse through the pores into a dialysate solution on the opposite side of the membrane. Large molecules, such as albumin and cells, are too large to pass through the pores. Electrolytes, such as Na, can easily pass through the membrane. Thus, dialysate solutions have physiologic electrolyte concentrations to prevent significant loss. Ultrafiltration removes fluid from the patient by creating a hydrostatic pressure gradient between the blood compartment and the dialysate compartment. Solutes dissolved in the fluid are also removed via convective clearance. If a large volume of fluid is removed to achieve adequate solute clearance by convection, fluid is infused into the extracorporeal circuit to avoid dehydration. There are several models and manufacturers of dialysis machines but each must be able to circulate blood in the extracorporeal circuit, to circulate dialysate or replacement fluid, and to precisely control ultrafiltration.

IHD involves rapid blood flow and rapid dialysate flow for efficient removal of uremic toxins and fluid, allowing treatments to occur at intervals. One regimen might include several hours per treatment, three to four times a week. Machines designed for IHD are capable of supplying the large volume of dialysate necessary by mixing purified water with concentrated electrolyte solutions. Na and bicarbonate concentrations can be independently adjusted and tailored to the patient's needs. Because of the complexity of equipment and the possibility of acute changes in patient status during treatment, IHD is usually performed by specially trained dialysis personnel. CRRT can be performed until renal recovery occurs or until the pet is stable and can be transitioned to IHD. Prepackaged sterile dialysate is used with these machines, and solutions with various concentrations of solutes (i.e., Na, K, bicarbonate) are available. Dialysate flow rates are much slower with CRRT (up to 8 L/h) compared with IHD (20 to 50 L/h), but duration of treatment is longer. Choice of modality, whether IHD or CRRT, has not been proven to affect outcome.[84,171] Both IHD and CRRT require vascular access. For short-term treatment, double lumen catheters, placed percutaneously with a guidewire (Seldinger technique; see ch. 76) or via minor surgical exposure of the vessel, are used. These catheters can be placed with a local anesthetic and mild sedation.

Anticoagulants

Some form of anticoagulation is needed during dialysis to prevent thrombosis in the extracorporeal circuit. Unfractionated heparin is commonly used and is monitored by activated clotting time. With regional citrate anticoagulation, citrate administered as a CRI into the extracorporeal circuit binds Ca and prevents coagulation in the circuit. Because the anticoagulation occurs outside the patient, bleeding complications associated with anticoagulation are minimal. Calcium chloride is administered through a centrally placed IV catheter, or via the extracorporeal circuit just at the point where the blood is reentering the body, to prevent hypocalcemia in the patient.

Complications

Complications encountered during dialytic management may be a result of the dialysis procedure or of the underlying renal failure. Dialysis disequilibrium syndrome is a condition characterized by a rapid decline in blood osmolality caused by rapid removal of osmoles (especially urea) by dialysis, and it leads to CNS signs (e.g., seizures, mentation changes). In small animals, removal of the blood volume necessary to fill the dialysis circuit can result in hypotension. Hemorrhage related to heparin anticoagulation is most likely during the first few dialysis treatments, while the individual response to heparin is being determined, and with prolonged sessions (>6 hours). Thrombosis at the tip of the dialysis catheter in the right atrium is common with catheters in place for over 3 weeks, and impairs adequate blood flow.

Treatment of Ureteral Obstruction

Ureteral obstruction is a relatively frequent cause of AKI in cats (see ch. 329). Some ureteral stones pass into the bladder within hours to days, but if not, relief of the obstruction is necessary to regain renal function. Obstructions that persist for 7 days are expected to permanently reduce renal function by a third and, after 40 days, no return of function is expected. Relief can be provided by surgical ureterotomy, placement of a ureteral stent, or placement of a ureteral bypass device, which involves connecting a nephrostomy tube placed in the kidney with a cystostomy tube placed in the bladder (see ch. 124). Cats too ill for anesthesia may benefit from dialysis (peritoneal or extracorporeal). An alternative to dialysis is placing a percutaneous nephropyelostomy tube, which should resolve azotemia within a few days if it was postrenal, but a definitive procedure to remove or bypass the obstruction will eventually be required.[175,176]

Treatment of Specific Diseases

Antimicrobials

Penicillin derivatives and doxycycline are an excellent initial choice for dogs with leptospirosis (see ch. 217), although penicillins do not eliminate the carrier state. Doxycycline and erythromycin are effective against the carrier state. Treatment should be continued for at least 4 weeks. *Borrelia burgdorferi* can be treated with doxycycline (see ch. 211). Pyelonephritis is usually caused by Gram-negative bacteria, against which fluoroquinolones have good spectrum and good renal tissue penetration. Ampicillin, amoxicillin, amoxicillin-clavulanic acid, or cephalosporins may be effective. Trimethoprim-sulfa drugs are effective against *E. coli* and Gram-positive bacteria. Sulfonamides do not reach effective intrarenal concentrations; only the trimethoprim component is effective. Aminoglycosides should be avoided due to potential nephrotoxicosis. Pyelonephritis treatment should continue for at least 4 to 6 weeks. Urine should be cultured 3 to 7 days after completing antibiotic therapy and repeated in 1 month if negative. If the culture is positive, treatment is indicated for an additional 4 weeks with appropriate antibiotic.

Other Medications

Use of 4-methylpyrazole or ethanol for ethylene glycol intoxication should be started within 8 hours of ingestion (see ch. 152). In addition to improving renal perfusion with fluid therapy, NSAID intoxication can be treated with misoprostol, a prostaglandin E analogue (1-3 mcg/kg PO q 6-8 h). When treating aminoglycoside toxicosis, ticarcillin and carbenicillin will complex aminoglycosides, thus preventing renal uptake and may be an early treatment after excessive dosing.[83] Urinary alkalinization is recommended for sulfonamide toxicosis and pigment nephropathy.[80,83] Maintenance of high urine flow rates with mannitol and high-volume fluid therapy may also be beneficial.

Treatment of Uremic Complications

Hyperkalemia

Acute Therapies

Renal excretion is the major mechanism for removing K from the body (see ch. 68). Chronic hyperkalemia is unlikely with normal renal function. Hyperkalemia, possibly life-threatening, is more likely to develop in oliguric or anuric AKI as compared with PU.[102] Increased extracellular K changes the electrical potential of excitable cells. Typical ECG changes include bradycardia, tall, spiked T waves, shortened QT interval, wide

QRS complex, and a small, wide or absent P wave. Severe hyperkalemia can lead to a sinoventricular rhythm, ventricular fibrillation, or standstill. Muscle weakness may be present with a serum K concentration >8 mEq/L.[177] A pet with suspicious ECG changes may require emergency therapy before results of the serum K are available. Ca gluconate 10% (0.5 to 1 mL/kg IV to effect, given slowly) can be used in critical situations to restore cardiac membrane excitability, but does not decrease K concentrations. During infusion the ECG must be monitored and the rate slowed or stopped if arrhythmias worsen. The cardiac effects should be apparent within minutes, but duration of effect is less than an hour.[178] Giving Ca increases risk of soft tissue mineralization if hyperphosphatemia is present.

Insulin, Glucose, Bicarbonate

Several methods can be used to move K from the extracellular space intracellularly. Regular insulin (0.5 units/kg IV) has an effect within 20 to 30 minutes. Dextrose (1 to 2 g per unit insulin as an IV bolus, then 1 to 2 g per unit insulin in IV fluids given over the following 4 to 6 hours) is necessary to prevent hypoglycemia when insulin is used. Dextrose induces endogenous insulin release in nondiabetic patients and can be used without concurrent insulin administration to control mild to moderate hyperkalemia, at a dosage of 0.25 to 0.5 g/kg IV.

Metabolic acidosis from mineral acids (e.g., NH_4Cl, HCl) but not organic acids (e.g., lactic acid, ketoacids) causes K to shift from cells to the extracellular space and circulation as hydrogen ions enter cells. Correction of metabolic mineral acidosis with bicarbonate causes K to return to cells as H^+ is combined with HCO_3^- and removed. The dose of Na bicarbonate used to treat hyperkalemia is based on calculation of the base deficit (ideally), or a fixed dosage of 1 to 2 mEq/kg IV over 10 to 20 minutes. Na bicarbonate is contraindicated if the partial pressure of carbon dioxide (PCO_2) is increased or if metabolic alkalosis is present as it may cause hypernatremia or paradoxical CNS acidosis. If the ionized Ca concentration is low, dextrose is preferred to bicarbonate because alkalemia exacerbates hypocalcemia (see ch. 69).[102]

Albuterol, Exchange Resins and Drugs to Avoid

The beta-agonist albuterol has been used to treat hyperkalemia in people because it moves K into cells.[102] The cation exchange resin sodium polystyrene sulfonate (Kayexalate, Kionex) can be administered orally or by enema (dosage: 2 g/kg q 6-8 h as a suspension in 20% sorbitol).[39] This binds K in the GI tract, releases Na, takes several hours to act, and includes side effects such as hypernatremia and constipation. The K-lowering effects of these drugs, with the exception of polystyrene sulfonate, are temporary. Serum K concentrations gradually rise within several hours of administration unless urine production is induced. Once even minimal urine production resumes, serum K concentrations usually decrease. Peritoneal or hemodialysis may be necessary to ultimately control K if oliguria or anuria persist. Drugs that contribute to hyperkalemia should be avoided, including nonspecific beta-blockers, digoxin, ACE inhibitors, angiotensin receptor antagonists, nonsteroidal anti-inflammatory drugs, K-sparing diuretics (spironolactone, amiloride, triamterene), high doses of trimethoprim, cyclosporine, and total parenteral nutrition (TPN).[69]

Hypokalemia

Low K can occur with AKI because of excessive urinary losses due to PU, diuretic use, or losses due to vomiting or diarrhea. The amount of K chloride added to IV fluids should be based on the serum concentration (see ch. 68). Oral K supplementation (1 to 3 mEq/kg/day) may be used for pets that are eating or have a feeding tube. The serum K concentration should be monitored frequently to avoid hyperkalemia or hypokalemia.

Sodium (Na)

Serum Na concentrations may be normal, increased, or decreased in AKI (see ch. 67). Hypernatremia prior to fluid therapy indicates excessive free water loss. Administration of Na bicarbonate or hypertonic saline may cause hypernatremia. Hyponatremia may indicate losses due to excessive urinary excretion, vomiting, diarrhea, or transient dilutional hyponatremia after giving mannitol, hypertonic dextrose, or colloid solutions. Solutions low in Na (5% dextrose, TPN, enteral formulations) may cause hyponatremia. In many situations, initial dehydration follows isonatremic fluid losses and a normal Na concentration.[39,102] Clinical signs are unlikely unless rapid changes occur in serum Na concentrations and are generally related to neurologic

dysfunction. The rate of Na change should not be more than 12 mEq/L per day.[179] Chloride changes tend to parallel Na changes.

Metabolic Acidosis

Metabolic acidosis is common in AKI. Daily H^+ load is excreted with NH_3 as NH_4^+ or with phosphate as $H_2PO_4^-$ (see ch. 128). Failing kidneys are unable to excrete H^+ or reabsorb HCO_3^-. Acidosis can be worsened by lactic acidosis from dehydration and poor perfusion. Intravenous Na bicarbonate therapy can be considered if acidosis persists after correcting dehydration and is usually reserved for animals with a pH less than 7.2 or HCO_3 < 12 mEq/L. Treatment with Na bicarbonate is geared toward causing acid (H^+) to combine with bicarbonate (HCO_3^-) to form H_2CO_3, which dissociates to H_2O and CO_2. If the lungs are unable to eliminate the CO_2, the reaction does not proceed. Bicarbonate administration, however, can increase the PCO_2 and lead to paradoxical CNS acidosis. Since CO_2 is highly diffusible, moving quickly from the circulation into the CNS, it is converted back to acid (H^+) in that environment. Na bicarbonate treatment is also contraindicated with hypernatremia. Bicarbonate doses are calculated from the formula: 0.3 × body weight (kg) × base deficit, where the base deficit = 24 − patient HCO_3. Give ¼ to ½ directly, IV, and an additional ¼ to ½ dose in the IV fluids over the next 2 to 6 hours. Adjust any subsequent doses based on serial evaluation of blood gas determinations. Oral alkalinizing agents can be used once oral intake is possible. K citrate (40 to 75 mg/kg PO q 12 h) addresses metabolic acidosis and hypokalemia. Oral Na bicarbonate (8 to 12 mg/kg PO q 12 h) is more palatable in tablet form compared with powder. Doses should be adjusted based on need.

Calcium (Ca) and Magnesium (Mg)

Hypocalcemia

One of many causes for Ca disorders in pets with AKI includes an acute decrease in glomerular filtration leading to an abrupt increase in phosphorus, which causes acute hypocalcemia due to the law of mass action (see ch. 69). Decreases in Ca stimulate parathyroid hormone synthesis and secretion, which increases Ca back to normal. Metabolic acidosis increases the ionized Ca (iCa) fraction. Symptomatic hypocalcemia (tetany) occurs infrequently in AKI. Hypocalcemia may be more severe with antifreeze-induced AKI (see ch. 152), because antifreeze phosphate can cause acute severe hyperphosphatemia while ethylene glycol is converted to oxalate which complexes Ca. Treatment with Ca increases risk of soft tissue mineralization in hyperphosphatemic pets. The minimal dosage of Ca gluconate that controls clinical signs should be used when needed. 10% Ca gluconate can be used (dosage: 0.5 to 1.5 mL/kg IV over 20 to 30 minutes). As when treating hyperkalemia, it is important to monitor the ECG during infusion.

Hypercalcemia

Hypercalcemia, based on total serum Ca concentrations, is usually mild and associated with normal iCa with no treatment necessary. If the iCa is increased, it may resolve with fluid therapy. Ca-containing fluids (such as LRS) should be avoided. Saline (0.9% NaCl) is an ideal fluid because the Na content increases calciuresis. Furosemide also promotes urinary Ca excretion. Na bicarbonate therapy decreases iCa as more Ca binds to serum proteins. Hypercalcemia from renal failure is not glucocorticoid-responsive.[180] Calcitonin or bisphosphonates could be considered if the hypercalcemia is severe, although bisphosphonates can induce renal failure.[180]

Magnesium (Mg)

Since the kidneys are the primary route of excretion, Mg concentrations may be increased in AKI, but specific therapy is generally not necessary (see ch. 68). Mg, such as that found in some phosphate binders, should be avoided. Hypomagnesemia may occur with PU and renal failure. Hypokalemia may be refractory to therapy if concurrent hypomagnesemia is present. Mg sulfate or Mg chloride can be given IV. Various forms are available for oral supplementation.[181]

Phosphorus (PO_4)

Dietary PO_4 is readily absorbed from the GI tract and excreted by the kidneys (see ch. 69). Decreased excretion commonly leads to hyperphosphatemia in both AKI and CKD. Intravenous fluid therapy may partially control PO_4 concentrations by addressing the hemodynamic component and improving renal blood flow. There are no specific treatments to decrease serum PO_4 in AKI other than renal replacement therapy. PO_4 binders prevent absorption from food. Oral PO_4 binders can be added when enteral feeding is started. Aluminum hydroxide or aluminum carbonate is administered at 30 to 90 mg/kg/day divided with meals. Ca acetate (60 to 90 mg/kg/day) and Ca carbonate may cause hypercalcemia and should be avoided in hypercalcemia. Ca carbonate combined with chitosan is a veterinary product for binding PO_4.

Hypertension

Hypertension is a common complication of AKI, affecting 37% of dogs at admission and increasing to over 80% during hospitalization (see ch. 157 and 158).[105] Progressive volume loading as a result of IV fluid therapy may contribute to the incidence and severity of hypertension. Acute hypertension can cause ocular damage (detached retina, hyphema, retinal edema; see ch. 11), CNS signs from hemorrhage (see ch. 260), cardiac abnormalities (see ch. 253), or progression of renal damage. Treatment is indicated if the systolic blood pressure is >180 mm Hg. Pets with both AKI and volume excess may also have hypertension that responds to decreasing volume overload. If antihypertensive medications are required, the goal is to decrease systolic pressure to <180 mm Hg, but to avoid precipitous decreases. Amlodipine (0.18 to 0.3 mg/kg PO q 24 h for cats, 0.2 to 0.4 mg/kg PO q 24 h for dogs) may provide a response within 24 to 48 hours. If the blood pressure does not improve within a few hours, additional doses can be administered in dogs, up to a maximum of 1 mg/kg/day.[105] ACE inhibitors are generally avoided in AKI because they may decrease renal perfusion by causing afferent arteriolar constriction. If immediate control of hypertension is necessary, the onset of action of hydralazine (2.5 mg/cat PO or SC once, 0.5 to 3 mg/kg PO q 12 h for dogs) is 15 minutes (SC) to 1 hour (PO). Blood pressure must be monitored closely after administration (see ch. 99).

Hematologic Disorders

Anemia may occur with AKI because of GI bleeding, repeated blood sampling, or dilution associated with volume overload. If clinical signs of anemia are present (i.e., tachycardia, heart murmur, weakness, dull mentation, anorexia), blood transfusion is indicated (see ch. 130). Packed RBC transfusion is preferred to whole blood if the pet is volume overloaded and/or oliguric. There is no absolute degree of anemia to dictate transfusion. More liberal criteria are generally used if the anemia develops acutely. Recombinant erythropoietin products (e.g., Epogen, Darbepoetin) can increase RBC production over a week. They have been used when anemia is anticipated, to decrease eventual transfusion requirements, although there are risks of immunologic reactions. Uremia induces platelet function defects. The buccal mucosal bleeding time (see ch. 80) will be prolonged despite a normal coagulation profile. Desmopressin (1-deamino-8-arginine vasopressin [DDAVP]; see ch. 201 and 296) is used in uremic people with active bleeding, but this treatment has not been evaluated in animals. Duration of activity in people is short (less than 24 hours), and would be considered immediately prior to invasive procedures.[182]

Gastrointestinal (GI) Disorders and Pancreatitis

GI complications (anorexia, nausea, vomiting, ileus) occur commonly in AKI, with bleeding in 10% to 30% of affected people.[80] Histamine blockers or proton pump antagonists are commonly used in AKI to inhibit gastric acid secretion. Because some of these drugs are excreted via the kidneys, dosage and frequency should be adjusted. Antiemetics are frequently needed (see ch. 39). Motility modifiers are indicated if ileus is present. If there is evidence of GI ulceration (e.g., hematemesis, melena, increased BUN : creatinine ratio, panhypoproteinemia with acute anemia), a gastric protectant (Sucralfate) should be administered (Table 322-4). Pancreatitis is common in AKI (see ch. 290 and 291). Antiemetics, pain management, and early nutritional support (parenteral [see ch. 189] if vomiting is not controlled, by feeding tube [see ch. 82] if patient is anorexic but not vomiting) are recommended.

TABLE 322-4

Common Drugs Used to Treat Gastrointestinal Signs in Uremia*

DRUG	INDICATION	DOSAGE—DOGS	DOSAGE—CATS	ADJUSTMENT FOR RENAL FAILURE AND COMMENTS
Famotidine	Decrease acid	0.5-1 mg/kg PO, IM, IV q 12-24 h	0.25-0.5 mg/kg PO, SC q 24 h	Prolong interval or decrease dosage
Ranitidine	Decrease acid, motility modifier	0.5-2 mg/kg PO, IV q 8-12 h	0.5-2.5 mg/kg PO, SC, IM, IV q 12 h	Prolong interval or decrease dosage
Cimetidine	Decrease acid	5-10 mg/kg PO, IM, IV q 4-6 h	5-10 mg/kg PO, IM, IV (slow) q 6-8 h	Prolong interval or decrease dosage
Omeprazole	Decrease acid	0.5-1 mg/kg PO q 24 h	0.7 mg/kg PO q 24 h	Do not open capsules
Pantoprazole	Decrease acid	0.5-1 mg/kg IV (over 15 min) q 24 h	0.5-1 mg/kg IV (over 15 min) q 24 h	
Metoclopramide	Antiemetic, motility modifier	0.1-0.5 mg/kg PO, SC, IM q 6-8 h, 0.01-0.02 mg/kg/h CRI	0.2-0.4 mg/kg SC q 6-8 h or 0.01-0.02 mg/kg/h CRI	Decrease dosage
Ondansetron	Antiemetic	0.1 mg/kg PO q 12-24 h	0.1 mg/kg PO q 6-8 h, 0.1-0.3 g/kg IV q 6-8 h	
Dolasetron	Antiemetic	0.5 mg/kg PO SC, IV q 24 h	0.5 mg/kg PO, SC, IV q 24 h	
Maropitant	Antiemetic	2 mg/kg PO q 24 h or 1 mg/kg SC q 24 h for 5 days	1 mg/kg PO, SC daily for 5 days	
Mirtazapine	Antiemetic, appetite stimulant	1.1-1.3 mg/kg PO q 24 h	1.88 mg per cat PO q 48 h	
Chlorpromazine	Antiemetic	0.2-0.5 mg/kg IM, SC q 6-8 h	0.2-0.5 mg/kg IM, SC q 8 h	
Prochlorperazine	Antiemetic	0.1-0.5 mg/kg IM, SC q 8-12 h		
Sucralfate	Gastric protectant	0.5-1 g PO q 6-8 h	0.25 g/cat PO q 8 h	
Misoprostol	Cytoprotective PGE analogue	1-3 mcg/kg PO q 6-12 h		
Cisapride	Motility modifier	0.1-0.5 mg/kg PO q 8-12 h	2.5-5 mg/cat PO q 8-12 h	

*Most of these drugs have not been approved for use in the dog or cat.

CRI, Continuous rate infusion; *PGE*, prostaglandin.

Nutritional Support

AKI is a highly catabolic condition. Although difficult to clearly identify the contribution of nutritional management to outcome, poor nutritional status is a major factor in increasing morbidity and mortality.[183] Early enteral feeding can help preserve GI mucosal integrity.[184] Although renal diets (reduced PO_4 and high-quality protein) are indicated for treating CKD, the ideal diet for AKI is not known (see ch. 184).[185,186] In the absence of information, enteral diets for critically ill animals or people have been used.[102] Anorexia is common in the hospitalized renal failure patient (see ch. 23). If the appetite does not return within a few days of therapy, feeding tube placement (see ch. 82) may allow administration of an appropriate quantity of the desired diet, easy administration of oral medications, and is strongly recommended in animals not voluntarily consuming adequate calories. If vomiting prohibits enteral feeding, partial parenteral nutrition or TPN may be used (see ch. 189).

Whether supplementation is enteral or parenteral, the volume that can be administered may be limited in anuric or oliguric patients. Most liquid diets suitable for use in a nasoesophageal or nasogastric tube have a caloric density around 1 kcal/mL.[187] Provision of 100% of the basal energy requirements generally will require

a volume of about twice insensible fluid requirements. Common formulas for calculation of total parenteral nutrition also use almost twice the insensible fluid requirements.[188] Need for nutritional support is an indication for fluid removal via dialysis in the oliguric patient. Glutamine supplementation may improve survival in human AKI patients, but further research is needed.[189]

Infections

Infections occur in 30% to 70% of people with AKI because of impaired defenses secondary to the uremia combined with use of antibiotic therapy.[80] Primary sites of infection include the urinary tract, sites where breaks occur in normal barriers (e.g., IV catheters), and the respiratory tract.[80] The infection rate in veterinary patients with AKI is unknown, but the rate of infections in dogs and cats receiving hemodialysis (predominantly for AKI) is at least 25%.

Prognosis

The mortality of both hospital-acquired and community-acquired AKI is high. In dogs with a mild increase in creatinine (<50% increase from baseline or ≥0.3 mg/dL increase but nonazotemic), mortality was 55% to 58%. In dogs and cats developing more severe AKI in the hospital, mortality was 41% to 66% in dogs and 58% to 73% in cats.[10,11,22] The mortality rate in dogs with community-acquired AKI was 56%.[21] Mortality rates in cats with community-acquired AKI, were 47% to 64%.[23,190] The mortality rate in people is about 50%.[191] Decreased urine production is a poor prognostic factor in dogs and cats with AKI.[22,23] The severity of azotemia was not predictive of outcome in most studies of cats or dogs with AKI, whereas an initial severe increase in serum creatinine was associated with failure to recover from AKI in one study in dogs.[21-23,192,193] In one case series of cats with AKI, for each unit increase in serum potassium, in mEq/L, there was a 57% decrease in chance of survival.[23] In another study, lower body temperature, serum albumin, and lactate dehydrogenase were predictive of mortality.[190] Of cats that survive the AKI episode, about half were discharged with a normal serum creatinine concentration. The other half of the survivors had persistent azotemia.[23] In dogs with AKI, 24 of 99 developed CKD (24 of 43 survivors).[21] Disease etiology is a prognostic factor with AKI (Table 322-5). In one study, 50% of cats with a nephrotoxic or other cause survived, whereas 75% of cats with ischemia survived.[23] In dogs with hospital-acquired AKI, 43% of dogs with nephrotoxicant exposure survived, although no association between type of renal insult and outcome was found in that study.[22]

TABLE 322-5

Survival Rates for Various Etiologies of AKI[2,23,52,202]

CATEGORY	NONDIALYTIC MANAGEMENT	HEMODIALYSIS
Obstructive (cats)	91%	70%-75%
Infectious	82%	58%-86%
Metabolic/hemodynamic	66%	56%-72%
Other	50%	29%-56%
Toxic	43%-69%	18%-35%

Overall, 40% to 60% of patients with AKI treated with hemodialysis survive, a notable achievement given that the patient population is comprised of animals unresponsive to conventional medical management.[194,195] The survival rate for AKI from infectious causes was about 58% to 100%.[192,193,196,197] Hemodynamic and metabolic causes had a 40% to 72% survival rate.[193,198] Only 20% to 40% of patients with AKI from toxic causes survive.[192,193] Of the patients receiving hemodialysis that do not survive, about half of those die or are euthanatized because of extrarenal conditions (e.g., pancreatitis, respiratory complications). About a third of nonsurvivors are euthanized because of failure of recovery of renal function. Ongoing uremic signs, dialysis complications, and unknown causes account for the remaining patient deaths. As with patients treated

medically, approximately half regain normal renal function (defined by normal serum creatinine concentration) and half have persistent CKD.

CHAPTER 323

Renal Transplantation

Chad W. Schmiedt

Client Information Sheet: Renal Transplantation

Renal Transplantation in Cats

Candidate Selection

The ideal renal allograft recipient is a cat with significant, compensated, chronic kidney disease (CKD) that is otherwise healthy. The optimal timing of transplantation relative to stage of kidney disease is unknown. Delaying transplantation until a cat is in end-stage uremia is not desirable, as the degree of azotemia is a known risk factor for poor outcomes.[1,2] Conversely, kidney transplantation in cats with asymptomatic, early-stage CKD also is not optimal given the long survival times that exist with medical management and the perioperative risk associated with transplantation. Several centers use a minimum serum creatinine of 4.0 mg/dL as a benchmark to maximize beneficial opportunities of medical management and mitigate perioperative risk for minimally affected cats.

Older cats have been identified as living shorter durations after transplantation compared to younger cats.[1,2] However, older cats without other significant comorbidities may still experience substantial improvement in quality of life following transplantation. Therefore, older animals may qualify for transplantation and should be considered in light of their complete clinical picture.

Prior to transplantation, a thorough systemic evaluation is performed to maximize the opportunity for a successful outcome and to ensure the donor's kidney is not wasted. While criteria vary slightly between transplantation centers, and these should be confirmed with each site, generally required testing is listed in Box 323-1. Conditions which definitively rule a cat out for transplantation include feline immunodeficiency virus (FIV) or feline leukemia virus (FeLV) infection, moderate to severe heart disease, neoplasia, pyelonephritis, other significant comorbidities, or an inability for owners to medicate or obtain veterinary care for their cat. Conditions that preclude transplantation until they are addressed include systemic hypertension, hyperthyroidism, active infection, and periodontal disease.

Box 323-1

General Testing Required Prior to Renal Transplantation

- Complete blood count and serum biochemical profile
- Urinalysis and culture
- Urine protein to creatinine ratio
- Blood pressure measurement
- Serum thyroid hormone concentration (T_4)
- Infectious disease testing
  - Feline immunodeficiency virus
  - Feline leukemia virus
  - *Toxoplasma* IgG and IgM
  - ±Coronavirus titers
  - ±*Mycoplasma* titers
  - ±*Bartonella* Western blot

- Echocardiogram
- Abdominal and thoracic radiographs
- Abdominal ultrasound
- Blood type
- Dental examination

Cats for which veterinarians have a clinical suspicion of a latent infection may undergo a cyclosporine trial for 1-3 months prior to transplantation. The goal of a cyclosporine trial is to achieve therapeutic blood concentrations of cyclosporine (300-500 ng/mL) and monitor for infection prior to the definitive procedure. Animals with CKD secondary to or concomitant with calcium oxalate urolithiasis may still undergo renal transplantation with good outcomes, although calcium oxalate nephrolithiasis in the allograft is possible.[3]

Donor Selection

Kidney donors should be young cats (≈1-2 years) that are free of disease. Transplant programs require the recipient's owners to adopt donor cats. The source of donor cats may be the recipient's household, a shelter or humane society, an intramural colony at the transplantation center, or a USDA-licensed, Class A vendor. The latter is most common as the use of purpose-bred cats minimizes potential risks of disease transmission. Donor candidates should be thoroughly screened for disease. Transmission of disease through the donated kidney is possible.[4,5] To optimize surgical planning, cross-sectional imaging can be used for investigating the donor cat's renal vasculature prior to surgery.[6]

Especially in Europe, there are ethical concerns about feline kidney transplantation, and particularly about using healthy cats as kidney donors.[7] Maintaining rigorous recipient criteria, positively impacting recipient quality of life, and rehoming shelter or purpose-bred research cats with devoted owners may mitigate concerns of removing a kidney from a donor cat. One study that followed 16 renal donors 2 to 5 years after uninephrectomy found renal and erythropoietic function to be preserved in 14 cats, while 2 cats developed dilute urine and proteinuria.[8]

Surgery

Details of surgical technique vary by surgeon; however, long-term surgical outcomes have been relatively consistent, suggesting long-term consequences of surgical preference are minimal.[1,2] Unless there is an indication, the two native kidneys are not removed. Renal allografts are implanted in a heterotopic location caudal to the native kidneys. The renal artery is anastomosed end-to-side with the aorta, and the renal vein is anastomosed end-to-side with the caudal vena cava.

There are two strategies for anesthetic and surgical timing of the kidney donor and recipient. With the simultaneous transplantation strategy, the renal donor and recipient are anesthetized at the same time.[9] Two surgical teams work side-by-side and coordinate donor harvest and recipient implantation. In this strategy, the overall ischemia time is reduced, as is the surgical stress endured by a single surgeon performing both the harvest and implantation. In contrast, in the sequential transplantation strategy, the kidney is harvested from the donor, flushed and stored in cold sucrose-phosphate solution, and implanted into the donor usually a few hours after harvest.[2] The longest reported cold ischemic storage time in cats using sucrose-phosphate is 7 hours.[10]

The advantages of the sequential strategy include requiring only one anesthetic and surgical team and utilizing the protective effects of cold ischemia to reduce cell injury.[11] Despite the longer ischemic time, cooling of the allograft reduces cellular damage associated with the injurious warm ischemic period. The sucrose phosphate solution significantly reduces cold ischemic injury compared to flushing with saline.[12] Regardless of the transplantation strategy employed, the goal is to limit warm ischemia time (i.e., the vascular anastomosis time) to 60 minutes or less. In the simultaneous technique, warm ischemia time begins at harvest, and in the sequential technique, warm ischemia time begins when the allograft is removed from the organ storage solution. Warm ischemia ends when blood flow is restored to the allograft.

Following release of the vascular clamps and restoration of blood flow to the allograft, the ureter is implanted into the host bladder. There are two major techniques currently employed for neoureterocystostomy. In the mucosal apposition technique, the ureter is transected near the donor

ureterovesical junction during the harvest procedure. The ureter is shortened and the distal end of the transected ureter is spatulated. The ureteral mucosa is sutured to the recipient's bladder mucosa by intra- or extravesical techniques.[13] The second technique is the ureteral papillae technique, wherein the donor's ureteral papillae is harvested along with the ureter and extravesically sutured to the recipient's bladder and serosa.[14]

Immunosuppression

Following renal transplantation, microemulsified cyclosporine and prednisolone are most commonly used for immunosuppression (see ch. 165). Cats are generally started with a cyclosporine dosage of 4 mg/kg PO q 12 h and the dosage is then adjusted based on whole blood concentration. Target blood concentration in the 3-6 months following transplantation is ≈500 ng/mL and reduced to ≈300 ng/mL over time. Importantly, microemulsified or modified cyclosporine (Neoral, Atopica) should be prescribed as it is more bioavailable and efficacious compared to non-emulsified cyclosporine.[15] Ketoconazole has been used for inhibiting cyclosporine metabolism and enable once daily dosing, which may be important for some owners (also see ch. 165).[16] Gastrointestinal cyclosporine absorption varies significantly between cats; therefore, the cyclosporine dosage should be based on an individual's blood concentration. Cyclosporine blood concentrations are monitored frequently (weekly) immediately after transplantation until the appropriate oral dosage is identified. Frequency of monitoring is extended over time with a maximum interval of every 3 months. In cats with poor absorption of microemulsified cyclosporine, treatment with vitamin B may increase absorption.[17]

Low-dosage prednisolone (0.25-0.5 mg/kg PO q 12 h) also is used frequently. Prednisolone can be continued chronically if well tolerated and required, or reduced or discontinued if complications develop. Other immunosuppressive regimens have been described experimentally in cats following renal transplantation[18] or suggested as options based on *in vitro* experiments.[19]

Complications

Several acute complications are predictable given the required surgical manipulations and they include hemorrhage, thromboembolism, and uroabdomen. Doppler ultrasound studies or ultrasound with contrast are performed routinely postoperatively to evaluate blood flow within the allograft (Video 323-1). Perioperatively, recipient cats can become hypotensive if hypovolemic secondary to anastomotic hemorrhage. Anemia also can be present and related to preexisting CKD or secondary to intraoperative hemorrhage. Perioperative blood transfusions should be administered if the animal has moderate to severe and/or symptomatic anemia (see ch. 130). Chronically, the return to normal of erythropoietin concentration and the concomitant resolution of anemia are extremely variable.[20] Most cats will return to a hematocrit above 28% around 1 month after transplantation.[20] In the absence of active postoperative hemorrhage, low-dosage heparin (125 U/kg SC q 8 h) is used for approximately 5 days after transplantation to minimize the risk of thromboembolism.

Severe systemic hypertension has been reported acutely after renal transplantation and is associated with neurologic clinical signs (see ch. 157).[21] In one study, 21/34 cats became severely hypertensive (systolic blood pressure ≥ 170 mm Hg) and treatment with hydralazine reduced occurrence of neurologic complications compared to a historical cohort (see ch. 158).[21,22] In feline kidney transplant recipients, the typical initial dosage of hydralazine for treatment of severe hypertension is 1 mg/cat SC. The cat's blood pressure is then monitored for reduction over 15-20 minutes (see ch. 99). If no improvement is observed, additional 1- to 2.5-mg increments are administered every 15 minutes to a maximum total dose of 5 mg.

Delayed graft function is a term used for describing lack of function in an allograft with otherwise normal blood flow and no evidence of post-renal urinary obstruction. It has been defined in the veterinary literature as the presence of a serum creatinine concentration ≥3 mg/dL occurring 3 days after transplantation and has been reported in 5 of 60 cats undergoing renal transplantation.[2] Delayed graft function is a consequence of pre-, peri-, or intraoperative graft injury. For example, in humans, allografts taken from older donors, diabetic or hypertensive donors, non-heart-beating cadavers, transplantation surgeries with long ischemic times, or allografts with postoperative ureteral obstruction are at greater risk of delayed graft function.[23] Allografts with delayed function often will eventually develop normal function, but have an increased risk of early and late allograft loss.[23] Concerns about marginal quality of donor kidneys are not an issue in veterinary

transplantation because of our ability to select healthy donors; thus, relevant risk factors in veterinary transplantation for delayed graft function relate to intraoperative ischemic injury or postoperative complications (e.g., ureteral stricture, thrombosis, etc.).

An acute rejection reaction is characterized by palpable enlargement of the allograft, hyperthermia or hypothermia, malaise, loss of appetite, weight loss, and loss of allograft function. Affected cats can be asymptomatic.[24] If cats undergo renal transplantation and do not receive immunosuppressive treatment, the median survival time is 23 days.[24] On an ultrasound examination, an allograft experiencing acute rejection has an enlarged cross-sectional area and loss of the definition of the corticomedullary junction because of increased echogenicity of the medulla (Figure 323-1).[25] There also can be perirenal or peritoneal fluid. The resistive index frequently is measured in renal allografts, but it has not been shown to be a sensitive indicator of allograft rejection.[25,26] Changes in ultrasonographic measurement of renal allograft size (length, width, cross-sectional area) have been associated with allograft dysfunction.[26] An allograft biopsy rarely is necessary and a delay in treatment for biopsy confirmation could be disastrous. A low cyclosporine blood concentration, azotemia, leukocytosis, characteristic ultrasound changes, absence of active infection, and an ill feeling patient, all support the working diagnosis of allograft rejection.

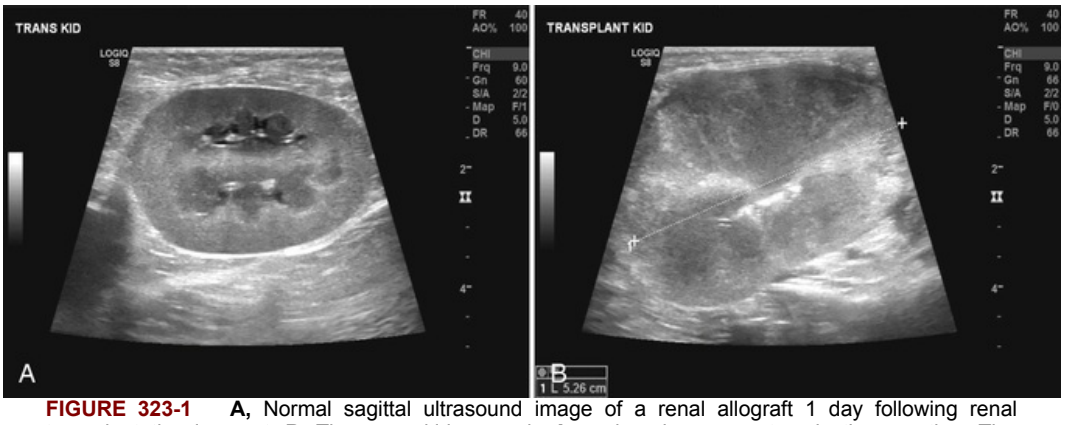

FIGURE 323-1 **A,** Normal sagittal ultrasound image of a renal allograft 1 day following renal transplantation in a cat. **B,** The same kidney as in **A,** undergoing an acute rejection reaction. The allograft is increased in size and has a heterogenous echotexture with loss of distinction of the corticomedullary junction.

Often, an acute rejection reaction can be controlled and reversed with intravenous administration of immunosuppressive dosages of corticosteroids, cyclosporine, and fluid therapy. Therapy should continue until the serum creatinine concentration plateaus, which often takes several days. The allograft may regain baseline function, depending on how rapidly the rejection reaction is diagnosed and appropriately treated. Often, even with successful treatment, there is some loss of function, increased antigenicity of the allograft, and an increased risk of future rejection reactions.[27]

Chronic complications are common following renal transplantation, necessitating dedicated postoperative management. A delayed acute rejection reaction can occur at any time after surgery if the immunosuppressive regimen is discontinued, if medication is administered incorrectly, or if there is altered drug absorption secondary to gastrointestinal disease or diet change. Frequent evaluation of cyclosporine blood concentrations is indicated to minimize the risk of a delayed acute allograft rejection.

Chronic, gradual loss of allograft function is a major problem in renal transplantation, especially in people. Historically, this condition was called *chronic rejection,* but has since been termed *chronic allograft nephropathy, chronic allograft dysfunction,* and, more recently, *interstitial fibrosis* and *tubular atrophy,* to describe the condition relative to hallmark histopathological lesions.[27] Changes characteristic of human chronic allograft nephropathy as they relate to feline renal allografts have been described.[28] Approximately 70% of evaluated feline allografts had histologic evidence of chronic allograft nephropathy.[28]

Because of the requirement for chronic immunosuppression, transplant recipients are at greater risk of infection. Infection can be *de novo*, a recrudescence of a latent infection, or transmitted to the recipient through the allograft. Infections following renal transplantation have been reported in 25-36% of patients.[2,29] Most infections are bacterial, but viral, fungal, protozoal, and mycobacterial infections also have been reported.[2,29]

The presence of uroabdomen and diabetes mellitus have been identified as risk factors for post-transplantation infection in cats.[2,29] Transmission of toxoplasmosis through the allograft and recrudescence of toxoplasmosis in feline transplant recipients has been reported. Treatment of active toxoplasmosis in immunosuppressed cats is routinely unsuccessful, underscoring the requirement for thorough screening for this disease prior to surgery.[4,5]

Following renal transplantation, cats have a ≈6-fold increased risk of developing cancer compared to age-matched control cats.[30-33] This problem is well recognized in people after solid organ transplantation and relates to the chronic antigenic stimulation of the allograft as well as the immunosuppressive and oncogenic influence of many immunosuppressive regimens.[34,35] Cyclosporine can promote oncogenesis by several mechanisms, including promoting tumor angiogenesis, inhibition of DNA repair, inhibition of apoptosis, and synthesis of transforming growth factor-beta (TGF-beta).[36,37] In cats, as in people, lymphoma is the most common malignant neoplasm to develop after renal transplantation and is commonly a mid- to high-grade, diffuse, large–B-cell lymphoma (see ch. 344).[30,32,33] Survival following diagnosis frequently is poor, with reported median survival times between 2 and 15 days.[30-32]

Peritoneal fibrosis has been reported in cats following renal transplantation.[38,39] Retroperitoneal fibrosis was reported in 21% of cats after transplantation,[38] but is not reported frequently in other case series.[1,2] Clinically, the condition is characterized by nonspecific signs including lethargy, anorexia, and a recurrence of azotemia. The allograft and associated ureter become encased in a fibrotic capsule, which results in ureteral obstruction, post-renal azotemia, hydroureter, and hydronephrosis.[39] The condition is reported to occur a median of 62 days after transplantation, and risk factors are unknown.[39] Treatment is surgical débridement of the scar tissue and ureterolysis, or surgically freeing the ureter from the retroperitoneal scar. Recurrence occurred in 6 of 25 cats that underwent surgery and those were treated by repeat ureterolysis.[39] Intraoperative prophylactic treatment with carboxymethylcellulose has been suggested as a means to minimize adhesion formation.[39]

Following renal transplantation, nutrition should be adjusted to the needs of the individual patient. If urinary stones were present prior to transplantation, an appropriate diet should be selected to prevent occurrence of these stones in the allograft (see ch. 324). Maintenance of cats on a renal diet after transplantation could increase the likelihood of obesity because of the increased carbohydrate content of these diets. Selecting a diet lower in carbohydrates, like a senior diet, and frequently monitoring weight may help to minimize weight gain. Diabetes mellitus is common in feline transplantation recipients and obesity will further predispose patients to developing diabetes. Transplant recipients have a 5.4-fold greater likelihood of becoming diabetic compared to control cats with CKD, and the occurrence of diabetes results in a 2.4-fold increase in mortality.[40] Risk factors for development of diabetes in the feline transplantation population are unknown.

Outcomes

Following transplantation, the 6-month survival is approximately 60-65% and the 3-year survival is around 40%.[1,2] When these statistics are considered for cats discharged from the hospital, the 6-month survival increases substantially to 84% and the 3-year survival increases slightly to 45%.[2]

Although it seems obvious, increasing age has been associated with shorter survival times.[1,2] Other factors reportedly associated with overall survival include preoperative azotemia, body weight, postoperative creatinine concentration, percentage of creatinine decline from preoperative levels, Doppler-derived arterial blood pressure, and the presence of preoperative infectious disease.[2] Further work is required to validate these risk factors in other patient populations.

Renal Transplantation in Dogs

Several clinical case series have been published regarding renal transplantation in dogs.[41-43] Uniformly, clinical outcomes have not been as positive as renal transplantation in humans or cats. These poor outcomes exist even after decades of experimental research evaluating a variety of immunosuppression regimens.[44] In the most recent clinical study, 26 dogs undergoing renal transplantation and receiving variations of a cyclosporine-based immunosuppressive regimen were reviewed; the median survival time was 24 days.[41] Dogs in that study had significant morbidity and mortality associated with thromboembolism and infection.

Another cohort of 15 dogs was reported previously and received a regimen of rabbit antidog antithymocyte serum, cyclosporine, azathioprine, and prednisone. These dogs achieved a median survival time of 8 months, with technical failures (venous avulsion, graft torsion), graft rejection, and infection accounting for most of the mortality.[42]

Technically, renal transplantation in dogs is easier to perform because of the typically larger size of the renal vasculature and ureter; however, other factors contribute to the poor outcomes described above. Optimal donor-recipient matching may be more difficult in dogs given the greater number of erythrocyte antigen types in dogs. The clinical studies described above used dog erythrocyte antigen matching alone or in combination with mixed lymphocyte response testing to pair donors and recipients. Suppression of rejection reactions in dogs is particularly challenging with current immunosuppressive protocols, and, frequently, if sufficient immunosuppression is achieved, dogs succumb to opportunistic infection. Additionally and especially in larger dogs, the cost of the immunosuppressive medications can be dramatic. Finally, the preponderance of dogs has a significant glomerular component to their renal disease, which may predispose them to thromboembolic events.[41] How proteinuria changes following transplantation is unknown. Currently, to help minimize some of these issues, renal transplantation is recommended only if related donors are available and it may be more economically feasible in smaller dogs.

CHAPTER 324

Chronic Kidney Disease

David James Polzin

Client Information Sheet: Chronic Kidney Disease

Overview of Chronic Kidney Disease

Definitions

Chronic kidney disease (CKD) is the most commonly recognized form of kidney disease in dogs and cats. It is defined as structural and/or functional abnormalities of one or both kidneys that have been continuously present for 3 months or longer. The archaic descriptors *kidney insufficiency* and *kidney failure* have not been uniformly and adequately defined; therefore, they have been replaced by a CKD staging system developed by the International Renal Interest Society (IRIS; www.iris-kidney.com). The IRIS CKD staging system provides specificity regarding the extent of kidney dysfunction and recognition of the full breadth of structural and functional CKD. The kidneys of dogs and cats with CKD have permanent reductions in their number of functioning nephrons. Although renal structure and function are not consistently parallel, primary kidney diseases usually display evidence of both structural and functional derangements. The clinical presentation of patients with CKD typically reflects the extent of reduction in renal function rather than the impact of structural lesions.

In most instances, CKD is irreversible and progressive, even with treatment. However, it is common for prerenal or postrenal azotemia or active kidney diseases (called acute-on-chronic kidney disease) to exist with CKD. In contrast to CKD, these complications may be reversible (e.g., pyelonephritis, ureteral obstruction, dehydration, etc.). After correcting reversible primary diseases and/or prerenal or postrenal conditions, further improvement in kidney function should not be expected because compensatory and adaptive mechanisms designed to sustain kidney function have largely already occurred, changes which promote progressive loss of remaining nephrons and kidney function. This characteristic of CKD (called "spontaneous progression of CKD") has been explained by the "trade-off hypothesis" which states that the consequence of the renal adaptive processes maximizing residual kidney function to sustain homeostasis results in a trade-off of ongoing damage to surviving nephrons. Thus, it is not necessary for the initial disease process to persist for the progressive decline in kidney function to continue.

CKD typically causes a slow but inexorably progressive decline in function. In some patients, this pattern follows an almost linear decline, while in others the pattern is characterized by periods of relative stability followed by episodes of precipitous decline in renal function. Some patients may have multiple periods of stable renal function and a series of precipitous declines before succumbing to CKD. However, exceptions to this progressive pattern are recognized, particularly among a substantial subset of cats who have stable renal function for years. In one recent study, only 101 of 213 (47%) cats with CKD showed evidence of progressive increase in serum creatinine values.[1] This pattern of stability may also be observed in some young dogs with renal dysplasia. Unless additional kidney injury occurs or CKD is advanced, rapid deterioration of remaining kidney function is atypical. Rather, kidney function often remains stable or declines over months to years.[2,3] Thus, regardless of initiating cause, CKD is an irreversible and slowly progressive disease. While no treatment can correct existing irreversible kidney lesions of CKD, the clinical and biochemical consequences of reduced kidney function can often be ameliorated by supportive therapy, and the natural progressive course of CKD may be slowed by therapeutic intervention.

Prevalence and Affected Populations

Overall Prevalence

The prevalence of kidney disease has been estimated to range between 0.5% and 7% in dogs and between 1.6% and 20% in cats.[4] However, it has been suggested that a reasonable estimate of the overall prevalence of CKD in general small animal practice in the United States would be 1% to 3% of cats and 0.5% to 1.5% of dogs.[5] One study estimated the prevalence of CKD in United Kingdom dogs to be 0.02% to 1.44%.[6] Of the dogs studied in this report, 95/136 (63.6%) were IRIS CKD stages III or IV, whereas 37/136 (26.6%) had blood urea nitrogen (BUN) concentrations at or above 112.0 mg/dL.

Cats

Although frequently considered a disease of older animals, CKD occurs with varying frequency in dogs and cats of all ages. In a retrospective study of cats with CKD, 53% of affected cats were >7 years old, but the age range was 9 months to 22 years.[7] In a study on age distribution of kidney disease in cats from data submitted to the Veterinary Medical Data Base at Purdue University between 1980 and 1990, 37% of cats with a diagnosis of "renal failure" were less than 10 years old, 31% of cats were between the ages of 10 and 15, and 32% of cats were older than 15 years of age.[8] Similarly, in a study of cats with CKD reported in 1988, their mean age was 12.6 years with a range of 1 to 26 years.[3,9] Mean age among 45 control cats in this study was 10.0 years. During the year 1990, the prevalence of kidney disease among cats of all ages was reportedly 16 cases for every 1000 cats examined. During the same year, the prevalence of kidney disease among cats 10 years of age or older was 77 per 1000 cats examined, and among cats older than 15 years, 153 per 1000.[7] In a study of cats >9 years of age, 30.5% of cats developed azotemia within 12 months.[10] Maine Coon, Abyssinian, Siamese, Russian Blue, and Burmese cats were disproportionately reported as affected.

Dogs

Dogs from the United Kingdom ≥12 years of age had 5.5 times the chance and dogs aged 4 to 7 years had 0.22 times the odds of CKD compared with dogs aged 7 to 12 years.[6] In the same study, Cocker Spaniels and Cavalier King Charles Spaniels had increased odds of CKD compared with crossbreds. However, purebred dogs did not show increased odds of CKD, either overall or for those younger than 5 years of age. An association between CKD and smaller body size has previously been reported in dogs, but no such association was found in the UK study.[6,11] Although CKD apparently occurs less commonly in dogs than in cats, the incidence increases with age in both. Based on data submitted from 1983 to 1992 to the Veterinary Medical Data Base at Purdue University, 18% of dogs with a diagnosis of "renal failure" were <4 years of age, 17% were 4 to 7 years, 20% were 7 to 19 years, and 45% were >10 years of age. The prevalence of a diagnosis of "renal failure" among dogs of all ages was 9 cases for every 1000 dogs examined. The prevalence of "renal failure" among dogs 7 to 10 years of age was 12.5 per 1000 dogs examined, for dogs 10 to 15 years it was 24 per 1000, and among dogs >15 years it was 57 per 1000. More recently, prevalence of CKD in dogs seen in general practice was estimated to be as high as 1.5%.[5] The observation of increasing odds of CKD with increasing age is consistent with the theory of CKD progression from early subclinical kidney damage to clinical disease.

Causes of CKD

Initial Suspicion

Most dogs and cats are initially suspected of having CKD after being noted to have an increase in serum creatinine concentration. Serum creatinine values above reference ranges imply that glomerular filtration rate (GFR) has decreased by 75% or more and that at least 75% of the nephrons in both kidneys have been injured or lost. Thus, diagnosis of CKD in dogs and cats is recognized relatively late in the course of disease. Typically, the kidneys are small because lost nephrons are replaced by scar tissue and chronic inflammation that fails to provide much guidance as to the etiologic origin of injury (Figure 324-1). Further, surviving nephrons reflect adaptive and compensatory modifications that may interfere with establishing the etiologic origin of CKD. Thus, the etiologic basis of kidney disease is not usually determined. Perhaps earlier detection of CKD (e.g., IRIS CKD stage I) might provide an opportunity to establish the initiating disease(s) responsible for CKD.

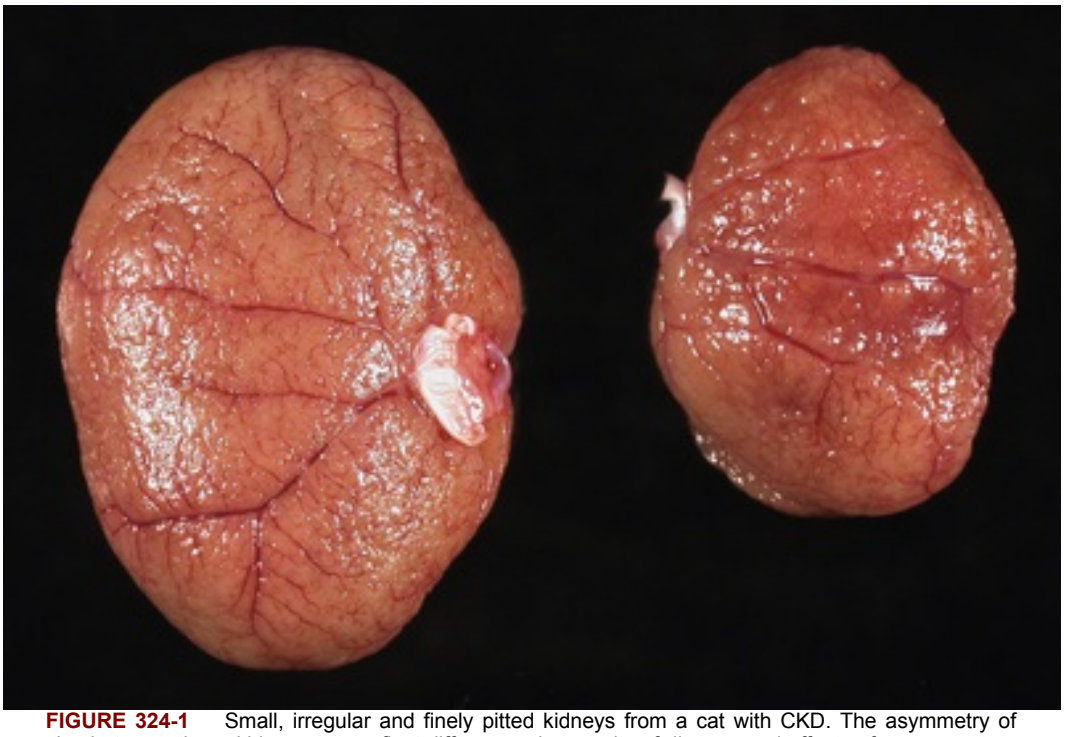

FIGURE 324-1 Small, irregular and finely pitted kidneys from a cat with CKD. The asymmetry of size between these kidneys may reflect differences in severity of disease and effects of compensatory hypertrophy.

Dogs

CKD may begin with a variety of different familial, congenital, or acquired conditions. Biopsy findings in 37 dogs with primary renal azotemia revealed that 58% had chronic tubulointerstitial nephritis, 28% had a glomerulonephropathy, and amyloidosis was observed in 6%, although earlier estimates suggested glomerular disease may account for over 50% of the CKD in dogs.[12,13] Over the past decade, the occurrence of glomerular disease appears to have increased substantially in selected geographic areas due to increased prominence of certain infectious diseases such as borreliosis in the United States (see ch. 211) and leishmaniasis in Europe (see ch. 221).[14] Many of these dogs have or develop CKD; however, an accurate measure of the prevalence of glomerular disease in dogs has not been established. The proportion of CKDs due to glomerular disease is confounded by affected dogs having several concurrent renal syndromes, including CKD, acute kidney injury (AKI), nephrotic syndrome, or isolated proteinuria (initially IRIS CKD stage I).

Cats

In cats with CKD, 70% had tubulointerstitial nephritis, glomerulonephropathy was seen in 15%, lymphoma in 11%, and amyloidosis in 2%. As with dogs, the initiating cause(s) of CKD often cannot be determined. The etiologic basis of diseases in the tubulointerstitium has been especially elusive. Glomerulonephropathies have been linked to a variety of neoplastic, metabolic, and infectious and noninfectious inflammatory processes.[15] Several infectious agents are proposed as possible factors promoting the remarkably high prevalence of feline CKD. Feline immunodeficiency virus (FIV) has been linked to renal disease in cats, although few with CKD are FIV positive.[16,17] A feline morbillivirus has been associated with tubulointerstitial lesions in cats.[18] Feline herpesvirus 1, calicivirus, and panleukopenia virus vaccines grown in feline tissue culture and given to kittens subcutaneously induce anti-feline-renal-tissue antibodies in serum, prompting concerns that vaccinations may play a role in development of CKD.[19-21] While these causes have been proposed as possible causes for feline CKD, they remain largely unsubstantiated.

It has been hypothesized that at least in some cats, renal disease may be an adaptive mechanism associated with normal aging.[22] Early onset renal tubulointerstitial changes occur in younger adult cats and this has been proposed as a defensive adaptation. Further, while older cats succumbed to overt renal disease with increased frequency, cats with renal tubulointerstitial changes have longer life spans regardless of cause of

death. More telomere shortening was noted in cats with CKD in their proximal and distal tubular epithelial cells than in healthy young or geriatric cats.[23] Telomere shortening was not detected in skin or liver samples from any of the cats, suggesting that it is specific to the kidneys. It was concluded that feline CKD is associated with shortened telomeres and increased cellular senescence in affected kidneys, which may present future targets for interventional therapy.

Specific Therapies

Despite the irreversibility of generalized renal lesions associated with CKD, it is important to formulate diagnostic plans to try to identify the underlying cause and to determine if it is still active. Although specific therapy directed at eliminating or controlling the primary cause will usually not substantially alter existing renal lesions, it is important in the context of minimizing further nephron damage. Renal diseases potentially amenable to specific therapy include bacterial pyelonephritis, obstructive uropathy, nephrolithiasis, renal lymphoma (particularly in cats), hypercalcemic nephropathy, perinephric pseudocysts, and some glomerulopathies.

Prognosis of CKD

Influencing Factors

Many factors influence the prognosis of CKD, both favorably and unfavorably, including the quality of medical care provided and level of owner commitment. Prognosis often influences an owner's choice of treatment and compliance in following recommendations. Therefore, it is important to provide the most accurate prognosis possible, best established after reviewing results of a comprehensive evaluation. Factors to be considered in establishing a prognosis for a pets with CKD include: (1) the nature of the primary renal disease, (2) severity and duration of clinical signs and complications of uremia, (3) probability of improving renal function (reversibility, primarily of prerenal, postrenal, and newly acquired primary renal conditions), (4) severity of intrinsic renal functional impairment, (5) rate of progression of renal dysfunction with or without therapy, and (6) patient age. While severity of uremic signs may be a reasonable predictor of short-term prognosis in some individuals, prerenal, postrenal, and active renal complications may be the instigators of signs and may be reversible. In order to most accurately establish the prognosis relating to the underlying CKD, prerenal, postrenal, and active complications (e.g., pyelonephritis) should first be treated. The IRIS CKD staging system is a useful guide for providing a preliminary prognosis. Cats with CKD survive longer than dogs.

Prognosing Cats with CKD

In a retrospective study, median survival time for 211 cats with CKD and serum creatinine concentrations 2.3 to 2.8 mg/dL was 771 days.[24] However, survival varied significantly with IRIS CKD stage. Cats with IRIS CKD stage II had a median survival time of 1,151 days with a 95% confidence interval (CI) of 1,014 to 1,565 days. Because these data only include a subset of IRIS CKD stage II cats, survival durations might have been longer had all stage II cats been included (1.6-2.3 mg/dL). Median life expectancy for cats with IRIS CKD stage III was 679 days (95% CI: 445-910 days) and it was 35 days for cats in IRIS CKD stage IV (95% CI: 21-99 days). In this study, serum phosphorus (PO_4) and IRIS stages were the only baseline parameters that significantly affect survival time. However, severity of proteinuria also influences survival.[25-27] Hypertension does not appear to be a primary determinant of survival in cats with CKD but does affect severity of proteinuria. Both concerns may be masked by the effect of antihypertensive therapy.[25,26]

Unlike people and dogs, amlodipine therapy of hypertension in cats is associated with a reduction in proteinuria which does influence survival stratified by IRIS staging.[27] Anemia has been found to be a prognostic indicator in some, but not all studies. Dehydration and therapy may confound use of packed cell volume as a prognostic indicator. In one study, weight loss was the most reliable indicator of clinical deterioration in cats with CKD and nephrolithiasis was identified as a common comorbid factor in cats with CKD.[1] In a case-control study of 14 cats with stages II and III CKD, nephrolithiasis unassociated with urinary obstruction was not associated with increased mortality rates or in rate of disease progression.[29]

Prognosing Dogs with CKD

In 228 dogs diagnosed at a first-opinion practice as having CKD, their median survival time from diagnosis

was 226 days (95% CI: 112-326 days).[6] During the study, 118/228 (52%) dogs died, 99/118 had been euthanized. IRIS CKD stage and BUN concentration were found to significantly influence their survival. Compared to IRIS CKD stages I and II, dogs with IRIS CKD stage III had 2.6 times and IRIS CKD stage IV had 4.7 times the mortality. Dogs with BUN concentrations ≥112 mg/dL at initial diagnosis had 7.8 (95% CI: 2.6-22.7) times the mortality rate due to CKD than dogs with BUN values <44.8 mg/dL.

Treatment of CKD in dogs appears to affect prognosis. In a clinical trial of 38 dogs with spontaneous CKD, mean serum creatinine concentration did not appear to influence survival when dogs were fed a renal diet and median survival for 21 dogs with a mean serum creatinine concentration of 3.3 mg/dL was 615 days. Median survival for the dogs in this group with serum creatinine values between 2.0 and 3.1 mg/dL was also 615 days.[2] However, in 17 dogs who had a mean serum creatinine of 3.7 mg/dL and were fed a maintenance diet, median survival was 252 days, and in those with serum creatinine values 2.0 to 3.1 mg/dL, it was 461 days. Less information has been reported on prognosis and risk factors for dogs versus cats with CKD. Proteinuria has been identified as a risk factor for development of clinical signs of uremia and for death in dogs with CKD.[30] In one study, proteinuria had a progressively adverse effect on outcome: risk of death due to CKD increased by 60% for each unit of urine protein-to-creatinine ratio (UPCR) >1.0.

Arterial hypertension (see ch. 157) has been identified as a risk factor for mortality in dogs with CKD, but as in cats, adverse effects of hypertension in dogs may be mediated, at least in part, by proteinuria.[31] Dogs with CKD and the highest baseline systolic blood pressures have a greater decline in renal function over time, have increased risk of uremic crises and death. While this does not prove a cause-and-effect relationship between hypertension and progressive renal disease, it does suggest that initial blood pressure values should be considered in formulating a prognosis for dogs with CKD. Higher body condition score (see ch. 170) is associated with a better prognosis (longer survival time) in dogs with CKD.[32] Similarly, obesity is associated with longer survival in humans with CKD, consistent with starvation having a significant role in the outcome (see ch. 176 and 177).

Congenital/Familial Diseases

Compared to the rate of progression of CKD in middle-aged to older dogs with acquired renal disease, CKD may progress more slowly in many dogs with congenital or familial nephropathies not characterized by proteinuria (renal dysplasia; see ch. 328). A comparably slower rate of progression has also been observed in young dogs with acquired CKD (e.g., following nephrotoxin exposure). Many such dogs appear remarkably resistant to developing clinical signs of uremia despite substantial elevations in serum creatinine and urea nitrogen concentrations.

Clinical Consequences of Chronic Kidney Disease

Uremia

Definition

Uremia is the clinical syndrome that results from loss of kidney functions. Impaired renal glomerular, tubular and endocrine functions lead to retention of toxic metabolites, changes in the volume and composition of body fluids, and excesses or deficiencies of some hormones. Clinical signs of uremia reflect the sum effect of these derangements throughout the body. An alternative definition of uremia is "the ill effects of renal failure that we cannot yet explain."[33,34] The pathogenesis of some abnormalities previously regarded as part of the uremic syndrome are now understood (e.g., hypertension due to volume overload, anemia due to erythropoietin [EPO] deficiency), so they would no longer be considered to be part of the uremic syndrome using this newer and more restrictive definition.

Clinical Signs

The clinical signs most likely to prompt veterinary consultation are polyuria and polydipsia (PU/PD). The most prominent clinical signs of uremia are related to the gastrointestinal (GI) tract: anorexia, nausea, vomiting, oral ulcerations, stomatitis, necrosis of the margins of the tongue, halitosis (uremic breath), diarrhea, melena, and hematochezia. Other clinical findings in dogs and cats with CKD may include: weight loss, muscle wasting, hypothermia, lethargy, weakness, muscle tremors, uremic pericarditis and pneumonitis, hypertension, altered behavior (uremic or hypertensive encephalopathy), renal osteodystrophy, and hemorrhagic diatheses. In one study, the most common signs of CKD were vomiting (50%), PU/PD (44%), impaired appetite (40%), diarrhea/melena (37%), weight loss/cachexia (29%), lethargy/depression (22%),

urinary incontinence (20%), halitosis (12%), and anemia (4%).[6]

Pathogenesis

The pathogenesis of specific signs of uremia is variably understood. In general, three major mechanisms are involved: (1) disturbed excretion of electrolytes and water, (2) reduced excretion of organic solutes (i.e., uremic toxins), and (3) impaired renal hormone synthesis. These alterations affect virtually every organ system, thereby producing the uremic syndrome. More than 70 clinical signs have been identified in uremic people.

Disturbed Excretion of Electrolytes and Water

A primary function of the kidneys is to maintain water and electrolyte balance. Excretion of water and electrolytes must accommodate changes in intake. As glomerular filtration rate (GFR) declines with kidney disease, the need for excretion of water and electrolytes remains the same unless intake is modified. As GFR declines, the excretory load of electrolytes and water per surviving nephron substantially increases but excretion of many substances can be maintained through parallel reductions in degree of tubular reabsorption. If GFR declines by three-fourths, the remaining nephrons must each excrete four times more sodium (Na). Thus, maintaining fluid and electrolyte balance requires that more water and electrolytes be excreted per surviving nephron. For Na, potassium (K) and water, a steady state can be maintained even though GFR may be reduced by more than 80%.[35] Although the kidneys have remarkable ability to maintain water and electrolyte balance well into advanced stages of disease, compensatory mechanisms are limited and ultimately fail in end-stage disease. The compensatory mechanisms for some electrolytes are more effective in maintaining balance. For example, adaptive excretion of PO_4 is less effective than adapted excretion of Na. If PO_4 intake continues unchanged and GFR declines, the requirement for PO_4 excretion may exceed adaptive maximum daily rates of PO_4 excretion, and PO_4 begins to accumulate, leading to progressive hyperphosphatemia (hyperPO_4). Clinical manifestations of disturbed water and electrolyte excretion may include edema, hypertension, hypoNa, hyperK, metabolic acidosis and hyperPO_4.

Reduced Excretion of Organic Solutes

Although urea and creatinine are the best known, the kidneys excrete a wide variety of organic solutes (see ch. 62). Many of these solutes are handled primarily by glomerular filtration, but renal tubular secretion and reabsorption may affect net renal excretion. An important difference between renal handling of organic solutes and renal handling of electrolytes and water is that excretion of organic solutes is generally not actively regulated and blood concentrations begin to rise with the initial decline in GFR and continue to progressively increase as renal function continues to decline.[33,34] When GFR declines below about 10% of normal, clinical signs may begin to appear, usually attributed to increased concentrations of organic solutes. However, presence of an increased concentration of a substance does not prove it is a uremic toxin. Nonetheless, that uremic solutes may in fact be contributory to the uremic syndrome is supported by the observation that some uremic abnormalities are transferable with uremic serum or plasma. Abnormalities that have been thus demonstrated include: inhibition of Na-K adenosine triphosphatase (ATPase), inhibition of platelet function, leukocyte dysfunction, loss of erythrocyte membrane lipid asymmetry, and insulin resistance.

In excess of 100 potential uremic solutes have been listed by the European Uremic Toxin Work group (EUTox).[33,34] However, it has been difficult to confirm substances as true uremic toxins. It has been suggested that most retained uremic solutes are probably not toxic, and those that are toxic may only exert their effects when present in combination with other uremic solutes. Urea and creatinine, by themselves, are not uremic toxins. However, plasma urea concentration is believed to be a good reflection of the systemic concentrations of many uremic solutes. Thus, demonstrating that a treatment lowers urea concentrations in and of itself is not conclusive evidence of reduced uremic toxicity (see ch. 62).

In addition to impaired excretion, many middle-sized molecules and various cytokines and growth factors accumulate in CKD because the kidney's capacity for catabolizing many substances is also impaired. Further, plasma levels of many polypeptide hormones, including parathyroid hormone (PTH), insulin, glucagon, luteinizing hormone, and prolactin, increase in patients with CKD because of impaired renal catabolism as well as enhanced glandular secretion.

Impaired Renal Hormone Synthesis

The kidneys normally produce a number of essential hormones, including calcitriol (vitamin D; 1,25-dihydroxycholecalciferol), EPO, prostaglandins, kinins and renin. In particular, calcitriol and EPO have well-established roles in the pathogenesis of clinically important consequences of severe CKD. Calcitriol, the most metabolically active form of vitamin D, is essential for Ca and skeletal metabolism. Vitamin D deficiencies can result in renal secondary hyperparathyroidism and renal osteodystrophy. PTH has been identified as a uremic toxin, although the consequences of hyperparathyroidism beyond its role in renal osteodystrophy in CKD are poorly established. In addition, most cells have receptors for calcitriol and inadequate activation of these receptors may contribute to clinical signs of uremia. It appears that restoration of adequate levels of calcitriol in dogs and humans with CKD may slow progression of kidney disease and prolong survival.[36] EPO deficiency is associated with nonregenerative anemia that may promote weakness, lethargy, and hyporexia.

Gastrointestinal Consequences

Anorexia, Vomiting

GI complications are the most common and obvious clinical signs of uremia. Clinical signs may include nausea, vomiting (see ch. 39), reduced appetite (see ch. 23), stomatitis, GI ulceration, diarrhea and colitis (see ch. 40). Decreased appetite and weight loss are nonspecific findings that may precede other signs of uremia in dogs and cats. Appetite may be selective for certain foods and may wax and wane. Factors promoting weight loss and malnutrition include anorexia, nausea, vomiting and the subsequent reduction in nutrient intake, hormonal and metabolic derangements, and catabolic factors related to uremia, particularly acidosis. Anorexia appears to be multifactorial in origin. Studies using rodent models suggests that a middle molecule "anorectic factor," perhaps a peptide, in the plasma can suppress appetite.[37] Elevated serum leptin concentrations have also been implicated as a factor contributing to anorexia.[38] Vomiting is frequent but inconsistent in uremia and may result from the effects of unidentified uremic toxins on the medullary emetic chemoreceptor trigger zone and from uremic gastroenteritis. Severity of vomiting correlates variably with the magnitude of azotemia. Because uremic gastritis may be ulcerative, hematemesis may occur. Although vomiting has been thought to be more frequent in uremic dogs, it occurs in about 25% to 33% of uremic cats.[3] Vomiting may impair compensatory PD, enhancing the risk of dehydration, and exacerbating prerenal azotemia and clinical signs of uremia.

Uremic Gastropathy

Definition

Uremic gastropathy and its associated clinical signs appear to be more common in dogs than cats.[39] In dogs it is characterized microscopically by mineralization of mucosal and submucosal blood vessels, edema, and glandular atrophy.[39] Mineralization appears to be related to the Ca × PO_4 product. Increased gastrin levels due to reduced renal clearance may have a role in development of uremic gastropathy.[40] Cats with CKD also have elevated levels of gastrin that worsen with severity of CKD.[40] Gastrin induces gastric acid secretion directly by stimulating receptors located on gastric parietal cells as well as by increasing histamine release from mast cells in the gastric mucosa. Enhanced histamine release may also promote GI ulceration and ischemic necrosis of the mucosa through a vascular mechanism characterized by small venule and capillary dilatation, increased endothelial permeability, and intravascular thrombosis.[41] However, gastric hyperacidity has not been documented in uremic dogs or cats, and mucosal necrosis and ulceration appear to be uncommon findings in uremic gastropathy in dogs.[39]

In a recent study of 37 cats with CKD, gastric ulceration, edema, vascular mineralization and hemorrhage were not observed; however, 16/37 (43%) cats had gastric fibrosis of varying severity and 14/37 (38%) cats had mineralized gastric walls.[42] Gastric mineralization was restricted to cats in IRIS CKD stages III and IV. Increased Ca-PO_4 products correlated with disease severity. Serum gastrin levels were significantly higher in CKD cats compared to nonazotemic cats, but increased gastrin concentrations were not associated with gastric ulceration. While inappetence occurred in 84% (26/31) and vomiting occurred in 45% (14/31) of the cats with CKD, significant relationship was not apparent between these clinical signs and gastric lesions and there was no significant relationship between clinical signs and gastrin concentrations. Cats with gastric

mineralization had poor appetites, suggesting that clinical signs of nausea and vomiting in cats with CKD are more likely to be due to the effects of uremic toxins on the chemoreceptor trigger zone than pathologic lesions of the gastric wall.

Dysphagia

In a study of 80 cats with spontaneous CKD, dysphagia and oral discomfort occurred in about 8% of uremic cats and 38% of cats with end-stage CKD.[3] Periodontal disease was observed in 31% of uremic and 35% of end-stage CKD cats. Halitosis was reported in about 8% of cats in both groups. Moderate to severe CKD may result in uremic stomatitis characterized by dry mucous membranes (xerostomia) oral ulcerations (particularly located on the buccal mucosa and tongue), brownish discoloration of the dorsal surface of the tongue, necrosis and sloughing of the anterior portion of the tongue (associated with fibrinoid necrosis and arteritis), and urine-smelling breath. Degradation of urea to ammonia by bacterial urease may contribute to these signs. Poor oral hygiene and dental disease may exacerbate onset and severity of uremic stomatitis.

Uremic Enterocolitis

Enterocolitis causes diarrhea and occurs in dogs and cats with severe uremia. It is typically less dramatic and less common than uremic gastritis. In one study, diarrhea was not reported by owners of 80 cats with spontaneous CKD.[3] When present, uremic enterocolitis is often hemorrhagic, although this GI hemorrhage may initially escape clinical detection. It may also be complicated by intussusception. Uremic enterocolitis may, at least in part, result from the irritant effect of increased ammonium production in the colon associated with high concentrations of urea. In contrast to diarrhea, constipation is relatively common in cats with CKD. However, it appears to be primarily a manifestation of dehydration rather than GI dysfunction. It may also occur as a complication of intestinal PO_4 binding agents.

Impaired Urine Concentrating Ability, Polyuria, Polydipsia and Nocturia

Among the earliest and most common clinical manifestations of CKD are PU/PD, nocturia and urinary incontinence due to reduced urine concentrating ability (see ch. 45 and 296). PD was the most common clinical sign reported in a study of 80 cats with CKD. Cat owners recognized PD more often than PU. Although urine specific gravity values of cats in CKD stages II through IV are usually below 1.035, some cats appear to retain adequate urine concentrating ability (i.e., specific gravity >1.035) especially early in the course of their CKD. Decreased urine concentrating ability results from several factors including: increased solute load per surviving nephron (solute diuresis), impaired genesis of the hypertonic gradient of the renal medulla due to disruption of the renal medullary architecture and counter-current multiplier system by disease, and impairment in renal responsiveness to antidiuretic hormone (ADH). Impaired responsiveness to ADH may result, at least in part, from an increase in distal renal tubular flow rate, which limits equilibration of tubular fluid with the hypertonic medullary interstitium. Additionally, ADH-stimulated adenyl cyclase activity and water permeability in the distal nephron may be impaired in uremia.[43] As urine concentrating ability is lost, urine volume is determined by the daily urine solute load. The solute load is predominantly composed of salt and urea, both of which can be modified by altering the dietary salt and protein content, respectively. Other important factors that can influence urine volume are thirst (water consumption) and therapeutic administration of fluids. PD is a compensatory response to PU. If fluid intake fails to keep pace with urinary fluid losses, dehydration will ensue because of the inability to conserve water by concentrating urine. Dehydration subsequent to inadequate fluid intake is a common problem in cats with CKD. Some dogs and cats with advanced CKD have limited ability to excrete ingested water, causing mild hyponatremia.

Arterial Hypertension and Cardiovascular Consequences

The major mechanisms thought to contribute to hypertension in CKD include fluid retention, activation of the renin-angiotensin-aldosterone system (RAAS), and increased activity of the sympathetic nervous system (see ch. 157).[35,44] Hypertension in humans with CKD is predominantly attributed to volume expansion. Removing fluid with diuretics or dialysis either eliminates hypertension or makes it more responsive to medications.[35] Similarly, hemodialysis that includes removal of excess fluids (ultrafiltration) have often been observed to reduce or normalize blood pressure in dogs and cats that were hypertensive prior to treatment. Where volume expansion is not the cause for hypertension in humans with CKD, increased RAAS activity appears to be an important determinate of hypertension. Enhanced renin release is presumed secondary to vascular

disease or focal areas of ischemia within the diseased kidneys. However, a study in cats reported that hypertensive cats often have significantly increased plasma aldosterone concentrations with decreased plasma renin activities, and that plasma renin activity declines with antihypertensive therapy, suggesting that retention of salt and water may be the major cause for hypertension. This may also explain, at least in part, why angiotensin-converting enzyme (ACE) inhibitors may be ineffective antihypertensive drugs in cats with CKD.

Hypertension may be primary (idiopathic) or secondary to diseases such as CKD. In dogs and cats, CKD is the most common cause for secondary hypertension while primary hypertension appears to be uncommon (see ch. 157). Hypertension may adversely affect long-term prognosis in dogs and cats with CKD, at least in part by promoting proteinuria.[31] Arterial hypertension has been purported to be among the more common complications of CKD; however, the true prevalence of arterial hypertension among dogs and cats with CKD is not known. Some studies have suggested that hypertension may be unusual in dogs with CKD, while other studies have reported that as many as 66% of cats and 50% to 93% of dogs with CKD have hypertension.[6,31,46,47] However, other studies in dogs suggest that a prevalence of 20% to 30% may be more accurate.[25,48] Dogs with glomerular diseases may be at higher risk for elevated blood pressure.[49] One study estimated the prevalence of systolic hypertension in cats with CKD to be approximately 13% to 28%.[46] The true prevalence and clinical impact of hypertension remains to be more clearly established in dogs and cats, but there appears to be a consensus among veterinary nephrologists that elevated blood pressures may lead to end-organ injury in dogs and cats with CKD and therefore warrants detection and treatment.[50] Organ systems most commonly affected by elevated blood pressure include the eyes, kidneys, nervous system and cardiovascular system.

Hypertension is present when there is persistent elevation of systolic and/or diastolic blood pressure, or when a patient previously diagnosed as hypertensive is receiving antihypertensive medication (regardless of the current blood pressure level). It is generally accepted that systolic blood pressure measurements in awake, nonanxious cats and dogs should not exceed about 160 to 170 mm Hg, and these figures probably represent a reasonable estimate of treatment threshold. In order to make blood pressure terminology more familiar to veterinarians and pet owners, the IRIS has changed its terminology to be similar to that used by the American Heart Association (Box 324-1). Categories from "normotensive" through "severe hypertension" imply sequentially minimal, low, moderate or high risk of hypertension-associated organ injury.[50]

Box 324-1

IRIS CKD Staging in Dogs and Cats

Data from http://iris-kidney.com/pdf/staging-of-ckd.pdf.

A IRIS CKD Stage

STAGE	SERUM CREATININE VALUES (mg/dL / mcmol/L)	
	DOGS	CATS
Stage I	<1.4 / <125	<1.6 / <140
Stage II	1.4-2.0 / 125-179	1.6-2.8 / 140-249
Stage III	2.1-5.0 / 180-439	2.9-5.0 / 250-439
Stage IV	>5.0 / >440	>5.0 / >440

B IRIS CKD Subclassification by Proteinuria (Urine Protein-to-Creatinine Ratio)

CLASSIFICATION	URINE PROTEIN-TO-CREATININE RATIO	
	DOGS	CATS
Proteinuric (P)	>0.5	>0.4
Borderline proteinuric (BP)	0.2-0.5	0.2-0.4

Nonproteinuric (NP)	<0.2	<0.2

C IRIS CKD Subclassification by Blood Pressure Stages for Dogs and Cats

ARTERIAL PRESSURE		
CATEGORY	**SYSTOLIC BLOOD PRESSURE (mm Hg)**	**DIASTOLIC BLOOD PRESSURE (mm Hg)**
Normotension (N)	<150	<95
Borderline hypertension (BH)	150 to 159	95 to 99
Hypertension (H)	160 to 179	100 to 119
Severe hypertension (SH)	≥180	≥120

Anemia

Anemia is a common in dogs and cats with CKD, although its magnitude is usually mild until the advanced stages of CKD. In humans, the packed cell volume begins to decline when GFR has reduced to about 40% of normal, and thereafter the severity of anemia is typically proportional to the loss of kidney function.[35] The anemia of CKD typically is characterized as normochromic, normocytic, and nonregenerative (see ch. 50 and 199). Bone marrow biopsy (see ch. 92) is typically characterized by hypoplasia of the erythroid precursors with little or no interference with normal leukopoiesis and megakaryocytopoiesis. On blood smears, spiculated and deformed red cells (burr cells or echinocytes) may be noted. Clinical signs of anemia include pallor of the mucous membranes, fatigue, listlessness, lethargy, weakness, and anorexia.

The primary cause for anemia of CKD is inadequate secretion of EPO by the kidneys. EPO is a glycoprotein hormone produced in the kidneys in response to decreased oxygen delivery. EPO binds to a receptor on erythroid progenitors causing these cells to differentiate into normoblasts and then mature erythrocytes. Inadequate EPO production results from the decline in renal functional mass. While the precise intrarenal site of EPO production has been elusive, peritubular capillary endothelial cells may be the most likely location.[35] The renal oxygen sensor is probably a heme protein that undergoes a transformational change in response to decreased oxygen delivery which increases EPO mRNA.[35] Hypoxia-inducible factors (HIF), and in particular HIF-2, have emerged as the transcription factor that regulates EPO synthesis in the kidney and plays a critical role in the regulation of intestinal iron uptake.[51]

Anemic CKD patients have a relative rather than absolute EPO deficiency in that plasma levels typically exceed the normal range, but are low relative to the severity of anemia.[52] Anemic CKD cats have been reported to have plasma EPO concentrations similar to normal cats.[53] Thus, the primary causes for anemia of CKD are insufficient renal EPO production, shortened red cell life span, nutritional abnormalities (notably iron, B_{12} and folate deficiencies), EPO inhibitor factors in uremic plasma, blood loss, and myelofibrosis.

Renal Secondary Hyperparathyroidism

Prevalence and Pathophysiology

Multiple factors promote development of renal secondary hyperparathyroidism (RSHP; see ch. 69 and 297). PO_4 retention, a consequence of declining GFR, even in early renal failure is closely associated with development of RSHP.[58,59] Increases in fibroblast growth factor-23 (FGF-23), in response to RSHP, also develops early in CKD. As a phosphaturic hormone, the action of FGF-23 is to mitigate PO_4 retention early in the course of CKD, but it also inhibits renal 1-alpha-hydroxylase activity, thus leading to decreased calcitriol levels.[59] The decline in calcitriol levels is among the earliest changes that promotes development of RSHP. RSHP is present in an estimated 47% of asymptomatic cats with only biochemical evidence of CKD. It develops prior to azotemia in some cats, even when serum PO_4 and Ca are within reference ranges.[54-56] The overall prevalence of RSHP in cats with CKD was about 84% in one study and all with "end-stage" CKD have RSHP. In general, plasma PTH levels increase as serum creatinine concentration increases.[57]

A relative deficiency of calcitriol has been described in dogs with CKD, although absolute concentrations

were within reference ranges.[60] Relative or absolute deficiency of calcitriol has been hypothesized to play a pivotal role in development of RSHP.[61] PTH promotes renal 1-alpha-hydroxylase activity and formation of calcitriol. In turn, calcitriol limits PTH synthesis by feedback inhibition. Absent this normal feedback inhibition, PTH levels increase. Initially, RSHP increases 1-alpha-hydroxylase activity despite continued PO_4 retention, thereby restoring calcitriol production toward normal. However, normalization of calcitriol production occurs at the expense of persistently increased plasma PTH activity: a classic example of the "trade-off hypothesis." As CKD continues to progress, loss of viable renal tubular cells ultimately limits renal calcitriol synthesis and concentrations remain low. Deficiency of calcitriol leads to skeletal resistance to the action of PTH and elevates the set-point for Ca-induced suppression of PTH secretion. Skeletal resistance to PTH limits skeletal release of Ca, while elevating the set-point for PTH secretion allowing RSHP to persist even when plasma ionized Ca concentrations are normal or elevated.[57,61]

PO_4 retention likely promotes RSHP directly. PO_4 restriction in dogs and people with CKD has been shown to decrease PTH secretion without influencing calcitriol levels.[62-64] In untreated people with mild to moderate CKD (serum creatinine concentration ≤3.0 mg/dL), serum PO_4 concentrations correlated directly with PTH, independent of serum Ca or calcitriol concentrations.[65] This correlation was present despite most patients having serum PO_4 concentrations within the reference range. Importantly overt hyperphosphatemia may not be a prerequisite for phosphorus to have an effect on PTH secretion. Reduced calcitriol levels may have a permissive effect and/or an additional direct effect on PTH secretion in this setting.[65]

In more advanced CKD, the presence of uremic toxins appears to prevent the inhibition of parathyroid cell proliferation induced by calcitriol.[66] At this point, only serum Ca concentration correlates with serum PTH activity.[65] Impaired GI absorption of Ca due to low serum calcitriol levels likely plays an important role in RSHP. Blood ionized Ca (iCa) concentrations are often reduced in cats with CKD. While iCa concentrations have been reported to range from low to high in dogs with CKD in one study, >50% of cats with advanced end-stage CKD were hypocalcemic.[54,67]

Clinical Consequences

Although RSHP and renal osteodystrophy are well-documented sequelae of CKD, renal osteodystrophy is uncommon in dogs and cats. In dogs, it most often occurs in the immature, presumably because metabolically active growing bone is more susceptible to the adverse effects of RSHP. For unexplained reasons, bones of the skull and mandible are usually the most severely affected and may become so demineralized that the teeth become moveable and fibrous changes are obvious, particularly in the maxilla (Figure 324-2). Marked proliferation of connective tissue associated with the maxilla may cause distortion of the face. Jaw fractures are uncommon. Other possible but uncommon clinical manifestations of severe renal osteodystrophy include cystic bone lesions, bone pain, and growth retardation. Potential nonskeletal consequences of RSHP include mental dullness and lethargy, weakness, anorexia, and an increased incidence of infections due to immunodeficiency.[57] Excess PTH levels may also promote nephrocalcinosis and consequent progressive loss of renal function.

FIGURE 324-2 Radiographs of a young dog with CKD stage III, renal secondary hyperparathyroidism and renal osteodystrophy. The dog presented for severe pain that was localized to the skull and particularly the maxilla and mandible. Pathologic examination of the bone structure revealed fibrous-cystic osteodystrophy.

RSHP may be associated with substantial enlargement of the parathyroid glands (see ch. 298). This is of clinical importance in cats because hyperthyroidism is also common and palpation of a cervical mass logically may raise suspicion of thyroid rather than parathyroid disease. However, in one report, hyperplastic parathyroid glands were palpable as paratracheal masses in 11 of 80 cats with CKD.[3] Care should be taken to confirm either condition prior to starting treatment.

Laboratory Findings

Metabolic Acidosis

Metabolic acidosis is relatively common in CKD, but severe acidosis is primarily noted in those with advanced CKD (see ch. 128).[28,68] A study on 59 cats with CKD revealed that blood pH <7.27 was found in 10 of 19 cats with severe azotemia, 3 of 20 cats with moderate azotemia and none of 20 cats with mild azotemia. Metabolic acidosis was not found to be a prognostic factor in cats or dogs with CKD.[24,26] However, metabolic acidosis is now recognized to promote CKD progression in humans, although this has not been confirmed in dogs or cats.[68-70]

A combination of tubular reabsorption of filtered bicarbonate and excretion of hydrogen ions with ammonia and urinary buffers, primarily PO_4, maintain normal acid-base balance. As renal function declines, hydrogen ion excretion is maintained largely by increasing the quantity of ammonium excreted by surviving nephrons. While the quantity of ammonium excreted increases per surviving nephron, total renal ammonium excretion typically does not increase above normal. At some level of CKD, the capacity to enhance renal ammonia production is lost and metabolic acidosis ensues. Decreased medullary recycling of ammonia due to structural renal damage may also contribute to impaired ammonium excretion.[28] Decreased filtration of titratable acids as PO_4 and sulfate compounds plus impaired renal tubular proton secretion may also contribute.[71] Impaired renal tubular reabsorption of filtered bicarbonate is not typical of dogs and cats with CKD, but may occur in selected tubular disorders such as Fanconi syndrome (see ch. 326). Retention of PO_4 and organic acid (uric acid, hippuric acid, lactic acid, etc.) in CKD promotes an increased anion gap. However, hyperchloremic acidosis (normal anion gap), high anion gap or mixed hyperchloremic-high anion gap acidoses may all occur in CKD. Hyperchloremic acidosis is more likely in less severely azotemic patients.

Chronic metabolic acidosis may promote anorexia, nausea, vomiting, lethargy, weakness, muscle wasting, weight loss, and malnutrition. Dietary acidification of dogs and cats can cause negative Ca balance, bone demineralization or negative potassium balance which may in turn promote hypokalemia, renal dysfunction, and taurine depletion.[72] Chronic acidosis may promote protein malnutrition despite adequate dietary intake.[68] Protein catabolism increases in patients with acidosis, providing a source of nitrogen for hepatic glutamine synthesis, the substrate for renal ammonia synthesis.[73] The combined effects of reduced protein synthesis due to uremia and accelerated proteolysis due to acidosis promote elevations in BUN, increased nitrogen excretion, and negative nitrogen balance typical of uremic acidosis. Alkalization therapy effectively reverses acidosis-associated protein breakdown and reverses many signs.

Dietary protein requirements appear to be similar for normal and those with CKD unless uremic acidosis is present (see ch. 184). When acid-base status is normal, adaptive reductions in skeletal muscle protein degradation protects those consuming low-protein diets from losses in lean body mass. Metabolic acidosis blocks the metabolic responses to dietary protein restriction in two ways: (1) it stimulates irreversible degradation of the essential, branched chain amino acids, and (2) it stimulates degradation of protein in muscle.[73] Thus, acidosis may limit the ability of patients to adapt to dietary protein restriction. Metabolic acidosis also suppresses albumin synthesis in humans and may reduce the concentration of serum albumin.

Azotemia, Blood Urea Nitrogen, Creatinine

Azotemia is defined as excess urea or other nonprotein nitrogenous compounds in the blood (see ch. 62). Loss of renal function leads to accumulation of a wide variety of nonprotein nitrogen-containing compounds, including urea and creatinine. Many waste products of protein catabolism are excreted via glomerular filtration. Thus, those with primary CKD have impaired ability to excrete proteinaceous catabolites largely because of marked reduction in GFR. Since these compounds are derived almost entirely from protein degradation, their production increases when dietary protein increases. Urea is synthesized using nitrogen derived from amino acid catabolism and it may be excreted by the kidneys, retained in body water, or metabolized to ammonia and amino acids plus carbon dioxide by bacteria in the GI tract. Regardless of whether urea *per se* is toxic, BUN concentrations are typically related to dietary protein content. Further, BUN concentrations tend to correlate reasonably well with clinical signs of uremia. For practical purposes, BUN may thus be viewed as a surrogate marker of retained "uremic toxins."

In addition to increasing protein intake and declining renal function, BUN concentrations may also be increased by GI hemorrhage, enhanced protein catabolism, decreasing urine volumes (due to prerenal factors such as dehydration), and certain drugs (e.g., glucocorticoids). BUN concentrations may decline with portosystemic shunts, hepatic failure, low protein diets, and starvation. In some settings, a reduced BUN may

indicate protein calorie malnutrition due to inadequate intake as a consequence of improperly formulated diets or inappetence. Because many extrarenal factors influence BUN, creatinine is a more reliable measure of GFR in CKD. BUN and serum creatinine concentrations should be used together in evaluating patients, particularly patients consuming reduced protein diets. The ratio of BUN to serum creatinine concentration should decline when dietary protein intake is reduced. In patients consuming reduced protein diets, an increase in the ratio of BUN to serum creatinine concentrations may suggest poor dietary compliance, enhanced protein catabolism, GI hemorrhage, dehydration, anorexia or declining muscle mass.

Hyperphosphatemia

The kidneys are responsible for PO_4 excretion, with amount in urine representing that in glomerular filtrate less that absorbed via tubules (see ch. 73). If dietary PO_4 intake remains constant, a decline in GFR leads to retention and ultimately hyperphosphatemia. However, during early stages of CKD, serum PO_4 typically remains within reference limits because of compensatory decreases in reabsorption by surviving nephrons. This renal tubular adaptation is a consequence of the phosphaturic effects of FGF-23 and PTH. When GFR declines below about 20% of normal, this adaptive effect reaches its limit and hyperphosphatemia ensues.

The primary consequence of PO_4 retention and hyperphosphatemia is progression of CKD. Serum PO_4 concentrations have been shown to be directly linked to mortality in humans, cats and dogs with CKD.[24,26,74,75] A recent study in people with CKD noted that every 1 mg/dL increase in serum PO_4 was associated independently with increased risk of kidney failure and mortality.[76] Higher plasma PO_4 concentration has been shown to predict progression in cats with IRIS CKD stage III.[1] The Ca × PO_4 product also has a mortality risk trend. Products >72 have an increased relative mortality.[74] Mortality risk associated with hyperphosphatemia appeared to be independent of elevated PTH levels, which alone appeared to have only a weak association with mortality. Analysis of Ca revealed no correlation with relative risk of death.

Hypercalcemia, Hypocalcemia, and Hypermagnesemia

Concentrations of total, ionized, complexed protein-bound Ca vary widely in CKD patients (see ch. 67-69).[67] Increases in iCa were detected in 6% and decreases in 26% of 80 cats with CKD.[67] The mean blood iCa concentration was significantly lower in CKD cats than in healthy controls; >50% of cats with advanced (stage IV) CKD were hypocalcemic. However, when these same 80 cats were evaluated using total serum Ca (tCa) concentrations, hypercalcemia was found in 21% and hypocalcemia in 8%. Clearly, serum tCa concentrations do not reliably reflect iCa concentrations in cats with CKD. Similar discrepancies have been observed in dogs.[67,77] Metabolic acidosis of CKD does not appear to explain the discrepancies between iCa and tCa concentrations in dogs.[78] Mechanism of increased serum tCa despite normal to reduced iCa concentrations is likely explained by the increased concentrations of Ca complexed to retained organic and inorganic anions such as citrate, PO_4, or sulfate.[67] Because of this effect, formulas developed to "correct" for variations in serum albumin are not useful in dogs and cats with CKD.

Hypermagnesemia is common in CKD because the kidneys are primarily responsible for magnesium (Mg) excretion.[54] Typically in CKD, protein binding of Mg is normal, complexed Mg is increased, and ionized Mg (iMg) may be increased, normal or decreased. Although the homeostatic mechanisms involved in the control of Mg are not well documented, they appear to rely on bone, gut and kidney, as found with Ca and PO_4 control.

Hypokalemia and Primary CKD

An association between CKD and hypokalemia has been described in cats but is uncommon in dogs.[78,79] Dietary Na restriction in cats with CKD may be associated with inappropriate kaliuresis that may promote hypokalemia.[48] Kaliuresis may result from dietary Na restriction activating the RAAS. Other factors that may promote hypokalemia are reduced food intake and persistent low-grade dehydration, both of which are common in cats with CKD (see ch. 68).

While hypokalemia continues to be detected in many cats with CKD, muscle weakness is uncommon. Likely this improvement is the result of increasing the K content of therapeutic diets. Although generalized muscle weakness has been described as the cardinal sign of hypokalemia, decreased renal function and anorexia are probably more likely explanations. In many cats with CKD and hypokalemia, renal function improves with K supplementation and restoration of normal K concentrations, suggesting that hypokalemia

may induce a reversible, functional decline in GFR. Interestingly, renal function was shown to be adversely affected in normal cats when an acidified, K-restricted diet was fed, the two possibly being additive.[82] On the basis of these results, it was hypothesized that CKD cats have a self-perpetuating cycle of excessive urinary K loss and whole body K depletion, likely to further decrease renal function.

Hypokalemia as a Cause of CKD

There is limited evidence that in addition to being a consequence of CKD, hypokalemia may be a cause of or promoter of progressive CKD in cats. In an uncontrolled study of the long-term effects of feeding a K-restricted and acidifying diet, evidence of renal dysfunction developed in 3 of 9 cats while lymphoplasmacytic interstitial nephritis and interstitial fibrosis were observed in 5 of 9.[79] However, it is not clear whether K depletion or hypokalemia precede the onset of CKD. In another study, 4 of 7 cats with induced CKD fed a diet containing 0.3% K developed hypokalemia while 4 cats with normal renal function fed the same diet did not.[80] Interestingly, muscle K content decreased in normokalemic cats with spontaneous CKD, suggesting that total-body K deficits may develop well before the onset of hypokalemia.[81]

Primary Hyperaldosteronism in Cats as a Cause of CKD

Primary hyperaldosteronism (PHA) has been described in a few geriatric cats.[100,101] These cats have been described as having hypokalemia that is often severe and associated with hypokalemic polymyopathy, and hypertension that may be marked, refractory and commonly associated with retinal lesions and blindness (see ch. 308). In addition, cats with PHA often appear to have concurrent evidence of kidney disease. Because cats with CKD may also have concurrent hypokalemia and hypertension, discriminating cats with PHA from cats with CKD is important.

It has been recommended that the diagnosis of PHA in cats be based on plasma aldosterone concentrations (PAC), plasma renin activity (PRA), and the calculation of the aldosterone-to-renin ratio (ARR).[101] It is suggested that low PRA and increases in both PAC and PAC : PRA ratio be considered consistent with diagnosis of PHA.[100,101] However, a recent study of 196 cats over 9 years of age and without a diagnosis of PHA reported that PAC is significantly increased in azotemic hypertensive cats compared with normotensive cats matched for renal function.[45] Further, PRA was significantly lower in hypertensive cats compared to nonhypertensive, nonazotemic cats, and ARR was significantly higher in azotemic, hypertensive cats. These data suggest that many cats with CKD and hypertension have low renin, high PRA values. The authors of this report suggested that since the increase in PAC was not driven by PRA, the increased PAC could be primary adrenal tumor-dependent. In another study, bilateral adrenocortical hyperplasia may be an "almost ubiquitous" finding in cats over 9 years of age (97%) and histopathologic scoring of adrenal lesion severity failed to discriminate normotensive from hypertensive cats.[102] These findings fail to confirm that an adrenal disorder is driving the elevation in PAC in hypertensive cats.

Because PAC, PRA and ARR testing trend similarly in cats with CKD and cats with PHA, confirming the diagnosis of PHA should be approached cautiously. In general, cats with PHA are likely to have higher PAC and ARR levels compared to those found in cats with CKD, but clear cutoff values have not been validated. Since adrenal adenomas and carcinomas are responsible for most reported cases of feline PHA, adrenal imaging should be included in the diagnostic workup.[100] Ultrasound findings in cats with PHA are reported to include adrenal masses, adrenal calcification or changes in adrenal echogenicity. Computed tomography (CT) and magnetic resonance imaging (MRI) may also be used to image the adrenals. However, presence of lesions in the adrenals is not proof of PHA because adrenal masses in cats are often incidental findings (see ch. 308). Surgical removal of the adrenal mass, when possible, may be curative.[100]

Diagnostic Evaluation

Overview

Appropriate diagnostic testing facilitates optimum treatment and accurate prognosis. The evaluation has six goals: (1) confirm the presence of kidney disease, (2) differentiate acute from chronic disease, (3) stage CKD, (4) identify all biochemical and hematological complications, (5) determine the type and/or cause of kidney disease if possible, and (6) identify the presence of any comorbid conditions (Table 324-1; see ch. 62, 321, and 357).

TABLE 324-1

Complications and Comorbid Conditions in CKD

COMPLICATIONS OF CKD	COMORBID CONDITIONS
Anemia	Cardiac disease
Arterial hypertension	Degenerative joint disease
Dehydration	Dental and oral diseases
Hyperparathyroidism	Hyperthyroidism (cats)
Hyperphosphatemia	Nephroliths and ureteroliths
Hypocalcemia and hypercalcemia	Urinary tract infections
Hypokalemia	
Malnutrition	
Metabolic acidosis	
Uremic signs	

Confirming the Diagnosis of CKD

Definition

Kidney disease is defined as either a functional or structural abnormality in one or both kidneys. Functional renal diseases are most commonly recognized by azotemia or other test abnormalities, whereas structural renal disease may be palpated or seen on imaging studies or renal biopsy. Abnormalities are considered "markers" of kidney disease and should prompt further investigation to determine whether they result from kidney disease (Box 324-2).

Box 324-2

Markers of Kidney Damage

Blood Markers*

Azotemia
Hyperphosphatemia
Hypoalbuminemia
Hyperkalemia
Hypokalemia
Metabolic acidosis
Hypocalcemia
Hypercalcemia
Hypoproliferative anemia
Hypoalbuminemia
SDMA

Urine Markers

Impaired urine concentration
Impaired urine dilution
Proteinuria
Cylindruria
Hematuria
Pyuria
Inappropriate urine pH
Inappropriate urine glucose
Cystinuria
Bacteriuria

Imaging Markers—Abnormalities in Kidney

Increased or decreased kidney size
Renal mineralization, nephroliths or ureteroliths
Abnormal renal shape
Absence of a kidney
Abnormal renal echo texture by ultrasonography

Arterial Hypertension

Measured blood pressure
Retinal lesions consistent with hypertension

SDMA, Symmetric dimethylarginine.

*Markers must be confirmed to be of renal origin to be evidence of kidney damage.

Serum Creatinine Concentration

Serum creatinine concentration, a surrogate for GFR, is the primary laboratory test used to identify impaired kidney function. However, it is relatively insensitive in estimating GFR until a substantial reduction in kidney function has occurred. A 75% reduction in GFR is needed before serum creatinine values consistently exceed reference ranges. The insensitivity of serum creatinine results from at least two important factors: the innate relationship between GFR and serum creatinine and understanding that conditions other than intrinsic renal disease can cause the serum creatinine concentration to increase.

The relationship between serum creatinine and GFR is such that every time the GFR declines by half, the serum creatinine concentration doubles. For example, if a dog has a baseline creatinine of 0.5 mg/dL and its GFR declines by 50%, the serum creatinine only increases to 1.0 mg/dL, still well within reference intervals. If a further reduction of 50% in GFR occurs (now 25% of the original GFR), the creatinine will rise to about 2.0 mg/dL, slightly abnormal and often recognized. A further decline of 50% in GFR (to 12.5% of normal) is reflected in a serum creatinine of about 4.0 mg/dL. Thus, the slope of the rise in serum creatinine concentration becomes much steeper after a substantial loss of GFR has occurred, but it is flat over most of the range of GFR. It follows that the wider the normal range for serum creatinine concentration, the less sensitive it is for detecting intrinsic kidney disease. However, if the range becomes too narrow, serum creatinine will lose specificity because other factors may influence the value: body muscle mass, breed, etc. This conundrum is intrinsic to the nature of serum creatinine and limits its utility in diagnosis of early CKD.

Blood Urea Nitrogen Concentration

Although BUN has traditionally been viewed as an additional surrogate for estimating changes in GFR, it is influenced by several important factors that do not relate to GFR, including renal perfusion, protein ingestion, upper GI bleeding, time interval between food intake and blood sampling, drugs (e.g., corticosteroids), urine flow rate, and liver function. In addition, urea excretion is the sum effect of glomerular filtration and renal tubular reabsorption. Thus, BUN values may diverge substantially from serum creatinine concentrations due to factors unrelated to GFR.

BUN may be better than creatinine as a measure of uremic toxins and thus tends to correlate better than serum creatinine concentration with clinical signs and prognosis.[6] However, interpretation of BUN values can be complex and even misleading. One goal of dietary protein restriction is to lower levels of uremic toxins and such a diet typically lowers BUN, seemingly a favorable change. However, lower BUN levels may are seen when little or no food is eaten. The low BUN in this instance can be misinterpreted as a favorable response to therapy when it is actually the result of starvation. Simultaneous measurement of serum creatinine and BUN has been shown to be of limited benefit compared to measuring serum creatinine alone.[83]

Azotemia versus Uremia

The terms *azotemia* and *uremia* are not interchangeable. Azotemia is defined as abnormal concentrations of urea, creatinine, and other nonprotein nitrogenous substances in blood, plasma, or serum. It is a laboratory finding that can have several fundamentally different causes. It does not imply presence or absence of clinical signs. Because azotemia may be caused by factors that are not directly related to the urinary system and by abnormalities of the lower urinary tract not directly related to the kidney, *azotemia* should not be used as a synonym for kidney disease or uremia. Azotemia may result from prerenal, renal or postrenal causes. Since

nonprotein nitrogenous compounds (including urea and creatinine) are endogenous substances, abnormal increases in serum may be caused by an increased rate of production (by the liver for urea; by muscles for creatinine), or by a decreased rate of loss (primarily by the kidneys). Prerenal azotemia may result from impaired renal perfusion (e.g., dehydration, cardiac failure, shock, etc.) or increased production of nonprotein nitrogenous compounds. Prerenal azotemia is not evidence of kidney disease and can be corrected by eliminating the cause for impaired renal perfusion or increased production of nonprotein nitrogenous compounds.

Uremia is defined as the polysystemic clinical syndrome that results from extensive loss of kidney functions. Kidney disease may be present without azotemia or uremia. Azotemia may occur absent uremia or kidney disease (e.g., prerenal azotemia). Uremia does not occur absent azotemia, but uremia can occur absent kidney disease (e.g., leakage of urine from the ureters or bladder into tissues may lead to azotemia and uremic signs).

Renal azotemia confirms a diagnosis of kidney disease and is the result of reduced GFR consequent to primary kidney disease or injury. It may or may not be reversible over time, but does not resolve in response to fluid therapy. Urine concentrating ability is impaired in dogs and cats with renal azotemia. Urine specific gravity values less than 1.030 in dogs and less than 1.035 in cats are considered to be evidence of "inadequate urine concentration" in azotemic or dehydrated patients. Finding azotemia concurrent with urine specific gravity values less than 1.030 in dogs and less than 1.035 in cats is highly suggestive of renal azotemia. Note that nonazotemic dogs and cats with adequate renal perfusion (normal hydration and renal blood flow) may normally have urine specific values below 1.030 or 1.035, respectively. Renal azotemia and prerenal azotemia may occur together. This combination should be considered when pets have azotemia and inadequate urine concentrating ability (renal azotemia), yet fluid therapy partially reduces the magnitude of azotemia (the prerenal component of the overall azotemia).

Postrenal azotemia is the result of obstructed urine flow or urine leakage into a body cavity or tissues (e.g., urinary bladder rupture). Urine specific gravity is of no use in identifying postrenal azotemia. Distension of the urinary collection system (ureter[s] and/or bladder) is suggestive of postrenal azotemia, as is urine in the peritoneal cavity or tissues around the urinary system. Contrast imaging studies of the urinary collection system may be used to confirm urinary obstruction or leakage. Correction of the urinary obstruction or defect usually resolves the azotemia. However, prolonged urinary obstruction (mostly with partial obstruction) may lead to renal injury and renal azotemia. Postrenal azotemia may occur concurrently with primary azotemia and/or prerenal azotemia.

Urine Specific Gravity

Obtaining a urine specific gravity (USG) at the same time as a serum creatinine concentration is pivotal for correct interpretation (see ch. 62, 72, and 321). As stated, USG is essential for immediate differentiation between prerenal and primary renal azotemia. Urine samples obtained after giving fluids or some drugs are likely to be altered, thus eliminating the value of USG. In general, serum creatinine concentration is interpreted as consistent with primary azotemia when USG is <1.030 in dogs and <1.035 in cats. Most dogs and many cats with CKD have USG values between 1.006 and 1.020, and, when in advanced stages of CKD, isosthenuria (USG = 1.008 to 1.012) is common. Finding isosthenuria indicates the kidneys are not modifying the concentration of urine from the concentration of plasma. A USG <1.006 is not consistent with renal azotemia because concentrations below isosthenuria requires adequate kidney function. Some cats with CKD may retain substantial urine concentrating ability (i.e., 1.020 to 1.035 and occasionally >1.035). An alternative means of differentiating primary from prerenal azotemia is to repeat the serum creatinine concentration after an appropriate IV fluid challenge that eliminates the prerenal condition. If azotemia resolves 24 to 48 hours after giving fluids, the pet is considered "fluid responsive" and, therefore, azotemia was due to prerenal causes.

SDMA in CKD

The process of protein degradation includes arginine being methylated and forming numerous molecules, including asymmetric dimethylarginine (ADMA) and symmetric dimethylarginine (SDMA).[84] ADMA is an endogenous inhibitor of nitric oxide synthase and is associated with endothelial dysfunction, vasoconstriction, and increases blood pressure. It is cleared by the liver and kidneys. In contrast, SDMA has little physiologic activity and ≥90% is eliminated by the kidneys. Renal clearance is through filtration, without tubular reabsorption.[85] Serum SDMA concentrations correlate well with GFR in cats and dogs. In dogs with X-linked hereditary nephropathy, serum SDMA correlated with both creatinine and GFR estimated by

iohexol.[86] In a canine model of CKD, SDMA correlated better with GFR than did creatinine.[87] In 69 client-owned cats with CKD, SDMA concentrations were increased and correlated with creatinine; SDMA also correlated well with a range of GFRs in aged cats.[88,89]

SDMA has been shown to be a marker for early kidney disease in dogs, cats and humans.[86,90,91] Dogs with X-linked hereditary nephropathy rapidly progress from normal at birth to end-stage renal disease. In a cohort of male X-linked hereditary nephropathy dogs the measurements of serum SDMA, creatinine and GFR estimated by iohexol clearance were followed over the course of their disease. SDMA increased earlier than creatinine. The SDMA value increased with 30% declines in GFR, whereas serum creatinine did not increase until 50% to 60% loss of kidney function. Creatinine was evaluated both as a single serum cutoff value and as trending over time and in both instances SDMA proved to be an earlier indicator of loss of kidney function.[86] Trending serum creatinine increases its sensitivity in detecting reduced kidney function and is better than a single measurement. However, SDMA outperformed creatinine trending and proved to be a better indicator of early kidney disease. Retrospective longitudinal studies in dogs and cats that developed CKD have provided further evidence that serum SDMA increases earlier than creatinine. Two retrospective studies on both dogs and cats conducted over several years as they developed naturally occurring CKD showed SDMA increasing before creatinine by a mean of 17 months in cats (range 1.5-48 months) and 10.2 months in dogs (range 0.5-32 months). SDMA increased after about a 40% decrease in GFR (25% in one case).[92]

SDMA is useful for identifying and monitoring kidney disease in sarcopenic patients (see ch. 177). A major issue with creatinine is its relationship to muscle mass. Increased muscle mass promotes higher creatinine values while reduced muscle mass is associated with lower values. For example, aged cats with CKD often develop severe sarcopenia. Because of their muscle mass loss, serum creatinine concentrations are low relative to GFR and underestimate severity of renal dysfunction. In contrast, SDMA is minimally impacted by muscle mass in dogs and cats.[86,91-95] In a study in dogs comparing lean body mass, age, serum creatinine and SDMA showed that lean body and age were significant variables for creatinine but not SDMA concentrations.[96] SDMA is best utilized to complement existing kidney tests. Serum SDMA concentrations >14 mcg/dL are abnormal in dogs and cats. Increases in SDMA and serum creatinine concentrations with concurrent inappropriately concentrated urine are consistent with kidney disease. Increased SDMA and a serum creatinine concentration within reference limits suggests early kidney disease. However, persistent increases in SDMA over months is stronger evidence of kidney disease. Persistent SDMA increases for >3 months in dogs with serum creatinine <1.4 mg/dL or cats with serum creatinine <1.6 mg/dL are consistent with a diagnosis of IRIS CKD stage I. Unlike creatinine, SDMA is not influenced by lean body mass and will therefore be a better marker of kidney disease in animals with low body condition scores. The IRIS board provides guidelines for using SDMA to adjust treatment recommendations in patients with low body condition scores (see CKD staging system).

Acute versus Chronic Kidney Disease

Diagnosis of CKD requires confirmation of kidney disease and evidence of chronicity. In CKD, *chronic* means an irreversible and usually progressive loss of kidney function and/or structure. In this scenario, capacity for kidney compensation has reached a maximum, which typically reflects duration of approximately 3 months or longer. In contrast, AKI (see ch. 322) is potentially reversible, either by resolving at least part of the kidney injury, development of adaptive compensatory enhancements in kidney function, or both. Thus, short- and long-term consequences of AKI and CKD are potentially quite different.

Chronicity of CKD may be estimated from the medical history, physical examination, historical changes in laboratory findings, or renal structural changes observed by imaging studies or renal pathology. The occurrence of weight loss, PU, PD, decreased appetite and other signs for about 3 months or longer provides substantial evidence of chronicity. Likewise, declining nutritional status and hair coat quality are more typical of CKD than AKI. Documented increases in serum creatinine over a period of ≥3 months add conclusive support for diagnosing CKD. The criterion of at least 3 months of reduced renal function is based on the observation that renal compensatory hypertrophy may continue for that long after AKI. Proteinuria persisting for ≥3 months also supports diagnosis of CKD. While nonregenerative anemias (see ch. 199) are typical, they are not diagnostic because unrelated conditions may cause anemia. Palpably small kidneys or small size noted on imaging strongly supports diagnosis of CKD; loss of nephrons is usually associated with fibrosis. In some instances, especially in cats, one kidney may become enlarged in association with compensatory changes after the other kidney shrinks due to fibrosis (see Figure 324-1). While uncommon, skeletal changes consistent with renal osteodystrophy (see Figure 324-2) may confirm presence of CKD because of the time

required for its development.

Staging CKD

Overview

The International Renal Interest Society (IRIS) has proposed a four-tier system for staging CKD in dogs and cats based on renal function, proteinuria and blood pressure (see Box 324-1). Such staging facilitates application of appropriate guidelines for diagnosis, prognosis and treatment. Although the specific values used to categorize patients with CKD into these stages are based largely on observational data, staging is nonetheless useful for establishing prognosis and managing patients with CKD.[6,24]

Assigning IRIS CKD Stage and Its Treatment

Staging CKD is based on the patient's serum creatinine concentration. As described, serum creatinine remains the most commonly used estimate of GFR in dogs, cats and humans. However, its limited specificity and sensitivity can lead to misclassification. Staging, therefore, should be based on a minimum of two serum creatinine values obtained when the patient is fasted, well hydrated, and determined over a period of several weeks. If stable, it is characteristic of CKD. The overall clinical status should be considered when interpreting serum creatinine concentrations and other laboratory tests and when planning patient management.

Interlaboratory variations, patient-specific characteristics (e.g., breed, age, gender, body condition and lean body mass) and transient prerenal and postrenal events may influence serum creatinine values. Reduced muscle mass is a common manifestation of advanced CKD and may result in a substantial reduction in serum creatinine concentration relative to true GFR, particularly in cats. The IRIS suggests that SDMA values may be used to modify IRIS CKD staging in dogs and cats where body muscle mass is markedly reduced (see www.iris-kidney.com). In IRIS CKD stage II pets with low body condition scores and an SDMA concentration ≥25 mcg/dL, extent of renal dysfunction is likely to be underestimated and treatment recommendations listed under IRIS CKD stage III should be considered. In IRIS CKD stage III pets with low body condition scores and an SDMA concentration ≥45 mcg/dL, the extent of renal dysfunction is likely underestimated and treatment recommendations listed under IRIS CKD stage IV should be considered.

The diagnosis of CKD should be based on the serum creatinine range established for your laboratory, rather than the IRIS CKD stage II cutoff value. Since published reference ranges for serum creatinine are often broad, however, some pets classified as having mild renal azotemia (stage II) may have serum creatinine values within published reference ranges. To avoid misdiagnosis, it is important that evidence of CKD beyond the serum creatinine value be sought. In addition, larger body size may be associated with a higher upper limit of serum creatinine in dogs. Preliminary studies suggest that these limitations of serum creatinine concentration may be clarified by concurrently measuring serum SDMA concentration.

Clinical Descriptions of IRIS CKD

Stages

Stage I includes nonazotemic dogs and cats with CKD. Stage II CKD includes dogs and cats that are mildly azotemic. Other than PU/PD, pets in one of these stages usually do not have clinical signs of kidney dysfunction. Occasionally cats and dogs in stage II have weight loss or selective appetites. However, many pets have clinical signs resulting from their kidney lesions (e.g., acute pyelonephritis, nephrolithiasis). Those with marked proteinuria or systemic hypertension due to CKD may have clinical signs related to these issues. Renal function is often stable or slowly progressive for an extended period in nonproteinuric, nonhypertensive dogs and cats with stages I and II CKD. However, when progression does occur, it is important to determine whether the primary etiopathologic process underlying their CKD may be contributing to progression.[4] Patients with stages I and II CKD should be evaluated with the goal of identifying and providing specific treatment for their primary renal disease where possible. In addition, renal function should be monitored for possible progression of their CKD.

Pets with moderate azotemia are classified as stage III CKD and they may have clinical signs referable to their loss of kidney function; however, with appropriate treatment, they typically do not have clinical signs of overt uremia. Since stage III CKD is typically progressive, in addition to identifying and treating primary CKD, therapy designed to modify factors promoting progression of CKD may be of benefit. Stage IV CKD includes dogs and cats with severe azotemia (serum creatinine values >5.0 mg/dL) and, usually, clinical signs

of uremia. Diagnostic and therapeutic initiatives in this stage include those appropriate for stage III patients as well as therapy designed to prevent or ameliorate signs of uremia.

Substaging IRIS CKD Stages

Because it may be useful therapeutically and prognostically, the IRIS staging system further subclassifies pets according to the magnitude of their proteinuria and/or arterial blood pressure. Before performing a UPCR, urinalysis and urine culture should be performed to rule out infection, hemorrhage, or inflammation as a cause for increased UPCR. The urine sediment should be determined to be inactive before performing the UPCR. Unless markedly elevated or <0.2, it is recommended that the UPCR be rechecked 2 to 3 times over at least 2 weeks. The average of these determinations should be used to classify the patient as nonproteinuric, borderline proteinuric or proteinuric (see Box 324-1). Urine collected at home has lower UPCR values than samples collected in-hospital.[97] Pets with borderline proteinuria should be reevaluated after 2 months. In some pets, classification of proteinuria may change due to the course of their disease or in response to therapy.

Systemic arterial pressure should also be determined several times over several weeks (see Box 324-1). Blood pressure measurement should be performed before physical examination or collecting blood or urine. This aids in minimizing "white-coat" hypertension. Ideally the pet is taken into a quiet exam room soon after clinic arrival. Owner and pet should not be disturbed for about 5 to 10 minutes to minimize anxiety. Then a veterinary technician trained to perform blood pressure measurements should quietly enter the room and obtain 5 to 10 measurements with as little pet restraint as possible. The values should be documented along with the heart rate and comments on the perceived anxiety level of the patient.

Identifying Clinical, Biochemical, or Hematological Complications of CKD

History and Physical Examination

When obtaining the history (see ch. 1), one should seek clinical signs that may date the onset of kidney disease (e.g., PU, PD, weight loss, decreased appetite), information on possible congenital or hereditary diseases, evidence of current or past infections, neoplasia, metabolic diseases, lower urinary tract signs or problems, drug history (current and past), toxin exposures, diet, appetite, and evidence of previous kidney problems. Physical examination (see ch. 2) should emphasize dental and oral conditions, retinal examination for hypertensive lesions, hydration, edema, body condition score, assessment of lean body mass, accurate body weight, hair coat quality, pulse rate and quality, palpation of the urinary tract, bone pain, body temperature (uremia may be associated with low body temperature), and rectal examination. In cats, the cervical area should be carefully examined for evidence of thyroid enlargement.

Recommended Testing

Since most body systems are affected by CKD and uremia, the recommended initial diagnostic database is broad. The minimum should include the medical history, physical examination, arterial blood pressure (see ch. 99), complete blood count (CBC), a complete serum chemistry panel including serum electrolytes, acid-base status (serum bicarbonate or total CO_2 concentration or blood gas analysis), complete urinalysis (see ch. 72), urine culture, UPCR, and survey abdominal radiographs and/or abdominal ultrasound (ideally both). In cats, T_4 testing should be performed to rule out concurrent hyperthyroidism (see ch. 301).

Renal Biopsy

Biopsy and histologic assessment of tissue obtained may be useful in identifying the cause of kidney disease (see ch. 89). However, dogs and cats in IRIS CKD stages III and IV typically have small fibrotic kidneys. Also, regardless of CKD stage, hypertension and small kidneys are relative contraindications to biopsy because of risks of hemorrhage and loss of renal mass. Recent reports on the histopathologic findings in cats with CKD have described renal lesions and linked some renal lesions to clinicopathologic characteristics; however, these studies have not revealed the etiopathological origins of the CKD.[98,99] The primary indication for biopsy is proteinuria (see ch. 325) where the biopsy findings may influence treatment.

Treatment of CKD

Overview and Goals

Conservative medical management is standard and the only realistic option for most dogs and cats with CKD. It consists of supportive and symptomatic therapy designed to ameliorate clinical signs, correct fluid deficits or excesses as well as electrolyte, acid-base, endocrine, and nutritional balance. Therapy should minimize clinical and physiologic consequences of reduced renal function and should be designed to slow progressive loss of kidney function. Specific therapy for active kidney disease and management of comorbid conditions may also be indicated. In order to best meet these goals, treatment recommendations must be individualized and based on their unique clinical and laboratory status. Because CKD is progressive and dynamic, serial clinical and laboratory assessment of the pet, and modification of the therapy in response to changes, is integral to conservative medical management. The treatment plan should take into account considering each pet's IRIS CKD stage, clinical signs, risk factors for progression, existing complications and comorbid conditions. Therapy being given for active renal disease must be identified. Despite the renal lesions of CKD being irreversible, progression may be slowed or stopped with therapy designed to eliminate active renal diseases. Thus a thorough diagnostic evaluation should include a search for active disease that may be complicating CKD.

Managing patients with CKD requires ongoing engagement with the pet owner. Thus, successful CKD management is optimized by developing a long-term plan that includes: (1) introductory owner education regarding their pet's disease and its management, (2) a specific plan for monitoring progress and response to treatment, and (3) ongoing facilitation of the pet owner's engagement in the treatment plan.[103] Failure to include owners on the decision-making team often results in a suboptimum therapeutic response. A well-developed early plan for facilitating initial success in implementing the treatment plan has the potential to greatly enhance the long-term clinical outcome through enhanced compliance (Box 324-3).

Box 324-3

Checklist for Managing Chronic Kidney Disease

1. Confirm that the patient has kidney disease.
   a. Renal function tests (serum creatinine, BUN, SDMA)
   b. Urinalysis, urine protein-to-creatinine ratio, and/or urine culture
   c. Imaging studies
2. Confirm that the kidney disease is chronic.
   a. Medical history
   b. Physical examination
   c. Renal imaging studies
3. Establish the IRIS CKD stage of the patient (see Box 324-1).
   a. Two fasting serum creatinine values in a well-hydrated patient
   b. Urine protein-to-creatinine ratio (2-3 values)
   c. Arterial blood pressure (2-3 values)
4. Develop a treatment plan for the patient's CKD.
   a. Determine the treatment options appropriate for the patient.
   b. Prioritize and select which treatment options to recommend based on medical priority and pet owner's preferences (which may include cost, demands on the pet owner, and owner's preferences).
5. Review treatment plan with pet owner and confirm willingness to engage in the selected treatments.
6. Schedule follow-up appointment(s) to assess patient response to therapy.
7. Arrange for regular telephone updates to evaluate response to therapy and confirm owner compliance and commitment to the treatment plan.
   a. Assess owner's understanding of the treatment plan.
   b. Determine if the owner is having compliance issues.
   c. Assess patient's response to therapy and determine whether the patient needs to be seen before next scheduled appointment.
      i. Activity
      ii. Behavior
      iii. Appetite and quantify food intake (and body weight if available)
      iv. Water consumption
      v. Owner's perception of the pet's well-being

Factors likely to influence the success of a therapeutic plan include: (1) pet owner attitude toward and acceptance of the therapeutic plan, (2) patience and sometimes creativity in promoting owner and pet acceptance of the recommended treatments, and (3) maintaining continuing owner commitment to the treatment plan and connection to the veterinary team for the duration of the pet's life. The first step in developing a long-term management plan for dogs and cats with CKD is to develop a treatment plan that works for the pet owner as well as the pet. If a treatment plan is too involved, time consuming, expensive, or if it is perceived as disrupting the human-animal bond, it is unlikely to be successful.

The final key to optimizing the long-term outcome of pets with CKD is a plan for active follow-up initiated by the veterinarian. In addition to scheduling follow-up clinic visits, it is highly useful for a veterinary technician familiar with the pet, owner, and treatment plan to maintain contact with caregivers at least weekly until the owner is comfortable that the treatment plan is going well and all questions have been satisfactorily answered. Reasons for maintaining communication are to encourage and coach the caregiver regarding the treatment plan, to assess response to therapy, determine whether there are problems with compliance, and to decide if any warning signs have developed indicating need for a recheck examination or phone discussion with the veterinarian.

Dietary Therapy *(see ch. 184)*

Overview

Of all therapies used to treat dogs and cats with CKD, renal diets have the greatest benefit and the most evidence to support their effectiveness.[103] Although commonly called "low-protein" diets, renal diets should not actually be low in protein. Renal diets should have other modifications, including reduced PO_4 and Na, added B vitamins, increased caloric density, added soluble fiber, a neutral effect on acid-base balance, and supplementation of omega-3 polyunsaturated fatty acids and antioxidants. In addition, feline renal diets typically contain supplemented K.

Dietary Phosphorus

Most maintenance diets contain substantial quantities of PO_4. Hyperphosphatemia and hyperparathyroidism develop when maintenance diets are consumed by dogs and cats with CKD. Protein typically contributes a substantial amount of the PO_4 in pet foods, but they are not the sole source. Studies in cats and dogs with CKD have linked hyperphosphatemia to decreased survival and renal lesions.[24,26,58,75] Limiting dietary PO_4 is indicated for dogs and cats in IRIS CKD stages II through IV.[104] Benefits of reducing PO_4 intake include reduced retention, lower serum PO_4, decreased RSHP, slowing progression of CKD and reduced mortality.[58]

Omega-3 Polyunsaturated Fatty Acids and Antioxidants

Oxidative stress appears to have adverse consequences in chronic kidney disease.[105] Dietary supplementation with omega-3 polyunsaturated fatty acids (PUFAs) has been shown to be beneficial in dogs with induced CKD.[106] Compared to dogs fed diets high in saturated fats or omega-6 PUFAs, CKD dogs given omega-3 PUFAs had lower mortality, better renal function, fewer renal lesions, less proteinuria, and lower cholesterol levels.[106] These benefits may be the result of favorable effects on lipid metabolism and renal hemodynamics, suppression of inflammation and coagulation, reduced blood pressure, and antioxidant actions.[107] One study evaluated the effects of giving omega-3 PUFAs (omega-6 to omega-3 ratio of 5 : 1) and dietary antioxidants (vitamin E, carotenoids, lutein) on progressive decline in GFR of dogs with induced CKD. Results indicated that both omega-3 PUFA supplementation and the antioxidants were beneficial.[108] However, combining the two may have had synergistic benefits. Thus, dietary supplementation with omega-3 PUFAs and antioxidants is recommended for dogs and cats with CKD. The optimum quantities and ratio of omega-3 to omega-6 PUFAs have not been established. Although omega-3 PUFA and antioxidant therapy in cats with CKD are unavailable, vitamin E, C and beta-carotene supplementation reduces oxidative stress in cats.[109]

Protein

Waste products of protein catabolism are thought to contribute to clinical signs of uremia. While the ideal quantity of protein to feed dogs and cats with CKD has not been established, the general consensus is that limiting dietary protein intake ameliorates clinical signs of uremia in CKD and is therefore indicated for CKD stages III and IV. While not regarded as an important uremic toxin, BUN is a surrogate marker for retained

nonprotein nitrogenous waste products and typically correlates better with clinical signs than serum creatinine concentration. However, reducing dietary protein intake in CKD pets that do not have clinical signs of uremia has been questioned. Limiting their protein intake has been justified by its potential to slow progression of CKD.[110] However, some have argued that high dietary protein intake has not been unequivocally shown to promote progression of CKD and may be needed to maintain adequate nutrition. Nonetheless, when consumption of a renal diet is adequate and protein restriction is not excessive, renal diets do not cause malnutrition. An additional reasonable argument for recommending renal diets in IRIS CKD stage II and early III is that it may be easier to initiate conversion to renal diets well before the onset of clinical signs of uremia.[104]

Diet Therapy—Evidence from Clinical Trials

Dogs

The effectiveness of diet therapy in minimizing uremic episodes and reducing mortality in dogs and cats with naturally occurring CKD has been established.[2,111,113] Studies compared a renal diet with omega-3 PUFAs to a prototypical maintenance diet. Renal diets had limited protein, PO_4, and Na compared to an adult maintenance diet. In dogs, the risk of developing a uremic crisis was reduced by about 75% when fed the renal diet.[2] The median symptom-free interval in dogs fed a renal diet was 615 days compared to 252 days for dogs fed an adult maintenance diet. Risk of death, regardless of cause, was reduced by 66% and the risk of death due to renal causes was reduced by 69% for dogs consuming a renal diet. Median survival time for dogs consuming a renal diet was 594 days compared to 188 days for dogs consuming a maintenance diet. In addition, owners who fed a renal diet reported significantly higher quality of life scores for their dogs than owners who fed a maintenance diet.

Cats

Forty-five cats with serum creatinine values of 2.0 mg/dL to 4.5 mg/dL (IRIS CKD stages II and III) were separated into two groups: 22 were fed a commercial renal diet and 23 were given a maintenance diet.[113] Risks of uremic crises and renal deaths were reduced when a renal diet was fed. Among the 22 cats fed a renal diet, there were no uremic crises, no renal deaths, and 3 deaths due to nonrenal causes over 2 years. Of the 23 cats consuming a maintenance diet, 6 developed uremic crises and 5 died of renal causes. Two additional studies, a nonrandomized trial and a retrospective study, support the effectiveness of renal diets in cats with CKD.[9,112] The nonrandomized clinical trial compared a manufactured renal diet to no diet change.[10] While neither randomized nor blinded, results yielded strong evidence supporting the efficacy of feline renal diets. Cats fed a renal diet (mean survival of 633 days) lived substantially longer than cats consuming their regular diet (mean survival of 264 days). In addition, cats fed a renal diet had lower BUN, serum PO_4, and PTH concentrations. A study performed in 31 first-opinion veterinary practices in The Netherlands compared survival times for cats fed one of seven commercial feline renal diets to cats fed a maintenance diet.[113] Median survival time for the cats fed a renal diet was 16 months compared to 7 for cats fed their usual diet. Further, feeding renal diets lowers plasma PO_4 and FGF-23 levels compared to cats with CKD consuming their usual diet.[113] Increases in PO_4 and FGF-23 concentrations have been implicated in promoting progression of CKD.

Summary

The clinical studies described here clearly support the use of renal diets for dogs in CKD stages III and IV and cats with CKD stages II through IV. The value of renal diets in dogs with CKD stage II has not been critically evaluated but they are beneficial in reducing the magnitude of proteinuria.[114] Thus, renal diets are recommended for all dogs with proteinuric kidney disease.[115,116] These studies did not selectively determine the benefits of modifying individual dietary components, but rather report the results of a "diet effect."

Phosphorus Retention, Hyperphosphatemia and Renal Secondary Hyperparathyroidism (RSHP)

Overview

Because the capacity to excrete PO_4 declines as CKD progresses, intake must be reduced in parallel with the decline in kidney function (see ch. 69 and 321). If not, PO_4 retention, hyperphosphatemia and RSHP will

develop, enhancing progressive decline in kidney function and mortality.[35,58,117] Minimizing retention and hyperphosphatemia is an important therapeutic goal in dogs and cats with CKD because it appears to slow progression of CKD and prolong survival.[58,75,118] Because impaired renal perfusion increases serum PO_4 concentrations, the first step toward correcting hyperphosphatemia is to assure that the pet is well hydrated. Then, minimizing PO_4 retention and hyperphosphatemia is furthered by limiting dietary content and/or using oral agents that bind PO_4 within the intestines.[119] The usual approach is to start with renal diet therapy. Binding agents are used when a renal diet, alone, fails to bring the serum PO_4 concentration into the target range (Box 324-4). Renal diets, alone, usually normalize serum PO_4 concentrations in most CKD stage II and many CKD stage III pets. Pets in advanced IRIS CKD stage III and stage IRIS CKD IV typically benefit from being given an intestinal PO_4 binder to achieve goals.[57,118] Current evidence suggests that the critical target is serum PO_4, rather than PTH.

Box 324-4

Recommended Treatment Goals for Serum Phosphorus Concentrations

IRIS STAGE	TARGET SERUM PHOSPHORUS CONCENTRATION	
STAGE	(mg/dL)	(mmol/dL)
I	2.5-4.5	0.81-1.45
II	2.5-4.5	0.81-1.45
III	2.5-5.0	0.81-1.61
IV	2.5-6.0	0.81-1.94

Dietary PO_4 Restriction

Treatment target goals are linked to the IRIS CKD stage (see Box 324-4). Reference or "normal" ranges for serum PO_4 concentration *are not the therapeutic goal* in pets with CKD. When the serum PO_4 concentration is greater than the goal, it should be considered increased and reducing its concentration is usually indicated for dogs and cats with CKD stages II through IV. Serum PO_4 concentration should always be assessed after a 12-hour fast to avoid postprandial effects and such diets require several weeks for results. In cats with CKD, full dietary effect was apparent after 28 to 49 days.[118] Serum PO_4 concentrations should be rechecked 4 to 6 weeks after initiating the renal diet. If in the target range, the diet should be continued and the serum PO_4 reassessed every 3 to 4 months (every 4-6 months may be adequate for IRIS CKD stage II dogs and cats if two sequential results are within the goal range). If a renal diet alone fails to achieve the serum PO_4 target after 4 to 6 weeks, adding an intestinal binding agent is reasonable.

Intestinal Binding Agents

Medications that trap PO_4 in the intestine prevent its absorption. The PO_4 binder must be present in the intestine at the same time as the food with its PO_4. Binders are most effective when given in conjunction with PO_4 restricted diets because less needs to be bound. High dietary PO_4 content may greatly limit the effectiveness of binding agents or substantially increase the dosage required to achieve the desired therapeutic effect. Administration of 1500 to 2500 mg of aluminum carbonate to dogs with moderate CKD failed to consistently correct hyperphosphatemia when dogs were fed diets containing greater than 1% PO_4 on a dry matter basis.[119] Because many dog and cat maintenance diets contain high levels of PO_4, it is unlikely that treatment targets can be achieved solely by adding binding agents. Minimizing the quantity of PO_4 needed to be bound is important because giving too much may decrease appetite or cause nausea, vomiting, diarrhea and constipation.[120]

Intestinal binding agents containing aluminum as hydroxide, oxide or carbonate salts have been the first choice in dogs and cats because they are effective and inexpensive (Table 324-2).[121] Although aluminum-containing binding agents are usually well tolerated and safe in dogs and cats, aluminum toxicosis has been reported in dogs with advanced CKD treated with high doses.[122] Toxicosis was noted as cranial, peripheral, and junctional neuropathies. Clinical signs included weakness, ataxia, absence of patellar reflexes, decreased pelvic limb withdrawal, decreased menace response, obtundation, tetraparesis, and lateral recumbency. Microcytosis was also noted and may be useful in the early detection of aluminum toxicosis. Chelation therapy was necessary to correct the toxicosis. Aluminum-based PO_4 binders may decrease palatability and cause constipation.

TABLE 324-2

Intestinal Phosphate Binding Agents

INTESTINAL PHOSPHATE BINDER	DOSAGE RECOMMENDATIONS
Aluminum hydroxide (Alternagel; 600 mg/5 mL)*	30 to 90 mg/kg/day† PO
Lanthanum carbonate (Fosrenol; 500 mg/chewable tablet)	12.5 to 25 mg/kg/day† PO
Lanthanum carbonate octahydrate (Renalzin; 200 mg/mL)	2 mL PO in food 1-2 times daily†
Calcium carbonate (Tums; 500 mg/tablet)	30 mg/kg† PO
Chitosan and calcium carbonate (Epakitin; powder)	4.4 g/10 kg† PO
Sevelamer hydrochloride (Renagel; 400 mg/tablet)	33-54 mg/kg† PO

*Aluminum hydroxide USP is also available as a powder.

†Daily dosage should be divided among daily meals (usually 2-3 feedings/day). Product should be either mixed into the food or administered immediately before or after each meal.

Calcium-based PO_4 binding agents are effective but they may cause hypercalcemia, especially when also giving calcitriol. That combination should be avoided. People given non–Ca PO_4 binders had reduced all-cause mortality as compared with people given Ca-based binders.[123] iCa concentrations should be monitored when Ca-based binders are used. Lanthanum carbonate and other salts of lanthanum appear to be quite effective in binding PO_4. These have few side effects because lanthanum is not absorbed, reducing risk of toxicosis when compared to aluminum salts. Lanthanum is well accepted and tolerated by cats and lanthanum carbonate has been reported to inhibit intestinal oxalate absorption, preventing nephrocalcinosis in a rat model.[124,125] Sevelamer, an anion-exchange resin, is not commonly used in dogs and cats. Unlike most PO_4 binders, sevelamer does not release a cation, but it can cause metabolic acidosis and hypercalcemia. Lanthanum salts and sevelamer hydrochloride are generally far more expensive than Ca or aluminum salts.

When to Administer Binding Agents

PO_4 binding agents must be given at or around meal time with a goal of binding dietary PO_4. Administering binders other than with meals markedly reduces their effectiveness. Ca-based binding agents that are given between meals function as a Ca supplement rather than as a PO_4 binder. The agents should be administered "to effect," meaning doses should be adjusted from the starting dosage to achieve the targeted serum PO_4 concentration without excessive doses. Therapy is usually begun using the lowest recommended dosage and increased as needed every 2 to 4 weeks. If dosage substantially exceeds those recommended, it is best to add a different binding agent rather than risk overdosage. Different binding agents may be combined to minimize the risk of overdosing one drug.

Dehydration and Fluid Therapy

Overview

Preventing and correcting dehydration is extremely beneficial for dogs and cats with CKD (see ch. 129). Fluid

balance in pets with PU should be maintained by compensatory PD and dehydration results if adequate quantities fail to be consumed. Cats with CKD appear to be particularly susceptible to chronic dehydration, perhaps because their compensatory PD is inadequate. Lack of access to good drinking water, some environmental conditions, and concurrent illness that limits fluid intake or promotes fluid losses (e.g., pyrexia, vomiting or diarrhea) may lead to dehydration. Dry oral membranes and decreased skin elasticity are common in dehydration, but these findings can be misleading. Xerostomia (dry oral membranes) may result from uremia. Loss of skin elasticity is common in dogs and cats that have lost weight, are older, or in poor nutritional health. Chronic dehydration can decrease appetite and/or cause lethargy, weakness, constipation, prerenal azotemia, and predisposition to AKI. AKI in pets with preexisting CKD is a common cause of disease progression (also see ch. 322). Owners of pets with CKD should be educated regarding episodic fluid losses due to vomiting or diarrhea that might have been minor when their pet was healthy but could lead to serious deterioration of kidney function or precipitate uremic crisis when their pet is afflicted with CKD.

Indications

One should consider giving subcutaneous (SC) fluids to CKD pets with signs of chronic or recurrent dehydration. The benefits of SC fluid therapy include improved appetite, increased activity, and less constipation. Recommendations regarding SC fluids should be made on a case-by-case basis. Not every pet with CKD requires or will benefit from such therapy. While many cats with CKD appear to benefit from SC fluid therapy, fewer dogs require it. Also, home administration of SC fluids is not appropriate for all owners. While inexpensive, SC fluid administration requires time and may be stressful on the owner-pet relationship. It also has the potential to promote hypernatremia, hypokalemia, hypertension and fluid overload.

Fluid Choice, Volume, Frequency

Usually, a balanced electrolyte solution (e.g., lactated Ringer's solution) is given SC every 1 to 3 days, as needed. The volume administered depends upon pet weight. Most cats are given about 75 to 125 mL per dose. If the clinical response is suboptimal, the dose can cautiously be increased, but fluid overload must be avoided. In addition, Na-containing fluids given SC do not provide the electrolyte-free water that healthy individuals consume. Therefore, it is physiologically more appropriate to provide water via a feeding tube, which may be easier than SC for some clients (see ch. 82). Since excess Na intake may harm the kidneys, recommendations for long-term Na administration in any form should be carefully considered.[126] Response to long-term SC fluid therapy should be assessed by frequently checking hydration status, clinical signs, blood pressure, kidney function and, possibly, electrolyte values. If a detectable improvement in clinical signs and/or renal function does not accompany fluid therapy, the need for long-term therapy should be reassessed.

Managing Gastrointestinal Signs of Uremia

Antiemetic Therapy

Poor appetite, nausea and vomiting are among the most common signs of CKD and uremia. Over time, the most important complication of CKD is inadequate food intake, making starvation the most common factor leading to death in dogs and cats with CKD. Gastric complications of uremia differ in dogs versus cats. While uremic gastritis with ulceration may develop in dogs, cats are more likely to have gastric fibrosis and mineralization.[42] The lesions in dogs are thought to be the result of increases in serum gastrin concentrations, which stimulates gastric hyperacidity. Use of H2-blockers (e.g., famotidine, ranitidine), proton pump inhibitors (omeprazole, pantoprazole, esomeprazole) and sucralfate is recommended for dogs with inappetence, nausea and vomiting. These therapies would be seemingly inappropriate in cats with CKD. Use of proton pump inhibitors has been linked with AKI in older people.[127]

In dogs and cats, activation of the chemoreceptor trigger zone by uremic toxins promotes anorexia, nausea and vomiting. Uremia likely also has direct GI effects. Antiemetic therapy is useful in managing uremic nausea and vomiting. Use of antiemetic drugs does not directly improve appetite, but they may minimize loss of food and fluids via emesis. Maropitant and ondansetron act on the chemoreceptor trigger zone as well as in the gut. Oral maropitant (4 mg/cat/day for 2 weeks) has been an effective antiemetic for cats with IRIS CKD stages II and III.[128] Maropitant can be used in dogs and cats with CKD at a dose of 1-2 mg/kg/day PO or 1 mg/kg/day SC or IV. Maropitant is not limited to 5-day treatment periods. While ondansetron has been documented to be effective in uremic humans, pharmacokinetic studies have indicated poor bioavailability when it is given orally with a short half-life in cats and dogs.[129] Ondansetron (0.1-1 mg/kg SC) has better

bioavailability and a longer half-life in cats.

Appetite Stimulation Therapy

Mirtazapine (1.87 mg/cat PO q 48 h; 3.75-30 mg/dog PO q 24 h) significantly increased appetite, activity, and body weight in cats with CKD while decreasing vomiting.[130] Overdose may cause hyperexcitability, tremors and vocalization. Cyproheptadine cannot be used concurrently with mirtazapine. A study in 6 Beagles indicated that dogs may have a different pharmacokinetic profile compared to cats and humans.[131]

Esophagostomy Feeding (see ch. 82)

Failure to stabilize a pet at an acceptable body condition score is likely to adversely affect long-term outcome. Esophagostomy tube feeding can be quite beneficial for dogs and cats with progressively declining body weight despite all efforts to achieve adequate nutrition. Esophagostomy tubes are painless, effective and convenient for delivering food, water and medications to dogs and cats with CKD. It is a useful means of stabilizing or improving nutrition, clinical signs, longevity and owner satisfaction. In general, tube placement is less likely to be effective when the decision to proceed is delayed until advanced uremia and malnutrition have developed.

Metabolic Acidosis

Diagnosis

Acidosis of CKD can promote malnutrition, clinical signs of uremia, and renal osteodystrophy (see ch. 128).[75] Studies in humans and rodents suggest that metabolic acidosis may also promote progression of CKD; however, it is unclear whether this is linked to low serum bicarbonate, high dietary acid load or both.[132,133] While data are not available for dogs, metabolic acidosis is reported to affect about 15% of cats with IRIS CKD stage III and about 53% with IRIS CKD stage IV.[28] These observations suggest that only a minority of cats with clinically stable IRIS CKD stages II and III are likely to benefit from routine alkalization therapy. Thus, the decision to intervene with alkalization therapy should be based on a laboratory assessment of acid-base status. Low serum or plasma total CO_2 values obtained by autoanalyzer techniques should be confirmed by blood gas analysis (see ch. 128).[134] When considering therapy for acidosis of CKD, acid-base status should be assessed by blood gas analysis when the pet is well hydrated. Oral therapy for acidosis should be considered when blood gas analysis confirms plasma bicarbonate values remain below 15 mmol/L. However, parenteral intervention should be considered for cats with metabolic acidosis and a blood pH <7.10 to increase the value over 7.20.[135]

Treatment

Treatment options for alkalization therapy include renal diets, K citrate, and Na bicarbonate. Most renal diets are neutral to slightly alkalinizing. If diet therapy alone fails to ameliorate metabolic acidosis, alkalization therapy should be considered. K-citrate solution provides both K and alkalization and is usually more palatable than Na bicarbonate. Dosage is "to-effect," with starting dosages of 40 to 60 mg/kg q 8-12 h and a goal of maintaining reference range blood bicarbonate concentrations. Na bicarbonate (initial dose: 8 to 12 mg/kg q 8-12 h) is generally unpalatable except when given by tablets. These medications should be given as small doses frequently to minimize blood pH fluctuations. Response to therapy should be assessed after 10 to 14 days, before the drug is given, and dosage adjusted accordingly.

Potassium Disorders (Hypokalemia and Hyperkalemia)

Hypokalemia (see ch. 68 and 321)

Potassium (K) depletion and hypokalemia (hypoK) are relatively common in cats with CKD stages II and III, estimated to occur in 20% to 30%. It is less common in stage IV cats.[3,7,8] Hypertensive cats have also been reported to have significantly decreased plasma K concentrations.[46] Total body K depletion is likely more common than hypoK.[81] By contrast, hypoK is uncommon in dogs with CKD. The mechanisms underlying development of hypoK in cats with CKD remain unclear, but inadequate intake, increased urinary loss, and enhanced activation of the RAAS due to chronic dehydration and/or dietary salt restriction may play roles.[48] While increasing K content of renal diets has reduced both incidence and severity of overt clinical signs of

hypoK, it remains a common laboratory finding in CKD cats. Of note, the antihypertensive agent amlodipine may promote hypoK in cats with CKD.[136]

HypoK and K depletion may adversely affect kidneys and muscle of cats with CKD. Diets low in K and high in acid have been implicated in impairing renal function and promoting development of lymphoplasmacytic tubulointerstitial lesions in cats.[82-85] K depletion may lead to reduced renal blood flow and GFR as a consequence of angiotensin II and thromboxane-mediated renal vasoconstriction. In addition, hypoK may promote PU by impairing renal responsiveness to ADH (see ch. 45 and 296) and by stimulating the brain thirst centers via angiotensin II. Hypokalemic polymyopathy, characterized by generalized muscle weakness and cervical ventroflexion, is a well-recognized complication of CKD in cats, although now less commonly observed perhaps due to K supplementation of feline renal diets.

While there is a consensus that cats with hypoK should receive supplementation to correct or prevent renal and muscular consequences of K depletion and hypoK, the value of "prophylactic" supplementation to normokalemic cats has not been established. Oral replacement is the safest and preferred route. Parenteral therapy is generally reserved for cats requiring emergency reversal of hypoK or for cats that cannot or will not accept oral therapy. As much as 30 mEq/L of K chloride may be added to fluids intended for SC administration. Oral K may be supplemented as gluconate or citrate salts; K chloride is not recommended because it is not palatable and is acidifying. The gluconate form (2 to 6 mEq/cat/day) is available as tablets, flavored gel, or a palatable powder (Tumil-K). Acidosis is a major risk factor for development of hypoK and therefore should also be treated. The citrate solution (40 to 60 mg/kg/day q 6-8 h; Polycitra-K Syrup, Baker Norton) is an excellent alternative with the advantage of providing simultaneous alkalinization therapy. Muscle weakness usually resolves within 1 to 5 days of starting K supplementation. Dosage, thereafter, is adjusted based on clinical response and serum K concentrations, which should initially be monitored every 7 to 14 days. In cats with hypokalemic polymyopathy, it may be necessary to monitor serum concentrations every 24 to 48 hours initially. It is unclear whether all cats require long-term K supplementation.

Intensive fluid therapy during uremic crises, particularly with K-deficient fluids, may promote hypoK in cats or dogs not previously hypoK. Therefore, serum K concentrations should be monitored during fluid therapy and maintenance fluids should be supplemented with K chloride to prevent iatrogenic hypokalemia (concentrations of 13 to 20 mEq/L are appropriate for maintenance fluids). IV K should not be given at rates exceeding 0.5 mEq/kg/h.

Hyperkalemia

Hyperkalemia (hyperK) is uncommon in CKD; however, it may develop in advanced IRIS CKD stage IV (see ch. 68 and 321). It tends to occur when food consumption approaches adequate calorie intake, most commonly with feeding by tube, and/or with use of ACE inhibitors or angiotensin receptor blockers (ARBs). HyperK can be managed by reducing dietary K or by preventing intestinal uptake.[137] Polymer resins (e.g., Na polystyrene sulfonate) have been found less than adequate. In humans with CKD, Na zirconium cyclosilicate, a highly selective cation exchanger that traps K within the intestine, has been shown to be effective in mitigating hyperK.[138]

Arterial Hypertension

Rationale for Therapy

CKD is the most commonly recognized cause for hypertension in dogs and cats. It has been linked with renal, ocular, neurological and cardiac complications (see ch. 157). Retinopathy occurs in about 60% of hypertension cats and is its most common clinical manifestation.[139] Clinical signs seen with hypertension in cats include lethargy, blindness, retinal hemorrhage, retinal detachment, cerebral hemorrhage, seizures, stupor, and ventricular hypertrophy.[140-142] In one study, retinopathy and hypertensive encephalopathy were reported in 3 of 14 dogs with blood pressure values >180 mm Hg.[46] Preexisting CKD reportedly increases the vulnerability of the kidneys to hypertension injury.[143] Hypertension may be an independent risk factor for progression of CKD in dogs, although proteinuria was not included in one statistical model used to confirm this association.[31] However, in CKD cats, hypertension is associated with increased proteinuria in dogs and cats, and, since proteinuria appears to promote progressive renal injury in both species, lowering blood pressure to limit proteinuria is an appropriate goal.[35,144] Clinical evidence from humans, dogs and cats indicates that pharmacological reduction in blood pressure (BP) is likely to reduce the risk of hypertensive organ injury. SC hydralazine has been reported to reduce the prevalence of seizures developing as a

consequence of hypertension after renal transplantation (see ch. 323).[141] Further, in an induced model of hypertensive kidney disease, only 2 of 10 cats receiving the amlodipine developed evidence of retinal lesions compared to 7 of 10 cats given placebo.[140]

Indications for Treatment

The indication for antihypertensive therapy is to treat and/or prevent development of end-organ injury including the kidneys, eyes, brain and heart (see ch. 158). However, the BP above which progressive renal injury may be induced is unknown. The IRIS recommendations for treating hypertension are based on risk estimates of end-organ injury developing in specific BP ranges in dogs or cats with CKD. Dogs and cats with mild hypertension (systolic pressures 160 mm Hg to 179 mm Hg) should have their hypertension confirmed with at least three determinations over a 1- to 2-month period. Treatment should be withheld until measurements establish that hypertension is persistent. In dogs and cats with more severe hypertension (systolic pressures >180 mm Hg), the waiting period should be reduced and the two rechecks completed in 1 to 2 weeks. However, when there is evidence for hypertension-related organ injury or if the systolic blood pressure is at emergency levels (>200 mm Hg), antihypertensive therapy should be started immediately. Reasonable efforts should be made to minimize risk that measured elevations in blood pressure represent a transient "white coat" effect, rather than a sustained elevation.[145] It is deemed unlikely that systolic pressures>200 mm Hg reflect any anxiety response. Note that some dog breeds, notably healthy sight hounds, may have BP ranges up to 40 mm Hg higher than those provided in these guidelines, and decisions on diagnosis and treatment should be adjusted accordingly. Evidence suggests that dogs and cats with CKD may be at increased risk for additional renal injury or developing complications associated with elevated BP.[31,51,140-142] Pets with IRIS CKD stages I through IV and confirmed hypertension or severe hypertension should be treated.

Goals and Guidelines for Treating Hypertension in CKD

The optimum endpoint for antihypertension therapy has not been established for dogs and cats with CKD (see ch. 158). In the absence of such information, treating arterial hypertension should be initiated cautiously with the goal of reducing BP to *at least* <160/100 mm Hg. Except in pets with acute, severe ocular or neurological lesions, rapid reduction in BP is not indicated. Dogs with hypertension may require several dosage and drug adjustments, taking weeks to months to achieve satisfactory control. In contrast, cats often respond much quicker. Reducing BP is a long-term process where gradual and sustained reduction should be the goals. Sudden or severe decreases in BP are never indicated, because it is important to avoid clinical hypotension. Treatment should be carried out in a step-wise fashion and adjustments made until the therapeutic endpoint is achieved (i.e., systolic pressure <160 mm Hg). While it is unclear whether Na restriction is effective in lowering BP in dogs or cats with hypertension, a gradual change to a lower Na diet is recommended at the time that pharmacologic intervention is begun. Generally, avoid initiating antihypertensive therapy until hydration is cautiously restored to avoid abrupt decreases in BP and/or renal perfusion. ACE inhibitors such as enalapril and benazepril, and the Ca channel blocker amlodipine, are the mainstays of antihypertensive therapy in dogs and cats. These drugs may have unique renoprotective benefits and are therefore appropriate initial options for managing hypertension in CKD.

Drugs, Dosages, Combinations

Treatment should begin with an ACE inhibitor given at a standard dosage (Table 324-3). The dosage may need to be progressively increased, with doubling the maximum recommended. If the target has not been achieved despite dosage adjustments, a Ca channel blocker (amlodipine) should be implemented. Again, the dosage may be increased to a double maximum, as needed. The ARB and/or hydralazine may be added if the other drugs have failed to achieve the target. People being treated for proteinuria with both an ACE inhibitor and an ARB, rather than just one, may be at risk of developing hyperkalemia, hypotension and/or renal failure.[146] The clinician should consider terminating the ACE inhibitor before adding the ARB or should monitor for hyperkalemia, hypotension and/or progressive azotemia. Treatment should begin with the Ca channel blocker amlodipine. If the initial dosage fails to normalize BP, the dosage may be gradually increased to a maximum of 1.25 mg/kg/day PO. If additional antihypertensive drug support is needed, the clinician should consider adding an ACE inhibitor to the Ca channel blocker. Treatment for arterial hypertension is usually lifelong. Once treatment has achieved the stated target BP, monitoring is essential for continued control. Dogs and cats on BP therapy should be monitored no less often than every 3 months (see ch. 158).

Examination for retinal lesions secondary to hypertension (see ch. 11 and 157) should be performed at the time as BP monitoring (see ch. 99). Using the step-wise medical scheme described, dosage adjustments are made as needed to keep BPs <160/100 mm Hg.

TABLE 324-3

Drugs Used to Manage Proteinuria and Hypertension in Dogs and Cats

DRUG (MECHANISM)	INITIAL DOSAGE	ESCALATING DOSAGE SCHEME
Benazepril (ACE inhibitor)	0.5 mg/kg PO q 24 h	Increase by 0.5 mg/kg/d to a maximum of 2 mg/kg/d
Enalapril (ACE inhibitor)	0.5 mg/kg PO q 24 h	Increase by 0.5 mg/kg/d to a maximum of 2 mg/kg/d
Telmisartan (ARB)	1 mg/kg PO q 24 h	Increase by 0.5 mg/kg/d to a maximum of 2 mg/kg/d
Losartan (ARB)	0.125 mg/kg/d PO	0.25 mg/kg/d in azotemic dogs 0.5-1.0 mg/kg/d PO in nonazotemic dogs
Amlodipine (CCB) Cats	< 5 kg: 0.625 mg PO q 24 h / cats ≥ 5 kg: 1.25 mg PO starting dose	Double dosage if blood pressure remains elevated (dose is per cat)
Amlodipine (CCB) Dogs	0.1-0.3 mg/kg PO q 24 h	Can increase dosage incrementally up to 0.75 mg/kg PO q 24 h until blood pressure reduced to target pressure (systolic BP < 160 mm Hg)

ACE, Angiotensin-converting enzyme; *ARB*, angiotensin receptor blocker; *CCB*, calcium channel blocker.

Increases in serum creatinine concentration, low BP and clinical signs of hypotension should prompt reassessment of the antihypertensive drugs and dosages. Small increases in serum creatinine that are not progressive may safely occur with antihypertensive therapy. However, large or progressive increases of creatinine concentration may reflect drug or dosage problems. If systolic BP persistently declines below 120 mm Hg or signs of hypotension such as weakness or tachycardia develop, antihypertensive drugs and dosages should be adjusted to increase BP and ameliorate the clinical signs.

Treatment of Anemia of CKD

Causes

Anemia of CKD can have a profound effect on quality of life. As many as 65% of cats develop anemia as CKD progresses.[147] Anemia in pets with CKD is often multifactorial in origin. The primary cause for anemia is inadequate production of EPO. Iatrogenic and spontaneous blood loss, poor nutrition (including protein, iron, folate and perhaps others), chronic inflammation/infection, and reduced red blood cell (RBC) life spans may complicate and contribute to anemia. Excessive blood sampling is worrisome and should be avoided. Failure to identify and correct these complications can impair the effects of hormone replacement.

Chronic low-grade GI blood loss can promote moderate to severe anemia in pets with CKD that would otherwise have sufficient endogenous EPO production to maintain their RBC counts and packed cell volumes (PCVs) in the subclinical range. These pets may or may not have overt GI signs or melena. Iron deficiency and BUN-to-creatinine ratios above what is expected in context of the diet may provide indirect evidence of occult GI blood loss. Thrombocytosis and hypochromic RBCs are consistent with iron deficiency and GI bleeding. Because of difficulty in confirming GI hemorrhage, a therapeutic course with histamine H2 receptor antagonists or H2 blockers and sucralfate should be considered. Improvements in PCV and/or appetite support a role for GI hemorrhage in the genesis of anemia. While gastric ulcerations are common in dogs with CKD, they are not common in cats, whose uremic gastropathy appears to differ.[42]

Erythrocyte-Stimulating Agents

The most effective means of correcting anemia of CKD is use of erythrocyte-stimulating agents (ESAs) to correct the EPO deficiency common in CKD. Absent factors that impair their effectiveness, administration of ESAs induces a dose-dependent increase in PCV. In dogs and cats, increasing the PCV to the low end of the normal range takes about 2 to 8 weeks, depending on initial PCV and dose administered. As the anemia is

corrected, most pets show increases in appetite, body weight, energy level and sociability.[148] The ESAs currently available include epoetin alfa (R-HuEPO: Epogen, Amgen; Procrit, Centocor Ortho Biotech Products; Eprex, Janssen), epoetin beta (Neo-Recormon, Roche), darbepoetin alfa (Aranesp, Amgen) and continuous EPO receptor activators (Mircera, Roche).[147] The principal differences among these products is their degree of glycosylation. This affects their renal clearance and therefore influences their duration of action. Clinical efficacy among these products is reported to be similar in humans. Available ESAs are based on human EPO. Canine and feline EPOs share 81.3% and 83.3% homology, respectively, with human EPO.[147] These levels of homology allow these drugs to be effective in stimulating substantial PCV increases in both dogs and cats. However, over the course of therapy, there is risk of developing anti-EPO antibodies, recognized in both dogs and cats, primarily with epoetin alfa.

ESA-Induced Antibodies

Approximately 25% to 30% of cats and up to 50% of dogs receiving epoetin develop neutralizing anti-EPO antibodies; however, not all cases with anti-EPO antibodies develop anemia.[148] These antibodies cross-react with all ESAs including the pet's endogenous EPO. Development of anti-EPO antibodies can markedly suppresses erythropoiesis and result in a pure red cell aplasia (PRCA; see ch. 199). Many pets with PRCA become transfusion dependent, although if they live long enough, response to endogenous EPO may return. Although controlled studies on development of antibodies directed at the ESA darbepoetin are not available, it appears that this product is much less immunogenic as compared to R-HuEPO.[149,150] It is suggested that the longer half-life of darbepoetin may reduce the antigen load administered compared to R-HuEPO, thereby reducing the risk of antibody formation.[147]

Other EPO-Related Adverse Effects

While development of anti-EPO antibodies is the most important adverse reaction linked to ESAs, other effects reported in dogs and cats have included systemic hypertension, seizures, reactions at injection sites, vomiting and fever.[148,149] Hypertension may develop or increase in severity due to increased peripheral vascular resistance secondary to improved oxygen delivery and reversal of the vasodilation induced by chronic hypoxia. Increased blood viscosity due to the increased PCV is thought to be minor. Seizures, reported in dogs and cats being treated with rHuEPO, are not directly caused by ESAs, but rather related to compensatory adaptations to increases in RBC mass.[148] Allergic reactions including cutaneous or mucocutaneous reactions or cellulitis sometimes with fever and arthralgia occasionally occur in both dogs and cats early in the course of EPO therapy.[148] Lesions generally resolve within a few days and most do not recur when therapy is reinstated.

rHuEPO versus Darbepoetin

ESAs are indicated in dogs and cats with: (1) advanced CKD (IRIS CKD stages III and IV), (2) PCV values below 22%, and (3) those with clinical signs attributable to anemia: tachypnea, tachycardia, weakness, and anorexia. While rHuEPO and darbepoetin are both available, darbepoetin is preferred for dogs and cats. The advantages of darbepoetin over epoetin include seemingly lower risks of anti-EPO antibodies and weekly administration. One study reported 56% (14/25) of cats given darbepoetin achieved the target PCV (25%). The cats reaching the target survived significantly longer than cats that did not respond (mean of 238 days for responders; 83 days for nonsurvivors).[149] In another study, 7 of 7 cats with CKD reached the target PCV (30%), and none had evidence of anti-EPO antibodies.[150]

Darbepoetin Protocol

Darbepoetin is initially given SC (1 mcg/kg, weekly) and continued until the pet's PCV reaches the low end of the target range (cats: 25%-35%; dogs: 37%-42%). Once achieved, either the dose of darbepoetin is reduced by 20% to 25% or the frequency of dosing is decreased to once every 2 weeks. The maintenance dose can then be adjusted monthly, as needed, to keep the PCV within the target range. Since excessive ESA doses have been linked to adverse outcomes in humans, it is recommended that abnormally high PCVs be avoided.[151] Initially, physical examinations and BP assessments (see ch. 99) should be performed weekly until the target PCV is achieved and then continued monthly. Usually, the PCV increases about 1% to 3% weekly; more rapid rates of increase should be avoided because of an association with hypertension. Once stable, recheck examinations should be conducted every 1 to 3 months. It is essential that regular follow-up examinations continue as long

as darbepoetin therapy continues.

Iron Deficiency

Many dogs and cats with advanced CKD are iron (Fe) deficient. Increasing the number of RBCs requires Fe iron, which should be given early with ESA therapy. While Fe can be supplemented orally, it is difficult to provide adequate amounts without causing GI complications. Therefore, Fe dextran (50 mg/cat; 50-300 mg/dog) should be given by injection. Although rare, Fe dextran can cause an anaphylactic reaction, so it is prudent to inform owners of this possibility and to observe the pet for a period of time after administration. If needed, Fe dosing can be repeated monthly.

Several causes of blunted response or failure to resolve anemia with ESA therapy have been identified: Fe deficiency, ongoing GI losses, hemolysis, concurrent inflammatory or malignant disease, and aluminum overload. Owner error related to drug storage, handling, or administration may account for poor response. If the anemia corrects with ESA therapy, but then PCV values again decline, development of anti-EPO antibodies should also be considered. The diagnostic approach to ESA treatment failure should consider history of drug administration, physical examination, CBC, serum chemistry profile, serum cobalamin, an Fe panel (serum Fe, ferritin, and transferrin saturation), bone marrow biopsy, and imaging (evidence of infectious or neoplastic disease). When these tests fail to identify a cause for treatment failure in dogs and cats that have initially responded to ESA therapy, anti-EPO antibodies should be suspected and ESA therapy stopped.[104] Absent an anti-EPO antibody assay, bone marrow myeloid-to-erythroid ratios may provide the best method to ascertain if resistance is due to antibody formation. When EPO is stopped early, antibody titers may decline and suppressed erythropoiesis may reverse.

Calcitriol Therapy

Rationale

Calcitriol (1,25-dihydroxyvitamin D), the most active metabolite of vitamin D, results from renal hydroxylation of 25-hydroxyvitamin D. It enhances GI Ca and PO_4 uptake, inhibits PTH synthesis and secretion, suppresses parathyroid gland growth, and activates cellular receptors. Possible causes of reduced calcitriol levels in CKD include PO_4 retention, increased levels of FGF-23, and reduced renal mass. PO_4 retention and hyperphosphatemia reduce calcitriol production by inhibiting renal 1-alpha-hydroxylase activity which converts 25-hydroxy-cholecalciferol to calcitriol.[59] As CKD progresses, reduced renal mass further limits the number of cells available to hydroxylate 25-hydroxyvitamin D. Calcitriol therapy has been shown to reduce PTH levels in dogs and cats with CKD.[57,36] Although PTH has been claimed to be a uremic toxin responsible for many constitutional signs or uremia, clinical benefits of reducing PTH have not been conclusively documented.[52,152] Results of one clinical trial indicated that calcitriol reduced mortality in dogs with CKD stages III and IV by slowing the progression of CKD.[36] People with CKD have had similar survival benefit after being treated with calcitriol.[153] However, a similar clinical trial in cats revealed equivocal benefits for calcitriol in altering the course of CKD. Neither study could confirm or refute a proposed drug-related improvement in clinical signs.

Treatment Guidelines

Calcitriol therapy (2-3 ng/kg PO q 24 h) is indicated for dogs with CKD stages III and IV and possibly those in CKD stage II to slow progressive deterioration in renal function, but its use in cats remains speculative. Prior to giving calcitriol, neither serum PO_4 nor iCa should be increased since calcitriol increases GI absorption of both. Both must be monitored during therapy to avoid hyperphosphatemia and ionized hypercalcemia. It is unclear whether renoliths containing Ca constitute a relative contraindication to calcitriol therapy. Life-long treatment is necessary to achieve the desired effect of reduced renal mortality. Because it enhances GI absorption of Ca and PO_4, calcitriol should not be given with meals. Giving calcitriol in the evening on an empty stomach reduces risk of inducing hypercalcemia. A compounding pharmacy is needed to prepare formulations that can be used in dogs and cats because the human formulation is too strong.

Overdose

Overdosage of calcitriol is dangerous and should be avoided due to the induction of hypercalcemia with possible renal injury (hypercalcemic nephropathy). Early detection of hypercalcemia, should it occur, is indicated to limit the extent of renal injury. However, hypercalcemia after giving vitamin D is unpredictable

(i.e., it may occur after days to months of treatment). Therefore, continued monitoring of serum Ca, PO_4, and creatinine concentrations after 2, 5, and 8 weeks is necessary to detect hyperCa, hyperPO_4, or deteriorating renal function before irreversible renal damage ensues. Hypercalcemia is more likely to occur when calcitriol therapy is combined with Ca-containing PO_4 binding agents, particularly Ca carbonate. If serum PO_4 and iCa concentrations remain well controlled after 8 weeks of calcitriol therapy, monitoring should continue every 1 to 2 months. The product of serum tCa × PO_4 concentrations should not exceed 60; the goal is values between 42 and 52.[69]

Calcitriol's rapid onset (about 1 day) and short duration of action (half-life less than 1 day) permits rapid control of unwanted hypercalcemia by stopping it completely. Therapy may be reinstituted at a reduced dose or altered dosing strategy after the serum Ca and PO_4 concentrations return to target levels. When calcitriol therapy is associated with hypercalcemia, the daily dose may be doubled and given every other day. This approach may be safer because the effect of calcitriol on the GI tract is related to duration of cell exposure to the calcitriol. When plasma PTH concentration is markedly elevated or when standard therapy with calcitriol fails to normalize plasma PTH levels, pulse calcitriol therapy has been recommended.[52] In this approach, pets receive 20 ng/kg of calcitriol PO twice weekly in the evening on an empty stomach. Pulse therapy is usually used no longer than 1 to 2 months to suppress resistant RSHP. If successful, calcitriol is then given at the standard daily dose. While calcitriol is effective in lowering PTH, the importance of measuring PTH concentrations during calcitriol therapy is unclear and the clinical benefits of suppressing RSHP remain unproven. In the canine study that confirmed survival benefits after therapy with calcitriol, doses were increased as high as 5 ng/kg/day (mean: 1.9 ng/kg/day) to lower PTH values into the normal range, unless hypercalcemia ensued. If hypercalcemia developed, the dosage of calcitriol was reduced.

Minimizing Progression of CKD

All pets with CKD are at risk for disease progression as a consequence of the primary renal disease, in association with a variety of secondary factors that may promote progressive renal disease, or both. An important therapeutic goal for managing patients with CKD is to minimize or prevent progressive loss of renal function. Treatment designed to limit progression of kidney disease may involve a variety of interventions including diet therapy, minimizing proteinuria, controlling hypertension, and calcitriol therapy. A recent hypothesis proposes that blood pressure, proteinuria and phosphate may in fact be linked in their effects on progression of CKD through, in part, the FGF-23/klotho system and calcitriol deficiency.[154] Effectiveness of diet therapy in prolonging survival of dogs and cats with CKD has been described. Renal diets are clearly indicated for dogs with CKD stages III and IV and in cats with CKD stages II through IV. Proteinuria and hypertension are well-established risk factors for progression of renal disease in humans.[55,156] Clinical studies have confirmed that proteinuria is a risk factor for increased mortality in dogs and cats.[25,31] In dogs, the risk of an adverse event (uremic crisis or death) was found to increase by 1.5-fold for every 1-unit increase increment in UPC above 1.0.[31] Elevated BP has been reported to be a risk factor for increased mortality in dogs, but not in cats.[31,144]

Treatments designed to limit proteinuria and hypertension have been proven to be of value in slowing progression of CKD in humans. The evidence in dogs and cats is similar, although somewhat less compelling. In dogs with glomerulopathies, treatment with the ACE inhibitor enalapril significantly reduced proteinuria, but the duration of the study was too brief to adequately assess the renoprotective value of the therapy.[157] However, in a study examining the effects of enalapril in Samoyed Dogs with hereditary nephritis, treated dogs survived 1.36-fold longer than untreated dogs. In cats with UPC values >1.0, treatment with benazepril appeared to be associated with longer survival times, although the effect did not achieve statistical significance. In cats with UPC values <1.0, the data were equivocal.[26] This later finding is consistent with observations in humans suggesting that the magnitude of benefit accruing from ACE inhibitors is proportional to the magnitude of reduction in proteinuria.

The ACVIM Proteinuria Consensus Group has advocated initiating efforts toward reducing glomerular proteinuria in dogs and cats with CKD stages I through IV.[50] Therapeutic intervention is indicated when the UPCR is >2.0 in dogs and cats with CKD stage I, and when it exceeds 0.5 in dogs and 0.4 in cats with CKD stages II through IV. It is now well established in people that therapeutically reducing proteinuria by suppressing the RAAS ameliorates the adverse effects of proteinuria on the kidneys. Experimental and clinical evidence has confirmed the beneficial effect of BP control on slowing progression of diabetic and nondiabetic nephropathies in humans.[155,158] In one large clinical trial, the renoprotective effect of

antihypertensive therapy was further enhanced by maintaining BP below the usual target value.[159] As a consequence, the "ideal" BP to attain using antihypertensive therapy in people with CKD depends on clinical characteristics of the patient. Factors such as presence or absence of proteinuria may influence the goals of therapy. Antihypertensive therapy was most effective in limiting progression of kidney disease in patients with proteinuria. Greater reduction in BP appears to be necessary for equivalent renoprotection with greater levels of proteinuria.[155,159] Studies performed in dogs with induced CKD indicate that administration of the ACE inhibitor enalapril limited glomerular and systemic hypertension, proteinuria and glomerular and tubulointerstitial lesions.[160] Interestingly, enalapril was renoprotective in this study despite the fact that the dogs had only mild hypertension and relatively modest proteinuria.

The renoprotective effects of ACE inhibitors cannot be explained entirely by their effects on blood pressure alone. It is likely that renoprotection results in part from suppressing renal levels of angiotensin II. Because of the role of angiotensin II in progression of CKD, angiotensin receptor blockers have also been considered for humans with CKD.[161] Angiotensin receptor blockers and ACE inhibitors differ in the mechanism by which they inhibit angiotensin II. The ACE inhibitors block conversion of angiotensin I to angiotensin II. However, angiotensin II formation is not completely inhibited because it can also be generated by a non-ACE-dependent pathway such as by the enzyme chymase. Also, because bradykinin is normally degraded by ACE, ACE inhibitor therapy is associated with elevated bradykinin levels. Bradykinin is a vasodilator that may have renoprotective effects by stimulating nitric oxide production. Angiotensin receptor antagonists block the type 1 receptor, but leave type 2 receptor effects unopposed, which appears to be important in vasodilation. In rats with nephropathy, angiotensin II antagonism has been reported to normalize proteinuria, eliminate inflammatory cell infiltration, and ameliorate glomerular and tubular structural changes.[162] A combination of an angiotensin receptor antagonist and an ACE inhibitor has been suggested as a way to maximize blockade of the renin-angiotensin system by affecting both the bioavailability of angiotensin II and also by affecting its activity at the receptor level.[163]

Each type of drug has been shown to be effective in reducing proteinuria and slowing progression of renal disease. However, in experimental and clinical models in humans, combination therapy has proven more effective than either drug alone.[161] In humans, there does not appear to be an increase in toxicoses or adverse events with combination therapy.[158] Whether combination therapy is safe, effective, and provides a therapeutic advantage needs to be determined for dogs and cats with CKD. However, the angiotensin II receptor blocker losartan may not achieve effective blood levels, possibly due to inadequate conversion to the active metabolite.[164] It is not known whether the same is true of irbesartan, but recommended dosages of irbesartan are much higher than those recommended for humans, suggesting a potential problem with conversion of this drug as well. Blockade of the renin-angiotensin system limits both angiotensin II and aldosterone while retarding progression of renal disease. Recent studies have implicated aldosterone as an important pathogenic factor in this process.[165,166] Selective blockade of aldosterone, independent of renin-angiotensin blockade, reduces proteinuria and glomerular lesions in rats with experimental kidney disease. Where blockade of the RAAS ameliorates proteinuria and glomerular injury, selective reinfusion of aldosterone restores proteinuria and glomerular lesions despite continued blockade. This observation suggests an independent pathogenic role for aldosterone as a mediator of progressive renal disease. Aldosterone appears to promote progressive renal injury through both hemodynamic effects and direct cellular actions.[165] It appears to have fibrogenic properties in the kidneys, perhaps in part by promoting production of the profibrotic cytokine transforming growth factor-beta (TGF-beta).[166] Experimental studies have shown that the aldosterone-receptor antagonist eplerenone may attenuate proteinuria and renal damage, independent of its effect on blood pressure. While ACE inhibitors initially cause an acute reduction in aldosterone concentration, this effect is not sustained. It has been proposed that use of aldosterone-receptor antagonists in addition to ACE inhibitors will have additional benefits toward protecting the kidneys.[165] However, the role of this form of therapy has yet to be established in dogs and cats. As described above, calcitriol appears to have renoprotective effects in dogs. It has also been reported to be renoprotective in humans with CKD. The mechanisms of renoprotection have not been fully elucidated, but may include activation of vitamin D receptors on various tissues in the body, improvement in podocyte viability, suppression of RSHP, and suppression of the RAAS.[117,153,167,168]

Patient Monitoring

Response to treatment should be monitored at appropriate intervals so that treatment can be individualized

to the specific, and often changing, needs of the patient. The database obtained before initiating therapy or after correcting an overt uremic crisis should be used as a baseline for comparison of the patient's progress. This evaluation should be repeated at appropriate intervals. In general, evaluations every 2 to 4 weeks are suggested until the initial response to therapy can be established. However, the frequency of evaluation may vary depending on severity of renal dysfunction, complications present in the patient, treatments applied, and response to treatment. Patients receiving therapy with EPO or calcitriol require frequent monitoring life-long. After the initial response to therapy, if any, has been established, dogs and cats in stage I CKD may require evaluation as infrequently as every 6 to 12 months, depending on the nature of their disease. For example, stage I dogs with substantial proteinuria may require monitoring much more frequently depending on the course of their disease. Cats in stage II CKD typically should be monitored about every 3 to 6 months. Dogs in stage II CKD and dogs and cats in stage III CKD should be reevaluated about every 2 to 4 months, depending on the stability of their renal function. Specific recommendations for monitoring are described in the various treatment sections.

CHAPTER 325

Glomerular Diseases

Shelly L. Vaden

Client Information Sheet: Glomerular Diseases

Glomerular diseases are a leading cause of renal disease in dogs.[1] In randomly selected dogs, the prevalence of glomerular lesions is as high as 43% to 90%,[2] and the prevalence appears to increase with age.[3] Glomerular diseases also occur in cats, although they are less common. Immune complex glomerulonephritis (ICGN), amyloidosis and glomerulosclerosis are considered to be the most common glomerular diseases of dogs, comprising nearly 84% of the lesions described in a recent report of 501 dogs with glomerular disease (Box 325-1).[4] Progress has been made in trying to develop a deeper understanding of the differing clinical presentations of the varied glomerular diseases that occur in dogs; fewer studies have been done in cats. Consensus recommendations have been published regarding the approach to the diagnosis, standard therapy and immunosuppressive treatment for dogs with suspect glomerular disease.[5-9]

Box 325-1

Glomerular Diseases Described in Dogs and Cats

- Immune-complex glomerulonephritis (ICGN)
  - Membranous*
  - Membranoproliferative
  - Lupus nephritis
  - Proliferative (rare)
  - Crescentic type (rare)
  - IgA nephropathy (rare)
- Glomerulosclerosis
  - Focal segmental glomerulosclerosis
  - Global glomerulosclerosis
- Amyloidosis
- Hereditary nephritis
- Minimal change glomerulopathy (rare)

*Membranous glomerulopathy is the most common glomerular disease in cats; other glomerular diseases appear to be uncommon.

Normal Glomerular Structure and Function

The glomerulus is a modified capillary bed that functions as a filter, across which an ultrafiltrate of the plasma is formed.[10,11] The filtration barrier is composed of three layers: the fenestrated endothelium, glomerular basement membrane (GBM), and visceral epithelial cells, or podocytes (Figure 325-1). Slit diaphragms are specialized cell junctions present between the podocytes that bridge the filtration slits. The filtrate passes through the endothelial fenestrae, permeates the GBM, and then passes through the filtration slits of the epithelial cells and into the urinary space.[12] This complex structure is freely permeable to water and small dissolved solutes, but retains cells and most macromolecules, such as proteins. The major

determinant of passage into the filtrate is molecular size; ionic charge may be of lesser importance. The epithelial slits likely provide resistance to liquid flow, whereas the GBM is probably the primary determinant of the size-selective barrier by acting as a modified gel through which macromolecules pass.[13] Small molecules, such as inulin (5000 Daltons), pass freely through the filter. Substances are retained with increasing efficiency as they increase in size to approximately 60,000 to 70,000 Daltons; only small amounts of substances larger than this are filtered. Albumin, a negatively charged protein with a molecular weight of 69,000 Daltons, is normally largely excluded from the filtrate. In the end, albumin is prevented from passing into the filtrate. It has long been believed that ionic charge also influences filtration, and that negatively charged proteins are retained to a greater extent than would be predicted by size alone.[14] The podocyte foot processes and the slit diaphragms between them, as well as the basement membrane and the endothelium, are rich in negatively charged glycoproteins, creating this charge barrier. These polyanions are believed to play an important role in the maintenance of normal glomerular permeability and visceral epithelial cell shape. Despite this complex filtration system, small amounts of albumin and other proteins are normally found in the filtrate. Substantial degradation of these proteins occurs, resulting in excretion only of peptide fragments, which are not detected by routine total protein assays. Proteins and peptide fragments may also undergo resorption in the nephron distal to the glomerulus.[14]

FIGURE 325-1 Electron micrograph of a glomerular capillary wall showing the filtration barrier composed of the fenestrated endothelium, the glomerular basement membrane, and the visceral epithelial cell (podocyte). (Courtesy J.C. Jennette, School of Medicine, University of North Carolina, Chapel Hill, NC.)

Clinical Findings

Signalment

Glomerular disease can develop at any age, but appears to be most common in middle-aged to older dogs. The prevalence of microalbuminuria, a marker of increased glomerular permeability, increases as dogs age, with more marked increases seen beyond 6 years of age.[15] The average age of 375 dogs with a variety of glomerular diseases reported in five studies was 8.3 years.[1,16-19] Dogs with nephrotic syndrome (NS) may present at a younger age (mean 6.2 years).[20] Male and female dogs were equally represented. However, the average age and gender predilection seen with specific glomerular diseases varies somewhat from the overall

averages. Glomerular diseases often occur secondary to another disease process. Infectious and noninfectious inflammatory diseases may be more likely in young and middle-aged animals, whereas neoplasms are more common as dogs become older. Familial glomerular diseases often are manifested at an early age. Several breeds of dogs are known to have familial glomerular diseases (Table 325-1); many of these are discussed in detail in ch. 328. Labrador Retrievers and Golden Retrievers may have a higher incidence of glomerular disease; however, the possibility that this increased representation reflects the popularity of these breeds requires further evaluation.[16,21]

TABLE 325-1

Select List of Breeds of Dogs and Cats with Familial Glomerulopathies

BREED	GLOMERULAR DISEASE
Abyssinian Cat	Focal proliferative glomerulopathy
Beagle	Amyloidosis
Bernese Mountain Dog	Mesangiocapillary glomerulonephritis
Bullmastiff	Glomerulopathy
Bull Terrier	Hereditary nephritis
Cocker Spaniel (especially English)	Hereditary nephritis
Dalmatian	Hereditary nephritis
Doberman Pinscher	Glomerulosclerosis, cystic glomerular atrophy
English Foxhound	Amyloidosis
French Mastiff	Progressive juvenile glomerulopathy
Greyhound	Glomerular vasculopathy and necrosis
Newfoundland	Glomerulosclerosis
Pembroke Welsh Corgi	Glomerulosclerosis, cystic glomerular atrophy
Rottweiler	Atrophic glomerulopathy
Samoyed (rare)	Hereditary nephritis
Shar-Pei	Amyloidosis
Soft Coated Wheaten Terrier	Podocytopathy

History

The clinical signs associated with glomerular disease vary considerably, depending on the severity of proteinuria and the presence or absence of renal azotemia.[16,17,22] Many animals with glomerular disease are asymptomatic, and proteinuria is detected during routine health screening. Alternatively, animals may manifest specific signs related to an underlying inflammatory, infectious, or neoplastic condition (E-Boxes 325-2 and 325-3). Signs of glomerular disease may be nonspecific (e.g., weight loss, lethargy) or consistent with chronic kidney disease or uremia (polyuria, polydipsia, anorexia, vomiting, and malodorous breath). Acute kidney injury is not a common presentation in animals with glomerular disease but does occur on occasion. When urinary protein losses are severe, signs of fluid retention (e.g., abdominal enlargement consistent with ascites, peripheral edema) or thromboembolism (e.g., dyspnea, loss of limb function) may be present. Hypertensive damage to the central nervous system (see ch. 260), eyes (see ch. 11), or heart may induce a variety of clinical signs (see ch. 157).

E-Box 325-2

Diseases Reported in Association with Glomerular Disease in Dogs

Systemic Disease

Infectious

Bacterial
- Anaplasmosis
- Borreliosis (MPGN)
- Bartonellosis (G)
- Brucellosis (G)
- Endocarditis (G)
- Pyelonephritis (A)
- Pyometra (A, G)
- Pyoderma (A, G)
- Other chronic bacterial infections (A, G)

Protozoal
- Babesiosis (MPGN)
- Hepatozoonosis (G)
- Leishmaniasis (A, MPGN, MN, P-E and M)
- Trypanosomiasis (G)

Rickettsial
- Ehrlichiosis (G)

Viral
- Canine adenovirus type 1 (P-M)

Parasitic
- Dirofilariasis (A, MPGN, MN)
- *Heterobilharzia americana* (MPGN)

Fungal
- Blastomycosis (A)
- Coccidioidomycosis (A, G)

Inflammatory

Chronic dermatitis (A, G)
Inflammatory bowel disease (G)
Pancreatitis (A, G)
Periodontal disease (A, G)
Polyarthritis (A, G)
Systemic lupus erythematosus (A, MPGN, MN, P-E and M)
Other immune-mediated diseases (G)

Neoplastic

Leukemia (G)
Lymphoma (A, G)
Mastocytosis (G)
Primary erythrocytosis (MCD?)
Systemic histiocytosis (G)
Other neoplasms (A, G, MN)

Miscellaneous

Corticosteroid excess (G)
Trimethoprim-sulfa therapy (G)
Masitinib (MCD)
Hyperlipidemia (?)
Chronic insulin infusion (A)
Congenital C3 deficiency (MPGN)
Cyclic hematopoiesis in gray Collies (A)

Familial (see Table 325-1)

Idiopathic (A, G, MPGN, MN, MCD, P-E or M)

A, Amyloidosis; *G,* glomerulonephritis, uncharacterized; *MCD,* minimal change disease; *MN,* membranous nephropathy; *MPGN,* membranoproliferative (mesangiocapillary) glomerulonephritis; *P,*

proliferative (*E*, endocapillary or *M*, mesangial).

E-Box 325-3

Diseases Reported in Association with Glomerular Disease in Cats

Systemic Disease

Infectious

Bacterial
- Chronic bacterial infections (G)
- Mycoplasmal polyarthritis (G)

Viral
- Feline immunodeficiency virus (G)
- Feline infectious peritonitis (MN)
- Feline leukemia virus (G, MN)

Inflammatory
- Pancreatitis (G)
- Cholangiohepatitis (G)
- Chronic progressive polyarthritis (G)
- Systemic lupus erythematosus (MN)
- Other immune-mediated diseases (G)

Neoplastic
- Leukemia (MN)
- Lymphoma (MN)
- Mastocytosis (G)
- Other neoplasms (G)

Miscellaneous
- Acromegaly (?)
- Mercury toxicosis (MN)

Familial (MN)

G, Glomerulonephritis, uncharacterized; *MN*, membranous nephropathy.
Idiopathic (MN)

Physical Exam Findings

The physical examination (see ch. 2) is often unremarkable in dogs with glomerular disease.[16,17,22] Nonspecific evidence of systemic disease may be present (e.g., poor body condition or poor haircoat). Dogs with advanced kidney disease may have oral ulcerations, pale mucous membranes, or dehydration. Subcutaneous edema or ascites or both are sometimes noted (see ch. 18). Occasionally dogs have physical evidence of thromboembolic disease, such as dyspnea or a decreased or absent peripheral pulse (see ch. 256). Evidence of a predisposing inflammatory, infectious, or neoplastic process may be detected during the physical examination. The kidneys of affected animals are variable in size. Animals with chronic kidney disease often have small, firm, irregularly shaped kidneys (see ch. 324), whereas those with disease of shorter duration often have normal-sized or, occasionally, enlarged kidneys (see ch. 322).

Clinicopathologic and Imaging Findings

Proteinuria is the hallmark of glomerular disease and is discussed in ch. 72. Thorough assessment of proteinuria includes locating the source and evaluating for persistence and magnitude.[5] A urine protein–to-creatinine ratio (UPC) >0.5 or 0.4 in a dog or cat, respectively, is abnormal in a urine sample free of inflammation or discoloration from hematuria (or >150 RBC/hpf). There is no magic number or range of numbers for the UPC that is diagnostic for any one renal disease; the overlap in expected ranges is too broad to be clinically reliable.[23] However, the greater the magnitude of proteinuria, as assessed by the UPC, the

greater the likelihood that the animal has glomerular disease. In three studies of urine albumin in canine models of glomerular disease, microalbuminuria was detected before increases in the UPC, and the magnitude of microalbuminuria increased over time in dogs that eventually developed an increased UPC.[24-26] A dog with persistent microalbuminuria of increasing magnitude should be assessed as having an injurious process to the glomerular filtration barrier and may eventually develop overt proteinuria. Glomerular lesions also have been identified in dogs without proteinuria.[27-29]

Isosthenuria is a variable finding in dogs and cats with glomerular disease. The presence of renal azotemia and an intact concentrating ability is indicative of glomerular disease. In one study, 37% of dogs with glomerulonephritis (GN) had urine specific gravities in excess of 1.035, and isosthenuria was detected in only 29%.[17] However, in dogs with amyloidosis, dilute urine (i.e., a urine specific gravity less than 1.016) was more common, occurring in 63% compared with only 5.1% showing evidence of being able to concentrate above 1.035.[22] Cylindruria is common in dogs with glomerular disease; casts are most often hyaline but can be granular, waxy, or fatty (see ch. 72). Proteinuria promotes the precipitation of Tamm-Horsfall mucoprotein, which in turn envelops the protein in the tubular lumen into a hyaline cast, thereby protecting the renal tubular epithelium from the protein's damaging effects. Granular and waxy casts form in the progressive degeneration of cellular casts, which are the result of damaged tubular epithelial cells. Renal hematuria develops with glomerular injury in humans and is more common in specific diseases (e.g., IgA nephropathy, mesangial proliferative glomerulonephritis), but it appears to be less common in dogs with glomerulopathies.[11] Erythrocytes that have passed through the abnormal glomerular capillary bed are often misshapen; the morphology of urine erythrocytes can be used to differentiate hematuria of glomerular origin from that resulting from other causes.

Hypoproteinemia caused by hypoalbuminemia develops in many dogs and cats with glomerular disease and is more likely in animals with heavy proteinuria. Hypoalbuminemia occurred in 60% and 70% of dogs with GN or amyloidosis, respectively.[17,22] Azotemia, hyperphosphatemia, and metabolic acidosis, consistent with renal failure, may be present in dogs with severe disease. Of dogs with GN or amyloidosis, 53% and 26%, respectively, were not azotemic at the time of diagnosis.[17,22] Nonregenerative anemia that develops secondary to chronic kidney disease or a systemic disease is observed in many affected animals. Other hematologic abnormalities also may reflect concurrent and possibly underlying systemic diseases. Thrombocytosis and hyperfibrinogenemia are common findings in dogs with glomerular disease.

The nephrotic syndrome (NS) of hypoalbuminemia, proteinuria, hypercholesterolemia, and edema, although pathognomonic for glomerular disease, was present in only 15% of dogs with GN in one study.[17] Incomplete NS (i.e., without edema or ascites) was more common, occurring in 49% of dogs.[17] NS is expected to occur more commonly in dogs diseases associated with marked proteinuria but was not associated with any specific histologic diagnosis in one study.[20]

The *nephritic syndrome* is a term that has primarily been used in people to describe a set of signs that develop secondary to renal inflammation, generally acute, that extends into the glomeruli. In people this syndrome is characterized by hematuria and RBC casts with one or more of the following: subnephrotic proteinuria, edema, hypertension, azotemia, and oliguria. Although the nephritic syndrome has not been fully characterized in dogs, perhaps because of the probable low prevalence of acute glomerulonephritides in dogs, it is possible that dogs with acute Lyme nephritis may have a "nephritic-like" syndrome (see ch. 211).

Radiographically, the kidneys may appear normal or small and irregular; some animals may have enlarged kidneys. Similar changes in shape and size can be seen with ultrasonographic scans; increased echogenicity of the cortex and loss of corticomedullary distinction may also be noted. The renal pelvis may be mildly dilated if polyuria is present or fluids are being administered.

Consensus recommendations state that the diagnostic evaluation should be more extensive for a dog with UPC above 3.5 and/or more clinical abnormalities as a result of glomerular injury than for a dog with only mild proteinuria.[5] An extensive evaluation would include tests that would facilitate the detection of underlying infectious, inflammatory, or neoplastic diseases (see E-Boxes 325-2 and 325-3). A thorough physical examination should be performed; diseases of the oral cavity or skin should not be overlooked as potential underlying disorders (see ch. 10 and 272). Aspiration cytology should be performed on all cutaneous and subcutaneous masses (see ch. 86). Serologic testing for regional infectious diseases should be performed. Evaluation might include tests for autoantibodies (e.g., antinuclear antibody, ANA) in animals with extrarenal abnormalities (e.g., thrombocytopenia, polyarthritis; see ch. 205). During radiographic or ultrasonographic evaluation of the abdomen, attention should be given to other organs to detect extrarenal disease processes (see ch. 88). Thoracic radiographs, particularly in middle-aged to older dogs, should be

evaluated for any evidence of neoplastic disease.

Renal Biopsy and Histologic Diagnoses

Renal biopsy provides a definitive diagnosis of glomerular disease, but may not be needed if treatment of a potential underlying disease leads to resolution of the proteinuria or end-stage renal disease is already present. When evaluated appropriately, renal biopsy specimens can provide important clinical information about the type and severity of lesions in dogs and cats with glomerular disease. In fact, obtaining an accurate histologic diagnosis may be one of the more important factors in successful management of the dog or cat with glomerular disease. Clinical decisions regarding the diagnosis, treatment, and prognosis can be made from the information obtained through renal biopsy.

Procurement and Processing of the Renal Biopsy Specimen

The procedure used to obtain a renal biopsy specimen is discussed in ch. 89 and 321. The renal biopsy procedure requires expertise and should be performed only by experienced personnel.[30] Hypertension (see ch. 157) and coagulation disorders (see ch. 196) should be controlled prior to biopsy. When a specimen is to be used for evaluation of glomerular disease, only cortical tissue should be obtained; biopsy of the medulla is not needed and is associated with a greater risk of hemorrhage, infarction, and fibrosis. The use of general anesthesia is associated with an ability to obtain better-quality specimens. An adequate sample of cortex has a minimum of five glomeruli when examined by light microscopy, although one glomerulus may be all that is needed to make a definitive diagnosis in animals in which the disease is diffuse (i.e., one in which most glomeruli are involved) and easily recognizable (i.e., amyloidosis).

If a percutaneous method is used to obtain a renal biopsy specimen from a patient with glomerular disease, at least two quality samples of renal cortex (i.e., each >10 mm long) should be obtained, using either a 16- or 18-gauge needle. A dissecting microscope can be used to verify that adequate biopsy samples have been obtained. One sample should be placed in formalin, and the other should be divided into two smaller pieces containing glomeruli. One piece is put into a fixative suitable for transmission electron microscopy (TEM) (e.g., 4% formalin plus 1% glutaraldehyde in sodium phosphate buffer), and the other piece is frozen for immunofluorescent microscopy (IFM). An alternative to freezing is to immerse the tissue in ammonium sulfate-N-ethylmaleimide (i.e., Michel's solution), which preserves tissue-fixed immunoglobulins. Wedge biopsies should be divided in a similar fashion; tissue for TEM should be minced appropriately. Tissue for TEM should be put into the fixative within 5 minutes of biopsy.

Thin sections (2 to 4 mm) of paraffin-embedded tissue should be used for light microscopy because standard sections of 5 to 6 mm are too thick for adequate assessment of glomerular cellularity and capillary loop thickness.[10,23] Hematoxylin and eosin staining can be used for initial assessment; however, periodic acid–Schiff (PAS), which stains glycoproteins, is the preferred stain of many nephropathologists and is particularly useful for demonstration of interstitial and glomerular scarring and assessment of the GBM. Methenamine silver specifically stains the basement membrane of the tubules, glomeruli, and Bowman's capsule. Trichrome is useful for evaluation of the mesangium and is also the best light microscopic stain for visualization of immunoglobulins. Congo red can be used to demonstrate the presence of amyloid. IFM or immunohistochemistry should include at a minimum stains for immunoglobulin M (IgM), IgG, IgA, and C3.

Evaluation of the Renal Biopsy Specimen

Only pathologists who have expertise in renal pathology should evaluate renal biopsy specimens. The inclusion of TEM and IFM are not only feasible, but required for determining the presence or absence of immune-complexes and making an accurate and clinically useful morphologic diagnosis.[23] Limiting the evaluation to light microscopy alone often allows for only a subjective interpretation of the glomerular lesion. A standard classification system for the characterization of glomerular lesions in dogs has been proposed.[23]

The normal glomerulus contains four to eight lobules, each composed of capillaries supported on a centrilobular core of mesangial matrix (Figure 325-2).[10,11] The GBM is thin, delicate, PAS-positive, and argyrophilic. The glomerular capillary lumen is normally widely patent and lined with eosinophilic endothelial cell cytoplasm (Figure 325-3). There should be only one or two nuclei per mesangial cell region. Parietal epithelial cells, visceral epithelial cells, endothelial cells, and mesangial cells comprise the normal glomerulus and can easily be identified by TEM (see Figure 325-1). The flattened parietal epithelial cells line the inner surface of Bowman's capsule. The visceral epithelial cells (podocytes) line the outer surface of the capillary loops and rest on the GBM. The podocytes, which are characterized by their foot processes, form the

outermost layer of the capillary wall. The endothelial cells line the inner surface of the capillary loops, with the nuclei disposed centrilobularly toward the mesangium. The fenestrations of the endothelial cell cytoplasm can be visualized easily. The normal GBM should be approximately the same thickness as the base of a foot process turned 90 degrees.

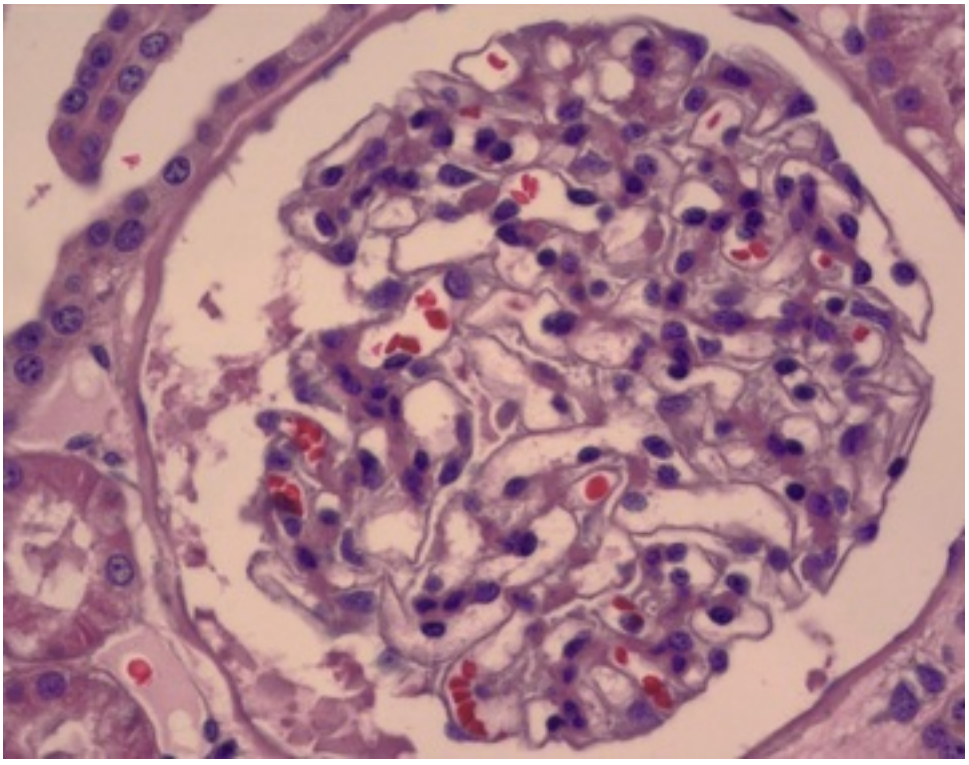

FIGURE 325-3 Normal glomerulus from a dog. Note that the capillary lumens are widely patent and the capillary loops are thin, often appearing discontinuous. Hypercellularity is not present.

Glomerular Diseases

Many glomerular diseases affect dogs; fewer appear to affect cats (see Box 325-1). The historical approach of lumping these under the umbrella of "GN" has limited advancement of our understanding and management of these disorders. A better approach is to treat these disorders as separate disorders to the best of our ability. This section outlines what is known about the individual diseases in dogs and cats, with additional information garnered from the wealth of knowledge on these diseases in humans. Acquired glomerular injury is the result of damage sustained after immune complex formation or deposition (e.g., membranous nephropathy, MN; membranoproliferative glomerulonephritis, MPGN) or damage caused by systemic factors that affect the glomerulus (e.g., amyloidosis). In a large study of 501 dogs, 48.1% had ICGN.[4] Immune complexes that are deposited in the glomerulus or that form *in situ* initiate glomerular damage.[31] Cell-mediated immune mechanisms also take part in the pathogenesis of glomerular inflammation. Once glomerular damage has been initiated, other processes contribute to glomerular injury, including activation of complement and the coagulation cascade and resident cells; influx of neutrophils, monocytes, and platelets; release of proteolytic enzymes; synthesis of cytokines or other growth factors; generation of proinflammatory lipid mediators; and alteration of hemodynamic factors. The mechanisms that determine whether progressive renal damage or resolution of the process occurs are unclear.

Membranoproliferative Glomerulonephritis

MPGN is one of the most common glomerular diseases in dogs. Although reported in up to 60% of dogs in various studies, in a recent report where renal biopsies underwent extensive pathologic evaluation, MPGN was identified in 26% of the 89 biopsies.[1,23,32] Glomerular lesions are most likely to be called MPGN when evaluation has not included the use of IFM and EM; the incidence of MPGN is most certainly overestimated in previous studies.

Clinical Features

The mean age of dogs with MPGN in one study was 10.5 years.[19] Males and females appear to be equally affected. Even though the disease is common, no thorough study of MPGN as a distinct glomerular disease has been done in dogs. In humans, the disease is characterized by a slowly progressive course, and about 50% of those affected develop NS. In a study of NS in dogs, 36% of dogs with MPGN had NS.[20] In one study of dogs, MPGN was associated with the most severe constellation of clinical abnormalities; the cluster of dogs with MPGN had among the highest median UPC ratio, the highest median serum creatinine concentrations, the lowest serum albumin concentrations, and higher frequency of hypertension than any other cluster.[23]

MPGN has been identified as a familial disease in Bernese Mountain Dogs. A unique, rapidly progressive form of MPGN that is accompanied by tubular necrosis and interstitial inflammation and is uniformly fatal has been reported in association with *Borrelia burgdorferi* infection in dogs.[21] The average age of affected dogs was only 5.6 years. Labrador Retrievers and Golden Retrievers were significantly predisposed to developing this lesion.

Pathogenesis

The form of MPGN identified in dogs more closely aligns with type I MPGN in people, which is also called *mesangiocapillary glomerulonephritis,* is often induced by infectious diseases and is characterized by immune complex accumulation on the subendothelial side of the GBM.[10,11] MPGN has been associated with a variety of infectious diseases in dogs (see E-Boxes 325-2 and 325-3). The accumulation of immune complexes leads to cytokine-mediated complement activation, expansion of the mesangium and an inflow of leukocytes.

In humans with MPGN, hypocomplementemia is so common that this disease is sometimes called *hypocomplementemic glomerulonephritis.* Hypocomplementemia appears to develop either from increased consumption secondary to immune complex activation of the classic pathway or from the presence of anticomplement autoantibodies known as nephritic factors. Interestingly, type I MPGN also occurs in Brittany Spaniels and humans with congenital C3 deficiency.[27] The pathogenic role of hypocomplementemia is not understood.

Histopathologic Characterization

MPGN is diagnosed when both thickened capillary loops and mesangial hypercellularity (more than three nuclei per mesangial region) are present (Figure 325-4 and E-Figure 325-5).[10,11,19,23] The glomerulus may become enlarged and segmented or lobular in appearance. The activated mesangium expands the capillary walls and extends into the subendothelial space, causing the double contour, or "railroad," appearance of the GBM that can be seen with light microscopy. With IFM, immune complex deposition can be identified in MPGN as granular deposits of C3 in combination with IgG, IgM, or IgA, or combinations thereof, in the GBM or mesangium or both. TEM can also be used to identify the immune deposits in MPGN.

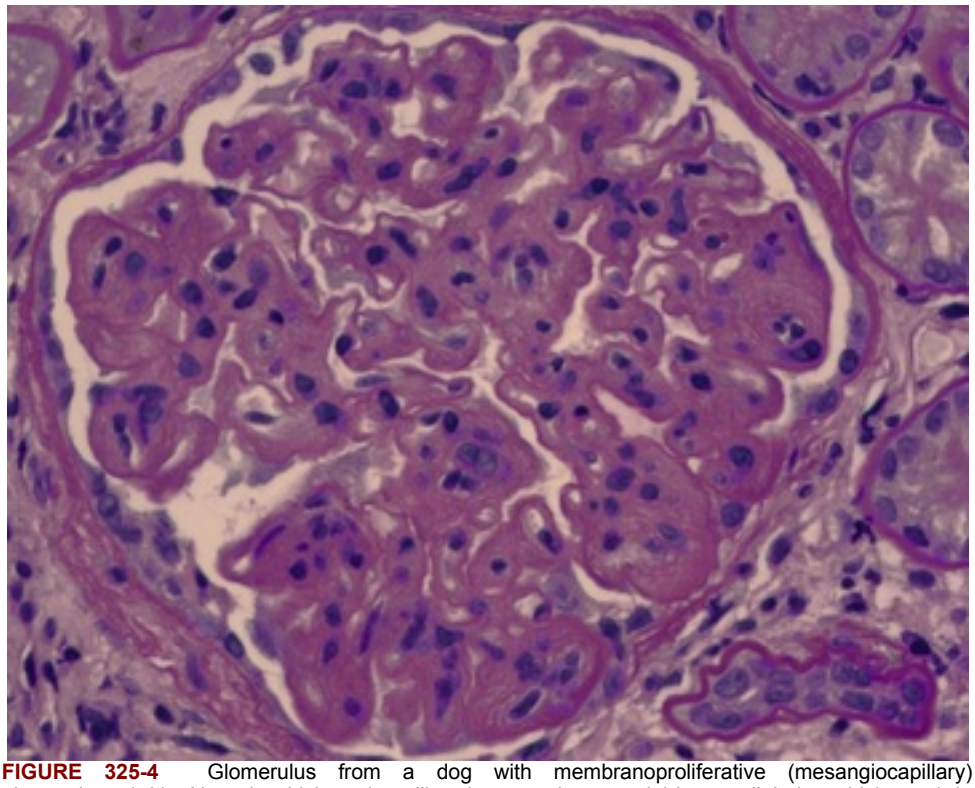

FIGURE 325-4 Glomerulus from a dog with membranoproliferative (mesangiocapillary) glomerulonephritis. Note the thickened capillary loops and mesangial hypercellularity, which result in the segmented and lobular appearance.

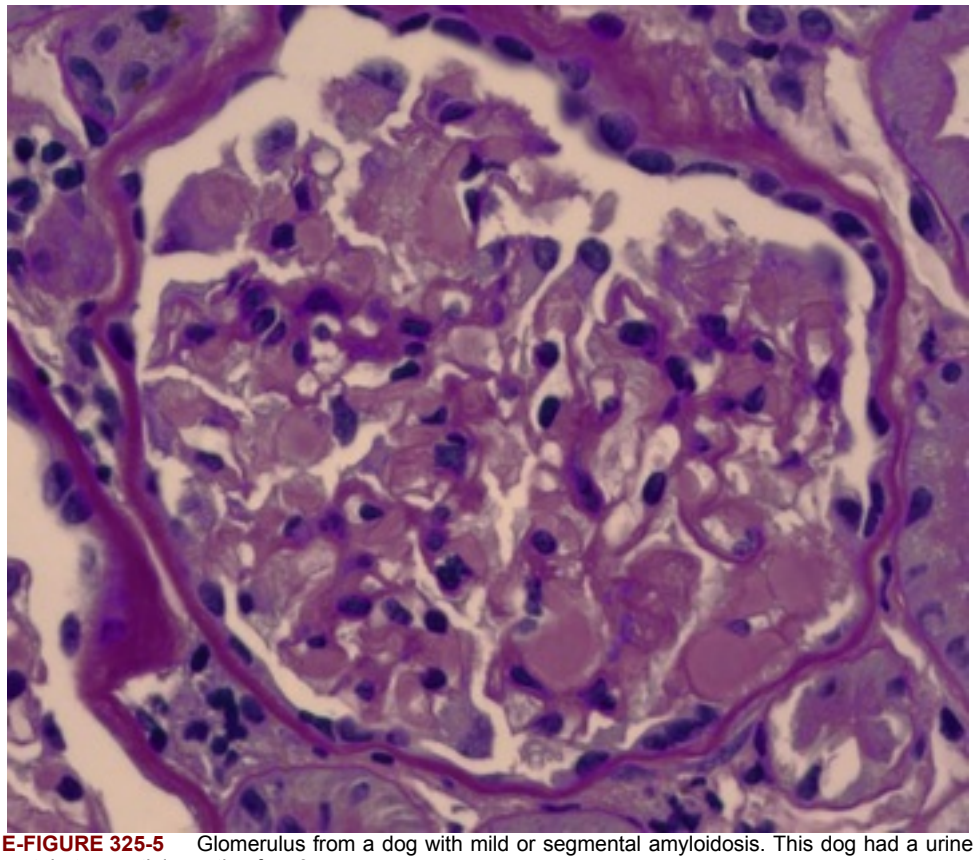

E-FIGURE 325-5 Glomerulus from a dog with mild or segmental amyloidosis. This dog had a urine protein-to-creatinine ratio of 4.73.

Specific Treatment

Effective treatment of the underlying infectious, inflammatory, or neoplastic disease is the cornerstone of management of patients with MPGN (see below). Immunosuppressive therapy should be considered in dogs that have severe, persistent or progressive disease. Because activation of platelets appears to be involved in the pathogenesis of this disease, antiplatelet drugs also should be given.[11]

Prognosis

Specific data regarding the prognosis of MPGN in dogs are lacking. In people, azotemia, severe proteinuria, systemic hypertension, and marked tubulointerstitial lesions at presentation are the most significant predictors of an unfavorable outcome.[11]

Membranous Nephropathy

MN is another common glomerular disease in dogs. While reported in up to 45% of dogs in various studies, it was identified in 26% of the thoroughly evaluated biopsies in a recent study.[2,19,23,33-35] It is the most common glomerular disease in cats, in which other forms of glomerular disease are uncommon.[36,37] The disease is sometimes called a *glomerulopathy* or *nephropathy*, rather than GN, because there is rarely evidence of an inflammatory response in the glomeruli or interstitium.

Clinical Features

MN appears to be more common in male dogs and cats (approximate male to female ratios, 1.75 : 1 in dogs and 6 : 1 in cats). The mean age of affected dogs from four studies was 8 years, but there was considerable range (1 to 14 years). The disease is more common in younger cats, with an approximate mean age of only 3.6 years (range, 1 to 7 years).[36] There does not appear to be any breed predilection, although a preponderance of Doberman Pinschers was seen in one report. Interestingly, four of five of these Dobermans were 3 years of age or younger, which may suggest a familial pattern.[34]

Proteinuria in animals with MN may be massive.[29] In a study of NS in dogs, 38% of dogs with MN had NS.[20] Microhematuria is reported in 30% to 40% of humans with MN, but has not been systematically studied in dogs and cats.[11] Cats and dogs with MN may present with signs of advanced kidney disease. Many cats have normal to enlarged kidneys at presentation.

MN has four ultrastructural stages that correlate with the temporal evolution of the disease and the clinical presentation in dogs, cats, and humans.[10,11,34,36] Although not universally accepted, there is some suggestion that these stages correlate with therapeutic outcomes in humans with MN, in that people may be more likely to respond to appropriate management if they are in one of the first two stages. More advanced stages in cats and dogs have been shown to correlate with more severe azotemia, whereas animals with milder disease were more likely to have NS.[34,36] In some cases, different stages were found within a single biopsy specimen.

Pathogenesis

In humans, MN is considered to be either primary (i.e., idiopathic) or secondary to another disease process; primary disease is most common.[11] The finding of antibodies on the subepithelial side is unique to MN and suggests that binding occurs on the urinary side of the GBM. The subsequent activation of complement and cytokine responses may be reduced, because the site of reaction is distant to the circulation, which contributes to the lack of inflammation associated with MN.

Although the exact pathogenesis of this disorder is unknown, primary MN is considered to be an ICGN. In humans with primary MN, the weight of evidence supports that immune complexes form *in situ*, when unbound antibody reacts with fixed antigens of the podocyte. In this regard, primary disease may be a true autoimmune disorder.

Circulating immune complexes most likely play a larger role in patients with secondary disease. Proteinuria probably develops through a complement-dependent mechanism, independent of inflammatory cells. The terminal complement complex (C5b-9 membrane attack complex) has been implicated in the pathogenesis of this disease. Increased urinary concentrations of the membrane attack complex have been demonstrated in some, although not all, individuals with MN. Demonstration of this complex may be more likely early in the disease process, when active immune deposit formation occurs. Myriad immune system irregularities have been reported in association with MN in humans (e.g., altered CD4+ to CD8+ ratio, Fc receptor dysfunction, and impaired lymphocyte and suppressor cell function), which supports a pathogenic role for an underlying immunologic defect. These irregularities are perhaps based on a genetic susceptibility, a theory supported by familial clustering of MN in humans.[10,11]

Histopathologic Characterization

The normally lacy-appearing GBM becomes uniformly thickened and more rigid as a result of the deposition of immune complexes in the subepithelial spaces in MN (Figure 325-6).[10,19,23] New basement membrane material accumulates around the immune deposits. Because the deposits do not become impregnated with silver, "spikes" may be identified on the outside of the GBM when an appropriate silver stain is used (E-Figure 325-7). Advanced cases may show irregular thickening and distortion of the capillary walls with occasional widening of the mesangium. IFM is useful in determining the site of immune complex deposition. Staining of the immune complexes produces a beaded appearance along the GBM and can be so heavy that it may be difficult to differentiate from a linear pattern. In secondary cases the mesangial spaces are also positive.

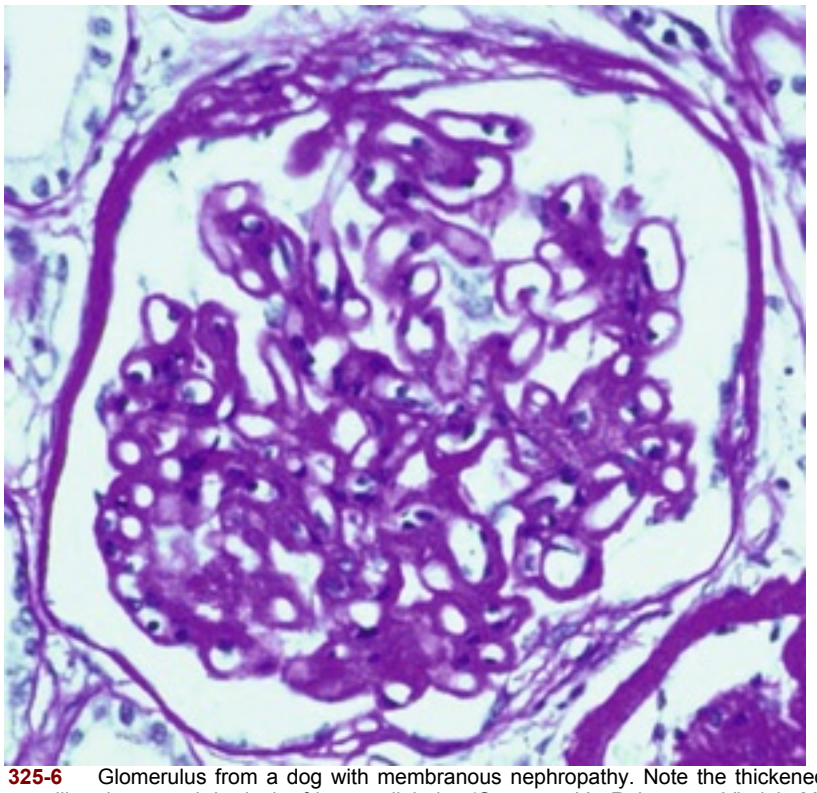

FIGURE 325-6 Glomerulus from a dog with membranous nephropathy. Note the thickened, rigid-appearing capillary loops and the lack of hypercellularity. (Courtesy J.L. Robertson, Virginia Maryland Regional College of Veterinary Medicine, Blacksburg, VA.)

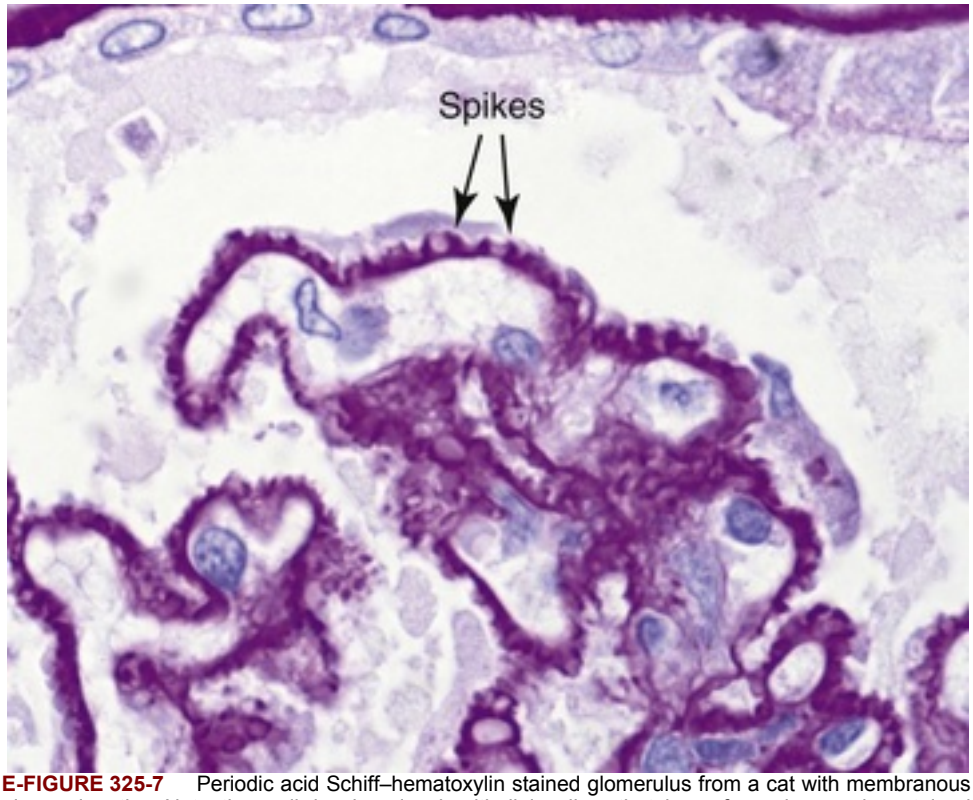

E-FIGURE 325-7 Periodic acid Schiff–hematoxylin stained glomerulus from a cat with membranous glomerulopathy. Note the well-developed subepithelial spikes that have formed around unstained immune deposits.

TEM should be used to confirm the location of the immune deposits and characterize the stage of disease progression (Figure 325-8).[11,23,34,36] Deposition of immune complexes, progressive engulfment of the complexes by the surrounding GBM, and eventual resolution of the deposits characterize the stages. Stage I has subepithelial dense immune deposits without adjacent projections of basement membrane material and only minimal thickening of the GBM. Projections of adjacent GBM material, or spikes, are identified in stage II. These projections eventually surround the immune deposits (stage III). In stage IV the GBM is markedly thickened, and electron-lucent zones have replaced some or all of the electron-dense deposits. In advanced stage IV disease, sometimes referred to as stage V, there is variable thickening of the GBM and apparent resolution of the electron-dense deposits. Sometimes staging is difficult because several stages of disease may be present simultaneously.

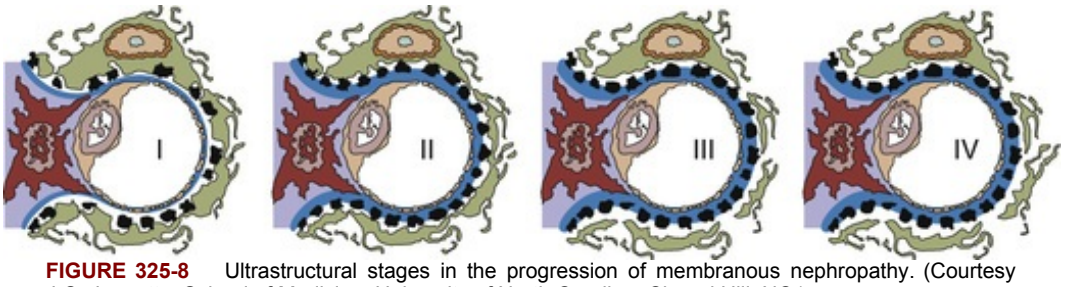

FIGURE 325-8 Ultrastructural stages in the progression of membranous nephropathy. (Courtesy J.C. Jennette, School of Medicine, University of North Carolina, Chapel Hill, NC.)

Specific Treatment

In addition to identification of potentially inciting disease processes and nonspecific management of proteinuria, immunosuppressive therapy may be warranted in dogs or cats with severe, persistent or progressive disease. Affected humans with similar clinical pictures may respond to immunosuppressive therapy.[11] Even when treatment is effective, relapses may occur. The use of immunosuppressive therapy in dogs and cats with MN needs to be studied.

Prognosis

Although MN appears to be progressive in some dogs and cats, the progression may be slow enough that many animals can lead relatively normal lives. In a study of 24 cats with MN, 4 (17%) survived 4 to 10 months, and 8 (33%) had long-term survival of 2.5 to 6 years; clinical remission occurred in 7 (29%) of the cats. Corticosteroids were administered to three of the eight long-term survivors. However, 11 cats (46%) died or were euthanized because of NS or advanced renal disease shortly after diagnosis.[37] Long-term survivors had only IgG deposition, C3 deposition, or both; cats that also had deposition of IgM or IgA had a shorter survival period. Stage III and IV MN, defined by the presence of intramembranous deposits, was associated with a poorer prognosis.[37]

Survival data for dogs appear to be similar to what has been reported in cats, with reported survival ranging from 4 days to greater than 3 years.[34] Spontaneous remissions have been reported. Spontaneous remission occurs in 20% to 30% of humans with MN, whereas 20% to 40% of cases progress to chronic kidney disease.[11] The risk of progression in humans appears to correlate with the magnitude of proteinuria and renal function impairment; patients with the highest degree of proteinuria and azotemia are more likely to have more rapid progression compared with other patients.

Proliferative Glomerulonephritis

Proliferative GN, caused by endocapillary or mesangial proliferation, accounted for 2% to 16% of glomerular lesions in dogs in two studies but none were identified in a recent pathologic study, most likely because uncommon diagnoses were excluded.[19,23,32] In humans, a pathologic diagnosis requires both a morphologic description (e.g., mesangial proliferative GN), and a specific disease designation (e.g., IgA nephropathy, lupus GN).[10,11] With the exception of IgA nephropathy, proliferative GN in dogs has not included the specific disease designation.[38,39]

Clinical Features

Dogs with proliferative GN reported in two studies were on average between 7 and 9 years of age.[18,19] Proteinuria and renal azotemia were the most common presenting signs. Azotemia may be mild or moderate and acute or chronic. Although hematuria is associated with this disorder in people, its presence in dogs is unknown.[11]

Pathogenesis

Proliferative GN is an ICGN. Anti-GBM disease causes proliferative GN in humans but has not been described in the dog or cat. Post-infectious GN of humans is a form of proliferative GN that most commonly occurs after resolution of a streptococcal infection. Persistent infections are more likely to cause MPGN or MN.[10]

Histopathologic Characterization

Mesangial proliferative GN is characterized by mesangial cell hyperplasia (≥4 cells per mesangial area) that is often accompanied by increased mesangial matrix (Figure 325-9).[10,19] Endocapillary proliferative GN has a proliferation of endothelial cells with or without increased mesangial cellularity that is partially due to an influx of mononuclear cells. Evaluation by IFM reveals fine granular deposits of IgG or IgM or both in the GBM and mesangium. TEM further localizes the immune complexes. Because proliferative GN often develops secondary to systemic diseases, immune complexes are frequently identified in the mesangium, although some complexes may be found in the capillary walls.

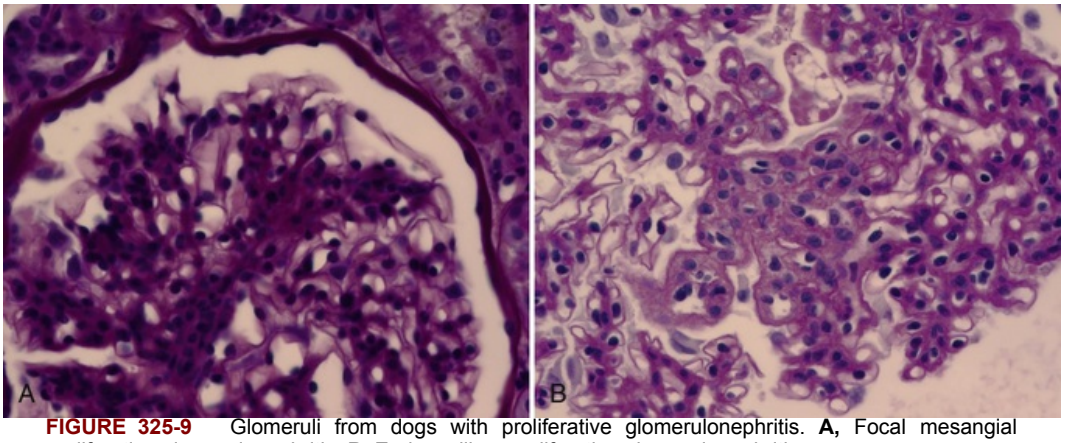

FIGURE 325-9 Glomeruli from dogs with proliferative glomerulonephritis. **A,** Focal mesangial proliferative glomerulonephritis. **B,** Endocapillary proliferative glomerulonephritis.

Specific Treatment

The potential source of immune complexes should be removed, and nonspecific management of glomerular diseases should be followed. Immunosuppressive therapy may be warranted in animals with severe, persistent or progressive disease.

Prognosis

While the prognosis has not been fully evaluated in dogs, the presence of advanced azotemia or the formation of crescents is likely associated with a poorer prognosis.

Immunoglobulin A Nephropathy

In several studies of canine glomerular disease, IFM has demonstrated mild to moderate frequency of IgA positivity, suggestive of IgA nephropathy.[38,39] IgA is predominantly polymeric in dogs and it may be nonspecifically trapped in the mesangium, more so than monomeric IgA, the predominant form in humans. The diagnosis of IgA nephropathy requires a predominance of IgA positivity on IFM evaluation; co-deposits of IgG, IgM, or C3 may be present but should be less intense than IgA. Mesangial proliferative GN is the

expected light microscopic lesion; some humans do not have any apparent glomerular lesions. In one study of clinically normal dogs with glomerular lesions, 85% had IgA deposits.[28] In another study of 100 dogs with and without renal disease, 47 had IgA deposition; in 6 dogs, IgA was the only immunoglobulin detected.[39] Increased deposition of IgA was associated with increased cellular proliferation. Dogs with enteric or hepatic diseases had the highest prevalence of IgA deposition. Excessive IgA immune complex formation caused by enteric disease or decreased clearance of IgA complexes in association with liver disease have been proposed in the pathogenesis of secondary IgA nephropathy in humans.[11]

IgA nephropathy was described in three young to middle aged (4 to 7 years) male dogs, demographics that are consistent with those of affected people.[11,38] The dogs had proteinuria, varying degrees of azotemia, and episodes of hematuria. Dogs were housed together but predisposing environmental factors were not identified. The most severely affected dog had uncontrolled hypertension and co-deposits of IgG or IgM, both of which are negative prognostic indicators in humans.

Treatment of patients with secondary IgA nephropathy should be directed at treatment of the associated systemic disease and control of hypertension. Fish oil rich in omega-3 fatty acids administered to affected humans resulted in slowed progression of renal disease but did not lead to a reduction in proteinuria.[11]

Amyloidosis

Amyloidosis accounts for approximately 15% of the glomerular lesions in dogs.[4] The term *amyloidosis* refers to a diverse group of diseases that have in common the extracellular deposition of fibrils formed by polymerization of proteins with a beta-pleated sheet conformation.[40] Reactive amyloidosis is the most common form of amyloidosis in dogs and cats, with the dog being the domestic animal most commonly affected by amyloidosis. With the exception of the Chinese Shar-Pei, amyloid is deposited primarily in the glomeruli of affected dogs.[22,41] Amyloidosis is relatively uncommon in the cat, with the exception of Abyssinians and Siamese (especially the Oriental shorthair color variant).[42] In Abyssinians, amyloid is deposited primarily in the renal medulla, although glomerular involvement has been described.

Clinical Features

Renal amyloidosis is more common in older dogs. The mean age of affected dogs was 9.2 years in one study, in which 85% of affected dogs were 7 years of age or older.[22] Females appear to be affected more often than males (the male to female ratio is 1 : 1.7). Collies and Walker Hounds may be at increased risk for amyloidosis; the disorder is familial in the Chinese Shar-Pei and may be familial in Beagles and English Foxhounds.[22,43]

Because proteinuria associated with amyloidosis may be massive, many animals brought to the veterinarian are in NS. In a study of NS in dogs, 56% of dogs with amyloidosis had NS.[20] However, contrary to popular belief, dogs with amyloidosis did not have higher UPC ratios or serum creatinine concentrations or lower serum albumin concentrations than dogs in other disease clusters.[23] In another study, six of seven dogs with amyloidosis had nonselective proteinuria, suggesting a marked loss of the size-selective properties of the glomerular capillary wall.[29] Although amyloid may be deposited in other organ systems (liver [see ch. 285], spleen, adrenal glands, gastrointestinal tract), clinical signs associated with deposition in these organs are rare in dogs. Chronic infectious and noninfectious inflammatory diseases and neoplasia have been reported in association with reactive amyloidosis in 32% to 53% of affected dogs; however, many dogs and cats with reactive amyloidosis do not have an identifiable inflammatory process at the time of presentation.[16,22]

Renal amyloidosis in the Shar-Pei develops at an earlier age (mean age 4.1 years) than in other dogs with amyloidosis, but like other breeds, the disease is more common in females (male to female ratio of 1 : 2.5).[41] In Shar-Peis, amyloid is most commonly deposited in the renal medulla; only 64% of Shar-Peis had glomerular involvement.[41] As a result, as few as 25% to 43% of affected Shar-Peis have proteinuria. Affected dogs may have signs of involvement of other organs, particularly the liver (see ch. 285). Many Shar-Peis have a history of recurrent fever and swelling of the tibiotarsal joints (commonly called *Shar-Pei fever* or *Shar-Pei swollen hock syndrome*; see ch. 203) before the development of renal amyloidosis, suggesting that this may be an animal model of familial Mediterranean fever.

Pathogenesis

The primary protein involved in the formation of amyloid deposits in dogs and cats is amyloid A protein

(AA), which is formed by the polymerization of the amino terminal portion of serum amyloid A protein (SAA), an acute-phase reactant.[40] SAA is synthesized and released by hepatocytes after they have been stimulated by macrophage-derived cytokines (e.g., interleukin-1 [IL-1], IL-6, tumor necrosis factor). Because of the association of amyloid A with inflammatory diseases, this form of amyloidosis has been termed *reactive*, or *secondary*, amyloidosis.

Concentrations of SAA increase 100- to 1000-fold after tissue injury. Although concentrations decrease to baseline by 36 to 48 hours after removal of the inflammatory stimulus, they remain increased if inflammation persists.[40] Chronic inflammation and persistent or prolonged increases in SAA concentrations are required for the development of reactive amyloidosis. Humans with familial Mediterranean fever, a disease similar to that reported in Shar-Peis, have defective formation of pyrin, a protein involved in the down-regulation of mediators of inflammation.[44] Because only a small percentage of animals with chronic inflammation develop amyloidosis, other factors must be involved in the pathogenesis.[40] There are multiple polymorphs of SAA, and certain polymorphs perhaps are more amyloidogenic. There may be inherited and acquired variations in the ability to degrade SAA, a two-step process that involves cell surface–associated proteases contained in monocytes. A defect in the second step of this process may predispose some individuals to the development of amyloidosis. It has been demonstrated that the AA-degrading property of normal serum is decreased in humans with reactive amyloidosis. This activity correlated with serum albumin concentrations; hypoalbuminemia associated with the inflammatory process or amyloidosis may contribute to decreased AA-degrading activity. Increased concentrations of other acute-phase reactants that are protease inhibitors (e.g., antitrypsin and antichymotrypsin) also may contribute to the pathogenesis of amyloidosis.

SAA concentrations are increased during the predeposition phase, before the appearance of tissue amyloid deposits, but may persist during the deposition phase. Abyssinians with renal amyloidosis have increased SAA concentrations.[40] Chinese Shar-Peis with renal amyloidosis have increased serum concentrations of IL-6, a cytokine that stimulates SAA synthesis and release.[45] The deposition phase, during which amyloid deposits appear in the tissue, is subdivided into two phases. The rapid phase is characterized by rapid increases in the amount of amyloid, whereas the plateau phase is a time when little net change occurs in tissue deposition.

Histopathologic Characterization

The beta-pleated conformation is responsible for the characteristic staining properties of the amyloid deposits.[10] When the kidney is evaluated by conventional light microscopy, amyloid deposits in the glomeruli appear as acellular material that expands the mesangium and GBMs and stains homogeneously eosinophilic with hematoxylin-eosin (Figure 325-10 and E-Figure 325-11). Glomerular deposits are most often diffuse and global but occasionally are focal and segmental. Deposits sometimes can be found in the walls of small blood vessels, tubular basement membranes, and interstitial tissues. When stained with Congo red and evaluated by conventional light microscopy, amyloid deposits take on various shades of red, depending on the amount of amyloid and the thickness of the section. Deposits stained with Congo red and evaluated by polarizing microscopy are birefringent and have an apple green color (Figure 325-12). Reactive amyloidosis can be confirmed by decolorization of the Congo red–stained amyloid deposits by potassium permanganate oxidation. TEM is not needed to confirm a diagnosis of amyloidosis.

E-FIGURE 325-11 Trichrome stained glomerulus from a dog with membranoproliferative glomerulonephritis. Note the large magenta deposits within the capillary wall (arrows), with fine deposits also present in the mesangial areas (arrowhead). Podocyte hypertrophy (*) is also present. Erythrocytes are present in the capillary lumen. Mesangial matrix and basement membrane stained blue with this stain. *RBC*, Red blood cell.

Specific Treatment

The beta-pleated sheet configuration of amyloid fibrils leads to their insolubility and resistance to proteolysis, making specific treatment relatively ineffectual. In humans with familial Mediterranean fever, colchicine prevented the development of renal amyloidosis even in patients who continued to have recurrent febrile episodes.[44,46] This led to the recommendation that colchicine be used in the management of Shar-Peis with renal amyloidosis. Ideally this drug is administered during the predeposition phase, which in Shar-Peis is presumably characterized by recurrent fevers and swollen hocks. However, colchicine administration may lead to remission of proteinuria even after the appearance of amyloid deposits. No evidence supports the effectiveness of colchicine once amyloidosis has resulted in persistent azotemia or hypoalbuminemia. Although the effects of the drug in the treatment of amyloidosis are not fully known, colchicine does impair the release of SAA from hepatocytes by binding to microtubules and preventing secretion. In addition, colchicine may prevent the production of amyloid-enhancing factor. The dosage of colchicine used is 0.01 to 0.03 mg/kg given orally every 24 hours. Gastrointestinal upset is the primary side effect. Colchicine use has been recommended on occasion for people with renal amyloidosis from causes other than familial Mediterranean fever and warrants further evaluation in dogs.

Dimethylsulfoxide (DMSO) has been shown to be beneficial in a limited number of dogs with renal amyloidosis, although the exact benefit remains controversial.[46] If given during the rapid deposition phase, DMSO leads to a decrease in SAA concentrations and resolution of tissue deposits. However, the amount of amyloid deposited in the kidneys of humans was unchanged after DMSO administration, which lends support to the current belief that DMSO does not solubilize amyloid fibrils. The anti-inflammatory effects of DMSO may account for some of the beneficial effects. Reduction of interstitial fibrosis and inflammation may lead to improved renal function and reduced proteinuria. DMSO has an unpleasant smell that may cause poor owner compliance. Furthermore this drug may contribute to signs of nausea and anorexia seen in some dogs. The recommended dosage is 90 mg/kg given orally or subcutaneously three times weekly. DMSO should be diluted 1 : 4 with sterile water before injection to limit the pain associated with injection.

Prognosis

The prognosis for dogs and cats with renal amyloidosis is generally poor. In one study of dogs with amyloidosis, 58% died or were euthanized at the time of diagnosis. In the remaining dogs, survival ranged from 2 to 20 months; survival of a year or longer was reported in only 8.5%.[40] The longest survival was observed in a dog treated with DMSO.

Hereditary Nephritis

The term *hereditary nephritis* (HN) refers to a diverse group of inherited glomerular diseases that are the result of a defect in basement membrane collagen (type IV).[47] These diseases are discussed in ch. 328. A brief discussion of hereditary nephritis is included in this chapter because it should be considered as a differential diagnosis for any dog presenting with proteinuric renal disease, particularly if the dog is young.

Clinical Features

Hereditary nephritis has been reported in several breeds of dogs. An autosomal recessive form of the disease occurs in English Cocker Spaniels and English Springer Spaniels, whereas Bull Terriers and Dalmatians develop an autosomal dominant form.[47-51] An X-linked dominant form of HN has been described in Samoyeds and mixed-breed dogs; carrier females may have mild disease.[48] The report in Samoyeds is of a single kindred; the disease is not considered to be common in this breed. HN is characterized by proteinuria, renal hematuria, and progressive glomerular disease. Concurrent hearing and ocular abnormalities, as described in humans with HN, appear to be uncommon in affected dogs, with the exception of anterior lenticonus, which occurs in some Bull Terriers.[49]

Pathogenesis

HN is the result of a genetic mutation or deletion in type IV collagen, the primary protein constituent of the GBM.[52,53] The presence of defective collagen leads to premature deterioration of the GBM and progressive glomerular disease.

Histopathologic Characterization

Before electron micrographic studies of English Cocker Spaniels, the renal lesions were described as renal cortical hypoplasia or membranoproliferative or sclerosing GN. TEM is required to make the diagnosis of HN. Multilaminar splitting and fragmentation of the GBM are seen, often with intramembranous, electron-dense deposits.

Specific Treatment

No specific treatment is available for affected dogs. Use of a diet formulated for kidney disease and administration of angiotensin-converting enzyme (ACE) inhibitors have proved beneficial in affected dogs. Early detection of HN through screening of dogs of relevant breeds for microalbuminuria allows early therapeutic intervention, which may slow disease progression.[24]

Prognosis

The rate of progression is predictable in Samoyeds and English Cocker Spaniels, with terminal kidney disease generally developing before 2 years of age.[47] However, disease progression is more variable in Bull Terriers and Dalmatians, with some dogs surviving for as long as 10 years.[49,50]

Minimal Change Disease

Although uncommonly described in dogs and cats, minimal change disease (MCD) is a common cause of NS in humans, especially children.[11,54] Because TEM is required for diagnosis, the disease most likely is underdiagnosed in dogs and perhaps in cats. In humans this disease is sometimes referred to as nil disease, lipoid nephrosis, or idiopathic NS. There have been isolated reports of dogs that appear to have MCD. However, there is only one well-described case report of MCD in a dog presenting with NS.[54]

Clinical Features

Proteinuria is likely to be of heavy magnitude with this disease, and NS is common.

Pathogenesis

In humans, MCD is usually idiopathic, although secondary disease also occurs. Increased production of lymphokines by dysfunctional T cells is believed to be responsible for an increase in GBM permeability.[11] The primary change is loss of anionic charge in the glomerular capillary wall, leading to collapse of the podocyte foot processes. This loss of charge selectivity is the crucial event leading to proteinuria. The resultant proteinuria is highly selective; albumin is the primary protein lost.

Histopathologic Characterization

There is a lack of light microscopic lesions in the glomerulus, hence the name MCD.[10] Occasionally, slight hypercellularity is present. Some lipid droplets may be present in the renal tubules, but there should not be any evidence of tubular atrophy or interstitial fibrosis. Immunoglobulin deposition is absent when evaluated by IFM; however, there may be increased staining of vimentin, a marker for visceral glomerular epithelial cells. The diagnosis is confirmed with TEM by identification of marked foot process effacement (Figure 325-13). In a study of glomerular lesions in dogs, 28 of 115 dogs fell into the World Health Organization classification of minor glomerular abnormalities, but only one of these dogs had MCD.[19] Therefore, identification of only minor glomerular abnormalities in a dog or cat with proteinuria does not make a diagnosis of MCD.

FIGURE 325-13 Electron micrograph of a glomerular capillary loop in a dog with presumed minimal change disease. Effacement of the foot processes has occurred.

Specific Treatment

An important reason to include MCD on the list of differential diagnoses for dogs with NS is the disease's seemingly exquisite response to corticosteroids; the expected response rate in humans with MCD is 80% to 90%.[11]

Prognosis

The prognosis for MCD in dogs is unknown. One or more relapses are seen in 75% to 85% of affected humans.[11]

Glomerulosclerosis

Glomerulosclerosis accounted for approximately 20% of the glomerular lesions of dogs in a large study.[4] Whereas glomerulosclerosis often develops as an end-stage lesion in response to glomerular injury, focal segmental glomerulosclerosis (FSGS) is a primary glomerular disease.[10] The prevalence of glomerulosclerosis increases with age, although the percentage of glomeruli expected to be sclerotic in dogs of advancing age groups has not been fully characterized. Glomerulosclerosis is a common finding in diabetic nephropathy of humans. Although glomerulosclerosis and proteinuria can develop in dogs with diabetes mellitus, the clinical relevance of this is unknown. Glomerulosclerosis can also develop after hypertensive renal damage.

FSGS was identified in 29% of the thoroughly evaluated biopsies in a recent study, making it one of the more common glomerular diseases (Figure 325-14).[10,19,23] FSGS is diagnosed in the proteinuric patient that has segmental glomerulosclerosis in a glomerulus that is otherwise normal, without other glomerular lesions present to explain the sclerosis. IFM evaluation should be negative in affected patients; however, nonspecific trapping of immunoglobulins and C3 can occur in sclerotic areas.

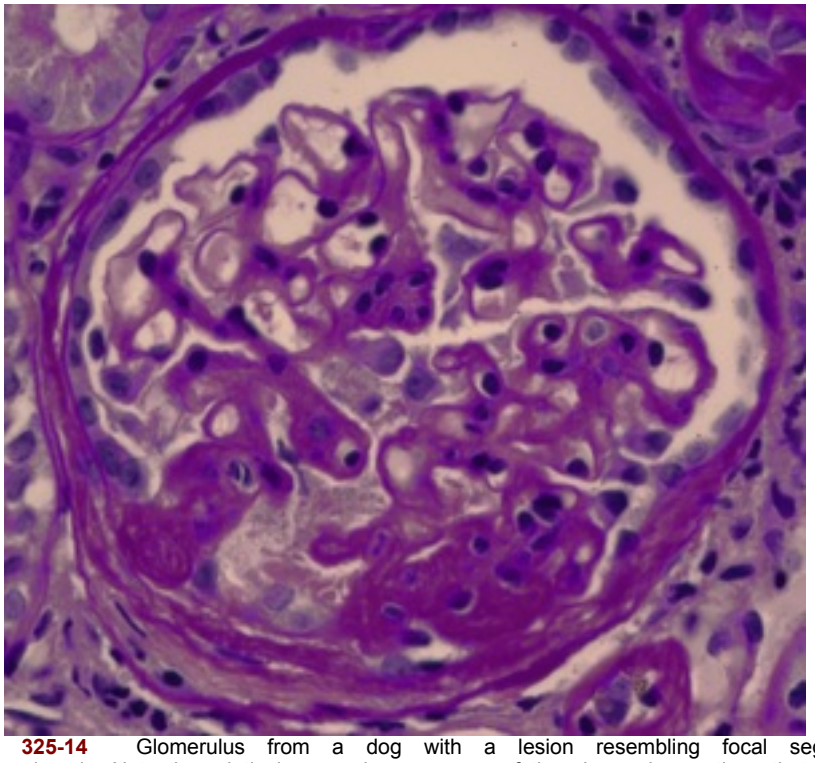

FIGURE 325-14 Glomerulus from a dog with a lesion resembling focal segmental glomerulosclerosis. Note the relatively normal appearance of the glomerular sections that are not sclerotic.

Tubulointerstitial Lesions Associated with Glomerular Disease

Proteinuria induces tubular damage, leading to progressive nephron loss.[55] Chronic proteinuria can lead to interstitial fibrosis, tubular degeneration and atrophy and peritubular capillary rarefaction. Heavy proteinuria is associated with a negative patient outcome in humans with various glomerular diseases; the urine of proteinuric humans shows mediators of renal inflammation and fibrosis, some of which are produced by renal tubules exposed to various proteins.[55] However, albumin is probably not the culprit because rats and humans with highly selective proteinuria appear to be at lower risk of eventual tubulointerstitial damage.

Protein in the tubules is resorbed by the proximal tubules; the reabsorbed proteins are cytotoxic to tubular epithelial cells.[56,57] Not only are proteins cytotoxic but they increase the workload of the tubular epithelial cells. Initially, this leads to compensatory hypertrophy of the tubular epithelial cells but eventually the cell cannot keep up with the increased workload and will die. Some damage also occurs secondary to obstruction of the tubules by protein casts.[58] Glomerular injury also results in decreased perfusion of the tubulointerstitium and additional injury. A direct link has not been established between proteinuria and

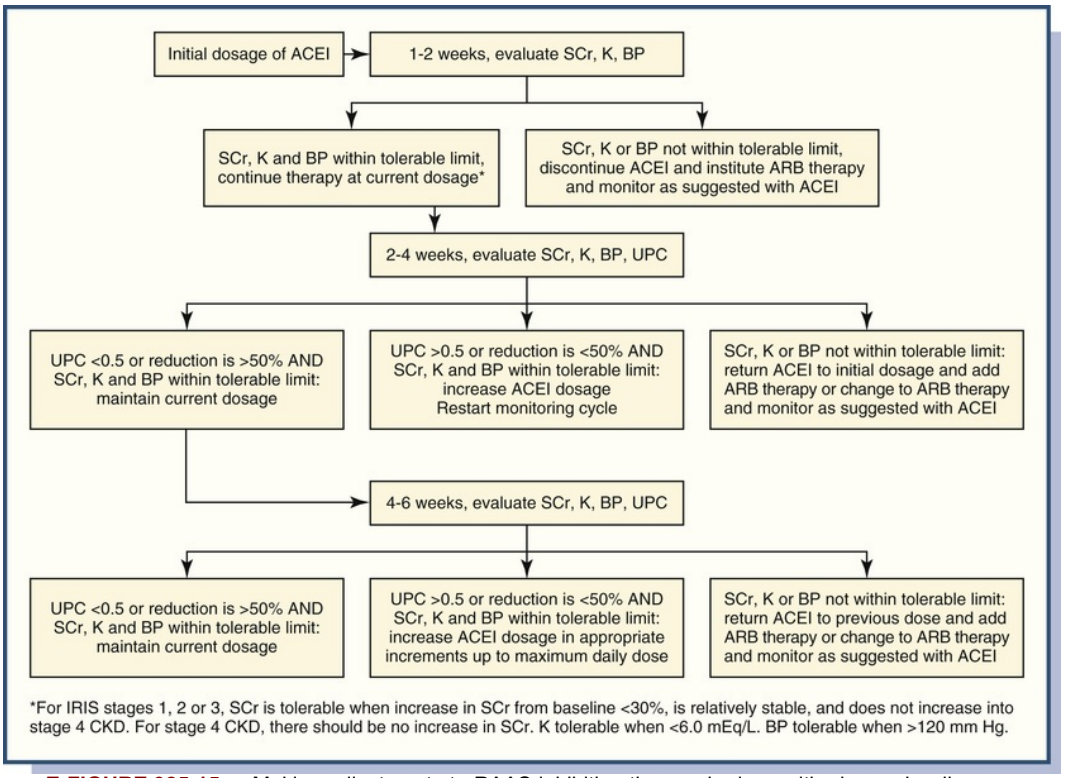
progressive renal damage in dogs, but it certainly exists to some extent. Because proteinuria may be a major factor responsible for progressive renal disease in patients with glomerular disease, aggressive management of proteinuria should be considered a cornerstone of the treatment of dogs and cats with glomerular disease.

Standard Therapy of Glomerular Disease

In addition to specific management that might be implemented with the various glomerular diseases, some therapeutic interventions are standard considerations for all dogs with glomerular disease.[6] This therapy can be divided into three major categories: (1) treatment of potential underlying diseases processes, (2) reduction of proteinuria, and (3) management of uremia and other complications of generalized kidney disease (discussed in ch. 324).

ICGN or amyloidosis develop after a strong, potentially malorganized, immune or inflammatory reaction, respectively, that has developed in response to a stimulus—often infectious, inflammatory or neoplastic. Accordingly, an underlying disease might have initiated the glomerular disease in up to 63% of affected dogs; a thorough evaluation for underlying diseases is warranted. Sometimes, the inciting agent is not obvious at first presentation because the offending disease is no longer present or is occult. Continued observation and scrutiny are necessary, because the causative disease process may become obvious in the ensuing months after presentation. The initial step in the management of a persistently proteinuric dog or cat is to treat and eliminate, if possible, any potential predisposing diseases. Animals that are seropositive for infectious diseases should be given specific anti-infective treatment immediately, even when there is not direct evidence that the infection is causing the proteinuria, and consideration should be given for immunosuppressive treatment using the same guidelines presented in the following discussion.[9] The dog should be subsequently evaluated for resolution of the proteinuria, which may occur slowly over a period of months. If proteinuria does not resolve or worsens, a renal biopsy to determine the histologic diagnosis may be warranted.

Antiproteinuric agents should be considered when the UPC is persistently above 0.5 in a dog; ACE inhibitors (e.g., enalapril, benazepril) are the drugs of choice for most affected dogs. Enalapril significantly reduced proteinuria and delayed either the onset or the progression of azotemia in dogs with GN.[59] Treatment of dogs with glomerular diseases with ACE inhibitors is now considered a standard of care.[59] ACE inhibitors may reduce proteinuria and preserve renal function by several possible mechanisms. The decreased efferent glomerular arteriolar resistance brought about by ACE inhibitors leads to decreased glomerular transcapillary hydraulic pressure and decreased proteinuria. Other proposed mechanisms include reduced loss of glomerular heparan sulfate, decreased size of the glomerular capillary endothelial pores, improved lipoprotein metabolism, slowed glomerular mesangial growth and proliferation, and inhibition of bradykinin degradation.[59] Typically enalapril or benazepril (0.5 mg/kg given orally) is administered once a day, although approximately half of the dogs may eventually need twice daily administration. The initial dosage can be gradually increased to achieve the therapeutic target of UPC <0.5 (ideal target) or >50% reduction from baseline (alternate target) (E-Figure 325-15). Serum creatinine concentration should be monitored; it is uncommon for dogs to have dose-limiting worsening of azotemia (i.e., >30% increase in serum creatinine or progression to IRIS CKD stage 4 CKD) because of ACE inhibitor administration alone. Hyperkalemia is a common side effect in dogs with glomerular disease that are treated with an ACE inhibitor and can be controlled by feeding a potassium-reduced home-prepared diet that has been formulated by a veterinary nutritionist.[60] If severe hyperkalemia develops or proteinuria is not adequately controlled with an ACE inhibitor, an angiotensin receptor blocker (ARB; telmisartan, losartan) can be substituted or added. Combination therapy with an ACE inhibitor and an ARB may lead to a greater reduction in proteinuria than monotherapy with either an ACE inhibitor or an ARB but should be used with caution and careful patient monitoring until results of controlled studies become available.[61]



E-FIGURE 325-15 Making adjustments to RAAS inhibition therapy in dogs with glomerular disease. *ACEI,* Angiotensin-converting enzyme inhibitor; *ARB,* angiotensin-receptor blocker; *BP,* blood pressure; *K,* serum or plasma potassium; *SCr,* serum creatinine; *UPC,* urine protein : creatinine ratio.

Adequate blood pressure control of hypertensive dogs (see ch. 158) may also lead to a reduction in proteinuria and slow the progression of disease (see ch. 157). Because ACE inhibitors are relatively weak antihypertensive agents, additional antihypertensive agents (e.g., amlodipine) may be needed if hypertension (i.e., systolic blood pressure greater than 160 mm Hg) persists after the initiation of ACE inhibitor therapy.

Platelets and thromboxane may play an important role in the pathogenesis of GN and thromboxane synthetase inhibitors have been shown to decrease proteinuria in dogs with experimentally induced GN.[62] Aspirin is a nonspecific cyclooxygenase inhibitor that may be used to reduce glomerular inflammation and inhibit platelet aggregation, which may have an added benefit of preventing thromboembolism. In theory, low doses of aspirin (1-5 mg/kg PO daily) may be used but the optimum aspirin protocol for platelet inhibition in dogs is unknown. Clopidogrel (Plavix, 1.1 mg/kg PO q 24 h) also may effectively reduce platelet activity in dogs, although there is no evidence that it is superior to aspirin.[63]

The IRIS consensus recommendation is to feed modified protein diets to dogs with glomerular disease (see ch. 184). Dietary protein reduction reduces proteinuria and slows progression of CKD.[64,65] Diets should not be supplemented with protein, because this may aggravate urinary protein losses. The enhanced omega-3 to -6 polyunsaturated fatty acid ratio and restriction in salt and phosphorus found in canine renal diets might also be of benefit to dogs with glomerulopathies. Omega-3 fatty acid supplementation has been shown to be renoprotective in dogs with kidney disease and mitigate hypertension and reduce serum triglyceride and cholesterol concentrations in humans with NS.[66] These positive effects are in part mediated through generation of the three-series prostaglandins. Sodium restriction is beneficial in the control of hypertension and fluid retention.

Immunosuppressive Treatment of Dogs With Glomerular Disease

The use of immunosuppressive drugs (see ch. 165) in the treatment of dogs with glomerular disease has not been fully studied and should still be considered experimental. However, consensus recommendations are to treat dogs that have severe, persistent, or progressive glomerular disease with evidence of an active immune pathogenesis based on biopsy findings.[7] Finding electron-dense deposits in subendothelial, subepithelial, intramembranous, or mesangial locations of the glomerulus by EM or demonstrating positive and unequivocal immunofluorescent staining for immunoglobulins and/or complement in an immune-complex

and antiglomerular basement membrane pattern of deposition in peripheral capillary loops or the mesangial compartment with IFM provides compelling evidence to initiate a trial of immunosuppressive therapy.[7] Probable evidence of an immunopathogenesis can be documented by LM with one of the following: red granular staining of capillary walls with Masson's Trichrome, spikes along the GBM or holes within the GBM with Jones Methenamine sliver stain. These findings would be expected in just under 50% of dogs with glomerular disease.[23] When renal biopsy results are not available it becomes more difficult to make a decision about using immunosuppressive treatment because approximately 50% of dogs with glomerular disease would be expected **not** to have an immunopathogenesis of their disease. Consensus recommendations are to consider immunosuppressive drugs in the treatment of dogs with glomerular disease when the source of proteinuria is clearly glomerular in origin, the drugs are not otherwise contraindicated, the dog breed and age of disease onset are not suggestive of a familial nephropathy, amyloidosis has been deemed unlikely and the serum creatinine is >3.0 mg/dL or progressively increasing, or the serum albumin is <2.0 g/dL.[8]

Dogs with more severe disease or rates of progression should be treated more aggressively than those with more stable disease. According to the IRIS consensus statement,[7] single agent or combination therapy for rapid onset of immunosuppression should be considered in dogs with high magnitude proteinuria with hypoalbuminemia, NS, or rapidly progressive azotemia. Mycophenolate, or cyclophosphamide, with or without short-term administration of glucocorticoids, was suggested as the first choice. Glucocorticoids should be limited to short-term therapy because proteinuria has been demonstrated in dogs with corticosteroid excess and may induce glomerular lesions and prednisolone administration was shown to reversibly increase proteinuria in dogs with hereditary nephritis.[17,67,68] Dogs with stable or more slowly progressive disease that have only partial or no response to standard therapy might be given drugs that have either a rapid or a more delayed onset of action, such as mycophenolate, chlorambucil or cyclophosphamide. Cyclosporine was also suggested as a first choice for stable or slowly progressive dogs; however, this is the only drug that has been studied prospectively in dogs with glomerular disease and was found to be of no benefit, although there were flaws in that study.[69] All dogs treated with immunosuppressive therapy for their glomerular disease should be monitored closely. Treatment should be discontinued or adjusted if adverse drug effects develop. In the absence of adverse effects, 8-12 weeks of therapy should be provided before changing the course of treatment. If the therapeutic response is suboptimal at the end of 8-12 weeks, an alternate drug protocol should be considered. However, if after 3-4 months a therapeutic response has not been achieved, consideration should be given to discontinuing immunosuppressive drug administration. If after this time, a response has been noted, the drug dose or schedule should be tapered to one that maintains the response without worsening of proteinuria, azotemia or clinical signs.[7]

Patient Monitoring

Dogs with stable glomerular disease and IRIS CKD stage 1 or 2 should be evaluated 3-14 days following changes in therapy, whereas those with unstable disease or IRIS CKD stage 3 or 4 should be evaluated 3-5 days after any change in therapy. If therapeutic changes are not being made and the dogs are seemingly stable, standard re-evaluations should be made every 3 months. The UPC, urinalysis, body weight, body condition score, systemic arterial blood pressure and serum albumin, creatinine and potassium concentrations should be included in these evaluations. Because histologic lesions do not necessarily resolve even though renal function may improve, repeat biopsies generally are not needed.

Response to therapy has historically been focused on a reduction in proteinuria. However, it is logical also to evaluate changes in serum creatinine and albumin concentrations. A complete response to therapy is defined as a reduction in UPC to <0.5, a reduction in serum creatinine to <1.4 mg/dL, or a sustained increase in serum albumin to >2.5 g/dL; whereas a partial response is defined as a >50% reduction in UPC, >25% sustained reduction in serum creatinine or >50% sustained reduction in serum albumin when compared with baseline values or an increase in serum albumin to >2.0-2.5 g/dL.[7] Day-to-day variations in the UPC occur in most dogs with glomerular proteinuria, with greater variation occurring in dogs with UPC >4.[70] Changing proteinuria is most accurately measured by assessing trends in the UPC over time. Because there is greater variation in dogs with UPC >4, consideration should be given to either averaging two to three serial UPC or measuring a UPC in urine that has been pooled from two to three collections.

Complications of Glomerular Disease

Complications of severe proteinuria include edema formation, systemic hypertension, hypercoagulability and

thromboembolism, hyperlipidemia, increased risk for infection, altered pharmacokinetics (see ch. 160), malnutrition, muscle wasting (see ch. 177), and endocrine abnormalities.[58] Edema formation, systemic hypertension, and hypercoagulability are the complications most frequently recognized in dogs, and less commonly in cats, with glomerular disease.

Edema Formation

Several factors contribute to the formation of edema in patients with NS (see ch. 18).[58] In severe forms of NS, decreases in the plasma oncotic pressure allow for transudation of fluid into the interstitial spaces. The resultant decrease in effective plasma volume leads to increased renin-angiotensin-aldosterone activity and retention of water and sodium and worsening of edema. However, most humans with NS do not have reduced blood volumes or increased plasma renin or aldosterone activities. Thus primary sodium retention must also be involved in the pathogenesis of edema in these patients. Proposed mechanisms in primary renal sodium retention include a reduced single nephron glomerular filtration rate with enhanced proximal tubular resorption and cytokine-induced modification of distal resorption, leading to resistance to natriuretic factors, including atrial natriuretic peptide. In humans, it is believed that mechanisms of primary renal sodium retention are the most important determinants of edema formation until the serum albumin concentration decreases below 2 g/dL. Below this concentration, the plasma oncotic pressure is sufficiently reduced to allow for transudation of fluid from the vascular compartment into the interstitial space.[58] Dogs may be more resistant to the formation of edema, which does not generally occur until the serum albumin concentration is below 1.5 g/dL. Plasma volume may be reduced at this point, making the use of diuretics in the management of edema relatively ineffective and also dangerous because of the increased risk of acute kidney injury and thromboembolism.[58] Dogs with glomerular disease should have careful assessment of their hydration status and vascular volume prior to and during fluid therapy. This evaluation should be based on serial body weight measurements, skin turgor, mucous membrane color and moisture, capillary refill time, temperature of the extremities, heart rate, pulse quality and systemic blood pressure. The use of diuretics should be limited to situations where ascites or pleural effusion is critically impairing organ function.[6] When indicated, furosemide may be the drug of choice for dogs with pulmonary edema or hyperkalemia and spironolactone for dogs with pleural or abdominal effusion.[6] Provision of adequate exercise also may help reduce the formation of edema or ascites.

Hypertension

Systemic hypertension has been reported in up to 80% of dogs with glomerular disease (see ch. 157). The frequency of hypertension in each form of glomerular disease has not been established fully in dogs but does vary in humans. Preliminary findings suggest a higher frequency of hypertension might be found in dogs with MPGN.[23] The primary mechanism of hypertension in association with NS is believed to be expansion of the plasma volume in association with primary renal sodium retention. However, generation of several vasoactive factors (e.g., renin, angiotensin II, endothelin) is increased in human patients with NS and may contribute to hypertension. Nitric oxide deficiency may also play an important role in the development of hypertension.[58] The blood pressure should be measured in all dogs and cats with glomerular disease, because uncontrolled hypertension is a risk factor for progressive renal injury (see ch. 157 for complete discussion of hypertension).

Thromboembolism

Thromboembolism (see ch. 256), perhaps the most serious complication of glomerular disease, was reported in 5% of dogs with GN, 14% of dogs with amyloidosis, and 13% of dogs with all forms of glomerular disease.[16,17,22] Because emboli may be difficult to detect, the prevalence of thromboembolism in dogs with glomerular disease may be higher than indicated by these studies. The risk of thromboembolism is highest in dogs with nephrotic-range proteinuria and hypoalbuminemia. Pulmonary thromboembolism is most common, but emboli may also lodge in other arteries (e.g., mesenteric, renal, iliac, brachial, coronary) or the portal vein (see ch. 243 for complete discussion of pulmonary thromboembolism).

Although urinary loss of antithrombin (AT) has gained the most attention in veterinary medicine, the pathogenesis of the hypercoagulable state is multifactorial.[58] AT is a serine protease inhibitor that modulates fibrin generation; heparin catalyzes these reactions. AT (65,000 Daltons) is similar in charge and size to

albumin (69,000 Daltons); serum AT activity closely correlates with the serum albumin concentration. Prior studies have suggested that this close correlation can be used to predict thromboembolism when the serum albumin concentration is <2 g/dL, when serum AT III activity would be expected to be less than 75% of normal.[16] A recent study of thromboelastography in dogs with glomerular disease failed to support this conclusion, demonstrating that hypercoagulability may develop before alterations in serum albumin or AT activity occur.[71] This is because the pathogenesis of hypercoagulability is complex; other factors are involved. Albumin binds to arachidonic acid, which, if unbound, would stimulate platelet aggregation through the generation of prostaglandins (i.e., thromboxane B_2); hypoalbuminemia is associated with increased platelet aggregation.[58] Hypercholesterolemia contributes to platelet hypersensitivity by influencing membrane-associated enzyme and receptor activity through alteration of the membrane composition. The role of platelet hypersensitivity in the development of hypercoagulability may be enhanced by thrombocytosis, which occurs in many animals with glomerular disease. Increased fibrinogen concentrations (i.e., above 300 mg/dL), which are often present in patients with NS, lead to increased fibrin complex formation and platelet hyperaggregation. The risk of thromboembolism may be further enhanced by increased concentrations of $alpha_2$ macroglobulin; $alpha_2$ antiplasmin; procoagulant cytokines; coagulation factors V, VII, VIII, and X; increased plasma viscosity and interstitial pressure; decreased plasma plasminogen concentrations; decreased plasma volume and blood flow; endothelial injury; and infections.[58]

Warfarin, aspirin and clopidogrel have been used in the prevention of thromboembolism in at-risk dogs. Warfarin is highly protein-bound. It is very difficult to titrate the dose adequately to prolong the prothrombin time appropriately (i.e., 150% of baseline) in dogs with hypoalbuminemia, and its use is not recommended. Alternatively, low-dose aspirin is inexpensive, easy to administer, and has the added benefit of potentially reducing proteinuria. Both aspirin and clopidogrel inhibit platelet function and there is not a clear therapeutic benefit of one agent over the other. In theory, heparin would be ineffective in dogs with reduced AT activity.

Hyperlipidemia

Hypercholesterolemia was reported in 79% of dogs with GN and 86% of dogs with amyloidosis (see ch. 182).[17,22] Cholesterol concentrations as high as 749 mg/dL have been reported, although the mean concentration was 325 mg/dL in 69 dogs with GN and 350 mg/dL in 23 dogs with amyloidosis.[16,17] Increases in total plasma cholesterol, very-low-density lipoprotein (VLDL), and low-density lipoprotein (LDL) occur.[72] Hyperlipidemia is variably seen in humans with NS and has not been fully studied in dogs. The pathogenesis of hyperlipidemia in association with NS is complex.[72] Hypoalbuminemia stimulates hepatic protein synthesis, including the synthesis of lipoproteins, leading to hypercholesterolemia.[58] The serum albumin concentration and plasma oncotic pressure inversely correlate with the magnitude of hypercholesterolemia. It is unclear whether hypoalbuminemia or the decreased plasma oncotic pressure, or both, induce the increased synthesis. Alterations in lipid catabolism also contribute to the development of hyperlipidemia. Orosomucoid, which plays an important role in the maintenance of glomerular permselectivity, is lost in the urine of patients with glomerular disease. Urinary losses of orosomucoid exacerbate proteinuria but also contribute to hyperlipidemia by indirectly causing decreased hepatic production of heparin sulfate, a cofactor needed in normal lipoprotein lipase function.[72]

Some evidence supports the theory that uncontrolled hyperlipidemia contributes to glomerular and tubulointerstitial injury. LDL and oxidized LDL may alter mesangial cell function and increase the synthesis of mesangial matrix, thereby accelerating the formation of glomerulosclerosis.[58] Glomerular and tubulointerstitial lipoprotein deposition and lipoprotein-induced cytotoxicity also contribute to renal injury. Interestingly glomerular lesions have been identified in cats with lipoprotein lipase deficiency and Miniature Schnauzers with hyperlipidemia.[7]

Prognosis

The prognosis for dogs and cats with glomerular disease is variable and most likely based on a combination of factors including the histologic diagnosis. Although progressive disease can be expected to occur in a large percentage of animals with glomerular disease, spontaneous remission and response to specific therapy can also be expected. Furthermore, disease progression can be slow enough for the animals to lead relatively normal lives, especially when the diagnosis is established early in the disease process. In humans, azotemia, severe proteinuria, systemic hypertension, and marked tubulointerstitial lesions at presentation are the most

significant predictors of an unfavorable outcome in most forms of glomerular disease. Clinical impressions suggest that these same variables affect the prognosis in dogs and cats.

The median survival of 53 dogs with GN and amyloidosis that were not dead or euthanized shortly after presentation was only 28 days, although individual dogs survived for more than 3 years.[16] Dogs with glomerular disease and NS had a shorter median survival than those without NS (12.5 vs. 104.5 days, respectively).[20] Survival of non-azotemic dogs (serum creatinine <1.5 mg/dL) with or without NS (51 vs. 605 days, respectively) was longer.[20] More study is needed to characterize the natural history and prognosis of the various glomerular diseases in dogs and cats.

CHAPTER 326

Renal Tubular Diseases

Marie E. Kerl

Renal tubules control body fluid balance, drug excretion, acid-base balance, and electrolyte regulation. While glomerular filtration rate (GFR) is the main determinant of renal function, the tubules determine the final composition of the urine. Glomerular ultrafiltrate contains all plasma solutes that are smaller than 69,000 Daltons; therefore all filtered glucose, amino acids, and electrolytes are delivered to the tubules via the ultrafiltrate. The bulk of filtered substances is reabsorbed. Tubular defects causing lack of function are uncommon to rare. They can occur regionally or globally in the tubules and are either congenital or acquired. Indicators from biochemical profiles, blood gas analysis, and urinalysis can be monitored to assess tubular function.

Renal tubules are described according to function and anatomic location. The proximal tubule receives ultrafiltrate from Bowman's space and reabsorbs 60% to 65% of the ultrafiltrate, a proportion that is maintained across a wide range of GFR. This property is responsible for preventing the more distal nephron segments from being overwhelmed by excessive solute delivery. Tubular absorption is accomplished by active transport of sodium (Na^+), which in turn promotes passive resorption of other solutes. The proximal tubule also actively secretes some solutes (e.g., organic anions, cations, and hydrogen ions [H+]).[1] Solutes are not reabsorbed uniformly; virtually all filtered glucose and amino acids are reabsorbed, whereas lesser amounts of bicarbonate (HCO_3^-), Na^+, and chloride are reabsorbed. The main function of the loop of Henle is to reabsorb approximately 30% of filtered sodium chloride (NaCl) against a concentration gradient to generate a concentrated medullary interstitium and create an ultrafiltrate that is hypoosmolar to plasma.[2] The distal tubule and the collecting tubule and duct are responsible for fine control of electrolytes, including Na^+, potassium, and calcium; final regulation of acid-base balance; and water resorption to produce concentrated urine.[3] Clinical manifestations of renal tubular disorders include formation of urinary calculi, metabolic acidosis, glucosuria, aminoaciduria, electrolyte disorders, and failure of urine concentration.

Cystinuria

Cystinuria is caused by inherited proximal tubular defects in which resorption of particular nonessential amino acids fails. Of these amino acids, cystine is relatively insoluble in urine, resulting in the formation of cystic calculi in acidic urine.[4-6] Many dog breeds have been reported with cystinuria, and rare reports have been made for cats.[7,8] The dog breeds reported with an increased risk of cystine urolith formation vary somewhat with geographic location, and include English Bulldog, Staffordshire Bull Terrier, Chihuahua, Newfoundland, Dachshund, Welsh Corgi, Rottweiler, Miniature Pinscher, and Jack Russell Terrier.[9-11] In one report, cystine stone diagnosis from Newfoundland dogs decreased to 38%, compared to 71% identified 10 years prior.[11] Cystine calculi identification is rare in cats.[12]

Inheritance patterns for cystinuria vary in people, and are classified as type 1 and non–type 1. Type 1 cystinuria is characterized by an autosomal recessive inheritance pattern, in which carriers have normal urine amino acid concentrations. Non–type 1 is characterized by an autosomal dominant inheritance pattern with incomplete penetrance. In non–type 1, the incidence of calculi formation is limited in carrier individuals with cystinuria. Defects in the *Slc3a1* and *Slc7a9* genes account for most of the genetic defects associated with cystinuria in people.[4,13] Similar to people, cystinuric dogs have different methods of inheritance. Newfoundland dogs and Labrador Retrievers have been identified with a severe form of type 1 cystinuria caused by a missense mutation that was identified in exon 2 of the *Slc3a1* gene.[4,13,14] More recently, Australian Cattle Dogs have been identified with an autosomal dominant form of cystinuria caused by a 6 base pair deletion removing 2 threonine molecules in the *Slc3a1* gene, and in Miniature Pinschers caused by a

missense mutation in *Slc7a9*.[15] Genetic testing has been available for the mutation in Newfoundland dogs for several years, perhaps accounting for the decreased identification of cystine calculi in this breed.[11,14] Genetic testing is also available for other affected breeds.[15]

The mean age of calculus formation is 4.9 years overall for cystine stones; however Newfoundland dogs and Labrador Retrievers typically are affected as early as 4 to 6 months of age.[4,11] The degree of cystinuria can vary among individuals, and may decrease with age.[5] Males are overrepresented for clinical cystine calculi, but cystinuria without calculi formation has been reported in females. Clinical signs associated with cystine calculi formation include stranguria, pollakiuria, and hematuria (also see ch. 331). Male dogs may develop secondary urethral obstruction. Evaluation of urine sediment reveals cystine crystalluria in some affected dogs, but a complete blood count and serum biochemical analysis do not aid diagnosis. Imaging studies may identify calculi, but the size, shape, and radiographic density of calculi vary. The radiographic opacity of cystine calculi is similar to that of struvite and silica calculi; therefore, larger cystine calculi can often be visualized on plain film radiographs. Ultrasonography and contrast cystourethrography may be diagnostic if plain film radiography is unrewarding.[16]

Treatment involves mechanical removal or medical dissolution of calculi and long-term medical management to prevent recurrence (see ch. 107 and 331). Surgical management is indicated in animals with urethral obstruction. Quantitative calculi analysis provides a definitive diagnosis. Bacterial urinary tract infection should be resolved with appropriate antibiotic therapy (see ch. 330). Dissolution and prevention strategies include exclusive feeding of protein-restricted diets. Cystine is twice as soluble at a pH of 7.8 as at 6.5; therefore, urinary alkalization is desired.[17] Some protein-restricted diets (e.g., Prescription Diet Canine u/d, Hill's Pet Nutrition, Topeka, KS) result in the formation of alkaline urine, but if dietary therapy does not maintain the urine pH at the desired level, oral potassium citrate is recommended.[16] Induction of diuresis (e.g., by feeding canned, low-protein food or adding water to dry food) is likely to be beneficial.[5,16]

Drug therapies to reduce the formation of cystine calculi include the thiol drugs D-penicillamine and 2-mercaptopropionylglycine (2-MPG) (tiopronin [Thiola, Mission Pharmaceuticals]). Cystine is formed by a disulfide bond between two cysteine molecules. Thiol drugs form a disulfide bond with cysteine to create a more soluble cystine-thiol drug complex. Although both drugs are effective, metal chelation and gastrointestinal side effects of D-penicillamine make it a less desirable choice.[6] 2-MPG (15-20 mg/kg PO q 12 h) is the treatment of choice, in combination with dietary modifications for dissolution and prevention of cystine calculi.[5,6,18]

Carnitinuria

Carnitine is a sulfur-containing nonessential amino acid that functions as an enzyme cofactor necessary to transport energy-generating fatty acids from the cytosol to the mitochondrial matrix. Continued deficiency, which has been reported in dogs with dilated cardiomyopathy (see ch. 252), may result from defective biosynthesis, defective tissue uptake or retention, or excessive renal excretion.[19,20] Carnitinuria has been reported in dogs with cystinuria.[19] Although high-fat, low-protein diets are recommended for the management of cystinuria, high-fat diets increase renal carnitine excretion in humans. Healthy dogs that consume low- and high-fat diets excrete similar amounts of carnitine; however, cystinuric dogs with altered amino acid resorption might excrete an excessive amount of carnitine if they consume a high-fat diet.[19] Chronic, excessive carnitine excretion eventually results in carnitine deficiency, leading to cardiomyopathy.

Hyperuricosuria

Hyperuricosuria is defined as an excessive quantity of uric acid, an intermediate product of protein metabolism, in the urine. The purine portions of nucleic acids undergo metabolism to form hypoxanthine and xanthine, which are oxidized to uric acid by xanthine oxidase (XO). In most mammals, uric acid is further metabolized to allantoin (a more soluble product) by hepatic uricase (see ch. 332). In healthy dogs, allantoin is the primary metabolic product that is renally excreted, while humans and higher apes excrete mostly uric acid.[21] Certain naturally occurring diseases, such as hyperadrenocorticism, cancer, and chronic kidney disease, can alter excretion patterns for these metabolites, resulting in greater excretion of xanthine or uric acid compared to allantoin.[22] Abnormal purine metabolism or excretion accounts for hyperuricosuria in dogs of certain breeds with a genetic predisposition to formation of urate calculi, or those with underlying hepatic disease. The dog breed that is most commonly affected with hyperuricosuria is the Dalmatian; however,

English Bulldogs and Black Russian Terriers have also been identified.[9,11] Dalmatians are intermediate between dogs of other breeds and humans with regard to purine metabolism, excreting approximately one half to two thirds as much allantoin as urate.[4] In humans, uric acid in circulation can precipitate into the joints to cause the clinical syndrome of gout; however Dalmatian dogs have serum uric acid levels more similar to non-Dalmatian dogs than people and do not develop gout.[23] Differences exist between Dalmatians and non-Dalmatian dogs in both hepatic and renal management of uric acid. The enzyme uricase, which converts uric acid to allantoin, is stored in hepatic peroxisomes. Uric acid must be transported into hepatocytes before conversion to allantoin can occur. Dalmatians have normal amounts of uricase compared with non-Dalmatian dogs, but Dalmatians have abnormal uric acid transport across the hepatic membrane, which limits uric acid metabolism.[24] Uric acid is secreted via glomerular filtration and reabsorbed in the proximal tubule; however Dalmatians appear to have less proximal tubular resorption than do non-Dalmatian dogs. In addition, Dalmatians have active distal tubular secretion of urates as a result of a membrane transport defect.[4,25] The defect, a missense mutation in the *Slc2a9* gene that encodes for a transporter of uric acid, is inherited as an autosomal recessive trait that all Dalmatians carry.[26] Clinical manifestations occur in 25% of male Dalmatians. This gene has also been identified as abnormal in English Bulldogs and Black Russian Terriers affected with hyperuricosuria.[27]

Dogs with primary hepatic disease have reduced conversion of uric acid to allantoin and of ammonia to urea. These metabolic defects cause hyperuricuria and hyperammonuria.[28] Portal vascular anomalies and hepatic microvascular dysplasia have been most commonly associated with urate calculi formation, although any severe hepatic dysfunction could predispose to calculi formation (see ch. 284).[29] Cats have been reported with urate urolithiasis. While some cats with urate stones have been diagnosed with portosystemic shunts, the cause is not apparent in other cats.[30,31]

Clinical signs of urate urolithiasis are consistent with lower urinary tract disease (see ch. 331). Male dogs can develop urethral obstruction (see ch. 107). Young to middle-aged dogs are more commonly affected than are older dogs.[9,11] For Dalmatians, males are more frequently diagnosed with urinary calculi than are females.[11] Dogs with primary hepatic disease have no gender predisposition for calculi formation; however, older male dogs are more clinically affected.[29] Cats that develop urate urinary calculi and are diagnosed with a hepatic vascular anomaly are generally younger (<2 years) compared to those not diagnosed with hepatic vascular anomaly (4-7 years), and are neutered.[30,31] Definitive diagnosis of cystic calculi depends on calculi retrieval and quantitative analysis. Urate calculi are radiopaque on plain film radiography, but can be visualized using abdominal ultrasonography or double-contrast cystography. Hepatic function studies (e.g., serum pre- and postprandial bile acids, blood ammonia evaluation) are appropriate for non-Dalmatian dogs and for cats. Urate calculi typically are small and smooth and vary in color from yellow to green to black.[32]

Treatment consists of calculi removal or dissolution, followed by long-term medical management to prevent recurrence. Dissolution therapy includes a calculolytic diet, medication with XO inhibitors, urine alkalization, elimination of secondary infections, and induction of isosthenuria.[32] A purine-restricted diet that is low in calculogenic minerals (e.g., Prescription Diet Canine u/d; Hill's Pet Nutrition, Topeka, KS) is recommended.[25,33,34] The synthetic XO inhibitor allopurinol is used for treating and preventing urate urolithiasis in Dalmatians because it can reduce serum and urinary uric acid concentrations by blocking metabolism of hypoxanthine and xanthine to uric acid. Allopurinol should be administered only to dogs consuming a purine-restricted diet, to avoid the formation of hypoxanthine and xanthine calculi, and the dosage should be adjusted based on reduction of uric acid concentration in the urine.[32,34,35]

Urine alkalization reduces renal tubular production of ammonia, thereby diminishing the production of urinary ammonium ions that complex with urate to form calculi. Alkalizing agents (e.g., oral sodium bicarbonate [$NaHCO_3$] or potassium citrate) should be administered at a dosage that maintains the urine pH near 7.0 to 7.5.[32,34,35] Dilute urine production is accomplished by feeding protein-restricted diets that reduce renal medullary concentrating ability.

Mechanical calculi removal should be considered in animals with urethral obstruction or in those that do not respond to dissolution therapy. The average time to dissolution of urate calculi is approximately 3.5 months (range, 1 to 18 months).[34] Dissolution sometimes occurs with definitive repair of a portovascular anomaly, but calculi do not resolve without resolution of underlying hepatic defects.[35] Because the causes of urate stones differ, allopurinol therapy is not recommended for dogs with hepatic defects, and should not be used in cats.[35]

The prognosis is fair to guarded for calculi recurrence in Dalmatians and long-term success depends on the owner's commitment to lifelong management. In dogs with underlying liver disease, the prognosis is good if definitive therapy for the liver disease exists but guarded to poor in dogs with irreparable liver disease.

Hyperxanthinuria

Xanthine calculi are rare. Xanthine is derived from dietary purines and is metabolized to uric acid by activity of XO (see ch. 332). Reduced enzymatic conversion increases urinary excretion of xanthine, which has solubility similar to that of uric acid in urine. Most dogs that form xanthine-containing calculi are receiving allopurinol, an XO inhibitor, for urate calculi; however, idiopathic xanthine calculi have been reported.[11,36] Xanthine uroliths are rare in cats, and have been reported in cats not receiving allopurinol.[36-38] Congenital xanthinuria has been reported in Cavalier King Charles Spaniels, and in one Wirehaired Dachshund.[39-41] Prevention consists of monitoring for xanthine crystalluria in dogs receiving allopurinol to prevent urate calculi, and tailoring allopurinol dosing to the patient.

Renal Glucosuria

Under normal conditions, glucose is freely filtered at the glomerulus and reabsorbed in the proximal tubules by facilitated diffusion in a cotransport mechanism with Na^+. The transport mechanism has a maximum capacity that is exceeded at a blood glucose concentration of 180 to 220 mg/dL (10-12.2 mmol/L) in dogs and 260 to 310 mg/dL (14.4-17.2 mmol/L) in cats.[42] When blood glucose concentration exceeds the renal transport maximum (e.g., hyperglycemia from stress or diabetes mellitus), glucosuria occurs. This is the most common explanation for glucosuria. Rarely, proximal tubular defects caused by tubular damage or inherited disorders can cause glucosuria in the absence of hyperglycemia.[42-45]

Primary renal glucosuria is rare but has been reported in Scottish Terriers, Basenjis, Norwegian Elkhounds, and mixed-breed dogs.[42,46,47] Persistent glucosuria typically causes polyuria and polydipsia from osmotic diuresis, although some dogs are asymptomatic. Evaluation of serial blood glucose measurements or the serum fructosamine concentration should be considered to diagnose renal glucosuria definitively by ruling out hyperglycemia as a cause for glucosuria.[48] There is no cure for primary renal glucosuria, but the long-term prognosis is good with appropriate fluid intake and control of concurrent urinary infections. In some dogs, renal glucosuria is the initial sign of Fanconi syndrome.

Fanconi Syndrome

In humans, Fanconi syndrome is an inherited proximal tubular defect that results in glucosuria, aminoaciduria, proteinuria, phosphaturia, and hypophosphatemia. Fanconi syndrome has also been reported in dogs, and Basenjis are most commonly affected.[44,45,49,50] Fanconi syndrome is inherited in 10% to 30% of all Basenjis. Genetic testing for this syndrome became available in 2011.[51] Idiopathic and inherited Fanconi syndrome has been reported rarely in other dog breeds.

Acquired Fanconi syndrome has been reported in association with a number of different causes including gentamicin administration, various toxicoses causing acute tubular necrosis, and primary hypoparathyroidism.[43,52-54] Recently, a number of cases of acquired Fanconi syndrome in dogs having consumed chicken jerky treats manufactured in China were identified.[55-59] The first documentation of acquired Fanconi syndrome in cats has been reported. Four cats being treated for alimentary lymphoma or inflammatory bowel disease were undergoing treatment with chlorambucil. Urine metabolic assays confirmed aminoaciduria and glucosuria, and glucosuria stopped in 3 of 4 cats when chlorambucil was discontinued.[60]

Fanconi syndrome causes abnormal fractional excretion of many solutes.[45] Abnormal glucose absorption, resulting in glucosuria and osmotic diuresis, is the most obvious finding. Amino acid resorptive abnormalities vary from one individual to another but generally include abnormal absorption of cystine. Abnormal absorption of bicarbonate, sodium, potassium, and urate also occur. Isosthenuria sometimes occurs prior to glucosuria and osmotic diuresis as a result of nephrogenic diabetes insipidus.[61]

The onset of clinical signs in affected Basenjis typically occurs by 4 to 8 years of age, and there is no gender predilection.[45] Clinical signs typically include polyuria, polydipsia, weight loss, poor hair coat, weakness, and dehydration. Diagnosis prior to the onset of clinical signs is possible if predisposed breeds are regularly

evaluated for glucosuria.[45] Diagnostic testing typically reveals glucosuria, euglycemia, and isosthenuria. As the disease progresses, hyperchloremic metabolic acidosis and renal failure occur. Clinically significant hypokalemia might contribute to muscle weakness. Progression is variable; some affected dogs develop renal failure within a few months of the onset of clinical signs, whereas others remain stable for years.[45]

Treatment is supportive, because there is no cure for the tubular defects. Monitoring for metabolic acidosis, urinary tract infections, and azotemia should be performed regularly. Veterinarians frequently are asked to participate in a Fanconi syndrome management protocol developed by Basenji breed enthusiasts known as the Gonto protocol.[45] This protocol involves intensive monitoring and treatment of secondary electrolyte abnormalities and metabolic acidosis. With this protocol, chronic proximal tubular bicarbonate loss that results in metabolic acidosis is managed by administration of oral sodium bicarbonate, 8-12 mg/kg PO q 12 h. This method of alkalinization will increase sodium load and result in bicarbonaturia; however, there is no information in the peer-reviewed literature of long-term effects of bicarbonate administration in dogs or cats with naturally occurring disease. Alternatively, management of chronic metabolic acidosis from renal tubular disease can be accomplished with administration of potassium citrate 40-75 mg/kg PO q 12 h. The goals of alkalization should be to maintain the serum [HCO_3^-] in a normal range (≈18-24 mEq/L), and the serum [K^+] at 4 to 6 mEq/L. Renal failure should be managed with dietary protein restriction, fluid therapy, histamine-2 receptor antagonists, and treatment of hypertension (see ch. 324). Treatment for acquired Fanconi syndrome should be directed at resolving the underlying cause of the disorder and providing supportive care. In a survey completed by owners and veterinarians of dogs affected with Fanconi syndrome to identify clinical and biochemical changes and long-term patient outcome, median survival time following diagnosis was 5.25 years (range, 7 days to 9.8 years).[45] In addition, 86% of owners reported quality of life as "excellent" to "good" during long-term management.[45] Of 29 dogs, 17 died or were euthanized for reasons unrelated to Fanconi syndrome.[45]

Renal Tubular Acidosis

The renal tubules regulate acid-base homeostasis through two processes: (1) resorption of 80% to 90% of filtered HCO_3^- in the proximal renal tubule, and (2) excretion of acids by means of titration of urinary buffers and excretion of ammonium in the distal renal tubule.[62] The term renal tubular acidosis (RTA) describes rare tubular disorders that lead to hyperchloremic metabolic acidosis. Various types of RTA have been described based on the area of the affected renal tubules. Proximal RTA (type II) occurs as a result of inability of the proximal tubules to prevent loss of HCO_3^-, and distal RTA (classic, or type I) occurs as the result of inability of the distal tubule to excrete H^+. Type IV RTA is distal RTA and hyperkalemia secondary to hypoaldosteronism or aldosterone deficiency. Unique diagnostic criteria exist for each type of RTA (Table 326-1).[63]

TABLE 326-1

Clinical Features of Proximal and Distal Renal Tubular Acidosis (RTA)[63]

FEATURE	PROXIMAL RTA	DISTAL RTA
Hypercalciuria	Yes	Yes
Hyperphosphaturia	Yes	Yes
Urinary citrate	Normal	Decreased
Bone disease	Less severe	More severe
Nephrocalcinosis	No	Possible
Nephrolithiasis	Not usually	Yes
Hypokalemia	Mild	Mild to severe
Potassium wasting	Worsened by alkali therapy	Improved by alkali therapy
Alkali required for treatment	>11 mEq/kg/day	<4 mEq/kg/day
Other defects of proximal tubular function*	Yes	No

Reductions in plasma bicarbonate (HCO_3^-)	Moderate	Variable
Fractional excretion of bicarbonate with normal serum bicarbonate	>15%	<15%
Urine pH during acidemia	<6.0	>6.0
Urine pH following administration of ammonium chloride	<6.0	>6.0

*Decreased resorption of sodium, potassium, phosphate, uric acid, glucose, and amino acids.

A defect in the basolateral membrane Na^+-HCO_3^- co-transporter, with leakage of HCO_3^- into the tubular lumen, results in proximal RTA.[64] This disorder can occur alone or as part of another tubular defect (e.g., Fanconi syndrome).[63] Ongoing loss causes a reduced plasma bicarbonate concentration, but the associated metabolic acidosis is self-limiting because of the distal tubule's ability to excrete acid. If oral sodium bicarbonate ($NaHCO_3$) is prescribed to normalize the plasma bicarbonate concentration, the amount of HCO_3^- presented to the distal tubule increases and overwhelms the distal buffering system, resulting in marked bicarbonaturia.[63]

The diagnosis of proximal RTA is based on an acidic urine pH and hyperchloremic metabolic acidosis, with a normal GFR but increased urine pH and fractional excretion of HCO_3^- (>15%) after normalization of the plasma HCO_3^- concentration with alkali administration. Identification of concurrent proximal tubular defects (e.g., euglycemic glucosuria, aminoaciduria) also helps localize proximal RTA.[63] Bicarbonate wasting makes metabolic acidosis from proximal RTA difficult to correct, and alkali therapy exacerbates potassium wasting. Potassium citrate is better suited for chronic use than is sodium bicarbonate.[63] One 540 mg tablet of potassium citrate provides 5 mEq of potassium and 1.7 mEq of citrate, and its metabolism yields 5 mEq of HCO_3^-.[17]

Distal RTA causes impairment of urinary acidification as a result of impaired H^+ secretion in the distal tubule.[62,63] Consequently, the kidneys are unable to maximally acidify urine in response to systemic metabolic acidosis. Under normal conditions, the distal tubule is able to excrete H^+ ions against a steep concentration gradient because of a hydrogen ion-adenosine triphosphatase (H^+-ATPase) pump. These tubular segments have tight junctions that resist back leak of acid, and they are able to generate ammonia to capture H^+ ions by forming ammonium ions, which are subsequently excreted.[64]

Type IV distal RTA is associated with hypoaldosteronism or aldosterone antagonism. Acidosis most likely results from loss of aldosterone stimulation of H+-ATPase and decreased distal Na^+ absorption. This syndrome has not been characterized in veterinary medicine but should be considered in animals with hyperchloremic metabolic acidosis and hypokalemia.[62,63]

Characteristics useful in the diagnosis of distal RTA include hyperchloremic metabolic acidosis with an increased urine pH (>6.0). In contrast to proximal RTA, with its relatively mild systemic metabolic acidosis, distal RTA can have a more severe metabolic acidosis because the distal tubule does not provide buffering ability. Clinical characteristics seen in humans with distal RTA include nephrolithiasis, nephrocalcinosis, bone demineralization, growth retardation, and hypokalemia.[62,64] Distal RTA has been reported in cats with pyelonephritis and in one cat with hepatic lipidosis, as well as in three dogs with immune-mediated hemolytic anemia, and one dog each with leptospirosis and receiving zonisamide therapy.[65-67] One cat with idiopathic distal RTA has been reported.[68] The diagnosis may be made by failure to acidify urine with an ammonium chloride challenge test. This test is performed by measuring the urine pH before and at hourly intervals for 6 hours after oral administration of 110 mg/kg of ammonium chloride. Normal dogs should acidify their urine to a pH of 5.0, and cats to a pH of 5.5.

Treatment for distal RTA consists of administration of an alkali source. A combination of potassium and sodium citrate, at a dosage range of 1 to 5 mEq/kg/day, orally, divided into 2 doses, may be preferred over HCO_3^- as the alkali source.

Nephrogenic Diabetes Insipidus

The term nephrogenic diabetes insipidus (NDI) describes any disorder in which the urinary concentrating mechanism is unable to respond to antidiuretic hormone (ADH) to produce concentrated urine. ADH is produced in the hypothalamus, stored in the posterior pituitary, and is released into circulation in response to

hyperosmolarity or hypovolemia.[69] Following release, ADH attaches to receptors at the basolateral membrane of the renal collecting tubules and collecting ducts, causing the tubular luminal surface to become permeable to free water, which promotes formation of urine that is more concentrated than plasma. Acquired NDI is a common cause of polyuria, because it can result from receptor interference caused by toxins (e.g., *Escherichia coli* endotoxin), drugs (e.g., glucocorticoids, chemotherapeutics), metabolic conditions (e.g., hypokalemia, hypercalcemia), tubular injury or loss (e.g., renal cystic disease, bacterial pyelonephritis), or alterations in the medullary concentration gradient (e.g., medullary washout).[70] Acquired NDI also has been identified as the initial presenting complaint that occurred 11 days prior to development of acute kidney failure from leptospirosis.[71]

Congenital NDI is a rare disease that is caused by a deficiency of ADH receptors. Clinical signs, apparent soon after birth, include severe polydipsia and polyuria, and hyposthenuric urine (specific gravity of 1.001-1.005; osmolarity <200 mOsm/kg). The diagnosis is based on failure to concentrate urine after modified water deprivation testing, failure to respond to exogenous ADH, and exclusion of more common causes of NDI.[69,72]

Treatment for acquired NDI should be directed at resolving the underlying cause. Congenital NDI therapy consists of free-choice water consumption, dietary sodium and protein restriction, and/or thiazide diuretics (chlorothiazide, 20-40 mg/kg PO q 12 h; or hydrochlorothiazide, 2 mg/kg PO q 12 h). Dietary sodium and protein restriction reduces the amount of solute presented to the kidney that must be excreted in the urine each day, further reducing obligatory water loss (see ch. 184).[72] The addition of diuretic therapy to dietary restrictions results in mild dehydration, increased fluid and sodium uptake in the proximal tubule, and 20% to 50% reduction of urine output.[72] If medical management is not an option for the client and polyuria can be tolerated, the animal can be maintained on free-choice water consumption alone. Diabetes insipidus is discussed further in ch. 296.

Evidence of Acute Tubular Injury Using Urine Biomarkers

Acute tubular injury (ATI) represents the initial phase of development of structural and functional kidney damage, and precedes development of clinically apparent acute renal failure since serum renal biomarkers are not typically above reference limits (see ch. 322). Initiation of ATI occurs from naturally occurring disease (e.g., toxic insult, renal ischemia, infectious disease) but can also occur secondary to other critical illnesses, secondary to the systemic inflammatory response, or from therapeutic intervention with nephrotoxic agents.[73,74] Early identification of ATI would allow the veterinary practitioner to alter therapy to halt ongoing renal injury, or be useful as a prognostic indicator when counseling clients. Serum biochemical findings, urinalysis, and sediment evaluations have been shown to be relatively insensitive indicators of acute tubular necrosis. The concept of urine biomarkers refers to the presence of biochemical substances in the urine that might provide an indication of tubular cell dysfunction and death.[75,76]

Examples of common urine biomarkers that are currently in use include urine glucose and albumin. Novel biomarkers currently undergoing investigation are in three categories: high molecular weight protein biomarkers from systemic circulation, low molecular weight protein biomarkers from systemic circulation or that are constitutively expressed in various renal cells, and enzyme biomarkers (also see ch. 321).[75,76] Enzyme biomarkers of greatest research interest are large (>80 kD) and are therefore only expressed in the urine from leakage of damaged tubular cells. These biomarkers may prove to have greater clinical utility because enzymes become elevated in urine prior to onset of overt dysfunction, analysis is often easier than for proteins, and the quantity or ratio to creatinine of certain enzymes may be able to predict the degree and severity of injury.[77-81] In the future, panels of biomarkers might be useful to localize the renal site of injury, determine severity, and monitor progression; however, urine biomarkers require further study to determine sensitivity and specificity for particular diseases, and assay standardization, prior to becoming available for clinical use to practicing veterinarians. Table 326-2 provides a summary of urine biomarkers studied for ATI in dogs.

TABLE 326-2

Urine Biomarkers Currently Undergoing Study to Determine Renal Dysfunction in Dogs[75,76]

BIOMARKER	NEPHRON SEGMENT	MECHANISM	COMMENTS

Intermediate/High Molecular Weight Proteins			
Albumin	G, PT	Glomerular leak, decreased reabsorption	Widely available. Not specific for location of injury (glomerular vs. proximal tubular)
Immunoglobulin A/G	G	Glomerular leak	No diagnostic advantage over monitoring urine protein: urine creatinine ratio
Low Molecular Weight Proteins			
Retinol binding protein	PT	Decreased reabsorption	Stable in acidic urine and when frozen Progressive increases with chronic kidney disease Wide intraindividual variation
Alpha-1 microglobulin	PT	Decreased reabsorption	Stable in acidic urine Decreased by hepatic disease
Beta-2 microglobulin	PT	Decreased reabsorption	Good predictor of GFR in dogs Unstable in acidic urine Not sensitive to monitor progression
Tubular Enzymes			
N-acetyl-B-D-glucosaminidase (NAG)	PT, DT	Increased release	Can measure from spot urine sample Affected by other diseases (e.g., hyperthyroidism, diabetes mellitus), pyuria, and long-term storage
Gamma-glutamyl transferase (GGT)	PT	Increased release	Can measure from spot urine sample Unstable in acidic urine Hematuria and pyuria cause assay interference
Alkaline phosphatase (intestinal variant)	PT, DT	Increased release	
Lactate dehydrogenase	PT	Increased release	
Neutrophil gelatinase-associated lipocalin	PT	Increased release	Stable with freeze-thaw cycles Hematuria and pyuria cause assay interference Malignancy, inflammation, and infection may decrease specificity

DT, Distal tubule; *G*, glomerulus; *GFR*, glomerular filtration rate; *PT*, proximal tubule.

CHAPTER 327

Pyelonephritis

Astrid M. van Dongen

Introduction

Pyelonephritis is an inflammation involving the renal pelvis but also the renal parenchyma. In companion animals, it is usually seen in the context of a complicated urinary tract infection due to bacteria that have ascended from the lower urinary tract (see ch. 330).[1] However, different routes of infection (e.g., hematogenous) can occur, and other infectious agents such as fungi[2-4] and even nematodal renal infestations have been described.[5]

This disease is a common sequel in companion animals with predisposing conditions that compromise systemic immunity, significantly change the urinary composition, or impair the host defense mechanisms of the urinary tract (ranging from abnormalities in voiding, to pre-existing tissue abnormalities in the upper urinary tract). If left untreated, bacterial pyelonephritis will give rise to permanent and progressive damage of the involved kidney, can expand to a retroperitoneal abscess[24] or even could lead to septicemia.

Timely recognition of affected patients can be challenging because the clinical signs and diagnostic findings sometimes are deceptively mild, especially if pyelonephritis is only unilateral. Moreover, associated signs are nonspecific and can easily be overshadowed by those arising from comorbidities. Likewise, the management of these patients is demanding, usually requiring repeat assessments as complications and/or relapses are not uncommon.

Pathophysiology

Ascending infection from the urethra, via the urinary bladder and ureter to the renal pelvis and renal tissue, is considered a much more likely route in companion animals, rather than hematogenous or via the lymphatic system (e.g., in the context of bacterial endocarditis or discospondylitis). Subsequent colonization of the renal pelvis and establishment of bacterial foci in the medullary area of the kidney is not easily accomplished and usually requires additional morbidity (Box 327-1).

Box 327-1

Comorbidities Associated with Bacterial Pyelonephritis

Compromising systemic immunocompetence

- Endocrine
  - Hyperadrenocorticism (spontaneous or iatrogenic)
  - Diabetes mellitus
- Infectious
  - Feline immunodeficiency virus

Impairing local defence mechanisms

- Kidney
  - Renal scarring
  - Renal glucosuria
  - Pyelectesia (due to ureteral obstruction, nephroliths, blood clot, etc.)
- Ureter
  - Ureteral obstruction (urolith, stricture, circumjacent pressure, etc.)
  - Ectopic ureter(s)

- Bladder
  - Vesicoureteral reflux
  - Pre-existing bacterial cystitis (occult bacteruria?)

Bacterial virulence properties

- Survival in urine
- Adherence to uroepithelium
- Ability to reside intracellularly
- Formation of biofilm
- Development of antimicrobial resistance

Predisposing Factors (see Box 327-1)

Bacterial pyelonephritis is cited as a complication in patients with a systemic disease hampering their immune system, such as hyperadrenocorticism in dogs[6] or cats with feline immunodeficiency virus infection.[11] Glucosuria, either of renal origin[12] or because of diabetes mellitus[7,13] also is associated with complicated urinary tract infections. Structural changes of the kidneys,[10] accumulation of material (e.g., a blood clot or nephrolith)[8] in the renal pelvis, and pyelectasis due to ureteral obstruction, will make it easier for uropathogens to colonize the upper urinary tract. Similarly, anatomical disorders like ectopic ureters[9] or functional abnormalities as occur in vesicoureteral reflux (VUR)[14] can facilitate the further ascension of urinary tract infection. For a more detailed discussion of these comorbidities the reader is referred to chapters concerning hyperadrenocorticism (see ch. 306 and 307), diabetes mellitus (see ch. 304 and 305), chronic kidney disease (see ch. 324), urolithiasis (see ch. 331 and 332), lower urinary tract infections (see ch. 330), and disorders of micturition (see ch. 333).

Apart from these host-related factors, bacterial characteristics regarding their capacity to persist in the urine, adhere to the uroepithelium, relocate intracellularly, form a biofilm, and develop antimicrobial resistance[19] will also impact their virulence.

Sequelae

Whether or not preexisting chronic kidney disease was present, additional kidney injury is likely to occur as a consequence of pyelonephritis. Depending on the magnitude, this injury can result in additional clinical signs (e.g., polyuria/polydipsia) and metabolic changes that are more severe.

At initial diagnosis, it can be challenging or impossible to determine the proportion of azotemia that is due to acute kidney injury as opposed to preexisting chronic kidney disease (commonly referred to as acute-on-chronic kidney disease). Nevertheless, during patient management, it is important to consider and address both the chronic kidney disease and the acute kidney injury, if one exists, because remarkable clinical and biochemical improvement can still occur in one to three months following successful treatment of an acute process like pyelonephritis.

Diagnosis (Box 327-2)

Environmental factors should be considered, as these can impact exposure to pathogens. Geographical differences exist with regards to occurrence of fungal and nematodal infections, but also can be applied on a more local level, like exposure to (possibly multiresistant) uropathogens in a hospital setting.[29]

Box 327-2

Checklist for Patients Suspected of Having Pyelonephritis

Geographic differences/regional prevalences

Signalment (species, breed, sex, age-associated predispositions to comorbidities)

History

- Risk factors (travel, diet, case and family histories, medication)
- Clinical signs involving the urinary system (dysuria, polyuria, polydipsia, abnormal urine)

- Clinical signs of systemic illness (fever, vomiting)

Physical examination

- Depending on comorbidities
- Abdominal palpation (especially kidneys and adjacent area)

Urinalysis

- Specific gravity
- Dipstick (glucose, ketones)
- Microscopic examination of sediment
  - Crystals, casts, cells (epithelial, erythrocytes, leukocytes)
  - Infectious agents (bacteria, yeast, fungi, ova)
- Microbiological examination (culture and sensitivity)

Complete blood count (hematocrit, leukocyte count and differential)

Serum biochemistry profile (azotemia, electrolytes, others based on comorbidities)

Diagnostic imaging

- Abdominal ultrasound
  - Kidneys, ureters, bladder
  - Pyelocentesis
- Contrast radiography (less commonly performed when high-resolution ultrasound with skilled sonographer is available)

Others based on comorbidities

Signalment

Differences between species can be considered because urinary tract infections are reported more commonly in dogs than cats. However, for pyelonephritis, there will likely be a bigger impact from sex, age, and breed predispositions for the various comorbidities as discussed under pathophysiology, above.

History and Chief Complaint

The medical history concerning a patient with possible pyelonephritis should include questions to assess risk factors through travel, diet, previous illnesses, medication, and suggestive family histories.

Owner-observed signs associated with pyelonephritis can range from abnormal body posture suggestive of abdominal pain, and various changes in micturition including dysuria, polyuria/polydipsia, and/or macroscopically abnormal urine. These are more suggestive of pyelonephritis if they coincide with generalized signs of malaise, vomiting, and/or recurrent febrile episodes. However, none of these is specific to pyelonephritis, which even can remain subclinical.

Physical Findings

For the reasons described above, the focus of the physical exam needs to include systems and possible abnormalities associated with suspected comorbidities (see Box 327-1). In all cases, thorough and careful abdominal palpation is indicated. In cats, the kidneys are only loosely attached to the dorsal abdominal wall, allowing for adequate assessment even if the cat is hunching. Palpating both kidneys in dogs often is difficult, but an assessment still can be made by judging the response to palpation in the renal and perirenal regions. Repeatable evidence of discomfort could be indicative of renal pain and adds to justification for diagnostic imaging.

Laboratory Tests

Urinalysis (see ch. 72) not only is instrumental in the diagnosis of pyelonephritis, but it will also provide valuable information on possible comorbidities. In turn, this determines the need for additional diagnostic tests and is an important element for guiding the treatment plan. Sampling method, sample volume, and macroscopic evaluation should be noted, and will help with interpretation of final result. A routine urine examination[15] generally includes refractometer determination of specific gravity and dipstick analysis for presence of at least glucose (combined with ketones) in view of predisposing factors.

Microscopic examination will help distinguish hematuria from hemo- (myo-) globinuria and could hold clues to help with localization (casts, different epithelial cells) and underlying disease (e.g., crystals, infection). Examination of stained, air-dried sediment[16] can allow identification of white blood cells and potential causal agents (ranging from bacteria, yeasts, and fungal components to parasite ova). The magnitude of presumed renal proteinuria, which is measured by means of a urinary protein-to-creatinine ratio, is best assessed after urinary tract inflammation is addressed.[17]

When signalment and history could be indicative of hyperadrenocorticism, a home-collected voided urine sample for assessing urinary corticoid-to-creatinine ratio may be worthwhile to consider (see ch. 306).[18]

Although a definitive diagnosis of bacterial pyelonephritis can only be established if indeed a positive culture of a pyelocentesis sample is found, a cystocentesis urine sample in the context of suggestive history, physical examination and/or imaging generally is accepted. Preferably, a quantitative aerobic bacterial culture and sensitivity is performed, but more cost-effective options such as urine dipstick paddle systems can be considered.[20]

Complete Blood Count

Assessing the hematocrit has no diagnostic value for pyelonephritis itself, but it can have an impact on patient management in view of suspected comorbidities, or when findings during physical examination were suggestive of either anemia or erythrocytosis.[22] Similarly, patients with pyelonephritis can display abnormal white blood cell counts ranging from leukopenia to (predominantly neutrophilic) leukocytosis. If characterized by a left shift, leukocytosis also can be indicative of secondary bacteremia.

Serum Biochemistry Profile

Whether cause or consequence, abnormal renal function is a common feature of pyelonephritis reflected not only in urinary abnormalities but also through serum electrolyte disturbances and possible development of azotemia if both kidneys are involved. For those patients that show other comorbidities, a much wider range of parameters can become of interest; for example, in cases with glucosuria, plasma glucose levels will also be of interest.

Diagnostic Imaging

Abdominal ultrasound offers a convenient modus to assess renal morphology, including corticomedullary distinction and renal pelvic diameter (Figure 327-1).[23] It also can provide guidance for percutaneous pyelocentesis and, depending on the ureteral diameter, operator experience, and patient cooperation, even can allow visualization of the ureter downstream, identification of an obstruction, and/or assessment of the location of its inflow in the bladder.

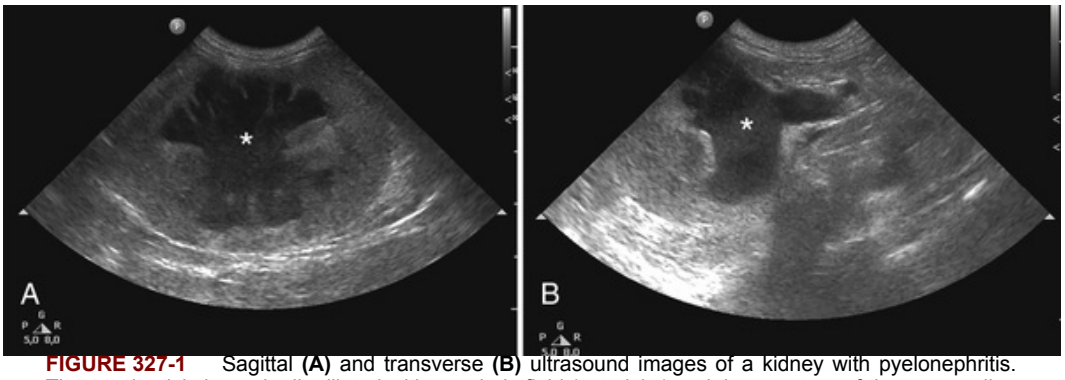

FIGURE 327-1 Sagittal **(A)** and transverse **(B)** ultrasound images of a kidney with pyelonephritis. The renal pelvis is markedly dilated with anechoic fluid (asterisks) and the structure of the surrounding renal parenchyma is distorted.

Survey radiographs provide limited information but can indicate the location of the kidneys, the location of adjacent structures, and the presence of material with abnormal radiopacity (e.g., calcifications) in the renal region and/or lower parts of the urinary tract.

With the aid of contrast fluid (administered antegrade or retrograde), radiographic imaging of the urinary

system can be greatly enhanced to identify anatomical (ectopic ureters) and functional disorders such as vesicoureteral reflux.

Computed tomography and magnetic resonance imaging can enhance specific features of the urinary tract, thus providing additional value in cases where doubt remains on the nature or degree of extension of the disease process, but such modalities generally are not needed to achieve a diagnosis of pyelonephritis.

Although renal tissue biopsies can facilitate the diagnosis of diffuse renal disease, it is far less likely that they can adequately identify very localized infiltrates that predominantly are present in the medulla. This limitation, added to the increased risks involved with biopsy of contaminated tissue, means that it is not recommended to obtain a core or wedge renal biopsy sample in cases with any urinary tract infection, including active bacterial pyelonephritis.

Patient Management (Box 327-3)

The treatment plan should be customized according to the patient's findings because pyelonephritis seldom is an isolated entity and inaccurate or incomplete treatment can give rise to serious or even life-threatening complications (from poorly addressed comorbidities, uncontrolled pyelonephritis, or both).

Box 327-3

Management of Patients with Bacterial Pyelonephritis

Stabilize if needed (fluid and electrolyte support, IV antibiotic)

Eliminate or reduce predisposing factors/comorbidities

Initiate antibiotic treatment, preferably based on culture and sensitivity (treatment duration: 3-4 weeks or longer)

Follow-up

- Check for clinical improvement (first week)?
- Check urinalysis before end of treatment
- Revaluate urinalysis for relapse of reinfection
  - 1 to 2 weeks after cessation of antibiotics
  - When clinical signs appear

Assess and monitor renal function (and other comorbidities)

The highest priority should be given to respiratory and hemodynamic stabilization if findings are indicative of severe systemic illness. This will usually require hospitalization, and combining IV fluids and electrolyte support with parenteral antibiotics. With severely ill pyelonephritis patients, antibiotic selection initially is empirical (e.g., ampicillin 20 mg/kg IV q 8 h), and is based on locally applicable antimicrobial susceptibility patterns[28] and regulations (e.g., banning use of last-resort antibiotics like fluoroquinolones and third-generation cephalosporins if not underpinned by culture and sensitivity results).

To the extent it is possible, measures to attempt eradication or at least reduction of treatable predisposing factors should be undertaken (e.g., initiation of treatment for diabetes mellitus, or initiation of measures to normalize micturition [see ch. 333]).

In patients that are more stable, it is appropriate to consider awaiting *in vitro* bacterial sensitivity results before determining which antibiotic is going to be used, or at least re-evaluating previous treatment choices and their results. This approach can both improve outcome compared to empirically chosen antibiotics, and (ideally) also contribute to halting the rise in antibiotic resistance.[21] Apart from *in vitro* sensitivity, it is worthwhile to also consider an antibiotic's capacity to penetrate into the renal tissue. Costs and potential for side-effects also should be weighed, as a prolonged treatment duration of at least 3-4 weeks or even longer routinely is appropriate in animals with complicated urinary tract infections. However, the evidence supporting these lengthy time frames is very limited and currently under scrutiny in view of the rise in antibiotic resistance patterns and occurrence.[25]

A reported alternative treatment option is ultrasound-guided percutaneous drainage with lavage,[26] where repetitive localized treatment with antiseptic solution successfully eliminated the infection in the renal pelvis. Unilateral nephrectomy[27] as treatment for pyelonephritis should be viewed as a last resort when, despite

appropriate antimicrobial treatment, relapses occur and a bacterial niche (e.g., nephrolith) in the kidney is likely. It is vital to try to ensure beforehand that the remaining kidney will have adequate function. Persistent azotemia therefore could be viewed as a contraindication because it implies that both kidneys are debilitated. In non-azotemic animals, other findings (e.g., urinalysis, renal ultrasound findings) can be helpful, but ideally renal scintigraphy should be considered for separating left from right renal function before considering nephrectomy.

Additional measures to address chronic kidney disease should be prioritized at this stage (see ch. 324); even when the patient is assumed to be clinically stable, he/she should be closely monitored to ensure adequate intake of fluid and food. If there is doubt, it is better to postpone any dietary changes that could influence this adversely, until appetite has improved satisfactorily.

Established treatment plans for pyelonephritis patients that already had preexisting chronic kidney disease could require several (temporary) adjustments until stabilization and stage are reconfirmed on follow-up, because control or elimination of pyelonephritis can play a minor to major role in disease progression depending on the severity of the condition and response to treatment.

Follow-Up

Apart from any underlying diseases, patients with pyelonephritis should be considered chronic unless proven otherwise, meaning they should have at least one, and preferably two, follow-up appointments.

Routine telephone follow-up is an easy way to ensure clinical improvement, which should be noticeable to the owner within a week if treatment is effective. This contact also can yield further substantiation for an actual follow-up visit or at least submitting a urine sample for recheck. Urinalysis to exclude persistent urinary tract infection is performed preferably before the end of treatment, and could be the best way to ensure the duration of treatment is indeed acceptable for that case. Ideally, urinalysis is also repeated after 1-2 weeks without antibiotics and at any time thereafter when clinical signs present themselves.

Microbial examination of the urine will allow for differentiation between relapse (same microorganism is present) or reinfection (different organism is present). A relapse is more indicative of a niche somewhere in the urogenital tract that allows that organism to persist and remerge even after an appropriate antibiotic, and this information has clinical importance in terms of eliminating the inciting cause.

Reinfection usually occurs in immunocompromised animals (systemic or locally in the urinary tract), and likewise, this information can focus the diagnostic and treatment plan more specifically.

Especially for those patients that were azotemic at, or before, the time of diagnosis, it is worthwhile to reassess the patient more fully by means of physical examination (including blood pressure measurement), urinalysis (preferably including urine protein-to-creatinine ratio), a complete serum biochemistry profile, and complete blood count.

An improvement in kidney function frequently occurs after treatment of an acute kidney injury like pyelonephritis. Performing rechecks at two time points after successful treatment of pyelonephritis allows the clinician to identify the presence and magnitude of such an improvement, and also determine the degree of residual function loss (i.e., staging chronic kidney disease once infection is controlled).

Frequency and extent of additional monitoring are highly dependent on the clinical picture, and should be executed more promptly in cases showing an acute exacerbation but can easily stretch to periods of one to three months in stable animals.[30] As chronic kidney disease is considered to be both at the origin of many cases of pyelonephritis, as well as a sequel to it, expanding routine urinalysis and culture with a urinary protein-to-creatinine ratio is recommended, as is monitoring the blood pressure, complete blood count, and serum biochemistry profiles as clinically indicated.[30]

Prognosis

The prognosis is highly dependent on efficacy of treatment, remaining issues that could lead to relapse/reinfection, and amount of damage that was inflicted on the renal tissue. Chronic kidney disease is considered to be both at the origin of, as well as a sequel to, pyelonephritis, but it does not necessarily carry a poor prognosis, as morbidity is quite variable and linked to the stage of disease. Patients with the earlier stage who respond well to antibacterial treatment can remain stable for extended periods of time with an excellent quality of life.

CHAPTER 328

Familial and Congenital Renal Diseases of Cats and Dogs

Gilad Segev

Client Information Sheet: Familial and Congenital Renal Diseases of Cats and Dogs

Introduction

Congenital diseases may result from either a genetic disorder or abnormal organ development during gestation; namely, congenital disorders are not necessarily inherited. Familial diseases are present in a relatively high prevalence in specific breeds, develop relatively early in life, and are assumed to have an inherited basis; however the latter assumption has yet to be proven. In both congenital and familial diseases, clinical signs may be present at birth or become apparent during various stages in life (i.e., a late onset). Due to their potential late onset, congenital and familial diseases should be suspected in animals that have signs of chronic kidney disease (CKD) at a relatively young age (e.g., <5 years). Congenital and familial diseases are more prevalent in dogs compared to cats and might affect different locations within the nephron (i.e., glomerulus, tubuli, interstitium). These diseases are often progressive in nature and ultimately become fatal; however, the progression rate is highly variable.

Developmental Diseases

Definitions

Renal Agenesis, Hypoplastic Kidneys

Renal agenesis is a complete absence of one or both kidneys. Bilateral agenesis has been reported, but results in death. Renal agenesis is often associated with other congenital urogenital abnormalities, such as ureteral agenesis. The etiology is unknown, but familial predisposition has been suggested in few breeds including Beagles, Doberman Pinchers and Shetland Sheepdogs.[1-3] Unilateral renal agenesis is a clinically silent condition, provided that the contralateral kidney function is normal. Hypoplastic kidneys are small, and have a reduced number of functioning nephrons. The condition is often congenital and should be differentiated from renal atrophy, which might be secondary to other congenital disorders.[4] Clinical signs and prognosis depend on the degree of hypoplasia and the overall kidney function.

Renal Dysplasia

Renal dysplasia represents a group of developmental anomalies, and is defined as an abnormal differentiation of the renal parenchyma.[5] Grossly, the kidneys are indistinguishable from those with advanced acquired CKD. Histopathologically, the most consistent finding is inappropriate differentiation (compared to the development of the host) of various nephron components. For example, one may observe immature (fetal) nephrons alongside normal nephrons. The functioning nephrons undergo compensatory hypertrophy. Fetal glomeruli and tubules are often present in radial segments, extending from the surface of the kidney to the corticomedullary junction. Additional histologic findings include persistent immature mesenchyme, persistent metanephric ducts, atypical tubular epithelial proliferation, and dysontogenic metaplasia. Secondary changes may also be present and include interstitial nephritis, fibrosis, mineralization, cystic glomerular atrophy, cortical and medullary cysts, and glomerular lipidosis. Proper assessment is often hampered by the more dominant secondary changes. Renal dysplasia has been suspected in multiple breeds. In some breeds, the disease has been extensively characterized but in other breeds, it may be limited to a

single case report or case series (Table 328-1).[5-13] Reports of congenital nephropathy in several breeds (e.g., Great Dane, Yorkshire Terrier, Keeshond) likely represented renal dysplasia.

TABLE 328-1

Congenital and Familial Kidney Diseases of Dogs and Cats

DISORDER	AFFECTED BREEDS	COMMENTS
Renal Dysplasia		
	Lhasa Apso, Shih Tzu, SCWT, CKCS, Bulldog, Standard Poodle, Bull Mastiff, Cairn Terrier, Alaskan Malamute, Golden Retriever, Chow Chow, Cocker Spaniel, Dutch Kooiker, Boxer, Finnish Harrier, Norwegian Elkhound, Miniature Schnauzer	In some breeds (e.g., Lhasa Apso, Shih Tzu) the disease is well characterized and the criteria are fully met, while in others the disease is poorly characterized, based on a single case report/series. Other breeds are likely affected.
Glomerulopathies		
Amyloidosis	Dogs: Chinese Shar-Pei, English Foxhound, Beagle Cats: Abyssinian	Possible autosomal recessive in Chinese Shar-Pei.23
Hereditary nephritis	English Cocker Spaniel, Samoyed, Dalmatian, Bull Terrier	
Podocytopathy	SCWT, Airedale Terriers	
MPGN	Bernese Mountain dog59	Deposition of immune complexes. suggested autosomal recessive inheritance.
	Brittany Spaniel60,61	Congenital deficiency of the third component of complement (C3).
Atrophic glomerulopathy	Rottweiler62	Diffuse global, atrophic membranous glomerulopathy with secondary degenerative changes. Both genders are affected and azotemia develops in the first year of life.
Other glomerulopathies	Pembroke Welsh Corgi,63 Doberman Pinscher,64 Soft Coated Wheaten Terrier, Bullmastiff,65 Newfoundland66	
Polycystic Kidney Disease		
	Dogs: Bull Terrier, Cairn Terrier, WHWT	
	Cats: Persian, Himalayan, British Blue	May be present in any cat crossbred with Persian cats.
Tubular Defects		
Primary glucosuria	Norwegian Elkhound67	
Cystinuria	Described in multiple dog breeds68,69 and in cats.70 Common dog breeds include English Bulldog, Newfoundland,71,72 Dachshund, Basset Hound, Rottweiler.73	Inherited proximal tubular defect. Classified as type 1 (autosomal recessive) and non–type 1 (autosomal dominant with incomplete penetrance). Predisposes to cystine uroliths (see ch. 331).
Hyperuricosuria	Dalmatian,68 English Bulldog, Black Russian Terrier	Membrane transport defect (autosomal recessive). Dalmatian dogs also present decreased proximal tubular resorption and active distal tubular secretion of urates.
Hyperxanthinuria	A congenital disorder reported in the Cavalier King Charles Spaniel74 and in the Wirehaired Dachshund75	
Fanconi syndrome	Basenjis55-57	

Congenital NDI	Various breeds[76]	Deficiency of antidiuretic hormone receptor in the distal nephron and collecting ducts. Affected animals present with profound polyuria and polydipsia.
Miscellaneous		
Telangiectasia	Pembroke Welsh Corgi[77]	Periodic gross hematuria typically at 2 to 8 years of age.
Reflux nephropathy with segmental hypoplasia	Boxer[78,79]	Atrophic, non-obstructive pyelonephritis due to vesico-ureteral reflux causing renal hypoplasia.
Cystadenocarcinoma	German Shepherd dogs[80]	An autosomal dominant trait. A mutation in the BHD gene has been suspected.[81] The disease has a late onset. May be associated with concurrent nodular dermatofibrosis and uterine leiomyomas.

CKCS, Cavalier King Charles Spaniel; *MPGN*, membranoproliferative glomerulonephritis; *SCWT*, Soft Coated Wheaten Terrier; *WHWT*, West Highland White Terrier.

Clinical Evaluation

Clinical and clinicopathologic findings in dogs with renal dysplasia are consistent with acquired CKD. However, some dogs with renal dysplasia have profound polyuria and polydipsia (PU/PD), perhaps due to concurrent nephrogenic diabetes insipidus (see ch. 45 and 296).[9] Ultrasonographic (US) changes are highly variable, depend on severity of disease, and are not necessarily symmetrical. These include decreased corticomedullary definition and presence of multifocal hyperechoic speckles within the renal medulla, along with generalized medullary hyperechogenicity.[14] Final diagnosis is established histologically by evaluating a large number of glomeruli, often necessitating a surgical wedge biopsy.[15]

Staging and Treatment Guidelines

Staging and treatment guidelines for dogs and cats with developmental kidney disease are similar to those recommended for acquired CKD (see ch. 324) with few modifications. Dietary protein must be closely assessed in growing animals. Animals with congenital CKD are often resilient to azotemia and may present few clinical signs even with advanced disease. However, complete staging and appropriate management should not be delayed, as one of the main therapeutic targets is to slow the disease progression rate.

Glomerular Diseases

Overview

Several familial and congenital glomerular diseases have been documented in a few breeds (see Table 328-1). The most common are hereditary nephritis and amyloidosis. Clinical signs of affected animals may be related to protein losing nephropathy (PLN) *per se*, or to azotemia (see ch. 62, 72, 324, and 325). The nephrotic syndrome (i.e., proteinuria, hypoalbuminemia, hypercholesterolemia, and edema/ascites) has been documented in a subset of dogs. Systemic hypertension (see ch. 157) and thromboembolism (see ch. 243 and 256) are also potential complications. The hallmark of glomerular disease is proteinuria; therefore, early detection requires urinalysis (see ch. 72), in the absence of genetic testing (see ch. 3 and 4).

Amyloidosis

Definitions

Amyloidosis is a heterogeneous group of diseases characterized by extracellular deposition of insoluble, fibrillary proteins with a specific beta-pleated sheet conformation.[16] Hereditary amyloidosis is caused by mutant genes encoding variant proteins whose structure makes them amyloidogenic.[17] Amyloid proteins may originate from multiple precursors and their formation may be primary or secondary (reactive).

Secondary amyloidosis is the most common form in dogs and cats.[18] Despite their diverse origins, all amyloid proteins possess similar structural, physical and chemical properties including formation of X-ray diffraction patterns characteristic of beta-sheet aggregates, uniform fibril morphology and fibril formation patterns, and specific staining with Congo-red and thioflavin T.[19] In dogs and cats, renal amyloidosis fibrils are composed of an N-terminal fragment of the acute phase protein, serum amyloid A (see ch. 325).

Familial Amyloidosis

Amyloidosis has been described in Chinese Shar-Peis (CSPs), Beagles, English Foxhounds, and in Abyssinian cats.[20-22] Amyloidosis is mostly reactive, and is relatively well characterized in CSPs.[23] Familial Shar-Pei fever, characterized by recurrent episodes of fever with concurrent swollen hocks (see ch. 203), likely predisposes to systemic reactive amyloidosis, similar to human Familial Mediterranean Fever.[24,25] Deposits are composed of the amino-terminal acute phase protein amyloid A, produced during inflammation as part of the acute phase response. The kidney is the most frequent and often the sole site of amyloid deposition. There are notable differences between amyloidosis in CSPs and other dog breeds. First, in CSPs (as in Abyssinian cats), renal medullar lesions predominate, although when advanced, renal amyloid deposition involves all parts of the nephron.[26,27] In CSPs, amyloid deposition is commonly noted in extra-renal organs: spleen, liver, adrenal glands, pancreas, gastric and intestinal submucosa, myocardium, thyroid, prostate and lymph nodes.[16,27,28]

The disease has a late clinical onset. Most dogs and cats are presented for medical care when in middle age; however, diagnosis is made in a very wide range of ages.[28] Most CSPs have severe azotemia and are not brought for veterinary care due to clinical signs associated with PLN. The nephrotic syndrome is uncommon in CSP because their amyloid deposition is predominantly medullary, which causes interstitial prior to glomerular damage.[28] Consequently, compared to other breeds, the degree of proteinuria in CSPs is lower and the degree of azotemia higher. Histology is required to confirm a diagnosis. The prognosis is poor, however survival times vary substantially, depending on the disease stage and the degree of azotemia.[28] This emphasizes the need for early diagnosis.

Hereditary Nephritis

Definitions

Hereditary nephritis, one of the most thoroughly characterized congenital kidney diseases, originates from a genetic mutation which causes abnormal formation of type IV collagen. Normally, glomerular capillary basement membranes are composed of a collagen heteromer network containing alpha-3-alpha-4-alpha-5 chains. A mutation in one of the encoding genes (COL4A3, COL4A4, COL4A5) results in improperly formed chains unable to interact with other chains to form the alpha-3-alpha-4-alpha-5 heteromers.

Mutations Demonstrated

Various mutations and modes of inheritance have been described, including X-linked, autosomal recessive, and autosomal dominant. X-linked hereditary nephritis was first reported in the Samoyed, with a single nucleotide substitution in the COL4A5 gene as the mutation origin, causing abnormal alpha-5 chains and abnormal assembly of type IV collagen. This results in splitting of the basement membrane, which can be detected via electron microscopy early in life. Proteinuria is the first diagnostic indicator of the disease and, in male dogs, can be detected at as early as 3 months of age. Azotemia in males develops and progresses over few months until death at approximately 1 year of age.[29] Carrier females develop mosaic expression of the alpha3-alpha4-alpha5 chains. As in males, their proteinuria can be detected early in life; however, azotemia progresses at a much slower rate and is apparent only after a few years of age.[30]

In English Cocker Spaniels, the disease is autosomal recessive and originates from a single nucleotide substitution in the COL4A4 gene. Due to this mode of inheritance, males and females are affected equally. Proteinuria is detected at as early as a few months of age, and azotemia progresses over the first and second years of life.[31,32] An autosomal dominant mutation has been described in Bull Terrier and Dalmatian dogs, mostly from Australia.[33-35] The underlying genetic mutation has not been fully characterized, but all affected dogs have proteinuria. The clinical presentation is highly variable and azotemia develops over a wide range of time spans, to become apparent by several months or as late as 7-8 years of age.[34,36] Consequently, dogs with subclinical disease may be bred and the disease is difficult to eradicate.

Diagnosis

Diagnosis of hereditary nephritis is based on kidney biopsy. In X-linked hereditary nephritis, light microscopy reveals morphologic features of membranoproliferative glomerulonephropathy. In the X-linked and autosomal recessive disorders, immunostaining of the glomerular basement membrane demonstrates the abnormal pattern of the type IV collagen, but in the Bull Terriers and Dalmatians, immunostaining shows a normal pattern of type IV collagen, and the diagnosis can only be made based on electron microscopic examination. For some of the hereditary nephritis disease types, genetic testing is available.[37]

Podocytopathy and Glomerulosclerosis

Protein-losing nephropathy is diagnosed in 10-15% of Soft Coated Wheaten Terriers, with a complex mode of inheritance.[38,39] Histology of kidney biopsies reveals glomerulonephritis, glomerulosclerosis and evidence of podocyte degeneration and loss. The disease has a late onset, with a mean age of 6 years.[39] Therefore, affected dogs are often bred before identified as affected. Clinical signs usually involve the intestinal tract as well as PLN. There is no biologic marker available for early identification; however, sequencing candidate genes in two Airedale Terriers revealed single nucleotide changes in the closely linked *NPHS1* and *KIRREL2* genes, which encode the slit diaphragm proteins nephrin and Neph3/filtrin, respectively.[39,40]

Polycystic Kidney Disease

Definitions and Breeds Affected

Canine

Polycystic kidney disease (PKD) has been reported in both dogs and cats. Affected dog breeds include the Bull Terrier, Cairn Terrier, and West Highland White Terrier (WHWT). A genetic mutation in the polycystin-1 (PKD1) gene[41,42] with an autosomal dominant mode of inheritance has been suggested in the Bull Terrier.[43] An autosomal recessive mode of inheritance was suggested in the Cairn Terrier and the WHWT.[44,45] Bull Terrier dogs have decreased kidney function in the first years of life, with cysts limited to the kidneys. Cairn Terriers and WHWT dogs develop clinical signs in the first months of life, with multiple cysts in both the kidneys and the liver.

Feline

PKD is the most common genetic feline disease affecting Persian cats and outcrossed breeds and is characterized by renal, hepatic and occasional pancreatic cysts. The reported prevalence in Persian cats is approximately 40%, worldwide.[46,47] The mode of inheritance is an autosomal dominant defect that originates from a single nucleotide mutation (C to A transversion) in Exon 29 of the *PKD1* gene, resulting in a premature stop codon.[48,49] No homozygous cats have been identified, supporting the suggestion that the mutation is embryonic lethal.[49] PKD has also been described in cats lacking the *PKD1* mutation and, therefore, other mutations may trigger PKD in cats.[50] Renal cysts grow slowly, resulting in a gradual decrease in the amount of the normal renal parenchyma.

Signs and Diagnosis

Clinical signs are consistent with CKD (see ch. 324). The kidneys are usually enlarged and irregular on physical examination. Early detection can be made using genetic testing tools (in cats)[51,52] and ultrasonography,[53] which demonstrates numerous cortical and medullar round or oval hypoechoic to anechoic cysts at as early as 7 weeks of age.[54] In both dogs and cats, their absence at 6 months of age is correlated with the absence of PKD.[48]

Tubular Disorders

Prevalence, Definitions

Tubular defects are uncommon in dogs and cats. Tubular disorders have been reported as an isolated condition or they may accompany other hereditary or familial renal disorders (see Table 328-1). Tubular

disorders include primary glucosuria, aminoaciduria (e.g., cystinuria), electrolyte disorders, acid base disorders (i.e., proximal and distal renal tubular acidosis), and water metabolism disorders (i.e., nephrogenic diabetes insipidus).

Fanconi Syndrome

Fanconi syndrome is a complex familial disorder in Basenji dogs, with a prevalence of at least 10% and an uncertain mode of inheritance (see ch. 326).[55-57] Renal tubular handling of glucose, phosphate, sodium, potassium, uric acid, amino acids, and bicarbonate may be impaired. On urinalysis, glucosuria, proteinuria (usually mild), and low urine specific gravity are often present. In dogs with advanced disease, azotemia, hypokalemia and variable degrees of hyperchloremic metabolic acidosis are often present. Clinical signs include polyuria and polydipsia, weight loss, and weakness. Most affected dogs are diagnosed between 4 to 8 years of age. The disease progression rate is highly variable with some dogs having normal life span.[58]

Miscellaneous Conditions

There are multiple other renal disorders that have been suggested to have genetic basis. Some of these are limited to a very small number of animals, are poorly characterized, and the genetic underlying cause is not yet determined (see Table 328-1).

Ureteral Disorders

Larry G. Adams

Client Information Sheets:
Ectopic Ureters: Laser Correction
Ureteral Stones (Ureterolithiasis)

Anatomy and Physiology of the Ureters

The ureters are fibromuscular tubes that carry urine from the renal pelvis to the bladder via a retroperitoneal course. The ureteral wall is composed of an outer adventitial layer, a muscular layer, submucosa, and a mucosa of transitional epithelium. The muscular wall of the ureter consists of an outer longitudinal, middle circular, and inner longitudinal muscle layer except at the ureterovesicular junction (UVJ), where only longitudinal fibers are present. The maximum ureteral luminal diameter in the dog is normally less than 2.7 mm even with fluid diuresis.[1,2] The normal ureteral luminal diameter in cats is only 0.3 to 0.4 mm; therefore, even small ureteroliths or cellular debris may occlude the ureter in cats. The ureters enter the urinary bladder on the serosal surface and tunnel though the bladder wall obliquely to the mucosal surface. The oblique path of the intramural ureter results in a valve-like effect termed the vesicoureteral valve. The vesicoureteral valve, along with ureteral peristalsis and a compliant bladder, promotes unidirectional flow of urine to aid in prevention of ascending infection or urine reflux to the kidneys (vesicoureteral reflux). The intramural ureter has a j-hook conformation terminally turning from a caudal to a cranial direction before entering the bladder at the trigone. The degree of curvature of the distal ureter at the trigone depends on the degree of bladder distension with greater distention of the urinary bladder resulting in greater degree of curvature of the distal ureter. Recognition of this curvature is important for interpretation of excretory urography studies and for retrograde access to the ureters during cystoscopy (see ch. 108). Attempts to pass a urologic guidewire and ureteral catheter retrograde up the ureter via cystoscopy are impaired when the urinary bladder is overdistended.

Innervation to the ureter includes both sympathetic and parasympathetic nerves; however, the sympathetic innervation appears to be most important for neurogenically mediated ureteral contraction.[3,4] Studies have shown the presence of alpha-1, alpha-2, and beta-adrenoceptors and muscarinic cholinergic receptors in the canine ureter.[4,5] Similar studies are lacking in cats. The density of alpha-1 receptors binding sites is significantly greater than that of the other receptor types in dogs. However, ureteral innervation is not responsible for normal ureteral peristalsis, which is myogenic in origin. Ureteral peristalsis occurs when urine enters the ureter, initiating electrical impulses to be conducted between smooth muscle cells. Normally peristaltic activity is initiated in the renal pelvis and urine is propelled toward the bladder. Because normal ureteral peristalsis is myogenic in origin, ureteral peristalsis persists with transplantation. During obstruction of the ureter, spasmodic contractions occur that are mediated via sympathetic input and normal peristaltic activity is inhibited. Stimulation of the ureter with alpha-adrenergic agonists causes ureteral contraction and stimulation with beta-adrenoreceptor agonists causes ureteral relaxation.[3-5] Furthermore, alpha-1 adrenergic antagonists inhibit basal ureteral tone, peristaltic frequency and ureteral contractions.[6] Understanding of innervation of the ureter may contribute to selection of medications for management of ureteral diseases. For example, drug therapy to facilitate relaxation of the ureter for expulsion of ureteroliths might include alpha-adrenergic antagonists or selective beta-2/beta-3 agonists to relax the ureters and reduce ureteral spasm.[4,7,8]

Diagnostic Approach to Diseases of the Ureters

The reader is referred to ch. 321 for an overview of the diagnostic approach to renal disease. For dogs and cats suspected of having ureteral disease, the diagnostic evaluation should include history, physical examination, complete blood count, serum biochemistry profile, urinalysis, urine culture, and abdominal radiographs. Abdominal radiographs should include the entire urinary tract from the diaphragm to the caudal-most portion of the urethra. Abdominal ultrasonographic examination of the urogenital tract is a useful complement to abdominal radiographs when available to the practitioner.

Abdominal ultrasound examination of the urogenital tract (combined with abdominal radiographs and urethrocystoscopy) has largely replaced excretory urography for evaluation of the ureters. Contrast CT scans are also useful for evaluating ureteral disorders such as delineating the extent and location of ureteral strictures, ureteroliths, ureteral neoplasia, or extramural compressive lesions that obstruct the ureter. If ureteral obstruction is highly suspected on the basis of abdominal radiographs and ultrasound, then antegrade pyelography may be performed during interventional procedures such as placement of ureteral stent or subcutaneous ureteral bypass (see ch. 124), often eliminating the need for CT scan or other contrast studies such as excretory urography.[9]

Ureteroliths

Diagnosis of Ureteroliths

Ureteroliths result from migration of nephroliths or nephrolith fragments into the ureter. Similar to uroliths in other portions of the urinary tract, ureteroliths are diagnosed on the basis of results from radiography or ultrasonography. Radiopaque ureteroliths are often visualized in the retroperitoneal region on abdominal radiographs (Figure 329-1), but should be confirmed by other imaging modalities prior to any type of intervention. Some ureteroliths are radiolucent and some radiopaque ureteroliths are too small to be detected on abdominal radiographs. Ultrasonography is often useful for detection of ureteroliths or for detection of renal pelvic or ureteral dilation proximal to obstructive ureteroliths (Figure 329-2).[10,11] Direct visualization of the ureteroliths is often possible with ultrasonography (see Figure 329-2); however, in one study, ultrasonographic confirmation was not possible in 23% of cats with ureteroliths.[11] Although comparable information has not been published for dogs with ureteroliths, results are likely similar to results in cats. Ultrasound-guided nephropyelocentesis for antegrade pyelography via injection of contrast media into the renal pelvis is a minimally invasive option for documenting ureteral obstruction; however, the technique requires that the renal pelvis be sufficiently dilated to permit accurate needle puncture of the pelvis.[12] During nephropyelocentesis, urine is aspirated from the renal pelvis, and then iodinated contrast medium is injected into the pelvis in a volume approximately equal to one half the aspirated volume. Serial radiographs or fluoroscopy are used to monitor the passage of the contrast to document the severity and location of ureteral obstruction. Computed tomographic (CT) scans obtained before and after intravenous contrast administration may also be used for confirmation of the number and location of ureteroliths. Contrast-enhanced CT is preferred over nephropyelocentesis, especially if the renal pelvis is not sufficiently dilated. Advanced imaging such as CT is often not necessary prior to interventional procedures because antegrade pyelography is performed as the initial step in interventional procedures to document and treat ureteral obstruction (see ch. 124).[9]

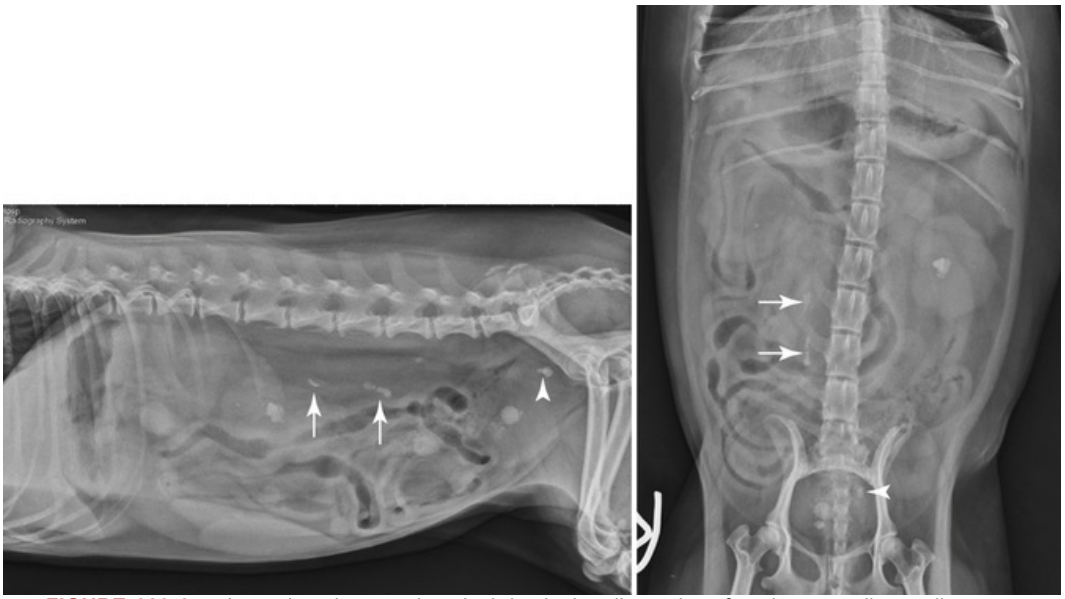

FIGURE 329-1 Lateral and ventrodorsal abdominal radiographs of a dog revealing radiopaque ureteroliths in the right ureter (arrows) and distal left ureter (arrowhead). A left nephrolith is also present and the margins of the left kidney are irregular. Ultrasonography revealed moderately severe dilatation of the right ureter and renal pelvis proximal to the ureteroliths. The distal left ureteroliths passed into the urinary bladder within 24 hours with IV fluid therapy.

FIGURE 329-2 Ultrasonographic image of two obstructive ureteroliths with mild fluid distention of the ureter proximal to the ureterolith. Note the acoustic shadow created by the ureteroliths.

Management of Ureteroliths

Removal of ureteroliths is more difficult than removal of uroliths from the lower urinary tract. Medical dissolution of ureteroliths is not an option without placement of a ureteral stent, because ureteroliths are not continually bathed in urine. In both dogs and cats, calcium oxalate is the most common composition of ureteroliths; therefore, most ureteroliths are not amenable to dissolution. Conservative medical management by serial monitoring of ureteroliths along with administration of intravenous fluids and diuretics (e.g., mannitol) has been recommended, provided there is minimal renal functional compromise and no infection, renal colic, or progressive ureteral dilation.[13-15] Typically, dogs and cats with evidence of complete obstruction by the ureterolith, worsening azotemia, or evidence of pyelonephritis should be treated by either minimally invasive procedures, open surgical intervention, or shock wave lithotripsy (SWL; in dogs only).[9,13,16-20] Because of several factors (size of the ureter, urolith susceptibility to SWL fragmentation, differences in urolith composition), the treatment approach for dogs and cats with ureteroliths is different for each species.

Spontaneous Passage of Ureteroliths

Size and location of the ureterolith may help determine if intervention is required. In humans, 68% of ureteroliths <5 mm in diameter and 47% of ureteroliths between 5 and 10 mm will pass spontaneously.[21] The majority of ureteroliths that pass spontaneously occur within 4-6 weeks. Most human ureteroliths >10 mm require intervention with SWL or ureteroscopic laser lithotripsy for removal.[21] It is difficult to apply these specific criteria to dogs and cats because of the wide variation in body weight and ureteral diameter, but the rate of spontaneous passage of ureteroliths appears to be much less in both dogs and cats than it is in humans. In an experimental study of artificial ureteroliths in Hound dogs, solid spheres 2.8 mm in diameter or larger became firmly impacted in the ureter; however, spheres 2.3 mm in diameter passed to the urinary bladder within 1 to 24 hours.[22] However, this study may not apply to smaller dogs with spontaneous ureteroliths because of their smaller ureteral diameter. Likewise, the normal cat ureteral luminal diameter of only 0.3-0.4 mm results in inability to pass even <1-2 mm ureteroliths in most cats. In one study of cats with ureteroliths, medical management for the treatment of cats with obstructive ureteroliths was only reported to be effective in 8-13% of cases.[13] Also, recent data indicate that over 20% of ureteroliths in cats are associated with concurrent ureteral strictures; therefore, success of medical management may be limited by concurrent strictures.[17]

Medical Expulsive Therapy

Medical expulsive therapy (MET) may have a role in management of obstructive ureteroliths. Suggested METs have included IV fluid administration with diuretics (e.g., mannitol), alpha-adrenergic antagonists, calcium channel-blocking agents (nifedipine), amitriptyline, and glucagon. In humans, the criteria for utilization of MET versus interventional procedures include adequate well-controlled pain during MET, no evidence of sepsis, and adequate renal reserve.[21] The medical therapy for MET in dogs and cats that most agree on is IV fluid administration with diuretics to increase urine flow to facilitate ureterolith passage with serial monitoring of the ureterolith position by radiographs and ultrasonography, along with administration of the alpha-adrenergic antagonist prazosin.[23,24]

In humans, if a ureterolith remains in the same location for 2 weeks, progressive enlargement of the ureter or renal pelvis is observed, pain cannot be effectively managed, or renal function is impaired by the obstruction, interventional techniques are recommended over MET,[21] and this information can also be applied to dogs and cats with ureteroliths. If an animal is monitored for 2 weeks and the ureterolith is not moving distally despite MET, some type of intervention should be considered. In dogs and cats, the ureteroliths may also spontaneously move retrograde back into the renal pelvis rather than passing distally towards the urinary bladder.[25]

In humans, meta-analysis of multiple clinical studies confirmed that alpha-adrenergic antagonists facilitate passage of ureteral calculi more effectively than other medications do. The alpha-adrenergic antagonist tamsulosin showed a 29% increase in the rate of successful ureterolith passage compared to control patients.[21] In dogs and cats, use of the alpha-adrenergic antagonist prazosin has been suggested for MET as an alternative to tamsulosin, but clinical studies of efficacy of MET are lacking in these species.[24] Overall success in MET in cats is low and concurrent ureteral strictures are often present; therefore, MET should only be considered for a limited time (usually 24-48 hours) and only for cats without evidence of oliguria, severe azotemia, severe hydronephrosis, sepsis, overhydration, or hyperkalemia. In dogs and cats, non-obstructive

ureteroliths (renal pelvis < 4-5 mm) that are not associated with infection or azotemia may be managed conservatively using MET for 1-2 weeks provided renal function is stable. However, frequent monitoring for complications such as progressive enlargement of the ureter or renal pelvis, progressive azotemia, oliguria, and evidence of urinary tract infection (UTI) or sepsis, is required to prevent the potential of permanent loss of renal function of the affected kidney.

Although there are anecdotal clinical reports that glucagon facilitates passage of ureteral calculi in cats, the only clinical study of glucagon administration in cats did not demonstrate any benefits for management of obstructive ureteroliths and an unacceptably high incidence of side-effects occurred.[26] Given the unacceptable number of side-effects and lack of documented efficacy, glucagon administration is not recommended for dogs and cats with ureteroliths.

In one report, amitriptyline facilitated passage of urethral plugs in male cats with urethral obstruction.[27] Although the article title implies urethral calculi, the cats in the report all appeared to have urethral *plugs* rather than actual *uroliths.* There are no clinical reports supporting the use of amitriptyline for expulsive therapy of ureteroliths in any species; therefore, its use for this purpose is also discouraged.

Management of Struvite Ureteroliths in Dogs

While the vast majority of upper tract uroliths in cats are calcium oxalate, infection-induced struvite nephroliths and ureteroliths are the second most common type of urolith in the upper tract of dogs. Clinical findings that would support struvite nephro-ureteroliths include UTI with urease-producing organisms *(Staphylococcus, Proteus, Klebsiella, Corynebacterium* and *Mycoplasma),* alkaline urine pH, moderately radiopaque uroliths in the renal pelvis or ureter, and struvite crystalluria. While struvite uroliths in the kidney and bladder may be medically dissolved in dogs, obstruction of the ureter by the ureteroliths prevents effective medical dissolution and causes obstructive pyonephrosis, which frequently leads to urosepsis.[28] In dogs with obstructive struvite ureteroliths, the obstruction must be corrected prior to attempts at medical dissolution.[28] In humans, the recommended treatment for pyonephrosis involves emergency drainage of the infected urine along with ureteral stent placement.[21] In a recent report in dogs, obstructive pyonephrosis was successfully managed by a minimally invasive approach of retrograde lavage of the renal pelvis using an open-ended ureteral catheter combined with cystoscopic-guided ureteral stent placement.[28] Both fluoroscopy and cystoscopy are required for this approach (see ch. 124). Once the initial pyonephrosis crisis is effectively managed by drainage, ureteral stent placement and IV antibiotic therapy, then medical dissolution of the ureterolith is possible using a combination of antimicrobial therapy of the UTI (guided by urine culture results) and struvite dissolution diets such as Royal Canin Urinary SO diet, Hill's Prescription diet s/d or c/d Multicare, or Purina Veterinary diet UR Urinary Ox/St Canine diet (see ch. 331 and 332). Medical dissolution of struvite ureteroliths should not be attempted without concurrent ureteral stent placement because of the risk of obstruction, treatment failure, and sepsis. The diet and antibiotics should be continued until radiographs and ultrasound document complete dissolution of the uroliths. The author's preference is to remove the ureteral stent by cystoscopic retrieval or to consider ureteral stent exchange prior to discontinuing the antibiotics.

Interventions for Ureteroliths

If dogs and cats with obstructive ureteroliths require intervention, options include ureteral stent placement, shock-wave lithotripsy (SWL), ureterotomy to remove ureteroliths, transection of the ureter and reimplantation of the proximal ureter into the bladder (ureteroneocystostomy), and subcutaneous ureteral bypass (SUB) placement. The relative success rates, indications and complications of these techniques vary by species (see ch. 124).

Ureteral Stents

Resolution of ureteral obstruction by ureteroliths is possible by placement of ureteral stents via surgery or cystoscopy to divert the urine through the stent around the ureteral obstruction. In dogs, ureteral stents may be placed retrograde up the ureter over a urologic guidewire via cystoscopy (Figure 329-3).[9,24,28] In cats, ureteral stent placement usually requires surgery for antegrade stent placement through nephropyelocentesis, and stent placement is much more difficult compared to dogs.[17] Stents may be used temporarily or left in place long-term. In dogs and female cats, if the ureteral stent is no longer needed to bypass the ureteral obstruction, the stent can be easily extracted via cystoscopy by grasping the distal end of the ureteral stent and providing gentle traction to withdraw the stent through the ureter and urethra. In cats, ureteral stents are

usually left in the ureter long-term, although periodic stent exchange may be required in approximately 20-25% of cats.[17] Indwelling stents may develop mineral encrustation on both outside and inside the stent, resulting in occlusion of the ureter and necessitating stent removal or exchange for a new stent (Figure 329-4).[16]

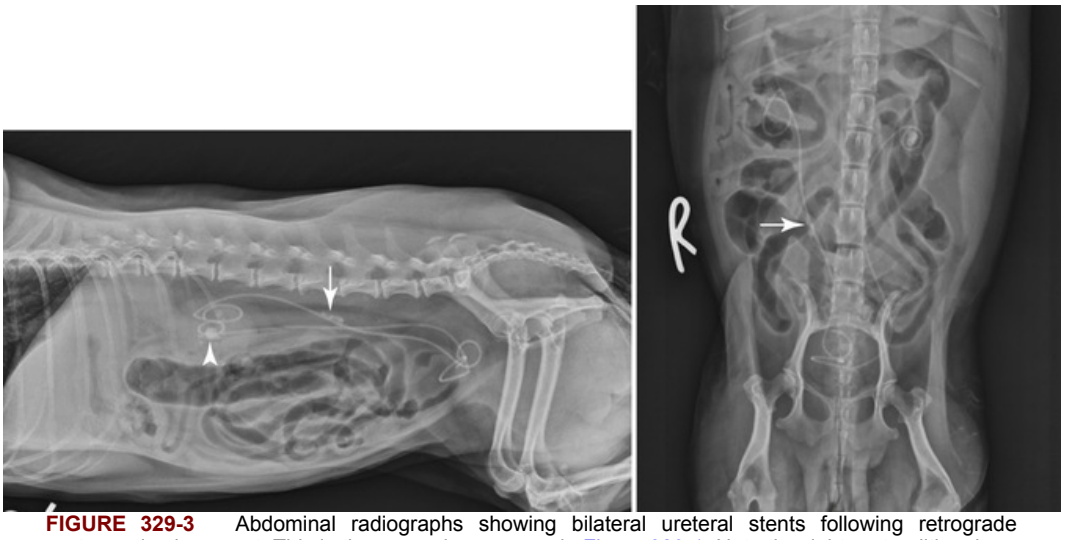

FIGURE 329-3 Abdominal radiographs showing bilateral ureteral stents following retrograde cystoscopic placement. This is the same dog as seen in Figure 329-1. Note the right ureteroliths along the outside of the right ureteral stent (arrow) and the left nephrolith (arrowhead). The dog was subsequently treated using shock-wave lithotripsy to fragment the nephrolith and ureteroliths, and then the stents and urolith fragments were removed by cystoscopy.

FIGURE 329-4 Ureteral stent removed from a dog because of encrustation with calcium oxalate deposits, which are visible on the outside of the stent. Mineral deposits inside the stent resulted in partial obstruction of the stent, requiring stent exchange.

Subcutaneous Ureteral Bypass (SUB) Devices

Surgical placement of a SUB device to provide a route for urine to bypass the obstructed ureter is a relatively new procedure. This technique has rapidly become one of the preferred options for management of ureteroliths and ureteral strictures in cats.[9] Compared to traditional ureteral surgery, SUB placement has a much lower perioperative mortality rate with 94% of cats having survived to discharge following SUB placement.[9] Long-term prognosis for cats with ureteral stents and SUBs correlates to the stage of residual CKD following relief of ureteral obstructions, with cats having stage 1-2 CKD surviving significantly longer than cats with stage 3-4 CKD.[20] See ch. 124 and references for details of interventional urology procedures such as ureteral stent and SUB placement.[9,17,19,24]

Ureteral Surgery

Open surgical ureterotomy is one option for management of ureteroliths in dogs and cats.[13,29] In the author's opinion, ureterotomy or ureteroneocystostomy are only appropriate for dogs and cats with single ureterolith without concurrent nephroliths or ureteral stricture (ureterotomy). Ureteral surgery may result in temporary obstruction of the ureteral lumen postoperatively because of mucosal swelling at the ureterotomy site; therefore, diversion of urine by a ureteral stent placement (see above) may be considered to assist with management of ureteral obstruction.[13,17,29] Because ureterotomy and ureteroneocystostomy have higher mortality and surgical complication rates than SWL and ureteral stent or SUB placement, the author prefers these minimally invasive alternatives to ureterotomy or ureteroneocystostomy.[9,13,17,19,20,29]

Shock Wave Lithotripsy for Ureteroliths

Shock wave lithotripsy is a minimally invasive option for fragmentation and removal of nephroliths and ureteroliths in dogs, but not cats.[16,30-32] In SWL, uroliths are fragmented using shock waves that are generated outside the body and targeted at the uroliths using integrated fluoroscopy or ultrasonography (see ch. 124). Approximately 80% of ureteroliths in dogs can be resolved by SWL although approximately 50% of dogs require 2 or more SWL treatments, which is a higher re-treatment rate than in dogs with nephroliths.[16,32] This is similar to observations in humans and in research models that confirm impacted ureteroliths are more difficult to fragment compared with nephroliths.[33,34] This difficulty in fragmenting ureteroliths compared to nephroliths appears to be due to the inability of cavitation bubbles to form and collapse on the surface of the ureterolith if it is surrounded by the ureteral wall rather than urine.[35,36] The advantages of SWL include that the procedure is non-invasive and complications occur in fewer than 10% of dogs, with transient ureteral obstruction by urolith fragments being the most common complication.[16,32]

Placement of ureteral stents is not essential for treatment of ureteroliths by SWL, but there are advantages of ureteral stents that facilitate SWL efficiency and patient management. Ureteral stents allow urine to bypass ureteral obstruction at the site of the ureterolith immediately and prevent additional renal damage from obstructive uropathy (see Figure 329-3). Because ureteral stents are radiopaque, they facilitate accurate targeting of ureteroliths during SWL. Ureteral stents also induce passive ureteral dilation, thus increasing the diameter of the ureter lumen by approximately 3-fold.[37] Although this has the theoretical advantage of increasing the efficiency of urolith fragmentation, ureteral stent placement is not recommended for SWL treatment of ureteroliths in humans.[30] Nonetheless, ureteral stents may be more beneficial with SWL in dogs compared to humans due to their smaller ureteral diameter. Passive dilation of the ureter also facilitates passage of nephrolith and ureterolith fragments following ureteral stent removal. Placement of a ureteral stent may also be used to prevent ureteral obstruction by ureterolith fragments following SWL treatment of larger nephroliths or ureteroliths in dogs (see Figure 329-3).[16]

Unlike dogs, SWL is *not* effective for fragmentation and removal of ureteroliths in cats.[16,32] Because of the small ureteral diameter in cats, even <1-mm fragments fail to pass down the ureter in cats, and in other species, SWL typically results in urolith fragments of 1-2 mm or larger. In addition to the smaller ureteral diameter, feline calcium oxalate uroliths are resistant to fragmentation compared to calcium oxalate uroliths from dogs.[38] In clinically normal research cats, kidney damage and reduced renal function were routinely

observed after less than 50% of the normal therapeutic shock-wave "dose" used in dogs for SWL.[32] In combination, all of these factors result in the recommendation that SWL should *not* be used for treatment of nephroliths or ureteroliths in cats.

Ureteral Obstruction

Clinical signs of ureteral obstruction may not be apparent unless bilateral obstruction or unilateral obstruction in combination with decreased function of the contralateral kidney occurs. Clinical signs of ureteral obstruction include abdominal pain or so-called ureteral colic (less consistently observed than in humans with ureteral obstruction), dysuria (especially with distal ureteral obstruction in cats), and signs of renal functional impairment such as anorexia, vomiting, and oliguria. Patients with complete, bilateral ureteral obstruction show signs of severe oliguric renal failure. Complete bilateral ureteral obstruction may be fatal within 48-72 hours. Many ureteral obstructions are partial, especially those associated with ureteroliths.

Ureteral obstruction may occur from intraluminal, intramural, or extramural causes. Intraluminal obstruction may occur as a result of ureteroliths, blood clots or other intraluminal debris. Intramural causes include ureteral stricture, ureteral stenosis, mucosal edema, and neoplasia. Extramural compression may occur from circumcaval ureters, retroperitoneal masses, retroperitoneal fibrosis, bladder neoplasia, or from accidental surgical ligation of the ureter during ovariohysterectomy. Circumcaval ureter (or retrocaval ureter) is a congenital anomaly characterized by ventral displacement (or duplication) of the caudal vena cava, which crosses over the ureter resulting in potential compression of the proximal ureter as it passes behind the vena cava. The right ureter is affected more often than the left ureter. In one recent study, circumcaval ureters were present in approximately 1/3 of cat cadavers and were not associated with obvious obstruction of the ureters.[39] However, in clinical reports of cats with ureteral obstructions, circumcaval ureters appeared to be associated with ureteral stricture formation just proximal to the location that the vena cava crossed the ureter.[40,41] The difference in these two reports may be that the presence of circumcaval ureters combined with even small ureteroliths may result in ureteral stricture formation. The clinical signs and outcomes of cats with obstruction associated with circumcaval ureters are similar to other causes of ureteral obstruction.[40] Ureteral strictures associated with circumcaval ureters may be more effectively managed by SUB placement compared to surgery or ureteral stent placement.[17,40] In humans, ureteral stenosis at the ureteropelvic junction (UPJ) is a commonly recognized disorder. Ureteral stenosis at the UPJ was recently reported in one dog.[42] The dog was successfully managed by retrograde cystoscopic ureteral stent placement. UPJ stenosis has also been reported in an adult cat resulting in severe renal failure from end-stage hydronephrosis.[43] Retroperitoneal fibrosis leading to extramural ureteral obstruction was reported in 29 of 138 (21%) of feline renal transplant recipients.[44] All 29 cats had azotemia from obstructive uropathy secondary to the retroperitoneal fibrosis. Surgery was performed to relieve the ureteral obstruction in 25 of the 29 cats, and recurrence of ureteral obstruction occurred in 6 cats (22%).[44]

The most common neoplasm resulting in ureteral obstruction in dogs is transitional cell carcinoma located in the trigone of the urinary bladder (see ch. 351). Metastatic neoplasia may also result in ureteral obstruction. Malignant ureteral obstructions can be bypassed using palliative ureteral stent placement.[45] Because it is difficult to identify the ureteral orifice via cystoscopy in dogs with extensive trigonal neoplasia, ureteral stents in these patients must be placed either percutaneous antegrade through nephropyelocentesis or via open surgery (see ch. 124).[45]

Primary ureteral neoplasia is rare in dogs and cats. Types of primary ureteral neoplasia include transitional cell carcinoma, leiomyoma, leiomyosarcoma, sarcoma, mast cell tumor, benign papillomas, and fibroepithelial polyp.[46-52] Fibroepithelial polyps are the most common type of primary ureteral neoplasia in dogs.[47,48] Ureteronephrectomy has been the most commonly reported treatment for unilateral ureteral neoplasia, but SUB or ureteral stent placement may be possible alternatives in some cases.[47,48]

Ureteral Trauma

Trauma to the ureters has rarely been reported in dogs and cats.[53,54] Ureteral injury can result from blunt abdominal trauma, penetrating wounds, or iatrogenic damage during surgery such as inadvertent ligation or transection of the ureter during ovariohysterectomy. Ureteral injury resulting from blunt trauma accounted for only 0.01% of canine hospital admissions in a one report.[53]

Rupture of the ureter results in accumulation of urine in the retroperitoneal space, post-renal azotemia,

hyperkalemia and metabolic acidosis. If the contralateral kidney and ureter are functioning normally, recognition of ureteral rupture may be delayed for several days. If the ureter ruptures near the ureterovesicular junction or if the retroperitoneum is disrupted by the trauma, uroabdomen may also occur. Ureteral rupture may also occur as an uncommon complication of ureteroliths.

The extent and location of ureteral injury and function of the contralateral kidney determine treatment of ureteral injury. Ureteronephrectomy has been reported as the most common treatment for unilateral ureteral rupture provided that the contralateral kidney and ureter are functioning normally.[53] For dogs with distal ureteral trauma, implantation of the healthy portion of the ureter above the damaged area (ureteroneocystostomy) is an alternative to ureteronephrectomy.[54] For incomplete tears of the ureter (<50% of the circumference), conservative management via urine diversion often allows for healing of the ureteral lesion. Ureteral stent placement via cystoscopy or surgery is a minimally invasive option for urinary diversion to allow for healing of partial ureteral tears (see ch. 124).

An uncommon consequence of ureteral trauma is formation of a paraureteral pseudocyst, or urinoma, which forms when urine that has leaked from a ureter into the retroperitoneum becomes encapsulated in a thick, fibrous wall.[55-57] Inadvertent ureteral transection during ovariohysterectomy was the cause of urinoma in a dog.[58] Ureteronephrectomy may be required for treatment of urinoma provided the contralateral kidney has normal function.

Anatomic Abnormalities

Congenital Ureteral Abnormalities

Congenital ureteral abnormalities include ectopic ureters, ureteroceles, ureterovesicular junction (UVJ) stenosis, ureteral agenesis and ureteral duplication. Ureteral agenesis and ureteral duplication are rare in dogs and cats.[59-61] Ureteral agenesis results from failure of development of the ureteral bud and may be complete or segmental. Ureteral agenesis is commonly associated with contralateral renal agenesis, because the ureteral bud induces the embryonic metanephric kidney to proliferate and differentiate.[60] Ureteral duplication occurs when more than one ureteral bud develops from the same mesonephric duct or from division of the ureteral bud.[59] Ureteral duplication may be associated with a duplex kidney and with ureteral ectopia.[59,61] Congenital UVJ stenosis was reported in 10 dogs; in 7 dogs the UVJ stenosis was associated with an ectopic ureteral opening.[62] Stenosis of the UVJ causes partial distal ureteral obstruction (Figure 329-5, *C*). The UVJ stenosis was corrected successfully by cystoscopic-guided laser ablation in all 10 dogs.[62]

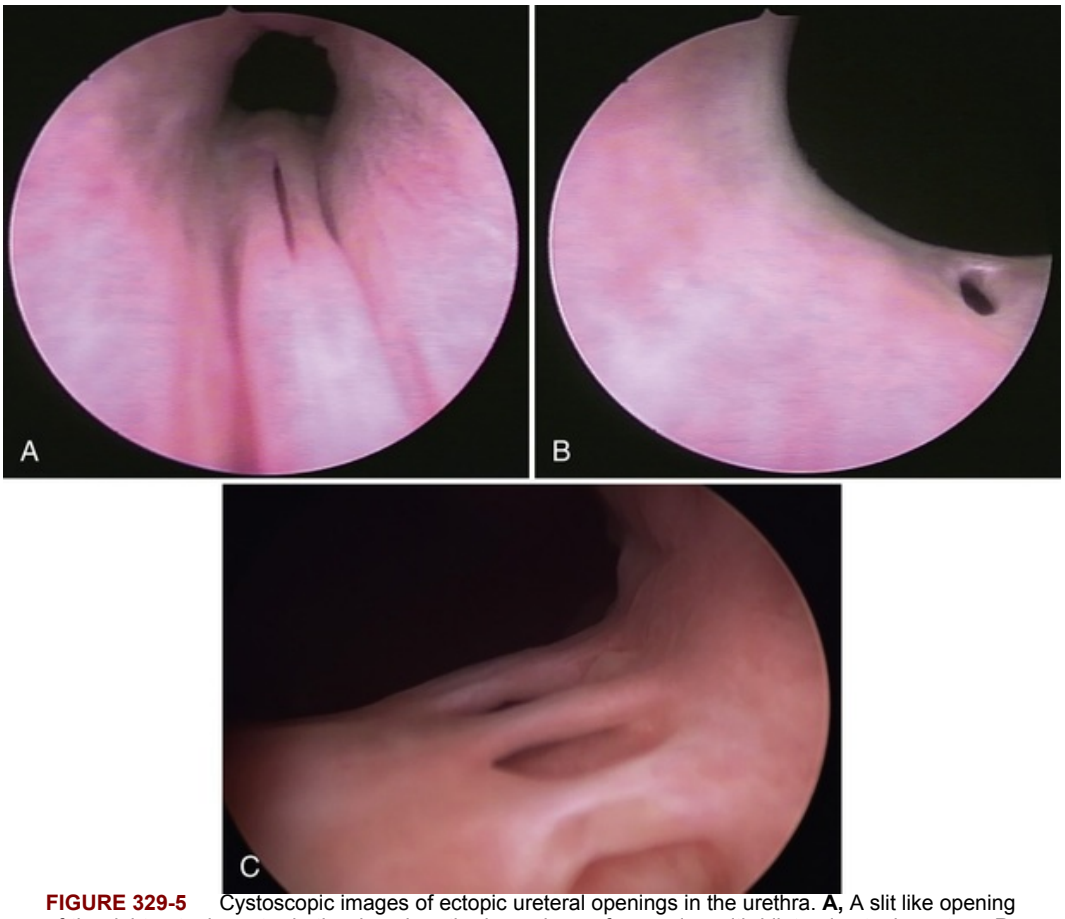

FIGURE 329-5 Cystoscopic images of ectopic ureteral openings in the urethra. **A,** A slit like opening of the right ectopic ureter in the dorsal urethral membrane from a dog with bilateral ectopic ureters. **B,** Stenotic opening of the left ectopic ureter in proximal urethra just distal to junction of the bladder and urethra (same dog as Figure 329-5, *A*). **C,** Multiple openings of an ectopic ureter in the proximal urethra of another dog.

Ectopic Ureters

Ectopic ureters are defined as ureteral openings located anywhere distal to the normal trigonal location (see ch. 336).[63] Ectopic ureters may be unilateral or bilateral and extramural or intramural. Extramural ectopic ureters bypass the urinary bladder entirely and insert at a distal location. Intramural ectopic ureters enter the serosal surface of bladder in a normal dorsolateral location; however, instead of opening in the trigone, the ureter tunnels through the submucosa of the bladder and urethra and opens in the bladder neck distal to the normal trigonal location, urethra, or vaginal vestibule. Variations of the configuration of intramural ectopic ureters include double ureteral openings, multiple fenestrated openings, two intramural ureters opening in a single orifice, and ureteral troughs (see Figure 329-5). Ectopic ureters commonly are associated with other abnormalities of the urogenital tract, including renal agenesis, renal hypoplasia, irregular shape of the kidneys, hydroureter, ureterocele, UVJ stenosis, urachal remnants, pelvic bladder, urethral abnormalities, and paramesonephric septal remnant.[62-68] Breeds reported to be at greater risk for ectopic ureters include the Siberian Husky, Labrador Retriever, Golden Retriever, Newfoundland, English Bulldog, West Highland White Terrier, Fox Terrier, Skye Terrier, Border Terrier, Griffon, Entlebucher Mountain Dog, and Miniature and Toy Poodle.[68-70] Female dogs are much more commonly affected by ectopic ureters than male dogs. Ectopic ureters are less common in cats compared to dogs. During cystoscopy or excretory urography, the ureteral openings in normal cats appear to be located in the proximal urethra and this normal anatomic location should not be confused as ectopic ureters.

While the diagnosis of ectopic ureters was historically made by excretory urography, where available, cystoscopy has become the preferred method of diagnosis (see Figure 329-5). Ultrasonography has also been advocated as a diagnostic option for detection of ectopic ureters; however, ultrasonography does not accurately detect all ectopic ureters.[71] Studies have compared the diagnostic accuracy of excretory urography,

contrast enhanced CT scans and cystoscopy for detection of ectopic ureters.[63,72] Contrast enhanced CT scans and cystoscopy were the most accurate diagnostic methods for detection of ectopic ureters.[63,72] Cystoscopy has the additional advantage that intramural ectopic ureters may be diagnosed and corrected by cystoscopic-laser ablation during the same anesthetic procedure.[73-75]

Laser ablation of the wall between the urethral lumen and the intramural ureteral lumen effectively moves the ureteral opening to the bladder lumen without open surgery (see ch. 108 and 124). Cystoscopic-guided laser ablation of intramural ectopic ureters may be performed using a holmium : YAG or diode laser.[73-75] Results appear to be similar to surgical results for correction of ectopic ureters, although there are no published studies directly comparing outcomes of surgical correction and laser ablation. Dogs with good urethral function are continent after laser correction of ectopic ureters, whereas dog with concurrent urethral incompetence continue to have urinary incontinence unless treatment of the concurrent urethral incompetence is effective.[73-75] Extramural ectopic ureters cannot be corrected by laser ablation and require surgical transection and re-implantation into the urinary bladder.

Ureterocele

A ureterocele is a cystic dilatation of the terminal portion of the ureter, which often protrudes into the bladder lumen (see ch. 336).[76-80] Ureteroceles are classified as either orthotopic (also called intravesical) if the ureter opening is in a normal trigonal location, or ectopic if the ureter opening is distal to the normal trigonal position. Ureteroceles may cause a variety of clinical signs depending on their size and whether or not the ureter is ectopic. Urinary incontinence is the most common clinical sign of ureteroceles.[76,77] Ureteroceles may place pressure on the bladder and proximal urethra, resulting in functional urinary retention or they may cause signs of dysuria, stranguria and pollakiuria. Dogs with ureteroceles may also present for recurrent UTI. Although ureteroceles are congenital abnormalities, some dogs with ureteroceles do not develop clinical signs until later in life.[76] Ureteroceles may be associated with developmental or acquired abnormalities of the upper or LUT including moderate to severe hydroureter and hydronephrosis, ectopic ureters, and urethral anomalies. Ureteroceles are diagnosed by excretory urography, cystoscopy or ultrasonography.

Treatment of ureteroceles depends on the type and extent of concurrent anomalies and whether or not the ureteral opening is ectopic. Surgical excision of the ureterocele with re-implantation of the ureter has been recommended for ectopic ureteroceles or ureteroceles associated with ureteral obstruction.[76,80] The author has successfully treated intramural ectopic ureteroceles via cystoscopic-guided laser ablation in 4 female dogs, thereby avoiding open surgery. Orthotopic ureteroceles may also be incised cystoscopically using a laser or by cystotomy; however, this often results in vesicoureteral reflux, which could contribute to pyelonephritis if UTI is also present. Effective control of UTI is therefore recommended prior to correction of ureteroceles.

Urethrorectal or Ureterovaginal Fistula

Fistulas between the urethra and the rectum or between the ureter and vagina are uncommon conditions in dogs that may be congenital or acquired (see ch. 336).[81-86] Ureterovaginal fistulas usually form as a result of ovariohysterectomy when the ureter is accidentally included in a ligature around the vaginal stump. Urethrorectal fistulas may be congenital or may be acquired after pelvic trauma. English Bulldogs are the most commonly affected breed with congenital urethrorectal fistulas.[85,86] Clinical signs of urethrorectal fistulas include passing of urine from the anus during voiding and most commonly recurrent UTI.[85,86] Urinary incontinence is the most common clinical sign of ureterovaginal fistulas in dogs.[81,82] Surgical correction of urethrorectal or ureterovaginal fistulas is recommended; however, surgical correction of urethrorectal fistulas may be difficult due to intrapelvic location and concurrent UTI. Resolution of secondary UTI is essential following surgical correction of urethrorectal fistulas and may require prolonged antimicrobial therapy.

CHAPTER 330

Lower Urinary Tract Infections

Michael W. Wood

Client Information Sheet: Recurrent Lower Urinary Tract Infections

Introduction

The development of urinary tract infection (UTI) is multifactorial, being dependent on the interplay between the virulence of an organism and alterations in anatomic, environmental, and immunologic competency of the host. Most commonly, the microbes are uropathogenic bacteria that originate from the enteric flora and ascend from the distal urogenital tract into the proximal urethra and urinary bladder.[1-3] For many dogs with normal urinary defenses, invading bacteria are cleared within 3 days without the need for antibiotic therapy.[4] It is those with compromised defenses that are at increased risk for colonization and persistent bacteriuria (Box 330-1).

Box 330-1

Natural and Acquired Host Defenses of the Lower Urinary Tract

- Normal micturition
  - Adequate urine volume
  - Frequent voiding
  - Complete voiding
  - Urinary continence
- Anatomic structures
  - Urethral high-pressure zones
  - Surface characteristics of urothelium
  - Urethral peristalsis
  - Prostatic secretions (antibacterial fraction and immunoglobulins)
  - Length of urethra
  - Ureterovesical flap valves
  - Ureteral peristalsis
- Mucosal defense barriers
  - Antibody production
  - Surface layer of glycosaminoglycans
  - Intrinsic mucosal antimicrobial properties
  - Exfoliation of urothelial cells
  - Bacterial interference by commensal microbes of distal urogenital tract
  - Mucosal innate immunity: toll-like receptors, etc.
- Antimicrobial properties of urine
  - Extreme high and low of urine pH
  - Hyperosmolality
  - High concentration of urea
  - Organic acids
  - Low-molecular-weight carbohydrates
  - Tamm-Horsfall mucoproteins
  - Host defense peptides (e.g., defensins)

Systemic immunocompetence
  Cell-mediated immunity
  Humoral-mediated immunity

Adapted from Osborne CA, Lees GE: Bacterial infections of the canine and feline urinary tract. In Osborne CA, Finco DR, editors: *Canine and feline nephrology and urology*, Baltimore, 1995, Williams & Wilkins, pp 759-797.

Other organisms like fungi account for UTI in ≈1% of dogs and cats and will not be discussed in this chapter. Please refer to the 7th edition of this textbook, ch. 313 (Urinary Tract Infections) by Barrak Pressler for a review of nonbacterial UTI.

Characteristics of Infection

Asymptomatic Bacteriuria

Traditional UTI definitions require invading organisms to adhere, multiply, and persist within the urinary tract.[5,6] Based on recent observations in human and veterinary medicine, microbiologic documentation of bacteriuria is not equivalent to diagnosing a UTI. Not all bacteriuria is associated with clinical signs of lower urinary tract (LUT) infection such as caudal abdominal pain, pollakiuria, stranguria, hematuria, and dysuria. In human medicine, persistently bacteriuric individuals lacking LUT clinical signs are termed as having asymptomatic bacteriuria (ASB).[7] In dogs and cats, recognizing subtle signs of UTI is challenging and the term subclinical bacteriuria (SCB) may be more appropriate.[8]

In people, the treatment of ASB is not recommended in many circumstances because eradication of ASB does not prevent future urinary bladder re-colonization[9] and the presence of ASB strains is hypothesized to convey a degree of protection against urinary tract colonization with more virulent bacteria.[10] Evidence demonstrating the benefit of ASB in veterinary medicine is lacking; however, in limited veterinary studies, the prevalence of ASB has been reported to be 2.1-8.9% in dogs[11, 12] and 10-28.8% in cats,[13,14] with *E. coli* and *Enterococcus faecalis* being the most common bacteria identified.[11-13]

Fitness and Virulence Factor Roles in Infection

Whether bladder colonization causes clinical disease ultimately depends on bacterial gene expression. Bacteria contain genomic islands encoding fitness factors that promote commensalism and/or virulence factors and dictate the severity of the UTI. The amount of genetic material a bacterium can contain is limited; therefore, bacteria typically evolve by increasing fitness or virulence.[15] Hence, bacteria with high fitness, such as multiple antibiotic resistance genes, are commonly found in chronic infections that also have decreased virulence potential.[16]

Fitness and virulence genes have tremendous plasticity, and bacteria constantly adapt to changes within their microenvironment.[17] Bacteria respond to changes in nutrient availability, osmolarity, and host defenses by obtaining genetic material via horizontal gene transfer, mutating existing genes, and altering expression of virulence and antivirulence genes.[18] Many ASB strains contain unexpressed virulence genes; therefore, the current bacterial phenotype is not necessarily predictive of future pathogenicity, particularly if the urinary bladder environment is in flux.[15,19] Certain genes are more important predictors of virulence than others, including genes that encode the production of toxins such as hemolysin or the expression of urothelial adherence pili.[20]

Bacterial adhesion molecules each have different affinities for areas of the urinary tract. In uropathogenic *E. coli* (UPEC), type 1 fimbriae, encoded by *fim* genes, bind mannose targets on the urothelium[21] and are expressed by nearly 100% of bacteria that cause pyelonephritis and cystitis and 77% of ASB strains.[22] Clinically, the presence of type 1 fimbriae usually is associated with an increased severity of infection[23] and they are commonly found on the surface of UPEC during initial colonization of the urinary bladder.[24] In contrast, P fimbriae encoded by *pap* genes bind to alpha-D-galactopyranosyl-(1-4)-beta-D-galactopyranoside receptors located in the upper urinary tract.[25] These adhesion molecules are found in 78% of pyelonephritis strains, 22% of cystitis strains, and only 15% of asymptomatic strains.[22] Among other uropathogens it is largely the Gram-negative organisms that express similar adhesion molecules with high affinity for kidney

tissue[26] and hence organisms such as *Streptococcus* spp. and *Enterococcus* spp. often are not associated with pyelonephritis.[27]

Diagnosing Urinary Tract Infection

Identifying Bacteriuria

Aerobic culture remains the gold standard for identifying bacteriuria. Quantitative urine culture identifies the specific infecting organism and colony count, both of which are important when considering the bacteriuria's clinical importance. Urine culture also provides information for identifying persistent infections and reinfections, and may provide some clues as to which therapeutics may be effective based on the organism isolated. Urine culture will not distinguish between ASB and UTI; however, urine sediment examination can provide evidence of inflammation, making it useful for these two diagnostic tests to be run in parallel (see ch. 72).

When interpreting the results of urine culture and sediment examination, sample collection and storage must be considered. Both diagnostic tests are affected by time to processing, storage temperature, and storage media. Red and white blood cells as well as casts can be destroyed in hypotonic or alkaline urine left at room temperature after only a few hours. Bacteria can begin to proliferate or die if urine samples are left unrefrigerated, yielding false positive or false negative results.[28] Urine sediment examination and culture should be performed within 30 minutes of collection to reduce these confounding variables. If diagnostics must be delayed, samples should be refrigerated at 4°C and testing performed within 24 hours.[28] Alternatively, if urine culture submission is contingent on pending diagnostics, storing urine in a preservative or reducing media vial such as a Port-a-cul (BD Biosciences) or Amies transport media can extend the time that bacteria will be viable for up to 72 hours without allowing for bacterial proliferation.[29,30]

Urine sediment examination can detect bacteriuria in some instances. Rod-shaped bacteria are readily detected when colony counts exceed 10,000 colony-forming units (cfu)/mL while cocci are largely undetectable until cfu/mL reach 100,000.[31] Overall, the sensitivity and specificity for detecting bacteriuria in unstained urine sediment are 75.9% and 56.7%, respectively.[32] Bacteriuria detection can be improved by staining the sediment with new methylene blue, Gram stain, or modified Wright stain, increasing the sensitivity of bacteriuria detection to ≥83% and specificity to ≥98%.[32-35] A catalase-based point-of-care urine test such as the Accutest Uriscreen (Jant Pharmaceuticals Co) can also improve the sensitivity of bacteriuria detection to 89%; however, cross reactivity of bacteria with somatic cells such as white blood cells (WBC) and epithelial cells decreases the assay specificity to 71%.[36] Catalase-negative bacteria such as *Enterococcus* spp. and *Streptococcus* spp. may also be difficult to detect. See ch. 72 for more information.

Epidemiology of Bacteriuria

The growth of most uropathogens on culture media will be apparent within 18-24 hours of incubation; however, some organisms such as *Corynebacterium* spp. and *Mycoplasma* spp. can take 4 to 7 days, respectively. Gram-negative bacteria are most commonly isolated in dogs, comprising >60% of positive cultures. Overall, *E. coli* is isolated from 45-55% of bacteriuric dogs while other Gram-negative organisms including *Proteus* spp., *Pseudomonas aeruginosa,* and *Klebsiella* spp., and the Gram-positive bacteria *Staphylococcus* spp., *Streptococcus* spp., and *Enterococcus* spp. are each cultured between 2-14% of the time.[37,38]

In cats, *E. coli* also is the most common cause of bacteriuria (37.3%) but Gram-negative and Gram-positive infections each occur roughly half the time, with Gram-positive *Enterococcus faecalis* present in 27% of culture-positive urine samples.[39] Overall, the incidence of bacteriuria is much lower in cats than in dogs, but in both species females and older animals are more commonly affected.[32,37,39]

Significant Bacteriuria

Upon detecting bacteriuria via urine culture or urine sediment examination, a clinician must differentiate urine contamination from colonization. In female dogs, the normal vaginal flora can harbor many uropathogenic bacterial strains. Gram-positive organisms such as *Enterococcus* spp., *Staphylococcus* spp., and *Streptococcus* spp. predominate, but *E. coli, Proteus* spp., and *Pasteurella* spp. also are common, making it essential to consider the urine collection method and colony count before diagnosing clinically significant bacteriuria.[40-42]

When significant bacteriuria is detected, finding concurrent pyuria (>3-5 WBC/high-power field) in the urine of cats or dogs is suggestive of infection even in the absence of clinical signs.[31] This is not true in people, where ASB can associated with pyuria.[7] Given the difficulty in detecting subtle clinical signs in dogs and cats, the veterinary definition for UTI errs on the side of overdiagnosis so that subtle pathogenic infections are not overlooked. Occasionally, such as in the immunocompromised individual, a virulent pathogen might colonize the urinary tract without causing clinical signs or an obvious inflammatory response (see ch. 306).[43] In these instances, the clinician must rely on his/her knowledge of the organism present to determine whether intervention is necessary.

Treatment of Urinary Tract Infection

Upon diagnosing true UTI, the use of antimicrobials remains the standard therapy. Treatment plans will vary depending on previous UTI history, concurrent diseases, neutering status, and species. However, broadly speaking, treatment strategies for UTI fall into two large categories: the treatment of uncomplicated UTI and the treatment of complicated UTI.

Uncomplicated UTI

An uncomplicated UTI, also known as a simple UTI, is defined as a bladder infection that occurs no more than once every 6 months in an otherwise healthy dog with normal urinary tract anatomy and function. Cats and intact male dogs are an exception. Infections in these patients should be considered complicated, as intact male dogs can have concurrent prostatitis and infection in cats commonly is associated with a concurrent systemic disease.[44-46]

Uncomplicated infections often are associated with severe lower urinary tract signs of dysuria, pollakiuria, and stranguria, and require therapy while awaiting urine culture results. When choosing an antibiotic for an infection of unknown bacterial susceptibility, selection should be made with consideration of local community resistance patterns, attainable urinary antibiotic concentrations, risk for adverse events, and cost. Veterinarians are encouraged to monitor antimicrobial resistance patterns within their clinic to select an antibiotic with a spectrum and efficacy against the suspected causative agent. The first-line antibiotic should have a local resistance rate of <10% for uncomplicated (not all) UTI detected in the clinic. Suggested first-line antibiotics to consider include amoxicillin, cephalexin, or trimethoprim-sulfonamide.[8]

If the patient's antimicrobial susceptibility results reveal that the colonizing bacteria are resistant to the chosen antibiotic but clinically the patient has improved, the antibiotic course should be completed as prescribed, with a follow-up urinalysis and culture performed 3-5 days after the conclusion of therapy to ensure eradication of the infection. Alternatively, if the colonizing bacteria are resistant to the chosen antibiotic and clinical signs remain, then the original antibiotic should be discontinued and an appropriate antibiotic begun.

The recommended treatment duration for uncomplicated UTI in veterinary medicine is 7-14 days.[47,48] However, short-duration (≤3 d) antibiotic therapy may be equally efficacious. Advantages of short-duration therapy include reduced patient side effects, improved compliance, reduced cost, and decreased antibiotic resistance while maintaining clinical efficacy. Recent studies have indicated that treatment of uncomplicated UTI in dogs with trimethoprim-sulfamethoxazole or high-dosage enrofloxacin for 3 days yielded similar cure rates when compared to 10 days of cephalexin or 14 days of amoxicillin-clavulanic acid.[49,50] Short-duration treatment protocols also reduce the risk of sulfonamide hypersensitivity reactions and of inducing fluoroquinolone-resistant mutants when high-dosage enrofloxacin is used.[49,51] Despite these studies, the use of second-line antibiotics such as amoxicillin-clavulanic acid, fluoroquinolones, and cefovecin is not recommended for the treatment of uncomplicated UTI when first-line antibiotics are options.

When the treatment course of an uncomplicated UTI is complete, additional monitoring or diagnostic testing usually is not required. Adjunctive therapies and preventive therapy (see below) also are not necessary.

Complicated UTI

Complicated UTI implies that an underlying anatomic, functional, or metabolic abnormality or comorbidity is present, either preventing the clearance of an infection (persistence and relapse) or allowing for reinfection. Addressing the primary reason for, and location of, bacterial colonization is important to avoid treatment

failure or recurrence of UTI.

Persistent Infection

Persistent (refractory) infections occur when appropriate antimicrobial therapy fails to sterilize the urine. Provided that the prescribed antibiotic was administered at the appropriate dosage/duration, persistent infections indicate that the infecting bacteria developed resistance, the immune system of the patient is compromised, or the mean urinary concentration (MUC) of antibiotic was unable to achieve concentrations at least four times the minimum inhibitory concentration (MIC) for bacterial growth.[47,52]

Since measuring drug concentrations in the urine is not widely available, recognizing when urinary drug excretion might be altered is necessary to prevent persistent infections. Reduced MUC of an antibiotic can occur with decreased intestinal absorption of oral medications, altered perfusion of infected tissue, altered drug metabolism, or reduced urinary concentrating ability. In short, persistent infections require screening for systemic disease, including an assessment of the function of the immune, gastrointestinal, hepatic, and renal systems. If the disorder resulting in a persistent infection cannot be corrected, then antibiotic doses should be adjusted to maximize the MUC or an alternative antibiotic should be chosen.

Over the last few decades, as the incidence of multidrug resistant (MDR) UTI has increased, there is a growing population of patients with infections not susceptible to first- or even second-line antibiotics. Alternative therapies have been proposed that are largely supported by individual case reports and anecdotal evidence. The use of high-dosage amoxicillin/clavulanic acid is one technique that uses urinary concentrating ability to treat MDR infections that otherwise appear resistant on susceptibility testing.[53] Another approach bypasses the steps of antibiotic absorption, metabolism and excretion by directly instilling aminoglycoside antibiotics into the urinary bladder.[54-56]

Occasionally, therapies that are more invasive may be indicated for the treatment of persistent infections such as encrusted cystitis. Associated primarily with *Corynebacterium urealyticum* UTI, encrusted cystitis occurs when urease-positive bacteria form mineralized plaques on the ulcerated and inflamed mucosa of the urinary tract.[57,58,58a] Suspicion of encrusted cystitis should occur when a urease-positive infection persists in combination with alkaline urine containing struvite crystals. Diagnosis can be assisted by ultrasonography and cystoscopy, and treatment frequently requires appropriate antibiotic therapy in conjunction with urine acidification and surgical debridement.[58]

Relapse

Relapse of UTI differs from a persistent infection in that, during relapse, urine can be cleared of infection but bacterial reservoirs remain allowing for urine recolonization with the same organism within a few days to weeks. Sites that can harbor bacterial colonies include the kidneys, prostate, uroliths, vagina, and possibly the urothelium.

The treatment goal for relapsing infections is to identify the site of infection so that eradication of the reservoir infection is ensured. For suspected tissue infections, bacterial sensitivities should be determined based on the achievable plasma concentrations and tissue penetration of the antibiotic and not the MUC. Therapy traditionally is prolonged, with general recommendations of treatment for 4-6 weeks. However, the optimal treatment duration to clear these infections is largely unknown. It is possible that in certain circumstances treatment duration could be safely reduced (see ch. 327, 331, 332, and 337).

Relapse due to the formation of intracellular bacterial communities is a unique example of complicated UTI of unknown clinical importance in dogs and cats. Bacteria expressing type 1 fimbriae, such as *E. coli* and *Klebsiella pneumoniae*, have been shown experimentally to rapidly move intracellularly during infection.[59-61] Small collections of intracellular bacteria can form quiescent intracellular reservoirs (QIR) that reseed the bladder weeks to months later upon exfoliation of urothelial cells.[62-64] Antibiotic therapy even with prolonged treatment duration is unable to clear QIR[65]; however, intravesicular and intraperitoneal administration of forskolin produced from the *Coleus forskohlii* plant did reduce urothelial bacterial loads in a mouse model of intraurothelial infection.[66] The clinical efficacy of forskolin treatment has never been proven and more evidence is necessary before recommending this therapy for UTI relapse.

Reinfection

Reinfection occurs when there is an alteration to host defenses that allows new bacterial strains to colonize the urinary bladder weeks to months after an initial UTI (see Box 330-1). In both reinfection and relapse, a time period exists when the patient's urine is sterile, making it challenging to differentiate between the two when

similar bacterial species are isolated in subsequent infections. Comparing antibiotic susceptibility patterns of prior and current infections is often used as a means of differentiating reinfection and relapse, but different bacterial strains can have similar susceptibility profiles and the same infecting organism can shift its antibiotic sensitivity, making this method unreliable.[67,68] Genotyping using pulse field electrophoresis provides definitive evidence of reinfection/relapse.[68] Correctly categorizing infection as reinfection or relapse is important, as the pathophysiology and necessary treatment of reinfection is different than that of relapse.

If reinfection is suspected, a complete systemic evaluation of the patient should be undertaken. When possible, an evaluation of the conformation of the external genitalia is performed, including a digital exam and voiding evaluation. Urine retention should be assessed by measuring the post-void bladder residual volume via catheterization or ultrasound estimation.[69-71] Residual volume should be low, with common estimates in the range of 0.1-0.4 mL/kg (Video 330-1).[72,73] Advanced diagnostics, including radiographs/contrast studies, ultrasound, cystoscopy, and urethral pressure profilometry, can assist with identifying alterations in host defenses, including anatomical and mechanical changes to lower urinary tract.

Treatment of reinfection requires a urine culture and sensitivity to guide therapy. In both dogs and cats, prior antibiotic administration is the leading risk factor for development of MDR infections[74,75] and therefore, patients with histories of reinfection will be at increased risk of treatment failure if antibiotics are chosen empirically. If clinical signs are mild at the time of diagnosis of the UTI, it is prudent to wait for antibiotic susceptibility results before starting therapy. In instances when treatment must be instituted immediately, a first-line antibiotic should be chosen as described for uncomplicated UTI, above. Since reinfection is caused by recolonization with a different bacterial strain each time, treatment duration is similar to the patient having numerous single infections, making long antibiotic courses usually unnecessary.

Preventive Therapies

In >25% of dogs, the defect allowing re-colonization is not identified or cannot be corrected.[76] In these patients, treatment of reinfection with antibiotics provides only transient urine sterilization.[76,77] A successful treatment plan focused on prevention of pathogenic UTI would be a superior treatment option. Unfortunately, there is little clinical evidence proving the long-term efficacy of nearly all preventive treatments. Most of the following therapies are based on theoretical ideas, *in vitro* studies, small case series, or anecdotal reports. The International Society for Companion Animal Infectious Diseases did not recommend any of the following therapies in the urinary tract infection treatment guidelines published in 2011.[8]

The first step in all preventative therapy plans begins with identifying whether a true UTI is present and then, if appropriate, eradicating the current infection. Upon sterilizing the urine, preventative protocols can be divided into therapies that allow the bacteria to remain viable and those that kill invading organisms. Successful treatment with nonantimicrobial therapies is most attractive because they do not apply bactericidal selective pressures, bacterial resistance is not induced, and the normal flora within the body remains viable. Categories of nonantimicrobial prophylaxis include adherence blockade and bacterial interference, while antimicrobial prophylaxis frequently centers on modified-dosage, long-term antimicrobial administration.

Anti-Adherence

The basis of anti-adherence therapeutics is to block the ability of bacteria to adhere to the urothelium, allowing urination to flush invading organisms from the urinary tract. One of the most widely accepted preventative therapeutics is the consumption of cranberries and cranberry extract. Proanthocyanidins (PAC) with type A-linkages isolated from cranberries have anti-biofilm properties and can prevent pyelonephritis-inducing P-fimbriated UPEC from binding to uroepithelial cells.[78-82] In veterinary patients, *in vivo* evidence demonstrating the clinical efficacy of PACs is lacking, although urine produced by PAC-consuming dogs has reduced *E. coli* adherence *in vitro*.[83] Therefore, the use of PACs might be effective in limiting the colonization of the urinary tract with certain P-fimbriated–expressing bacterial strains.

The oral administration of D-mannose is a second anti-adherence therapeutic. D-mannose aims to disrupt bacterial adhesion to the urothelium by blocking the ability of lectins on the tips of type 1 fimbriae to interact with carbohydrate moieties located on urothelial cells.[84,85] Several rodent studies have demonstrated decreased UPEC colonization after incubation of bacteria with D-mannose.[86-88] Although questions remain about whether orally administered D-mannose is capable of concentrating within the urine,[89] a recent clinical study in women suggested that regular oral consumption of D-mannose might reduce UTI recurrence.[90] Clinical evidence of efficacy in dogs and cats is lacking.

A third anti-adherence therapeutic is the use of glycosaminoglycans (GAGs). During *E. coli* UTI, virulence factors produced by bacteria can injure the protective GAG barrier overlying the urothelium.[91,92] GAG therapy contends that exogenous GAG will adhere to the urothelium or bind to invading bacteria, preventing bacteria-induced injury. In people, several independent studies have demonstrated that direct instillation of the GAG hyaluronic acid into the urinary bladder significantly reduces UTI recurrence rates[93-95]; however, in veterinary medicine, the efficacy of GAG bladder instillations to prevent UTI remains unproven.

Bacterial Interference

The use of bacteria to prevent UTI is based on the idea that established colonies of nonvirulent organisms alter the microenvironment, stopping proliferation of virulent colonizers. One form of bacterial interference involves the intravesicular instillation of nonpathogenic *E. coli.* This therapy aims to colonize the urinary bladder with an organism that will utilize local nutrients, reducing the ability of uropathogens to colonize.[96] In people with disorders of urine retention causing reinfection, instilling *E. coli* 83972 into the urinary bladder to induce ASB reduced reinfection by up to 50%.[97,98] Two studies attempting to inoculate healthy dog urinary bladders with *E. coli* 83972 were unable to consistently establish persistent colonies[99,100]; however, a defect such as urine retention might be necessary for colonization success.

A second method of altering the urinary microenvironment is with the use of probiotics. *Lactobacillus* and other lactic acid-producing bacteria are theorized to decrease vaginal pH, thereby inhibiting uropathogenic bacterial colonization.[101] Frequently, uropathogenic bacteria colonize the vaginal mucosa of women with recurrent UTI.[101,102] Oral and vaginal administration of *Lactobacillus* have been shown to effectively increase the population of lactic acid-producing bacteria within the vagina, reduce the number of uropathogenic bacteria isolated, and reduce the recurrence of UTI.[103-105] In female dogs, the importance of *Lactobacillus* as a vaginal colonizer is not known, as it sporadically colonizes the vaginal vault of both dogs with recurrent UTI and normal, spayed female dogs.[41] Orally supplementing female dogs with lactic acid-producing bacteria also failed to alter the vaginal bacterial population, suggesting that oral supplements containing lactic acid-producing bacteria are of limited utility for preventing reinfection in dogs.[106]

Miscellaneous Non-Antimicrobial Preventatives

The use of estrogens helps to prevent reinfection in women by altering the urinary microenvironment through promotion of vaginal *Lactobacillus* growth, lowering of vaginal pH, and restoration of atrophic mucosa within the urethra.[107] Vaginally applied and not orally administered estrogen supplements reduce the number of recurrent UTIs in postmenopausal women.[108] It is unknown how this treatment translates to dogs and cats, but patients with subclinical urethral sphincter mechanism incompetence may benefit from estrogen therapy (see ch. 335).

Methenamine salts are urinary antiseptics that produce formaldehyde from hexamine in an acidic urine environment. Since a urinary pH of 5.5 is required to convert methenamine to bacteriostatic concentrations of formaldehyde,[109,110] vitamin C or other urine acidifiers are co-administered to achieve this low pH. Contraindications to methenamine use include urease-positive UTI and conditions associated with metabolic acidosis such as chronic kidney disease/uremia.[111] A Cochrane review suggested that methenamine hippurate might benefit people without appreciable urinary tract abnormalities when used for a week or less. Methenamine appears ineffectual in patients with neuropathic bladders and no definitive information is known about its long-term effectiveness.[112] No veterinary recommendations for its use exist.

Additional therapies that appear promising for the future include the development of anti-bacterial antibodies using various vaccination strategies[113, 114] and the introduction of bacteriophages able to lyse UPEC.[115] Some vaccination therapies have achieved modest success in human clinical trials and may provide additional prophylactic treatment options for preventing bacterial adherence and colonization of the urothelium.

Antimicrobial Preventative Therapy

In both humans and veterinary patients, the use of long-term, modified-dosage antibiotic prophylaxis is controversial.[8,116] In human studies, active prophylaxis did reduce the recurrence of infection, and this therapy might be useful in some animals suffering from severe clinical signs.[111] This treatment will not prevent infection once the antibiotics are discontinued, and selective pressures applied to bacteria via

repeated courses of antibiotics could lead to the development of multidrug resistant uropathogenic bacterial strains and treatment failure.[74,75,117]

The basis of prophylactic antibiotic therapy is to provide ⅓ to ½ of the total daily dose of an antibiotic, usually at night after the last void of the day. Antibiotics concentrate in the urinary bladder overnight, preventing colonization of the urine. The daily treatments are continued for 6 months with monthly cultures to ensure a breakthrough infection has not occurred. After 6 months, if the urine remains sterile, the antibiotics can then be discontinued and the therapy repeated as necessary.

CHAPTER 331

Lower Urinary Tract Urolithiasis in Dogs

Jody P. Lulich, Carl A. Osborne

Client Information Sheet: Urinary Stones in the Bladder and Urethra of Dogs

Urolithiasis is a general term referring to the causes and effects of stones anywhere in the urinary tract. Urolithiasis should not be viewed conceptually as a single disease with a single cause but rather as a sequela of multiple interacting abnormalities. Thus, the syndrome of urolithiasis may be defined as the occurrence of familial, congenital, or acquired pathophysiological factors that in combination progressively increase the risk of precipitation of excretory metabolites in urine to form stones (i.e., uroliths; Figure 331-1).

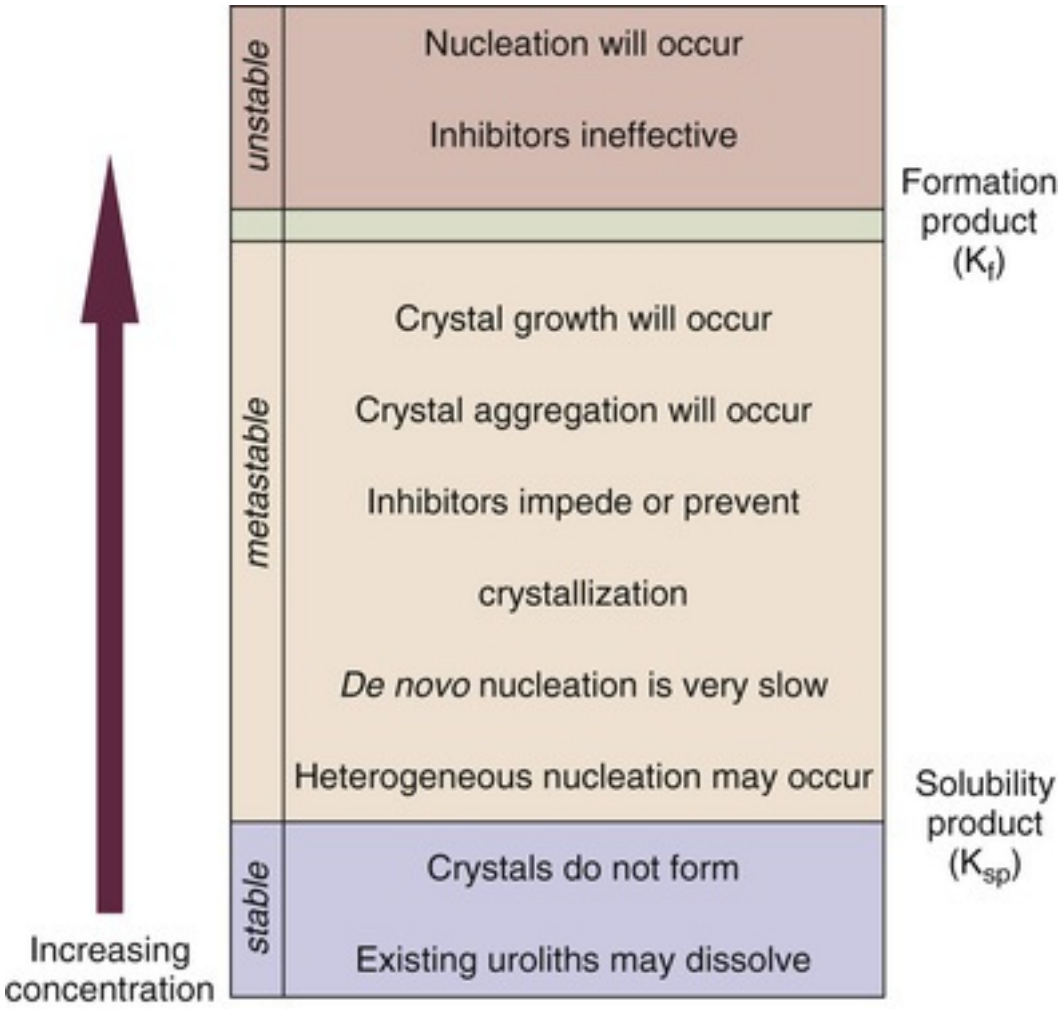

FIGURE 331-1 States of saturation related to the formation of crystals in urine.

Diagnosis

Lower urinary tract signs (see ch. 46) are a common indication to evaluate dogs for uroliths. Medical imaging is the most utilized confirmatory test.[1] When performing abdominal radiography, it is important to include the entire urinary tract to avoid overlooking the possibility that uroliths may also reside in any region within the urethra. Because small uroliths less than 2 mm in diameter and some stone types have poor radiographic opacity (e.g., urate, cystine), abdominal ultrasonography (US), contrast urethrocystography, or other more sensitive techniques should be considered before uroliths can be completely eliminated as the cause for clinical signs. These imaging modalities have also been useful in differentiating mineralized urothelial neoplasia or cystic foreign bodies from uroliths. Although palpation of the lower urinary tract is an insensitive method of diagnosis, this simple diagnostic tool should not be abandoned. In some instances, rectal palpation of the pelvic urethra has revealed uroliths that were obscured by the pelvic bones when viewed radiographically or were inaccessible by routine US.

A diagnosis of urolithiasis without predicting their composition is insufficient to optimally select effective therapy. For example, a dog with infection-induced struvite nephroliths and cystoliths cannot be adequately managed with cystotomy alone. Similarly, if urine was not cultured for aerobic bacteria prior to therapy, treating with a therapeutic diet would not be as effective as controlling the underlying infection. Review of appropriate imaging and urinalysis with a portion saved for bacterial culture is essential in all urolith cases. In addition, many require evaluating a serum biochemical profile, especially those with liver disease or urethral obstruction.

Predicting Mineral Composition

Overview

Accurately predicting mineral composition of uroliths, prior to their removal, permits developing a safe and effective therapeutic plan. For example, avoiding nonsteroidal pain medications and anesthetics that are primarily metabolized by the liver will improve patient outcomes in dogs with suspected urate uroliths caused by hepatic portovascular anomalies (see ch. 284). Likewise, some dogs with suspected cystine uroliths may benefit from castration at the time of urolith removal to minimize recurrence.[2] Crystalluria, the primary method of predicting urolith composition, is insensitive and unreliable.[3] Once stones form, crystals associated with that stone type often decrease or disappear from the urine. To more accurately predict urolith composition, survey radiography should be the first tool used, together with stone prevalence, breed, and gender (Table 331-1). This information, crystal identification, and urine pH are often sufficient to accurately predict the major component of most uroliths.

TABLE 331-1

Predicting Mineral Composition of Uroliths in Dogs

UROLITH TYPE	PREVALENCE (%)	RADIOGRAPHIC APPEARANCE	COMMON BREEDS	GENDER % (I/N)	CRYSTALLURIA	URINE PH
Calcium oxalate monohydrate	37.5	Markedly to moderately radiopaque Round, bosselated to irregular	Mixed, Mn Schnauzer, Shih Tzu, Yorkshire Terrier, Chihuahua, Bichon (59.2%)	F-22 (3.2/18.8) M-76.8 (15.4/61.4)	Dumbbells, pickets	<6.5
Calcium oxalate dihydrate	5.3	Markedly to moderately radiopaque Spiculated and star-shaped rosettes	Shih Tzu, Yorkshire Terrier, Mn Schnauzer, Bichon, Chihuahua	F-17.1 (2.3/14.8) M-81.4 (26.1/55.3)	Envelope with cross	<6.5
Struvite	36.8	Moderately to markedly radiopaque Round to faceted	Shih Tzu, Mn Schnauzer, Dachshund, Pug, Bichon	F-82.2 (15.2/67.0) M-14.4 (7.2/7.2)	Prismatic	>7
Urate salts	4.0	Radiolucent to	Dalmatian, Mixed,	F-19.2	Amorphous,	≤6.5

		marginally radiopaque Round smooth to mulberry	Yorkshire Terrier, English Bulldog, Shih Tzu, Miniature Schnauzer	(4.8/14.4) M-79.1 (25.1/54.0)	speculated globules with and without spicules	
Cystine	2.1	Radiolucent to marginally radiopaque Round smooth to mulberry	English Bulldog, Mixed, Chihuahua, Dachshund, French Bulldog, Pitbull	F-0.9 (0.4/0.5) M-97.2 (76.8/20.4)	Hexagon	≤6.5
Silica	0.4	Moderately to markedly radiopaque Star shaped with geometrically radiating low to high spikes	Mixed, Labrador Retriever, Shih Tzu, German Shepherd Dog, Chihuahua, Golden Retriever	F-6.7 (2.1/4.6) M-91.5 (37.3/54.2)		
Calcium phosphate carbonate	0.5	Moderately to markedly radiopaque. Smooth round to faceted.	Mixed, Shih Tzu, Bichon, Pug, Mn Schnauzer, Chihuahua (57.2%)	F-77.8 (11.9/55.9) M-31.3 (13.8/17.5)	Amorphous	≥7.5
Brushite	0.3	Small moderately to markedly radiopaque. Smooth round.	Shih Tzu, Mixed, Bichon, Yorkshire terrier, Papillon, Maltese (71.3%)	F-32.0 (4.6/27.4) M-66.8 (31.4/35.4)	Amorphous	>6.5
CaP apatite	0.1	Small moderately to markedly radiopaque. Smooth round.	Mixed, Shih Tzu, Pug, Labrador Retriever, Dachshund, Papillon (60.5%)	F-34.8 (4.6/30.2) M-62.8 (22.1/40.7)	Amorphous	>6.5
Xanthine	0.1	Radiolucent round to irregular	Mixed, Dalmatian, Labrador, Not reported, Cavalier KCS, Rottweiler (66.14%)	F-16.9 (7.0/16.9) M-81.7 (33.8/47.9)	Globular	
Compound	9.9	Larger stones with inner and outer layers of different radiopacity	Mixed, Shih Tzu, Mn Schnauzer, Yorkshire Terrier, Bichon, Dachshund (61.1%)	F-69.9 (13.8/56.1) M-28.7 (9.4/19.3)	Variable	
Mixed	3.2	Variable	Mixed, Shih Tzu, Mn Schnauzer, Bichon, Yorkshire Terrier, Pug (61.7%)	F-77.3 (14.3/63.0) M-21.0 (8.6/12.4)	Variable	

I/N, Intact/neutered; *Mn*, Miniature.

Urolith Prevalence

Knowing the frequency at which different mineral types of uroliths are diagnosed is of value when predicting their composition. Calcium oxalate and struvite stones accounted for about 80% of almost 70,000 canine uroliths analyzed. Calcium oxalate predominated in North America, Asia and Europe, while struvite was the most common stone in Africa, Australia (but not New Zealand), and South America.[4] In this analysis, the majority of dogs that formed calcium oxalate were male (78%) and the majority of dogs that formed struvite were female (82%).

Radiographic Appearance of Uroliths

The radiographic appearance of uroliths (radiopacity, uniformity of radiopacity, size, shape, and contour) is highly correlated with composition and is one of the most reliable tools for predicting urolith type prior to

analysis (Figure 331-2).[5] Uroliths composed of calcium oxalate, calcium phosphate, and silica are radiopaque. Struvite is moderately radiopaque, but cystine, urate, and xanthine stones are commonly radiolucent. Radiopaque uroliths <2 mm may be difficult to discern on survey radiographs, requiring US or contrast enhancement techniques to be seen. Radiolucent uroliths >5 mm may be visible on survey radiographs. A urolith whose central area has a radiopacity different from the outer layer is consistent with a compound urolith. The same radiographic generalities for noncompound uroliths apply to the layers of compound uroliths. Urinalysis is usually most consistent with the composition of the stone's outer layer.

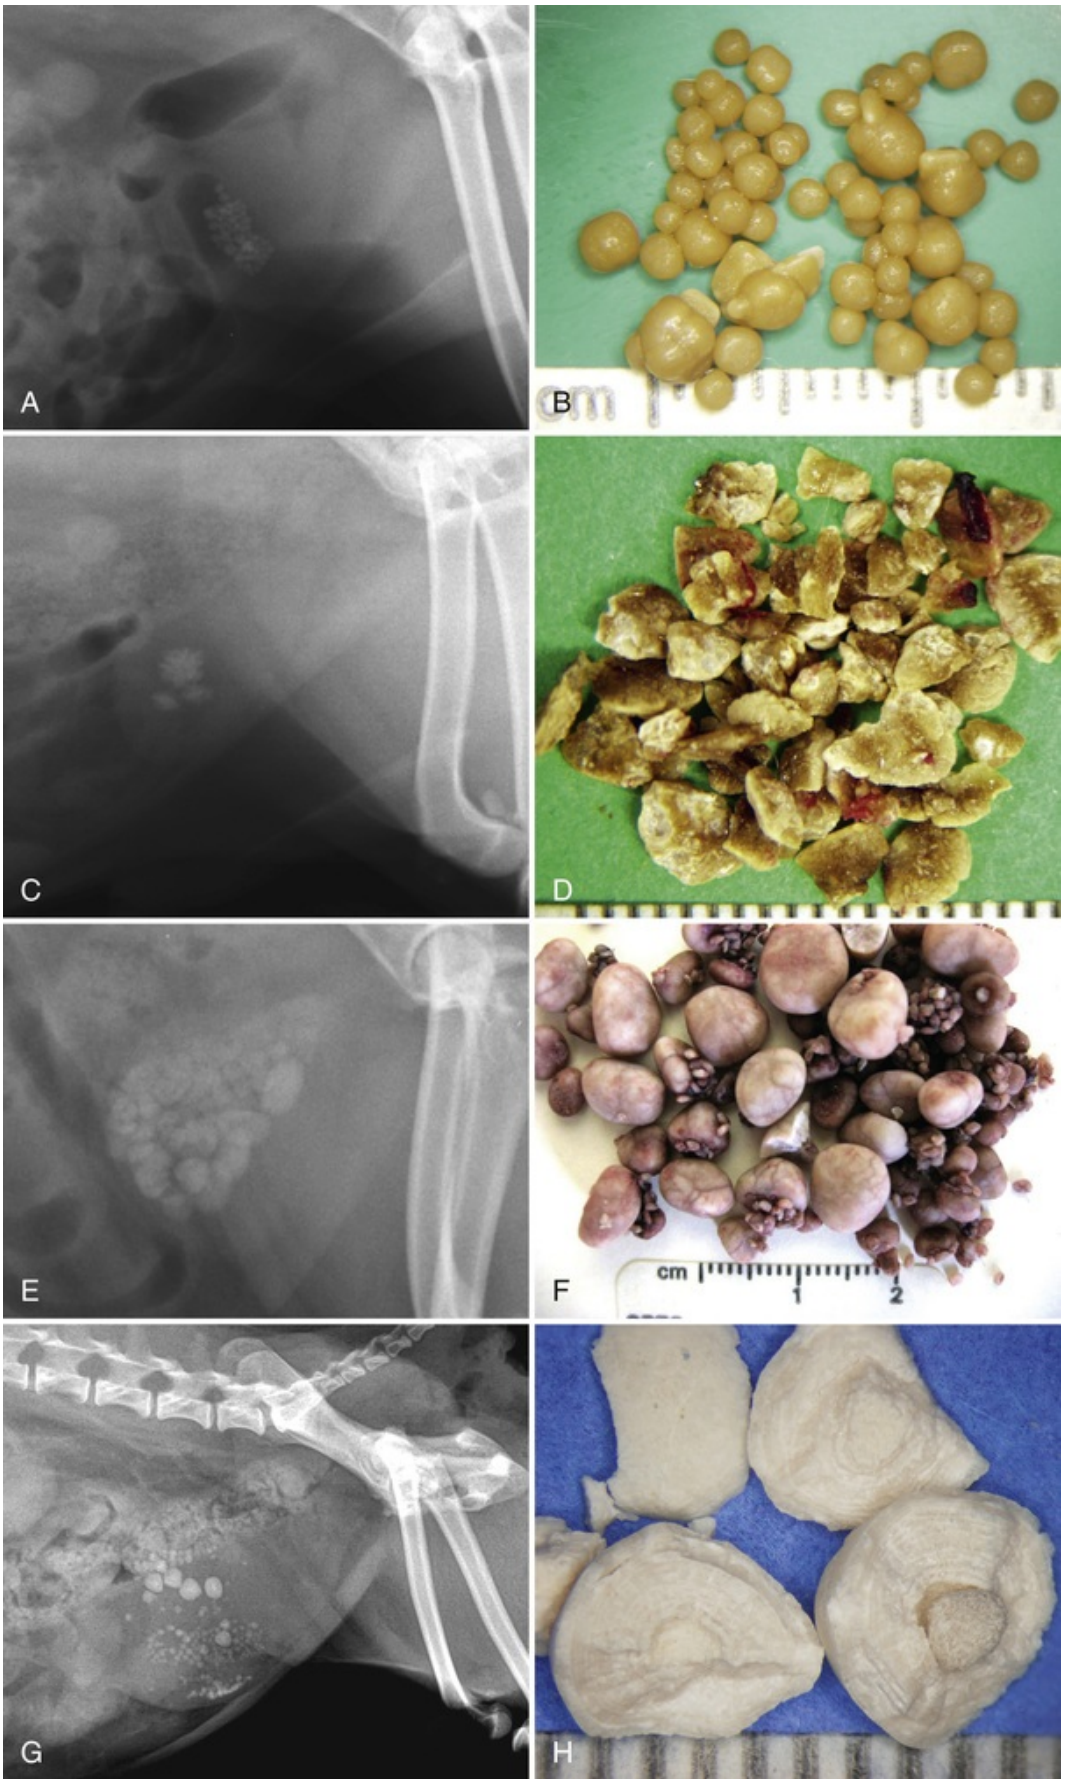

FIGURE 331-2 Calcium oxalate monohydrate uroliths before and after voiding urohydropropulsion **(A** and **B),** calcium oxalate dihydrate uroliths before and after laser lithotripsy **(C** and **D),** infection-

induced struvite uroliths before and after cystotomy **(E** and **F),** compound stones with a center of calcium oxalate and an outer layer of struvite before and after laser lithotripsy **(G** and **H).**

Breed

Breed predispositions and genetic inherited defects in the processing of calculogenic precursors support utilization of patient signalment to assist prediction of urolith composition.[2,6,7] While calcium oxalate uroliths have been identified in >100 breeds, 50% are identified in 6 breeds: Miniature Schnauzer, Shih Tzu, Yorkshire Terrier, Chihuahua, Bichon Frise, and Maltese. These and related breeds of small dogs are also overrepresented in the prevalence of other stone types (see Table 331-1). English Bulldogs are overrepresented among urate and cystine urolith formers.[8] Breed would be a more reliable predictor of urolith type if it segregated out as nicely as Dalmatians and urate uroliths: 96% of urolith-forming Dalmatians produced uroliths of salts of urate.[9]

Urinalysis

Knowing the type of urine crystals and pH can be helpful in managing dogs with urolithiasis, but such information is not perfectly sensitive or specific as a predictor of urolith composition.[3] Once stones form, it is thermodynamically more favorable for minerals to deposit on the surface of a preformed stone than to form new crystals. As a result, crystals are often absent in the urine of a pet with cystic calculi. When present, crystals may not represent urolith composition but instead form as a function of pH or factors unrelated to the urolith. This may explain why struvite crystalluria is observed in dogs with calcium oxalate uroliths as urine is therapeutically alkalinized.

Urolith Retrieval

Accurately predicting mineral composition of some uroliths may be difficult, especially those that are mixed (i.e., not composed of a primary mineral), compound, or uncommon. If uroliths are less than 3 mm, they can be collected during voiding or catheter retrieval (Video 331-1).[10] During voiding, owners can position a fine meshed cooking strainer or fishnet in the urine stream path. If urolith collection is not successful after several attempts, uroliths can be retrieved with a large-bore urinary catheter after placing a dog in left or right lateral recumbency. Local anesthetic lubricant is instilled in the urethra, but some anxious dogs are helped by sedation. Using clean technique, the tip of the urinary catheter is inserted in the distal urethra and passed forward to the trigone. Precise location can be determined by measuring distances using radiographs. A syringe should be attached to the catheter, and gentle intermittent negative pressure should be applied as the catheter tip is withdrawn from the bladder. As the tip of the urinary catheter is moved from the bladder to the urethra, urine flow will cease. Then advance the catheter toward the bladder and urine flow resumes when the tip of the catheter enters the trigone. The catheter tip can also be positioned with fluoroscopy or US guidance. While agitating the bladder, remove the remaining urine and inspect the syringe contents for small stones. If no stones are retrieved, repeat the procedure by instilling 5 mL/kg body weight (up to 50 mL when using a 60-mL syringe) of sterile isotonic solution through the catheter and agitate the bladder while emptying (Videos 331-2 and 331-3). The procedure can be repeated until stones are collected. Submit retrieved uroliths for quantitative mineral analysis.

Urolith Removal

Overview

Urolith removal has, classically, been the province of the surgeon. Less invasive procedures have been developed, and some can be performed by any veterinarian (e.g., medical dissolution and voiding urohydropropulsion). Others may require advanced training and special equipment (e.g., basket retrieval, laser lithotripsy [Figure 331-3], percutaneous cystolithotomy; see ch. 124).

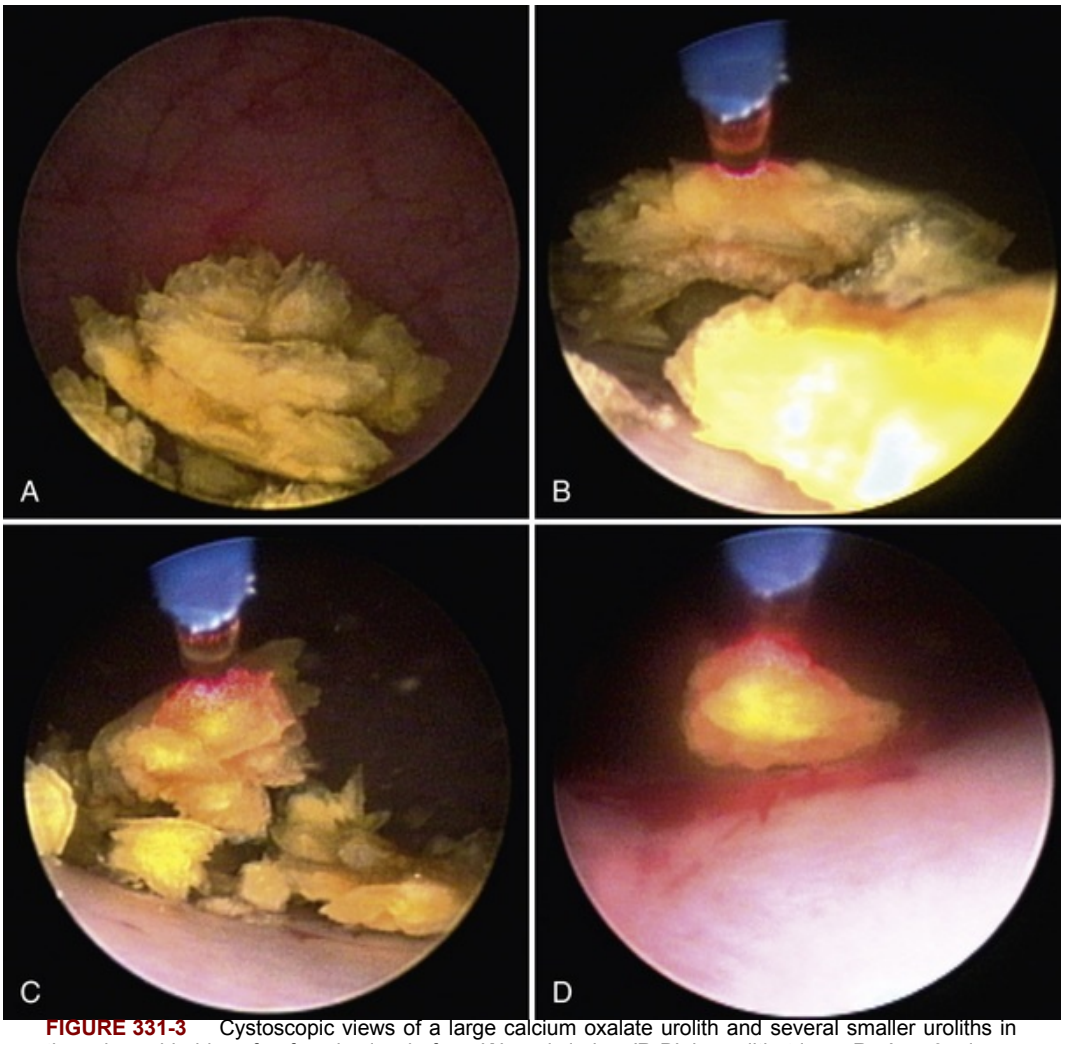

FIGURE 331-3 Cystoscopic views of a large calcium oxalate urolith and several smaller uroliths in the urinary bladder of a female dog before **(A)** and during **(B-D)** laser lithotripsy. **B,** A 550-micron diameter flexible quartz laser fiber is positioned near the surface of the urolith, which has broken into two larger fragments. Notice the red aiming beam visible on the surface of the urolith. **C,** Calcium oxalate urolith fragments after additional laser lithotripsy. **D,** Notice a small urolith fragment adjacent to the mucosa and that the laser energy fragments the urolith without damage to the adjacent mucosa. There is a minimal amount of mucosal trauma from the sharp projections of the urolith fragment. (Reprinted with permission from Adams LG, Berent AC, Moore GE, Bagley DH: Use of laser lithotripsy for fragmentation of uroliths in dogs: 73 cases [2005-2006]. *J Am Vet Med Assoc* 232:1680-1687, 2008.)

Goals

When selecting a procedure to remove uroliths, consider the following patient-centered goals:

1. Remove all stones and stone fragments. Chance of future urethral obstruction can follow failure to remove all uroliths. Failure to remove all stones may cause signs of hematuria, stranguria and dysuria to continue, and urinary tract infection will remain as well. Thus, there would be need for additional urolith extraction procedures.[11,12] Surgery has not consistently resulted in removal of all stones. In 128 dogs undergoing surgery for cystic calculi removal, only 19 (15%) had appropriate postsurgical imaging and incomplete urolith removal was identified in 8/19 (42%).[13] Efficacy of laser lithotripsy was prospectively evaluated in 100 dogs with naturally occurring uroliths and incomplete removal was identified in 18 (9 with uroliths ≥3 mm, 7 with uroliths 1-3 mm, and 3 with uroliths <1 mm).[14]
2. Minimize injury to healthy tissues. The advantage of noninvasive and minimally invasive procedures is their ability to preserve normal anatomy. Avoiding surgery or minimally disrupting tissues is likely to be associated with reduced infection, reduced pain, shorter hospitalization, faster return to function, fewer complications and less scarring.[15]

3. Select procedures less likely to contribute to urolith recurrence. Recurrence of uroliths following removal is commonly attributed to failure of medical therapy. However, when recurrent uroliths from 1733 dogs were analyzed, 163 (9.4%) were attributable to a nidus of suture.[16] These findings emphasize the risk of surgical procedures to contribute to recurrent disease that may have been avoided by minimally invasive techniques.

Methods of Removal in Asymptomatic Pets

Treatment of asymptomatic uroliths composed of struvite involves urine acidification and antibiotics.[17,18] Cystine stones are often managed with a prescription diet (Hill's u/d).[19,20] Urate stones are managed with allopurinol and prescription diet u/d.[21] Allopurinol-induced xanthine stones require stopping the allopurinol. An attempt should be made to dissolve these stones medically, unless previous attempts were ineffective or poorly tolerated. Uroliths can be monitored and removed when symptoms develop (Table 331-2). Asymptomatic uroliths small enough to pass through the urethra should be removed with voiding urohydropropulsion (see Video 331-2) or basket retrieval (Video 331-4).[14,22,23] Larger uroliths should be left alone until the patient becomes symptomatic. Owners should be advised of the clinical signs and follow-up plans in the event of a urethral obstruction. Pets in whom owner monitoring is unreliable may be best managed with urolith removal prior to the onset of clinical disease.

TABLE 331-2

Minimally Invasive Methods of Stone Removal

METHOD	SUITABLE CANDIDATES	RELATIVE CONTRAINDICATION	STRATAGEM	COMMON MISCONCEPTIONS THAT ARE NOT TRUE
Spontaneous voiding	Small uroliths (e.g., <2 to 3 mm) that can easily pass through the urethra	Symptomatic dogs with uroliths of potential size to obstruct the urethra	A small cooking strainer or fishnet placed under the dog's urine stream will allow collection of passed stones for analysis.	
Medical dissolution	Highly successful for struvite, allopurinol-induced xanthine, and cystine uroliths. Less successful for urate uroliths	Urethral obstruction A single large stone occupying almost all of the urinary bladder	For infection-induced struvite, administer antibiotics throughout the entire period of dissolution.	Dogs are at increased risk for urethral obstruction.
Voiding urohydropropulsion	Stones likely to pass through the urethra; usually smooth uroliths <4 mm, or irregular uroliths <3 mm but this is influenced by the size of the dog and its urethra. Dogs of a weight that are suitable for lifting	Urethral obstruction Recent cystotomy Urethral stricture	Avoid anesthetics that increase urethral tone (e.g., dexmedetomidine). Administer a caudal epidural (lidocaine) to ensure urethral relaxation. To further relax the urethral in anesthetized dogs, administer 1 mg/kg propofol IV just prior to bladder expression. With many irregular stones, consider basket removal	A light plane of anesthesia is sufficient to relax the urethra. A stone that becomes lodged in the urethral is difficult to flush back into the urinary bladder.

			before voiding urohydropropulsion.	
Stone basket retrieval	Stones or stone fragments likely to pass through the urethra; usually, smooth uroliths <4 mm but this is primarily influenced by the size of the dog and its urethra		Orient stones so they are lengthwise when passing through the urethra with their sharp edges pointing opposite to their direction of retraction. Use baskets that permit dislodgement of the uroliths in case uroliths become entangled in urethral lumen and need reorientation or repositioning.	
Intracorporeal laser lithotripsy	In males ≥6 kg with not more than three stones requiring lithotripsy (i.e., between 4 to 7 mm in diameter). In females, no restriction in stone size, but struvite stones should be medically dissolved. All uroliths in the urethra	Marked hematuria will markedly reduce visibility. Large stone burden, unless more than one lithotripsy session is anticipated to complete removal. Male cats and small male dogs in which the scope cannot be passed through the urethral lumen	To improve visibility initially and periodically, use an 8-Fr catheter to empty bladder, then flush repeatedly with sterile isotonic solution. Avoid anesthetics that increase urethral tone (e.g., dexmedetomidine). Administer a caudal epidural (lidocaine) to ensure urethral relaxation.	Urolith fragments will pass during spontaneous voiding and do not need to be removed.
Percutaneous cystolithotomy	Males with greater than three larger (>7 mm) stones but can be performed for all types if lithotripsy is not available. In females, most stones can be managed by lithotripsy.		Place a Foley catheter in the urethra such that the inflated cuff occludes the proximal urethra to minimize distal migration of stones.	

Methods of Removal in Symptomatic Pets

Once uroliths cause clinical signs, they are often too large to be flushed out of the urinary tract by voiding urohydropropulsion. Medical dissolution should be attempted first for those amenable to dissolution. If urethral obstruction has occurred, stones should be removed to prevent reobstruction. Strive to remove all uroliths by a combination of basket retrieval (see Video 331-4), laser lithotripsy (Videos 331-5 and 331-6) or percutaneous cystolithotomy (see ch. 124).[14,24-29] If these procedures are not available, uroliths can be removed by cystotomy after any urethroliths have been flushed back into the bladder prior to surgery. Because of the high frequency of adverse effects associated with urethral surgery (e.g., stricture, recurrent urinary tract infections, etc.), urethrotomy and urethrostomy are discouraged except in special circumstances (e.g., client inability to afford additional care with recurrent obstruction).[30]

Urolith Prevention (Table 331-3)

Calcium Oxalate (CaOx)

CaOx urolithiasis is a chronic disease with a high rate of recurrence (about 50% in 2 years).[30] Hypercalciuria appears to be the primary driving force for stone formation, but selecting effective therapy can be challenging because (1) the precise etiologic causes are poorly understood, (2) it is not known which risk factors contribute most to disease, and (3) surrogate endpoints of therapeutic efficacy such as relative supersaturation are mathematical models that may not correlate well with urolith formation, especially when evaluated in clinically healthy dogs without uroliths.[32-34] Therefore, CaOx uroliths tend to recur despite our best efforts. Current therapeutic strategies to reduce urinary quantity of Ca available to bind Ox include feeding only high-moisture foods (e.g., canned, loaf, gravies) to achieve a urine specific gravity <1.020 and avoiding foods that promote urine acidification (<pH of 6.6 to 7). Diets that promote formation of acidic urine in dogs (pH <6.6) were associated with increased Ca excretion and CaOx uroliths.[35,36] One can administer potassium citrate or other citrate salts to dogs with consistently acidic urine. Add hydrochlorothiazide diuretics (2 mg/kg PO q 12 h) to the treatment strategy in dogs with persistent CaOx crystalluria or highly recurrent disease.[37]

TABLE 331-3

Common Medications Used to Manage Uroliths in Dogs

NAME	DOSE	MECHANISM OF ACTION	ADVERSE COMPLICATIONS	ADDITIONAL INFORMATION
Allopurinol	Dissolution:15 mg/kg q 12 h Prevention: 5 to 7 mg/kg q 12 to 24 h	Allopurinol and its active metabolite, oxypurinol, inhibit xanthine oxidase, blocking the conversion of hypoxanthine and xanthine to uric acid	Xanthine uroliths Hypersensitivity Renal disease	Newer xanthine oxidase inhibitors (Febuxostat) are not purine analogs and do not require hepatic metabolism to extend duration of action.
Potassium citrate	75 mg/kg q 12-24 h titrated to achieve a urine pH between 7 and 8	Augments renal excretion of citrate which binds calcium, reduces calcium oxalate formation and their attachment to urothelium	Decreased appetite Hyperkalemia	Give with food. Most formulations inappropriately contain cranberry, which may augment urine oxalate. Most are formulated with silica dioxide, which may contribute to silica in recurrent stones.
dl-methionine	100 mg/kg q 12 h	Urinary acidifier to enhance struvite dissolution in dogs not managed with therapeutic foods	Decreased appetite Acidemia	Give with food.
Vitamin B_6	2 to 4 mg/kg q 24 to 48 h	Favors conversion of oxalate precursors to glycine, minimizing oxalate production		Only recommended for dogs consuming B_6-deficient foods.
Hydrochlorothiazide	2 mg/kg q 12 h	Reduce urine calcium excretion by enhancing renal tubular reabsorption of calcium	Hypercalcemia Mild dehydration	
Tiopronin (Thiola)	Dissolution 15 to 20 mg/kg q 12 h Prevention 5 to 15 mg/kg q 12 h	Binds to cysteine to form a more soluble complex than the cysteine dimer (i.e., cystine)	Proteinuria Thrombocytopenia Anemia Pustules	Difficult to obtain—consider consulting a compounding pharmacy.

Commercially manufactured diets have been designed to prevent CaOx recurrence, but they may not be

ideal for all pets. Hill's Prescription diet u/d has been shown to decrease Ca and Ox excretion and recurrence in dogs with CaOx urolithiasis.[37] This diet has lower levels of sodium and protein, promoting neutral to alkaline urine. Although it has passed AAFCO feeding trials, some consider the protein content too low. If this is the case, consider feeding ½ u/d and ½ of a canned moderate protein senior food that does not acidify the urine (e.g., Hill's Prescription diet g/d or Hill's Prescription diet c/d multicare). Because u/d is high in fat, dogs with hereditary hyperlipidemia (e.g., some Miniature Schnauzers) may benefit from a similar feeding mixture. Hill's Prescription diet w/d has been recommended for dogs with CaOx urolithiasis with fat/lipid intolerance or fat/lipid responsive disorders (e.g., a history of pancreatitis). Because this diet promotes formation of acidic urine, administer potassium citrate to promote a more favorable urine pH (>6.5). Royal Canin SO has been shown to decrease CaOx relative supersaturation in dogs with CaOx uroliths.[34] Because this diet promotes acidic urine, concomitant administration of potassium citrate is necessary to achieve a more favorable urine pH (>6.5).

Struvite

The majority of struvite uroliths form as a consequence of urinary tract infection (UTI) with bacteria that produce urease. Urease is responsible for converting urea to ammonia, which alkalinizes urine and favors struvite precipitation. Therefore, the most effective strategy to minimize urolith recurrence is to eliminate future urinary tract infections (see ch. 330; Figure 331-4). Sterile struvite uroliths, by contrast, are effectively prevented with therapeutic foods (Hill's Prescription diet c/d multicare, Royal Canin SO, others).

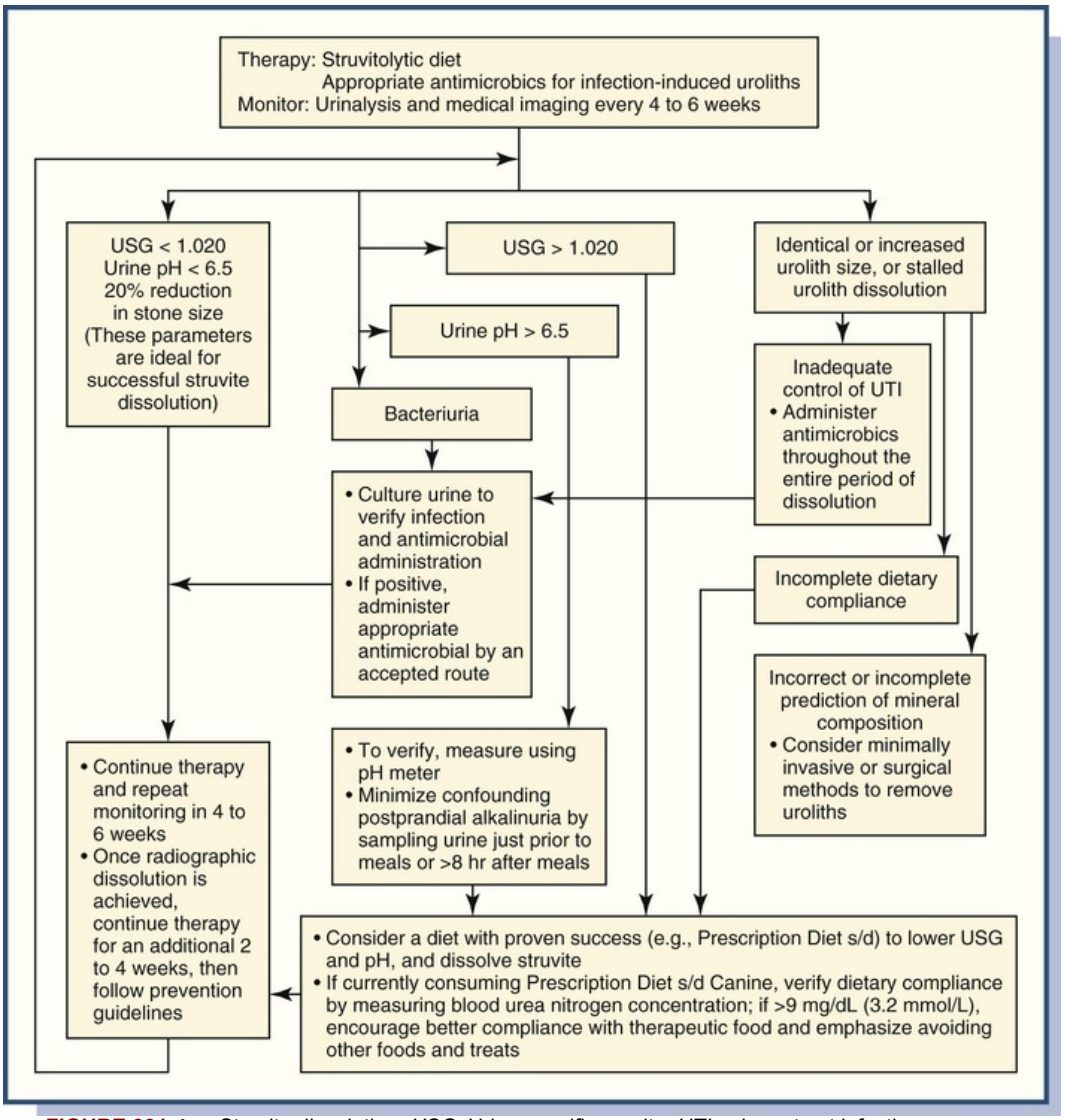

FIGURE 331-4 Struvite dissolution. *USG*, Urine specific gravity; *UTI*, urinary tract infection.

Urate Uroliths

Two distinct diseases are associated with urate urolithiasis in dogs: an inherited alteration of the urate transporter encoded by the SLC2A9 gene (Figure 331-5) and hepatic portovascular anomalies (see ch. 284).[7,38] Common to both is inefficient transport of uric acid into hepatocytes where it normally is enzymatically oxidized into the highly water-soluble end product, allantoin. Instead, high concentrations of uric acid are excreted in the urine. Minimizing urolith recurrence is achieved by decreasing hyperuricosuria (e.g., reducing dietary purine intake and blocking metabolism of urate precursors) and increasing urate solubility (i.e., increasing urine pH [7.0 to 7.5]). Several therapeutic foods have been formulated to lower purine intake (Purina HA, Royal Canin UC, and Hill's Prescription diet u/d). Feed high-moisture foods or add water to food to achieve consistently low specific gravities (<1.020). If urine pH is <7, consider potassium citrate.

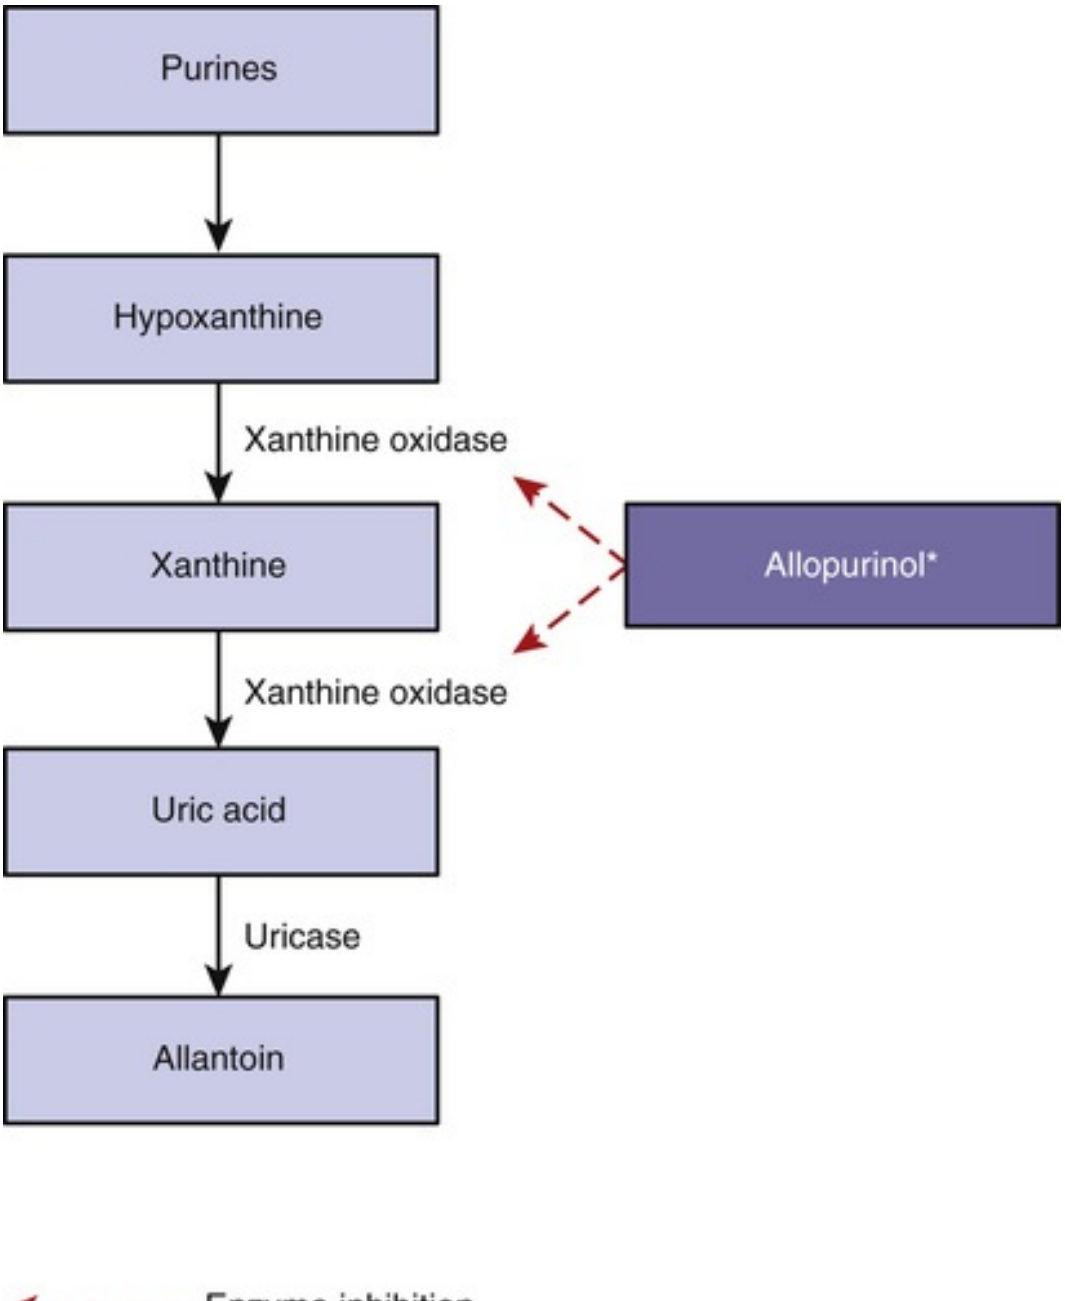

FIGURE 331-5 Metabolic pathway of purine degradation to allantoin showing site of action of allopurinol. *The major metabolite of allopurinol, oxypurinol, is also an inhibitor of xanthine oxidase.

Preventing uroliths in dogs with portovascular anomalies is complicated. Low doses of allopurinol (xanthine oxidase inhibitors) are commonly administered to dogs without liver disease (e.g., Dalmatians, Bulldogs, etc.) to minimize the conversion of purines to uric acid. However, sufficient liver function is needed to convert allopurinol to its more effective, longer-acting analog, oxypurinol. Lower purine/protein foods and vegetable proteins of lower biological value may not be ideal for dogs with liver disease. Lastly, surgical correction of the vascular anomaly is not typically sufficient to eliminate urolith recurrence. Therefore, sufficient water and urine alkalization are important.

Cystine

Cystinuria is a rare inherited disease characterized by failure of renal tubular reabsorption of cystine (a poorly soluble amino acid; see ch. 328). Affected pets have recurrent cystine urolith formation. To minimize urolith recurrence, it is best to increase fluid consumption, limit animal protein intake, limit sodium intake, and

alkalinize urine. Recurrence has been controlled with pharmacologic therapy alone (Thiola) and nutritional therapy alone (Hill's Prescription diet u/d).[19,21] In some forms of cystinuria, neutering has been associated with reductions in urine cystine concentration and prevention of recurrence. To identify which dogs can be effectively managed by neutering, measure urine cystine before and after castration. It is unknown if castration alone will promote urolith dissolution in this subset of dogs.

Compound Uroliths

The most common compound urolith is an inner layer of CaOx and an outer layer of struvite. To prevent recurrence, select nutritional therapy to manage CaOx and antimicrobial therapy to manage struvite. The second most common compound stone is an inner layer of struvite and an outer layer of calcium phosphate carbonate. Control of urinary tract infection will prevent both of these minerals from forming.

Xanthine Uroliths

Naturally occurring xanthinuria results from genetic defects in the enzymes or cofactors that catalyze the final steps of purine degradation. To minimize urolith recurrence, increase fluid consumption, limit animal purine/protein intake, and alkalinize urine. Allopurinol-induced xanthine uroliths can be controlled by eliminating or reducing allopurinol dosage at the same time that a reduction in purine/protein consumption is instituted.

Calcium Phosphate

Hydroxyapatite, calcium hydrogen phosphate dihydrate (Brushite), tricalcium orthophosphate (Whitlockite), and octacalcium phosphate uroliths are rare. Strategies to prevent these stones from forming are the same as those employed for CaOx, unless associated with hypercalcemic disorders, which, when corrected, should prevent recurrence (see ch. 69 and 297). In contrast, prevention of calcium phosphate carbonate uroliths depends on early diagnosis and eradication of urinary tract infections while avoiding nutritional strategies that promote calcium excretion (e.g., urine acidification).

Silica

The cause for silica uroliths is unknown but appears to be associated with three sources: silicon dioxide found as an inert ingredient of many tablets; consumption of whole grains, particularly rice, beet pulp, and soybeans; and using water and plant foods derived from active geothermal (volcanos, hot springs, geysers) locations. Replacing each of these sources with lower or nonsilica substitutes and encouraging high fluid consumption should reduce recurrence.

CHAPTER 332

Lower Urinary Tract Urolithiasis—Feline

Mary Anna Labato

Client Information Sheet: Lower Urinary Tract Urolithiasis—Feline

Introduction

Urolithiasis is defined as the formation of uroliths (calculi or stones) within the urinary tract. Uroliths can vary in their mineral composition.[1] Recent studies have reported that 7-28% of cats presenting for lower urinary tract signs were diagnosed with urolithiasis.[2-4] The most common feline urolith types are struvite (magnesium ammonium phosphate) and calcium oxalate (CaOx) (each >40% of uroliths).[2-8] Purine uroliths represent about 5% of cases, with about 7% being composed of other substances such as matrix, calcium phosphate, blood stones, compound stones and drug-induced.[7,9] (Figure 332-1).

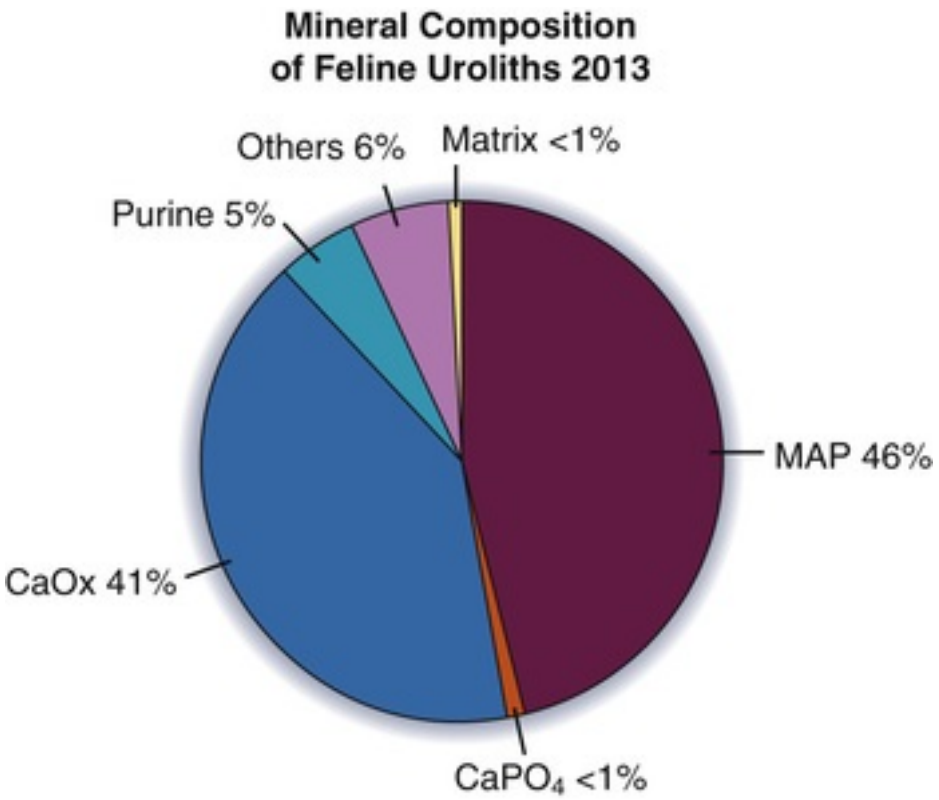

FIGURE 332-1 Mineral composition of feline uroliths—2013 data. *CaOx,* Calcium oxalate; *$CaPO_4$,* calcium phosphate; *MAP,* magnesium ammonium phosphate (struvite). (From Minnesota Urolith Center.)

Clinical Signs

Cats with cystouroliths can present with a variety of lower urinary tract signs. These include pollakiuria, stranguria, hematuria, periuria, or a combination of these signs. When a urolith becomes lodged in the urethra, the clinical signs are those related to urethral obstruction (see ch. 334 and 335). These signs are not specific for uroliths and include as differentials urinary tract infections, feline idiopathic cystitis and neoplasia. Frequently cystouroliths do not result in any clinical signs and are an incidental finding on either abdominal palpation, survey radiographs or abdominal ultrasound.

Clinical Testing

For cats presenting with clinical signs suggestive of urolithiasis, a basic diagnostic minimal database workup consists of a complete blood count and serum biochemistry profile. In most instances these will be within normal parameters but may reveal underlying conditions that could predispose to urolith formation such as diabetes mellitus, chronic kidney disease, and liver function tests, suggesting a preexisting condition such as a portosystemic shunt. In the geriatric cat, a thyroid level should be determined as well.

A urinalysis is essential (see ch. 72), although uroliths can be present without crystalluria and crystalluria may not accurately predict urolith type. Crystalluria is not a consistent feature of urinalysis in cats with uroliths. Urine specific gravity is important to determine, especially in those cats with a history of prior urolith formation. In these cases, it is important to create dilute urine so that minerals in the urine do not reach the point of saturation to result in crystal aggregation and ultimate stone formation. Urine pH affects crystal formation as well. Struvite, calcium carbonate, and calcium phosphate (apatite) are less soluble in alkaline urine. Ammonium urate, silica and cysteine are less soluble in acid urine. Urine samples should be analyzed within one hour of collection to minimize temperature and time-dependent *in vitro* crystallization.[10] Urine culture should be submitted if there is an active sediment or if the urine specific gravity is low and infection is high on the list of differentials.

Diagnostic imaging should be utilized to confirm the presence of uroliths. Survey radiographs should be positioned to include the entire urinary system. Mineralized stones that can be visualized with radiographs include CaOx, struvite, apatite and silica (Figure 332-2). Most ammonium urate and cysteine uroliths are nonmineralized and thus not visible with radiographs unless they are mixed with some mineralized stones. Contrast cystourethrography is needed to visualize these uroliths.

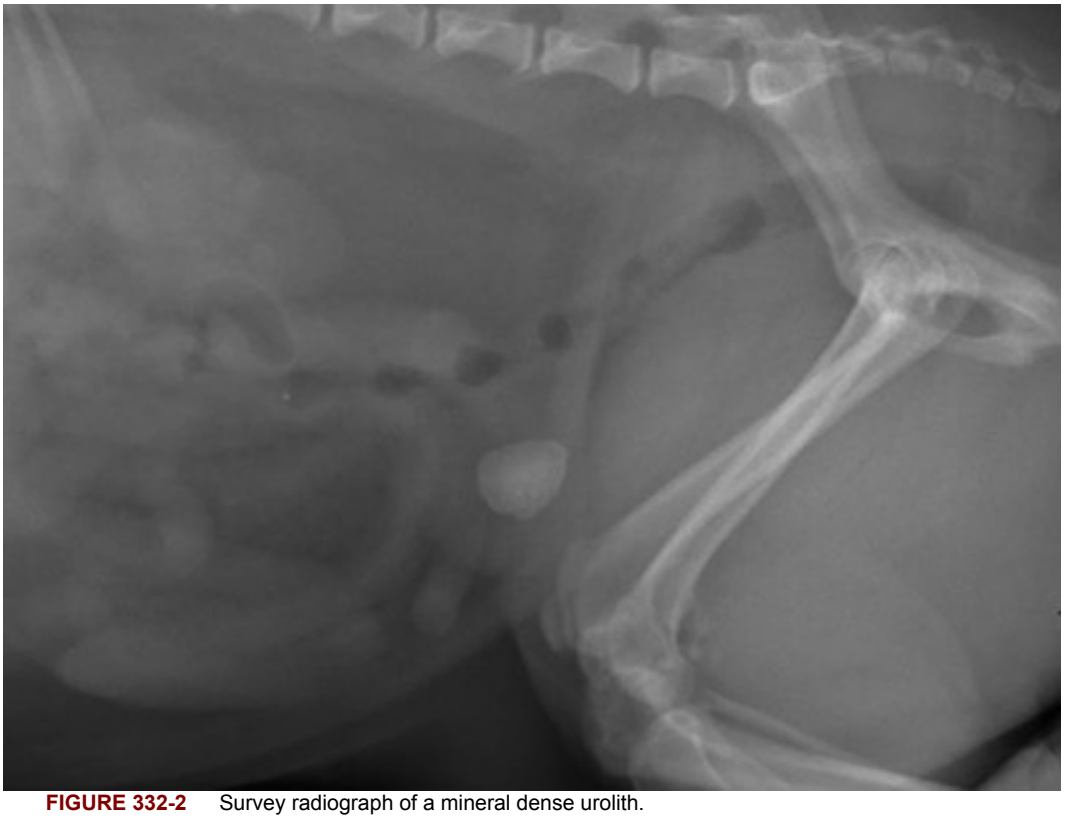

FIGURE 332-2 Survey radiograph of a mineral dense urolith.

Abdominal ultrasound is useful in identifying uroliths, both mineralized and nonmineralized varieties. As a diagnostic modality, it is able to detect large nonmineralized stones, as well as those very small uroliths that can often be successfully voided by the patients (especially female cats) (Figures 332-3 and 332-4 and Video 332-1).

FIGURE 332-3 Abdominal ultrasound image of cystic calculi.

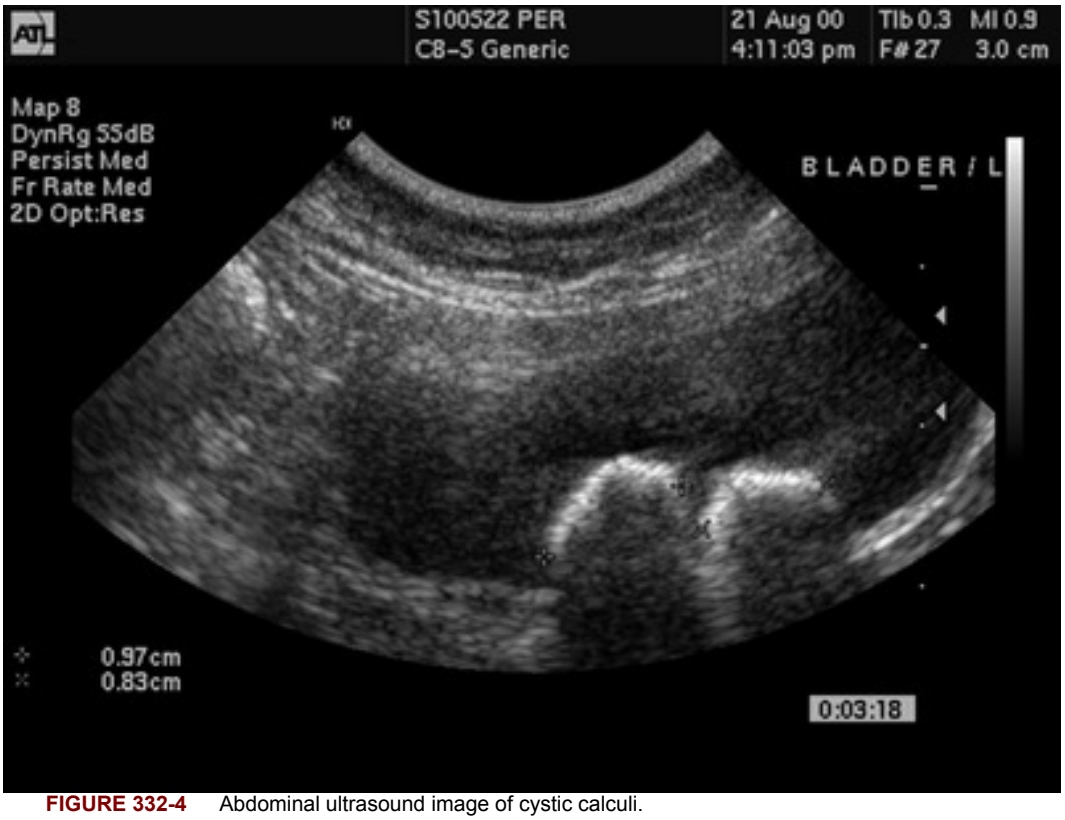

FIGURE 332-4 Abdominal ultrasound image of cystic calculi.

Principles of Stone Analysis

There is a variety of methods available to analyze stones, offered by a number of diagnostic laboratories (Box 332-1). If a stone is available for analysis, the stone should be submitted. The results will aid in management recommendations. The only time when analysis is not required is when there are mineral dense uroliths that respond to dissolution diets, which would confirm the working diagnosis of struvite urolithiasis.

A noninclusive list—check with your diagnostic laboratory for other locations.

Management of Urolithiasis

Most cystic uroliths are removed surgically via a routine cystostomy (also referred to commonly as cystotomy); however, there are a number of alternative methods that can be employed depending upon urolith number and size. A less invasive surgical approach is to perform a laparoscopic-assisted cystostomy, but for most small cats it is essentially easier to perform just a routine cystotomy. If there are small uroliths in the 1- to 3-mm range in female cats, a noninvasive method is voiding urohydropropulsion. This requires general anesthesia and the patient should be in a deep plane of unconsciousness. An indwelling urinary catheter is aseptically placed (3- or 5-Fr catheter). The bladder is distended with sterile saline until full, but

not taut. The cat is then held vertically, allowing the uroliths to fall into the trigone and proximal urethra. The catheter is removed and the bladder expressed while the urine is collected in a container with a filter ("stone strainer") to trap the uroliths. This should not be attempted in male cats unless they have had a perineal urethrostomy. Complications with this procedure include minimally hematuria or as a significant complication, bladder rupture.[10]

Purine Urolithiasis (Urate and Xanthine)

The prevalence of purine-based uroliths has been relatively stable over the years with reports varying between 3 and 10%.[11-13] Urate uroliths are the third most frequently reported in cats. Uric acid is one of several biodegradation products of purine nucleotide metabolism. Ammonium urate is the most common form of naturally occurring purine uroliths observed in cats. There is little information available for urate uroliths in cats. The form of urate urolith most commonly identified was ammonium hydrogen urate[12] (Figure 332-5).

FIGURE 332-5 Purine metabolic pathway. *UC*, Uricase; *XDH*, xanthine dehydrogenase.

The study reported by Appel et al. examined uroliths from 10,083 cats.[11] There were 398 urate stone formers (3.9%), of which the majority were ammonium urate (385) and uric acid (13). Males represented 58% and females 41% of the stone formers. In this particular study, the prevalence of urate urolithiasis was highest in the Egyptian Maus (82%) and consistent with other reports, the Birman (27%) and Siamese (13%) breeds were also both significantly overrepresented compared with other breeds.[11]

There is also an association between urate urolithiasis and age. The mean age of urate urolithiasis is younger than for nonurate urolith stone formers. Egyptian Maus seem to be significantly younger compared with other breeds combined among all stone formers.

Predisposing conditions for the formation of urate urolithiasis include portovascular anomalies (see ch. 284), microvascular dysplasia (see ch. 284), and any form of severe hepatic dysfunction (see ch. 280). Additionally, an underlying genetic metabolic defect in certain cat breeds may exist. The presence of urate urolithiasis in cats should prompt a complete evaluation of liver function and hepatic vascular abnormalities.

Management of Urate Urolithiasis

Surgical removal of urate uroliths is still the treatment of choice until further studies are performed confirming safety and efficacy of medical dissolution in cats. A protein-restricted alkalinizing diet is recommended for the prevention of recurrence. Canned food is preferable to help increase fluid consumption. Periodic abdominal ultrasonography is recommended to assess for recurrence and is preferable to double contrast cystography because sedation or general anesthesia is typically not required.

Xanthine Urolithiasis

Xanthine urolithiasis is uncommon in felines and is usually associated with allopurinol administration.[14,15] There have been a few case reports of naturally occurring xanthine uroliths in cats.[14,16,17] Xanthine is a rarely recognized disorder characterized by a deficiency in xanthine dehydrogenase (XDH) enzyme activity observed in humans and other mammalians. XDH deficiency leads to excess urinary excretion of xanthine and hypoxanthine. Hypoxanthine is very soluble, but xanthine is extremely insoluble in urine at any pH.

Management of Xanthine Urolithiasis

No medical dissolution protocol for feline xanthine uroliths exists. The treatment of choice is surgical removal. Prevention involves feeding a protein-restricted alkalinizing diet and creation of a dilute urine by ensuring extra water intake.

Cystine Urolithiasis

Feline cystinuria was first documented in 1991.[18] Cystine uroliths are rare and represent only 0.1% of all uroliths seen in cats in the United States and Canada.[6,13,18] Cystinuria is a hereditary renal transport disorder involving cystine and the dibasic amino acids ornithine, lysine and arginine (COLA). This inborn error of metabolism leads to the formation of cystine crystals and ultimately to uroliths. Recently, feline cystinuria caused by a missense mutation in the SLC3A1 gene was identified in a young male domestic shorthair cat with cystine calculi.[1] There is a large degree of genetic heterogeneity of cystinuria in dogs and humans; mutations in the *SLC3A1* gene coding for a globular protein with a single transmembrane tail (rBAT) are observed most commonly.[19-21] The *SLC7A9* gene encodes for an intramembrane transporter protein called $b^{o,+}$ AT protein. The COLA amino acid transporter is a heterotetramer formed from 2 heterodimers of $b^{o,+}$ AT and r BAT.[22] There in fact may be other mutations responsible for cystinuria in cats that have not been identified as yet. Screening of 5 other cystinuric cats did not have this mutation.[19]

Cystine uroliths have been diagnosed in cats from 4 months to 12 years of age with a mean age of 3.6 years. There appears to be no sex or breed predisposition. Although most cats are domestic shorthairs, the Siamese seems to be slightly overrepresented.[23] Although cystine nephroliths have been identified in humans and dogs, thus far all cystine uroliths in cats have been found in the lower urinary tract.

In addition to lower urinary tract signs, cystinuric cats have been reported to have hypersalivation, lethargy and seizures. These clinical signs have been attributed to secondary hyperammonemia arising from impaired intestinal absorption and excessive renal excretion of COLAs. Arginine deficiency in cats can cause hyperammonemia. Cystinuric cats with impaired intestinal absorption and renal reabsorption of arginine will become arginine-deficient.

Management of Cystine Uroliths

Medical, dietary and surgical treatment options have been described for the management of cystine uroliths in humans and dogs but have not been described in cats. Cystine solubility increases above pH 7.5, so urinary alkalinization with potassium citrate (75 mg/kg PO q 12 h) along with ensuring adequate fluid intake are important in prevention of cystine uroliths. D-penicillamine and 2-mercaptoproprionylglycine (2-MPG) are cystine chelating agents that have been used in dogs and humans but not in cats. 2-MPG has been reported to have been used safely in cats.[23] A nonacidifying canned food, perhaps supplemented with arginine, should be fed as well.

In type III cystinuria in dogs (an androgen-dependent form), neutering of adult males seems to be curative. It is unknown if this form occurs in cats, but castration would seem to be a logical consideration.

Silica and Mixed Compound Uroliths

At one urolith analysis laboratory, silica-containing calculi accounted for approximately 0.3% of feline accessions. There did not appear to be a gender or sex predisposition. There are no dissolution diets available. Recommendations for preventing this urolith type are not well established. In dogs, a diet low in vegetable content and higher in animal protein and moisture is recommended. In cats, a similar strategy seems to make sense.

The Minnesota Urolith Center reported an incidence of 6% for mixed compound stones. If a dissolution diet is tried initially, as for struvite, and it does not appear to be successful, another mineral type may be found in the core of the urolith.

Struvite Uroliths

In cats, struvite uroliths typically form in sterile urine. This is unlike dogs and humans where struvite uroliths are most often associated with a urease-producing bacterial infection. The pathophysiology of struvite urolith formation is not completely understood but likely results from a combination of breed, sex and dietary factors. The influence of magnesium on struvite formation depends on urine pH and influence of ions, minerals, and other components in urine. Alkaluria is associated with increased risk of struvite formation. Struvite is more soluble in acidic urine (pH < 6.8). Factors that may be associated with the formation of alkaline urine such as a low animal protein diet, distal renal tubular acidosis, or family history of struvite uroliths should be considered in cats with struvite urolithiasis.[23] Increasing ionic concentrations of urinary minerals are the driving forces underlying crystal formation. Persistently alkaline urine and subsequent struvite crystalluria may be an indication to culture the urine for urease-producing microbes including

Staphylococcus sp., *Proteus* sp., and *Ureaplasma* sp., even though the urine of most cats is sterile.[24] Sterile struvite uroliths form typically in cats 1-10 years old. The Minnesota Urolith Center reported that struvite uroliths represented 46% of their submissions.

Management of Struvite Uroliths

The choice of urolith treatment method depends on clinician experience, patient factors, and client preferences. Several therapeutic foods are marketed for dissolution of struvite uroliths and are formulated to avoid excessive magnesium and phosphorus and to maintain acidic urine pH (this increases struvite solubility)[24] (Boxes 332-2 and 332-3). Therapeutic diets are formulated to avoid excessive magnesium and phosphorus and to maintain acidic urine pH, resulting in increased struvite solubility. Dissolution diets have not been associated with urethral obstruction as uroliths decrease in size. When feeding a diet formulated for dissolution, abdominal radiographs should be reevaluated 2 to 4 weeks after starting the diet. At this time the uroliths should be 33% to 100% smaller. With minimal change in size, the mineral composition of the urolith is unlikely struvite or nutritional recommendations are not being followed by the owners. After radiographic dissolution of the uroliths, the dissolution diet should be continued for an additional 2 to 4 weeks. In the rare circumstance when there is a concurrent urinary tract infection, an appropriate antibiotic should be administered throughout the entire period of dissolution.

Box is not inclusive of all dietary possibilities.

In female cats and males having had perineal urethrostomies, when urolith burden is low and the size is less than 4 mm, then voiding urohydropropulsion is another minimally invasive procedure (see Management of Urolithiasis, above). This technique will provide uroliths for analysis and culture, as well as providing a means of urolith removal, especially if the cat is demonstrating marked clinical signs or the owners prefer not to pursue a dissolution diet. The final management technique is a surgical intervention of either a cystostomy or a laparoscopic-assisted cystostomy.

Prevention of Struvite Uroliths

Prevention strategies for struvite uroliths include creating a dilute urine by encouraging the cat to drink water or increasing the water content of the diet. This will promote frequent voiding, thus allowing the passage of struvite crystals or small uroliths. There are several commercial diets that are produced not only for dissolution but for prevention of recurrence (see Box 332-3). There are several advantages of multipurpose foods including the ability to feed long-term as a maintenance diet, as well as the fact that they can be fed to all other healthy cats in the household and thus improve owner compliance. Typically they are relatively

palatable and there is no need to transition cats to a different food for urolith prevention.

Calcium Oxalate Uroliths

Epidemiology

Cats affected with CaOx urolithiasis typically are middle-aged to older, male, and neutered. Cat breeds at higher risk include the Persian and Himalayan.

Clinical Signs

The clinical signs have been discussed earlier in this chapter. They include pollakiuria, stranguria, hematuria, periuria, or a combination. Male cats can also present with urethral obstruction secondary to a urolith lodged in the narrow distal urethra. None of these signs are specific for uroliths and other rule-outs including idiopathic cystitis (see ch. 334), urinary tract infections (see ch. 330) and neoplasia (see ch. 351) should be considered. Cystic uroliths may also be incidental findings without the cat demonstrating any clinical signs.

Pathophysiology

The physical chemistry governing crystal formation in urine is complex, and many variables must be considered. The two major factors that affect this process are supersaturation of urine with calculogenic materials (calcium and oxalate) and the balance between substances that promote and those that inhibit CaOx formation. When urine is supersaturated with calcium and oxalate, crystal formation is more likely to occur; one measure that reflects this state is the relative supersaturation of urine (RSS). This measure is used widely to assess the risk of CaOx formation in people and is finding use in veterinary medicine as well.[8,25]

To assess supersaturation of the urine with calculogenic materials, the relative importance of urinary water content, calcium concentration, and oxalate concentration have been examined. Water content is perhaps the single most important variable affecting CaOx formation. Increased water dilutes the urine and increases urine volume, thereby reducing CaOx RSS. Hyperoxaluria also plays a role. Urinary excretion of oxalate depends on dietary intake, intestinal absorption, renal tubular secretion, and the rate of endogenous synthesis. Intestinal absorption is influenced by factors that determine the amount of free oxalate in the gut lumen. Calcium and magnesium both can bind oxalate, creating complexes that are excreted instead of absorbed. Intestinal flora such as *Oxalobacter formigenes* and lactic acid bacteria can degrade oxalate and may play a role in the pathophysiology of this disease. Hyperoxaluria due to endogenous overproduction has been found to be a primary genetic condition in people caused by metabolic defects and exists in two forms (type I and type II). A few cases of primary hyperoxaluria also have been reported in cats and appear to be most similar to the type II variant in people.[8,25,26]

Like oxalate excretion, urinary calcium excretion depends on dietary intake, intestinal absorption, and renal tubular excretion. Intestinal absorption of calcium is similar to that of oxalate in that calcium is poorly absorbed when it exists as a complex but is absorbed more readily when unbound. The appropriate level of calcium intake to minimize urinary CaOx RSS is thus intertwined with the amount of oxalate present, as well as the amount of other substances with which it may form complexes (e.g., phosphate). Hypercalciuria also can result from hypercalcemia and impaired tubular reabsorption of calcium.

Several substances have been identified as promoting or inhibiting CaOx formation in urine. Inhibitors include magnesium, citrate, and pyrophosphate, which form soluble complexes with calcium in the urine and prevent crystal formation with oxalate. Citrate also may lower the risk of CaOx formation by alkalinizing the urine. Proteins such as nephrocalcin and Tamm-Horsfall glycoprotein interfere with CaOx crystal formation and may play an additional role.

There is controversy over the importance of the role of urinary pH in the formation of CaOx formation. The absolute solubility of CaOx in urine is affected marginally over a broad pH range, but there are several reasons why a low pH may promote CaOx formation: persistent aciduria is associated with low-grade metabolic acidosis, which induces calcium resorption from bone and can increase urinary calcium excretion; acidic urine may diminish the ability of citrate and pyrophosphate to act as CaOx inhibitors; and increased reabsorption of calcium from the distal tubule occurs when the urine is alkaline. Furthermore, feeding an acidifying diet has been identified as a risk factor for CaOx formation in cats. In cats, the risk was three times higher when diets were fed producing a urinary pH of 5.99 to 6.15 compared with diets producing a pH of 6.5 to 6.9.[27] Studies also have evaluated the effect of pH specifically on CaOx RSS, but results so far have been conflicting.

Diagnosis

The initial evaluation of a cat with CaOx urolithiasis should include a thorough investigation for any underlying cause. A complete blood count, chemistry panel, urinalysis, and urine culture are considered a minimum database. Urinalysis should be evaluated ideally within 60 minutes of collection to minimize time and temperature effects on *in vitro* crystal formation.[8] The urine specific gravity should be recorded, and reasonable goals to decrease this value can be established after urolith identification. The urine pH in cats with CaOx is variable, and CaOx crystals are not always present in cats with CaOx-containing uroliths.[8] If the total calcium concentration is elevated, the ionized calcium level should be measured, and if hypercalcemia is confirmed, measurement of parathyroid hormone, parathyroid hormone–related protein, and possibly serum vitamin D levels is recommended (see ch. 297). Imaging should include both abdominal radiography and ultrasonography because in some cases stones may be missed when only one modality is used. As CaOx uroliths have a mineral opacity, they typically are easily seen with survey radiographs. However, very small uroliths may require ultrasound to detect their presence. Additionally, uroliths in the urethra are difficult to detect with ultrasound and so imaging the caudal abdomen including the pelvis requires radiography.

Management

Surgical and Interventional Management

There is no known protocol to dissolve CaOx uroliths at this time, and in many cases the only effective treatment is removal. Urolith removal can be achieved surgically, and less invasive methods are becoming increasingly available such as laparoscopic-assisted percutaneous cystostomy, cystoscopy (in females with uroliths < 3 mm in size) and voiding urohydropropulsion (in females and males with perineal urethrostomy and uroliths < 3 mm in size). If there have been prior uroliths, than radiographs or abdominal ultrasound should be performed every 2 to 3 months.

Dietary Management

CaOx uroliths occur in two common forms, CaOx monohydrate (whewellite) and CaOx dihydrate (weddellite). Management approaches for the two different forms are the same.

Perhaps the most important dietary modification that can be made is to increase water intake and urinary volume while decreasing urine specific gravity. Retrospective studies of cats with CaOx urolithiasis found a significantly lower risk of CaOx formation with higher dietary moisture content.[27] Feeding a canned diet is the best way to increase water intake, but some cats will not eat canned food. In these cases, water or broth can be added to dry food, or broth can be added to the water supply. Water fountains also may be helpful to increase water intake in cats. Appropriate targets for specific gravity are less than 1.025 in cats; achieving dilute urine can be very difficult in cats.

There are several commercially available prescription diets that have been designed to influence the RSS of CaOx and by decreasing the RSS lessen the likelihood of urolith recurrence. These diets typically have a slightly higher sodium chloride concentration and are slightly restricted in protein (see Boxes 332-3 and 332-4). Supplementation of sodium chloride has been investigated as a means of increasing water consumption but has been a point of controversy. Increased sodium consumption increases urinary calcium excretion and may increase the risk of CaOx urolithiasis. However, prospective studies have shown that increasing dietary sodium content significantly decreased the CaOx RSS in healthy and CaOx stone–forming cats.[28] The *total* daily urinary calcium excretion increased in these studies, but apparently the effect on CaOx RSS is offset by the increase in water intake and urine volume. These findings suggest a benefit to NaCl supplementation, but long-term studies still are needed. Sodium supplementation can be considered if there is an inadequate response to dietary therapy and the urine is not dilute, but patient selection must be done carefully. Short-term studies in cats have shown no adverse effects on kidney function or blood pressure, but caution is required when considering adding salt to the diets of cats with kidney disease or hypertension until longer-term studies are done. Additionally, high-sodium diets are contraindicated for animals with heart disease.[25]

Box 332-4

Diets Designed for Calcium Oxalate Prevention Only

Iams Urinary-O Plus can and dry—prevention only

Box is not Inclusive of all dietary possibilities.

Higher protein level historically has been associated with an elevated risk of CaOx formation because it can promote acidosis and hypercalciuria. However, retrospective studies in cats have found a lower risk of CaOx formation with higher dietary protein.[25,29] Overall, the exact amount and type of protein that is ideal has yet to be determined, but most diets designed to reduce CaOx urolithiasis have reduced protein levels.

Other nutrients to consider in the dietary management of CaOx uroliths include magnesium, citrate and phosphorus. Urinary magnesium and phosphate (and citrate) are thought to act as inhibitors of CaOx urolith formation and should not be restricted in the diet. Dietary phosphorus should also not be restricted because reduced serum phosphorus levels could activate the parathyroid gland, resulting in increased vitamin D_3 levels and increased intestinal absorption of calcium.

Acidifying diets have been associated with a higher risk of CaOx formation in cats, but further studies have yielded conflicting results regarding the importance of daily urinary pH in CaOx prevention. Overall, it can be said that pH generally appears to be less important in controlling CaOx stone formation than in controlling formation of other stones such as struvite. Given the available information it seems prudent to avoid significant acidification of the urine. An appropriate initial target urine pH is approximately 7.0; however, with this in mind, the target urinary pH values achieved by feeding almost all of the diets listed in Boxes 332-3 and 332-4 are acidic. This is because the goal of the Royal Canin Urinary SO formulation and Hill's Prescription Diet C/D Multicare is to prevent both CaOx *and* struvite uroliths. Since urine pH control is more important for dissolution and prevention in treating struvite stones than in treating CaOx stones, these diets target a lower pH as part of the strategy to prevent struvites. Despite causing a mildly acidic urine, all the listed diets are effective in producing urine with a low CaOx RSS. This apparent paradox exemplifies the complex nature of CaOx urolithiasis, and many factors must be considered in designing an appropriate diet. Of course, if CaOx uroliths continue to be a problem despite feeding an appropriate diet, alkalinization of the urine can be considered (see later) to potentially improve control.[25]

Medication

Pharmacologic agents can be added to the management plan for CaOx urolithiasis if dietary therapy alone is not effective in preventing urolith growth or regrowth. Potassium citrate has been used effectively in people as a urinary alkalinizing agent, and it also may enhance the inhibitory action of citrate on CaOx formation. However, no study to date has shown a clear benefit to the use of citrate in cats. Furthermore, there is no evidence for hypocitraturia as a risk factor for CaOx formation in cats. The recommended dosage of potassium citrate is 75 mg/kg q 12 h PO. If potassium citrate is used clinically for alkalinization, the starting dosage mentioned previously can be used and the dosage increased until a pH of approximately 7.0 is achieved. To avoid hyperkalemia, serum potassium levels should be monitored when this drug is used. Further studies are necessary in the cat.

Thiazide diuretics provide another medical option to reduce CaOx saturation. These drugs inhibit the sodium-chloride cotransporter in the distal tubule and by doing so stimulate calcium reabsorption and decrease urinary calcium excretion. In a study of healthy cats treated with hydrochlorothiazide at a dosage of 1 mg/kg q 12 h PO, a significant decrease in urinary CaOx RSS was found.[30] Studies of the safety and effectiveness of long-term administration are lacking.[25]

Monitoring

The probability of CaOx urolith recurrence varies among studies and has been reported to be as high as approximately 7% (this may be higher in that a recurrence of uroliths does not always prompt repeat analysis). Two studies in cats have found differing results: resubmissions of uroliths were recorded from 7.1% of over 2000 affected cats within a 5-year period (mean resubmission time, 25 months), whereas 40% of a group of cats with ureteroliths exhibited recurrence within about a year.[25,31,32] Neither study group reflects the total population at risk. If new stones are identified before they become large, less invasive therapies such as voiding urohydropulsion may be used. The size of stone that can be expelled varies depending on breed and size, but in general bladder stones smaller than 5 mm in female cats, and 1 mm in male cats are amenable to voiding urohydropropulsion. Removal of larger uroliths requires a more invasive method. Four weeks after the initial procedure, then at 3 and 6 months, and every 6 months thereafter radiography or ultrasonography is recommended immediately following a removal procedure to verify that no uroliths

remain.

CHAPTER 333

Diseases of Abnormal Micturition

Julie K. Byron

Client Information Sheet: Diseases of Abnormal Urination

Introduction

Physiology of Micturition

The primary purpose of the lower urinary tract is to store urine and to facilitate its elimination at an appropriate time. The bladder stores urine 99% of the time and is in emptying phase only 1% of the time. Coordination of storage and emptying requires a complex interaction between the somatic and autonomic nervous systems, as well as normal function of the organs and tissues involved.

All three components of the peripheral nervous system are involved in the micturition cycle (Table 333-1). In addition, conscious voiding involves the lumbar and sacral spinal cord, as well as the brainstem and cerebral cortex.

TABLE 333-1

Peripheral Nervous System Components of Micturition

TYPE	LOCATION	NERVE	FUNCTION WHEN STIMULATED	FUNCTION WHEN BLOCKED	FUNCTION WHEN INAPPROPRIATELY STIMULATED	FUNCTION INAPPRO BLOCKEI
Parasympathetic (M3 muscarinic)	Bladder body (detrusor)	Pelvic nerve (S1-S3)	Contraction and bladder emptying	Detrusor relaxation and bladder filling	Overactive bladder	Bladder ato retentio
Sympathetic (beta-3 adrenergic)	Bladder body (detrusor)	Hypogastric nerve (L1-L4)	Detrusor relaxation and filling	Detrusor relaxation and urination	Urine retention	Decreased b compliai increase pressure
Sympathetic (alpha-1 adrenergic)	Bladder neck/urethra	Hypogastric nerve (L1-L4)	Contraction and continence	Urination	Urine retention	Open ureth incontin
Somatic (nicotinic)	Distal urethra/pelvic floor	Pudendal nerve (S1-S2)	Conscious/reflex contraction and continence	Urination	Urine retention	Open ureth incontin

During filling and storage, activation of stretch receptors in the bladder wall leads to a reflex arc increasing urethral tone and relaxing the detrusor muscle via sympathetic pathways (Figure 333-1). During initiation of micturition, stretch receptors send afferent signals along myelinated fibers of the pelvic nerve to the lumbar spinal cord and cranial to the pontine micturition center in the brain. If the situation is appropriate for urination, parasympathetic pathways are activated to stimulate bladder smooth muscle contraction and parasympathetic signals are inhibited to relax the urethra (Figure 333-2). There is also a local urethral reflex arc that causes the somatic-mediated contraction of the striated muscle surrounding the urethra in response to

a sudden increase in abdominal pressure and movement of urine into the urethra, such as during a cough or sneeze.

In addition to normal neurologic mechanisms, several other factors are important for the normal function of the micturition cycle in dogs and cats. The integrity of the smooth muscle of the urethra, normal urethral mucosa, associated vasculature, and the support of connective tissues are also key.[1,2] In females, estrogen appears to have a significant impact on these tissues.[3,4] Its decline after neutering appears to play a role in urethral sphincter mechanism incompetence.[5,6] Prostatic hyperplasia in intact male dogs can lead to functional urethral obstruction and urinary retention.

Disorders of Storage

Storage disorders primarily occur due to an inability to maintain adequate urethral tone in the face of normal

bladder pressures. These may result from an anatomic or developmental abnormality or acquired dysfunction in the spinal cord, urinary bladder, or urethra and surrounding tissues. Congenital abnormalities (see ch. 336) such as ectopic ureters or urogenital sinus malformation can result in the unconscious loss of urine in juveniles, while acquired urinary incontinence disorders including urethral sphincter mechanism incompetence (USMI), lower motor neuron bladder (LMB), and overactive bladder (OAB) may develop later in life (see ch. 46).

Urethral Sphincter Mechanism Incompetence

Urethral sphincter mechanism incompetence is the most common urinary storage disorder in dogs.[7] The urethral sphincter mechanism involves the smooth muscle of the urethra, as well as the surrounding support tissues, submucosal vasculature, and urothelium. USMI is thought to result from the breakdown in this complex through reduced muscular responsiveness and tone and changes in the periurethral tissues. In female dogs, these changes appear to be associated with a reduction in estrogen and increases in follicle-stimulating hormone and luteinizing hormone after neutering—thus the term "hormone-responsive incontinence."[8,9] The pathophysiology of its development in neutered male dogs is poorly understood; however, increases in follicle-stimulating and luteinizing hormone levels have been documented in response to decreased testosterone.[10,11]

Urethral sphincter mechanism incompetence is most common among neutered female dogs. It is less common in neutered males and rare in intact male dogs and cats.[11] It appears to affect up to 20% of neutered females and up to 30% of large-breed dogs. Several breeds have been found to have increased risk including the Doberman Pinscher, Giant Schnauzer, Old English Sheepdog, Rottweiler, Weimaraner, and Boxer, but any breed may be affected.[12] Recent literature has demonstrated an increased risk of development of USMI in dogs neutered before 3 months of age.[13,14] Other studies have found no relationship to age at neuter,[15] and the most optimal time to neuter for prevention of USMI remains controversial (see ch. 313). It is possible that this is related to the development and sensitivity of the sphincter mechanism tissues to estrogen and other hormones; however, the mechanism is incompletely understood.

Predisposing factors such as a pelvic bladder, short urethra, or recessed vulva may also be associated with increased risk of developing USMI; however, the presence of any of these does not necessarily lead to incontinence. A reduction in pressure transmission from the abdomen to the proximal urethra has the potential to lead to urinary incontinence in animals with a short urethra or pelvic bladder by setting up a negative pressure gradient from the bladder to the urethra. The leakage of urine seen with a recessed or "juvenile" vulva may be related to pooling of urine in the vestibule during urination, which leaks out at a later time.

Clinical Presentation and Diagnosis of USMI

Incontinence due to USMI often appears within a few years of neutering but has a wide range of age of onset. Dogs with USMI usually have normal bladder capacity and are able to urinate normally, with complete emptying of the bladder. While most of these dogs are otherwise healthy, clinical signs can worsen dramatically if comorbidities develop, especially those leading to polyuria. In patients with polyuric conditions, the increased volume of urine in the bladder may lead to increased pressure on the already weakened sphincter mechanism and leakage. Lower urinary tract infection can also increase clinical signs (see ch. 330). It is suspected that USMI, and urinary incontinence of any cause, are associated with increased risk of urinary tract infection, but no studies have been conducted to fully evaluate this.

Owners often seek veterinary care when the frequency of incontinence becomes bothersome, although in the author's experience, the incontinence may have been present for months or years. It is essential to establish that the animal is passing urine unconsciously. Many owners will complain of "incontinence" when the animal is demonstrating submissive urination or is otherwise consciously urinating in inappropriate places (see ch. 9). Dogs with USMI may leak urine when recumbent, sleeping, or after exertion. Although the passage of urine is involuntary, dogs may increase grooming of the perivulvar or preputial area. USMI is an acquired condition, so questioning of the owner regarding the onset of clinical signs is important. Animals that have been incontinent from birth or prior to neutering should be assessed for congenital malformations such as ectopic ureters prior to making a diagnosis of USMI (see ch. 336).

Physical examination of these animals is often normal, with the exception of perivulvar or preputial urine staining. The conformation of the vulva and condition of perivulvar skin should be noted. The presence of perivulvar dermatitis may increase the risk of urinary tract infection. Rectal examination and palpation of the

urethra are usually normal. Urination is observed to be normal and complete, with little or no residual volume. The assessment of residual urine is essential in male dogs with urinary incontinence to differentiate USMI from detrusor urethral dyssynergia, a disorder of incomplete bladder emptying (see below).

The presence of urinary incontinence in an otherwise healthy neutered female dog that was previously continent is often adequate for presumptive diagnosis of USMI and a trial of empirical therapy. Due to its lower prevalence outside the neutered female dog population, intact female dogs, intact or neutered male dogs, and cats with similar histories and clinical signs require additional evaluation before making a diagnosis of USMI.

A urinalysis and urine culture should be performed (see ch. 72). The presence of isosthenuria or hyposthenuria may contribute to severity of incontinence and necessitates additional evaluation for an underlying cause. As noted above, the risk of urinary tract infection in animals with USMI has not been evaluated, but its presence may lead to worsening signs. Complete blood count and serum biochemistry panels are not essential for diagnosis of USMI, although they may be helpful when making treatment decisions and are important in evaluating animals with polyuria.

If anatomic abnormalities are suspected, imaging such as contrast radiography, abdominal ultrasound, or contrast computed tomography is indicated. Cystoscopic evaluation of the lower urinary tract may also be necessary to assess conformation of the lower urinary tract and vagina (see ch. 108). Advanced diagnostics such as urodynamic studies are designed to quantify the pressure produced along the urethra and the compliance and detrusor function of the urinary bladder. These are available at some referral institutions and may be indicated in patients with equivocal signs and poor response to therapy.

Medical Treatment of USMI

Medical therapy of USMI is generally considered the first line of management; only after failure or intolerance of medical therapy are surgical options considered. Medical treatment of USMI in the neutered female dog consists of increasing number and sensitivity of alpha-receptors in the urethral sphincter with estrogen, or by stimulating those receptors with an alpha-agonist (Table 333-2).

TABLE 333-2

Drugs Frequently Used to Treat Urethral Sphincter Mechanism Incompetence[38]

DRUG	CLASS	DOSE	SIDE EFFECTS	CAUTION
Phenylpropanolamine	Alpha-agonist	1-1.5 mg/kg PO q 8-12 h	Hypertension, aggression, restlessness, gastrointestinal upset, anxiety	Hypertension, hyperadrenocorticism, renal disease
Diethylstilbestrol (DES)	Estrogen	0.1-1 mg/dog PO q 24 h for 5-7 days, then weekly or as needed	Myelosuppression (rare at these dosages), attractiveness to males, mammary/vulvar swelling, behavior changes	Males (can develop prostatic metaplasia)
Conjugated estrogen	Estrogen	0.02 mg/kg PO q 24 h for 5-7 days, then q 2-4 days as needed	Same as DES	Same as DES
Estriol	Estrogen	2 mg/dog PO q 24 h × 14 days, then reduce to 1 mg q 24 h	Same as DES	Same as DES
Testosterone cypionate	Androgen	2.2 mg/kg IM q 4-8 weeks	Behavior change, aggression, perianal adenoma, prostatic hyperplasia	Cardiac disease, renal disease, hepatic disease, prostatic disease

The most commonly used estrogens are diethylstilbestrol (DES) and estriol (Incurin, Merck Animal Health, Madison, NJ). DES is not available commercially, so it must be compounded. Estriol appears to have a higher response rate among female dogs than DES (89% and 65%, respectively).[16,17] Adverse effects associated with estrogen use are dose-related and include mammary gland development, vulvar swelling, and attractiveness

to males.[16] These usually subside with dosage reduction. A more serious adverse event associated with estrogen use is irreversible bone marrow suppression (see ch. 199).[18] It is considered standard of care to monitor the complete blood count in animals receiving estrogen compounds; however, the doses associated with bone marrow suppression are much higher than those recommended to treat USMI. The author recommends performing a complete blood count before starting treatment with an estrogen compound and then rechecking it one month later.

Phenylpropanolamine (PPA, Proin, PRN Pharmacal, Pensacola, FL) is the most widely used alpha-agonist for the treatment of USMI. The dosage and frequency needed for each animal vary widely and may need to be increased over time to maintain continence. Adverse effects associated with PPA include restlessness, aggression, changes in sleeping patterns, and gastrointestinal signs. These are also usually alleviated by a reduction in dosage or frequency.[19,20] Clinical response to PPA administration ranges from 75%-90%.[20,21] Frequently, both an estrogen and PPA are used in the same patient for severe or refractory incontinence. There are anecdotal reports of greater improvement when used together, but there is little published evidence to support a synergistic effect.[22]

Phenylpropanolamine is also frequently used in male dogs and cats with USMI. In addition, neutered male dogs may be treated with testosterone cypionate as monthly injections; however, its efficacy is not well documented. Although male dogs with USMI are most responsive to PPA, it is at a rate of only 43%, much lower than in females.[11] Estrogen compounds should not be used in males due to the risk of prostatic metaplasia. They are rarely used in cats, and care should be taken to monitor the mammary glands for neoplasia in cats receiving estrogens.

Surgical Treatment of USMI

In patients that fail medical therapy, it may be necessary to consider surgical intervention. This is generally only pursued if the animal does not respond to, or cannot tolerate, medical treatment. Several surgical procedures have been used to treat USMI, many to increase abdominal pressure transmission to the proximal urethra. These include colposuspension, transobturator vaginal tape, and urethropexy. Outcomes are variable, and they are considered to have poor long-term efficacy, particularly in animals with normal bladder position.[23] The most promising and commonly performed surgical procedure for USMI is placement of an artificial urethral sphincter, which may be adjusted via a subcutaneous port (see ch. 124). Recent studies have shown a significant increase in continence in male and female dogs that had failed medical therapy for USMI.[24-26]

Historically, injectable urethral bulking agents have been used, particularly bovine cross-linked collagen, to increase resting urethral pressure in dogs with USMI. In 2009 the manufacturers of the most commonly used product removed it from the market, so at the time of writing, injectable bulking agent therapy for USMI is considered unavailable, except in some research settings.

Lower Motor Neuron Bladder

Incontinence as a disorder of storage can also occur secondary to spinal cord injury or disease. Lesions in the S1-S2 region will lead to weakness of the striated muscular sphincter. Disruption of the local reflex arc at these segments leads to an easily expressible bladder, which may empty with minor increases in abdominal pressure. Decreased anal tone and a poor perineal reflex, as well as their easily expressible bladder, identify these animals (see ch. 259). Most of these animals are unable to voluntarily void and require intermittent catheterization (see ch. 105) or manual expression by the owner. Correction of the underlying lesion may lead to some return to normal function. Because of the tendency to have incomplete emptying of the bladder with manual expression, these animals are at increased risk of developing urinary tract infection and appropriate surveillance must be in place (see ch. 330). The muscarinic agonist bethanechol has been used in these patients to increase detrusor contraction; however, the evidence for its efficacy remains controversial.[27,28]

Detrusor Hyperreflexia/Overactive Bladder

Detrusor hyperreflexia/overactive bladder (OAB), is the most common form of urinary incontinence in people, but it has been poorly characterized in companion animals. The true incidence of OAB and its importance as a cause of urinary incontinence in dogs and cats are unknown. In people, it is characterized by sudden urgency to urinate and involuntary loss of urine associated with bursts of detrusor contractions at bladder volumes far below capacity. In dogs, it may manifest as loss of bladder compliance and capacity and

thus the need to urinate more often without polyuria or inflammation of the lower urinary tract. OAB may be a cause of treatment failure in some dogs treated for presumed USMI and should be considered in these cases. Diagnosis of OAB in animals can be challenging and is only definitively made using urodynamic studies such as cystometrography. Response to therapy with antimuscarinic drugs is often used to presumptively diagnose OAB in veterinary species. The most commonly used include oxybutynin and imipramine, the latter of which also has alpha-agonist effects, potentially increasing urethral sphincter tone. Adverse effects of these medications include gastrointestinal abnormalities such as diarrhea and constipation, as well as parasympatholytic signs like tachycardia and hyposalivation.

Disorders of Emptying

The inability to completely empty the bladder during a normal void can result from either a functional or mechanical obstruction of the outflow tract and urethra, or an abnormality of the detrusor muscle, which would impair the bladder's contraction. Overflow incontinence can result from the lack of complete emptying, often when the animal is at rest. An owner may not be able to differentiate this from an animal with a storage disorder (e.g., USMI), and it is up to the clinician to determine the underlying process so that appropriate therapy can be instituted. Inability to completely empty the bladder is a risk factor for UTI, and these animals should be monitored for infection.

Detrusor Atony

Complete emptying of the urinary bladder is dependent on the normal contraction of the detrusor muscle. In the normal animal, the bladder relaxes during filling, with only small increases in intravesical pressure. As the bladder continues to fill, the pressure increases to a threshold, which triggers a detrusor contraction and emptying. Loss of adequate detrusor contraction can result from neurogenic or non-neurogenic abnormalities. Injury to the sacral spinal cord (S1–S3) or pelvic nerves can lead to bladder atony and is often associated with weakened urethral tone. These animals often have decreased perineal reflexes and easily expressed bladders (LMB). Treatment of the underlying lesion, if possible, may lead to improved voiding function. However, until normal function returns, careful management of urination must be followed. Male dogs are manually expressed or aseptically catheterized 2-4 times a day either in the hospital or at home (see ch. 105), and cats and female dogs are often manually expressed.

Direct damage to the detrusor muscle can occur from overdistension due to mechanical or functional outflow obstruction of an acute or chronic nature. The muscle fibers of the detrusor transmit action potentials, which initiate contraction via tight junctions. With overdistension, these tight junctions are interrupted, leading to an absent or ineffective contraction. The overdistension may be acute as with obstructive feline idiopathic cystitis in a male cat, or chronic, as in a dog with a functional obstruction of the urethra. Relief of the obstruction and maintenance of a small bladder volume for up to 2 weeks may allow the junctions to reestablish and the return of coordinated detrusor function. This is usually managed by either indwelling or frequent sterile catheterization of the bladder. Bethanechol may be used in these patients to enhance stimulation of the detrusor contraction since the pelvic nerve is intact. Other medications that have been shown to enhance detrusor function are cisapride and metoclopramide; however, the individual response varies widely.[29,30] It is essential that relief of any urethral obstruction, functional or mechanical, be attained before starting medical therapy to enhance detrusor contraction.

Detrusor Urethral Dyssynergy

Functional urethral obstruction, or detrusor urethral dyssynergy (DUD), arises from an abnormality in the reflex arc that normally allows the urethral sphincter to relax at the initiation of urination. The lesion is thought to be in the reticulospinal tract, Onuf's nucleus, or the caudal mesenteric ganglion, and likely involves the loss of inhibitory signals to the pudendal and hypogastric nerves.[31] It is unknown if injuries to peripheral nerves, neuromuscular junctions, or smooth or striated muscular sphincters are also involved.[32] Unlike the “upper motor neuron bladder” seen in animals with thoracolumbar intervertebral disc disease and other spinal cord lesions, these animals typically have an otherwise normal neurologic examination (see ch. 259).

The disorder affects primarily middle-aged, large and giant-breed male dogs, although female dogs and cats can be affected. One case series of 22 dogs reported a mean age of 4.9 years.[33] Clinical signs are similar to those of mechanical obstruction. The animal often postures to urinate and is able to produce a urine stream

that quickly becomes attenuated or stops completely. The animal may continue to posture to urinate or make several attempts without fully emptying the bladder (Video 333-1). The retention of large amounts of residual urine typically leads to overflow incontinence and may be mistaken for USMI. This leakage can occur because the hypertonicity of the involved sphincter is often dynamic and is triggered by the act of voiding. In chronic cases, bladder overdistension and subsequent atony may develop. Unlike animals with mechanical obstruction, these dogs are typically easy to catheterize (see ch. 105) and contrast urethrography may be normal or reveal areas of narrowing of the urethra (urethrospasm).

Presumptive diagnosis of DUD is often made by observing the dog urinate with a typical interrupted pattern, documentation of a large residual urine volume, easy passage of a urinary catheter, and ruling out of a mechanical obstruction. Normal residual urine volumes in 48 normal dogs were reported to be 0.1-3.4 mL/kg body weight with a mean of 0.2 mL/kg (see ch. 330 and Video 330-1).[34] The author uses <0.5 mL/kg as a general guideline. Ultrasonography is recommended to assess the ureters and renal pelves for dilation secondary to chronic obstruction and ureterorenal reflux of urine.

Treatment of the hypertonic urethral sphincter generally consists of alpha-adrenergic blockade with prazosin, an $alpha_1$-specific antagonist with demonstrated effects on both the internal and external urethral sphincter.[35] Tamsulosin, which is specific for the $alpha_{1A}$ subtype found in the internal urethral sphincter, has also been successful in these dogs. Some dogs will require additional therapy if the striated muscle is more significantly affected. Benzodiazepines, such as diazepam, or other skeletal muscle relaxants, including acepromazine and methocarbamol, may be more effective if the external urethral sphincter is involved. Diazepam is typically administered 30 minutes before voiding to decrease external urethral sphincter pressure. Dantrolene and baclofen have been used in the past as skeletal muscle relaxants; however, the potential for adverse effects has decreased their use in veterinary patients.[35,36] In severe and refractory cases, intermittent sterile catheterization by the owner at home may be necessary (see ch. 105). Medical therapy of associated bladder atony should only be started after adequate relief of the functional urethral obstruction has been reached (Table 333-3). Close monitoring of these patients for residual urine volume and UTI is needed to assess efficacy of treatment and prevent complications (see ch. 330).

TABLE 333-3

Drugs Frequently Used to Treat Disorders of Bladder Emptying[38]

DRUG	MECHANISM	DOSAGE	SIDE EFFECTS/CAUTION
Prazosin	Alpha-1-antagonism, smooth muscle relaxant	1 mg/animal < 15 kg; 2 mg/animal > 15 kg; q 8-12 h PO	Hypotension, weakness, syncope, gastrointestinal (GI) upset/renal disease, cardiac disease
Tamsulosin*	Alpha-1A-antagonism, smooth muscle relaxant	0.01-0.2 mg/kg PO q 24 h	Hypotension
Phenoxybenzamine	Nonspecific alpha-antagonism, smooth muscle relaxant	Dog: 0.25 mg/kg q 8-12 h, Cat: 1.25-7.5 mg/cat q 8-12 h PO	Hypotension, tachycardia, miosis/ first dose hypotension
Acepromazine	Nonspecific alpha-antagonism, smooth muscle relaxant, anxiolytic	0.5-2.2 mg/kg q 6-8 h PO	Sedation, hypotension
Diazepam	Skeletal muscle relaxant, anxiolytic	Dog: 0.5-2 mg/kg q 8 h PO or 30 min prior to voiding	Sedation, ataxia/liver dysfunction, do not use in cats
Methocarbamol	Skeletal muscle relaxant	22-44 mg/kg q 8 h PO	Sedation, weakness, hypersalivation
Baclofen*	Skeletal muscle relaxant	Dog: 1-2 mg/kg q 8 h PO	Weakness, GI upset/do not use in cats
Dantrolene	Skeletal muscle relaxant	Dog: 1-5 mg/kg q 8 h PO, Cat: 1-2 mg/kg q 8 h PO	Weakness/liver disease
Bethanechol	Parasympathomimetic	Dog: 2.5-15 mg/dog q 8 h PO, Cat: 1.25-5 mg/cat q 8 h PO	Diarrhea/GI or urethral obstruction
Cisapride	Prokinetic	Dog: 0.1-0.5 mg/kg q 8-12 h PO, Cat: 2.5-5 mg/cat q 8-12 h PO	Ataxia, GI upset/GI obstruction

Prognosis for recovery of normal voiding is good, but most dogs will require lifelong therapy for DUD. Attempts to taper medications to the lowest effective dosage may be hampered by relapse of clinical signs after months of normal voiding.[33] Prognosis appears to be worse in patients with bladder atony or UTI secondary to urine retention. Anecdotally, urethral stenting may improve clinical signs (see ch. 124); however, this is considered a salvage procedure, with several potential complications, and is indicated only in the most refractory of cases.

Upper Motor Neuron Bladder

Spinal cord lesions cranial to the sacral segment generally cause neurogenic functional urethral obstruction. This leads to loss of inhibitory signals to the hypogastric and pudendal nerves that prevents sphincter relaxation upon voiding. This is the classic "upper motor neuron bladder" in which the patient is unable to urinate normally and is difficult to manually express. The most commonly affected patients are those with intervertebral disc disease and associated paresis (see ch. 266). These animals typically have additional neurologic deficits including paresis and nociceptive loss (see ch. 259). Treatment of the underlying lesion typically leads to partial or complete return to normal voiding function after days to weeks. Until normal voiding resumes, the patients are managed as for DUD with alpha-adrenergic blockade and manual expression or catheterization. Monitoring for overdistension and UTI are critical in these patients, as is nursing care, particularly since the overflow incontinence that can accompany this process may lead to skin breakdown in these recumbent animals.

Dysautonomia

Dysautonomia is a rare condition involving the degeneration of the neurons of the autonomic nervous ganglia, leading to sympathetic and parasympathetic dysfunction. It has been most commonly reported in both dogs and cats in the United Kingdom and Scandinavia, but small clusters of cases in both species have been seen in the United States.[37] Its underlying cause is unknown, but neurotoxin exposure is strongly suspected. In addition to the classic findings of unresponsive mydriasis and prolapsed nictitans, the abnormalities seen with dysautonomia can range from ileus and constipation to decreased systolic function of the heart. These dogs and cats often have significant voiding dysfunction and urine retention due to bladder atony and overflow incontinence secondary to urethral sphincter incompetence. There is no specific treatment for dysautonomia, and spontaneous remission is uncommon. The prognosis is related to the severity of the clinical signs and the specific organ functions affected.

CHAPTER 334

Feline Idiopathic Cystitis

C.A. Tony Buffington

Client Information Sheet: Feline Idiopathic Cystitis

Introduction

Feline idiopathic (interstitial) cystitis (FIC) is the most common cause of chronic lower urinary tract signs (LUTS) in cats.[1] We coined the term feline interstitial cystitis[1] because of the similarities of FIC to interstitial cystitis (IC) in humans,[2] which used to require cystoscopic evaluation of the bladder to make the diagnosis. We use the term FIC to refer to idiopathic cystitis in this chapter since cystoscopy no longer is required to make the diagnosis in humans[3] and is rarely available (or indicated) for cats.

In addition to the "classical" chronic LUTS etiologies, I recently proposed a central nervous system cause for FIC in some cats, which I called Pandora Syndrome[4]; others have suggested a similar etiology in humans.[5-7] Additionally, periuria can represent marking behavior or be "related to primary environmental or social factors."[8] Clinicians also must consider whether they are seeing an initial episode or recurrence of a chronic disease.[9,10]

Recent Epidemiology

In 2014, the Banfield State of Pet Health[11] reported that "cystitis" (LUTS) accounted for approximately 5% of diagnoses in cats older than one year of age presented for care for a health problem, and Veterinary Pet Insurance reported that "bladder/urinary tract problems" was the most common insurance claim for cats in 2013.[12] The prevalence of diseases in cats presented for evaluation of LUTS appears to be on the order of (% of cases) FIC—55-73%, urolithiasis—10-20%, microbial infection—1[13-15]-25%[16-18] (what, if any, role viruses play in FIC remains unknown[19]), and other causes—5-20%.

A 2011 retrospective case-control study[20] reported that cats with FIC had a significantly higher body weight and body condition score; were more likely to be housed in multicat households, more nervous and fearful, more prone to hide from unknown visitors in the house, more likely to use a litter container; had lower owner-reported water intake, activity level, hunting behavior, and less access to the outside than did control cats. Of the stressful situations queried, only house move occurred with increased frequency in cats with FIC. Pyuria, hematuria, and an increased urine protein : creatinine ratio were significantly higher in obstructed males compared with nonobstructed males, and obstruction was significantly more likely in the presence versus absence of struvite crystalluria. While this finding suggested an association between struvite crystalluria and obstruction in male cats with FIC, it cannot clarify whether crystal formation occurred before, during, or after the obstructing event.

A prospective study of causes of LUTS in 119 primary care cases of cats (34 were obstructed) in Norway between 2003 and 2007 also was reported in 2011.[21] Sixty-five cats (55%) were diagnosed with FIC, 25 (21.0%) had urethral plugs, and 14 (12%) had either bacterial urinary tract infection (UTI) or urolithiasis. Seventy-three (62%) cats were having a first episode of LUTS, whereas 44 (38%) were recurrences.

A 2014 study[22] reported on 302 cats presented for care of LUTS at the Clinic of Small Animal Medicine, Ludwig Maximilian University Munich between 2000 and 2007. The most common diagnoses were FIC (55.0%), UTI (18.9%), urethral plug (10.3%), urolithiasis (7.0%), and neoplasia (3.6%). Six cats (2.0%) had severe struvite crystalluria without urethral obstruction, and nine cats were identified with neurogenic disorders (3.0%). Urethral plugs were significantly more frequent in cats with FIC than in cats with UTI, and

cats with FIC and urethral plugs had significantly higher body weights and were significantly younger (<10 years of age) than were cats with UTI or neoplasia. Males were significantly more likely than females to have FIC or a urethral plug than a UTI or neoplasia. No differences between affected and unaffected cats regarding breed distribution, living conditions, diets, outdoor access, number of cats in the household, or seasonal variation were identified.

Results of epidemiological studies must be interpreted cautiously. Significant (unintentional) selection bias, in addition to the ability to identify associations but not causations, often occurs in cases presented for care of a clinical sign from which most samples are drawn. Determining the population-level prevalence and distribution of causes of LUTS would require a population-based study, as has been done for humans with IC and related disorders.[23] Another potentially informative approach would be a prospective longitudinal study, such as the currently ongoing Bristol Cats Study.[24]

Pathophysiology

Because the presenting complaint of most owners of cats with FIC is LUTS, for many years most research focused on identification of intraluminal or intrinsic abnormalities of the bladder.[25-35] As mentioned, observation of submucosal petechial hemorrhages (glomerulations) by cystoscopy used to be required for the diagnosis of IC in humans, but these lesions are neither sensitive nor specific for IC[36] and so are no longer part of the diagnostic criteria.[37] Cystoscopy still can be used to rule out the presence of "confusable" diseases in complicated cases, however.[3,38] A variety of other abnormal bladder findings also have been reported,[32,33,35,39-42] but their role in the etiopathogenesis of FIC is unknown.

Changes in sensory nerve function occur in cats with FIC.[4,43] A modest increase in substance P (SP) immunoreactivity in sensory neurons[44] and upregulation of the neurokinin-1 receptor for SP[35] has been found in the bladder of cats with FIC and in humans with IC.[45,46] Clinical trials of SP antagonists have been disappointing, however,[47] and recent evidence[48,49] suggests that SP might limit the severity of inflammatory reactions, opening the possibility that the changes observed in patients might reflect a protective response. Abnormalities also have been identified in dorsal root ganglion cell bodies throughout the lumbosacral (L4-S3) spinal cord from cats with FIC.[50,51]

Treatments targeting bladder sensory neurons have been tested without success to date. Controlled trials of both capsaicin and resiniferatoxin in human beings with IC failed to find significant benefits over placebo.[52] In 2006, one expert concluded, "Intravesical instillation therapy has basically not changed during the last few years, although some studies have disconfirmed some regimens.[53]" This continues to be the case,[54] and in 2014[55] pentosan polysulfate (Elmiron, Janssen Scientific, Titusville, NJ) was found to be equivalent to placebo for human patients with IC, a finding reported in cats in 2009.[56]

Abnormalities of the central stress response system (SRS) also have been identified.[4] Pursuing some anomalous results obtained during experiments with a corticotropin-releasing factor receptor antagonist,[57] we identified significantly smaller zonae fasciculata and reticularis in the adrenal glands of cats with FIC compared to healthy cats.[58] The most parsimonious explanation identified to date for these findings is the occurrence of a stressful early life event that permitted maternal glucocorticoids to cross the placenta and inhibit fetal ACTH release.[59,60]

Sufficiently intense activation of the maternal SRS also can cause other changes in her offspring.[61,62] Recent research has shown how evolutionarily conserved developmental processes can interact with environmental cues, often transmitted from the mother via the placenta, to attempt to match the physiology of the developing organism to its postnatal environment. One prominent mechanism underlying these effects is epigenetic modulation of gene expression.[63,64] Once the SRS becomes sensitized, repeated activation by environmental events can adversely affect a variety of organs based on familial (genetic, epigenetic) susceptibility. In addition to abnormalities of the LUT, cats with FIC often have a variety of other health problems.[65-67] Although these health problems might result from a severe chronic bladder pain syndrome, they often *preceded* the diagnosis of FIC, making this explanation unlikely. A similar pattern has been identified in human beings.[68-70]

It is important to appreciate that the SRS can be activated either peripherally by local factors like infection or inflammation ("bottom up"),[71] or centrally by perception of an external environmental threat ("top down").[72,73] External environmental threats can be physical, psychological, or social and can be acute or

chronic. Increased SRS activity is common in cats confined in unenriched environments,[74] which can complicate clinical interpretation of diagnostic procedures by influencing the cat's temperature, heart and respiratory rates and blood pressure,[75,76] and may play a role in predisposing, precipitating, or perpetuating a variety of chronic health problems in cats.[77] Additionally, increased sensitivity of the acoustic startle response, a brainstem reflex that responds to unexpected loud stimuli,[78] has been identified both in cats with FIC[79,80] and humans with IC[81] and to be responsive to environmental enrichment (EE) in cats with FIC.[80]

Activation of the SRS can increase autonomic, particularly sympathetic outflow, which in turn can increase epithelial permeability acutely and result in epithelial damage if chronic.[82] In cats with FIC, exposure to external stressors increased circulating catecholamine concentrations,[83,84] which increased further as exposure to the stressors continued,[84] possibly due to desensitization of alpha-2 adrenergic receptors.[85,86] In contrast, plasma catecholamine concentrations decreased in healthy cats as they acclimated to the stressors.[84]

Chronic psychosocial stress also is well known to stimulate low-grade systemic inflammation,[87-89] which can result in the expression of sickness behaviors.[90] Sickness behaviors refer to variable combinations of vomiting, diarrhea, periuria, inappetence, fever, lethargy, somnolence, and enhanced painlike behaviors, as well as decreased general activity, body care activities (grooming), and social interactions. Sickness behaviors in cats can result from peripheral *or* central immune activation.[74,84,91] In cats, external stressors were associated with significant increases in sickness behaviors, most commonly manifested as decreased food intake and elimination, and increased elimination outside the litter box.[67] Thus, some of the most commonly observed abnormalities in client-owned cats, such as "finicky" eating and litter-box problems, occurred after exposure to external threats in both FIC and healthy cats, suggesting that clinicians should include the presence of environmental threat in the differential diagnosis of cats presented for care for these signs. Importantly, we also have observed resolution of these behaviors in both laboratory[67] and clinical[66] studies of cats with FIC in response to multimodal environmental modification (MEMO).

Summary

Current understanding of the etiopathogenesis of FIC has expanded from the bladder to include roles for developmental influences, probably mediated by epigenetic modulation of gene expression, and complex interactions between individuals and their environments. It remains to be determined how these systems communicate and manifest as FIC in some cats but not in others. Environmental and behavioral stressors also are associated with exacerbations of signs of FIC and can result in sickness behaviors in both healthy and affected cats. The number and variability of physiological and behavioral abnormalities identified in cats with FIC may represent different disease entities and/or different manifestations of a common underlying problem because of natural variation in the relative activation of neural, endocrine, and immune responses by the SRS. While there is still much to be learned about FIC, this perspective has led directly to refinements in diagnosis and to principles of treatment that have resulted in better clinical outcomes.

Diagnosis (see ch. 46)

Cats of any age, breed, or sex can develop FIC, although it is diagnosed most commonly in younger and middle-aged cats. The majority of cats with chronic LUTS have FIC, and most cats with FIC resolve their clinical signs in a few days without treatment,[10,20,67,92,93] so diagnostics may not be needed (but can always be offered to the owner) for young cats presented for a first episode of LUTS. Additional evaluation is indicated for cats with recurrent signs.

An abdominal radiograph that includes the entire urinary tract can identify radiopaque stones, and a contrast cystogram and urethrogram can identify radiolucent stones, mass lesions, blood clots, or strictures. Contrast studies of the bladder and urethra usually are normal, although diffuse or asymmetrical thickening of the bladder wall occurs in about 15% of cases.[34,94] Contrast studies or ultrasonographic examination are indicated in cats >10 years of age, when FIC is less likely (see ch. 332).

Abdominal ultrasound (see ch. 88) allows visualization of blood clots, polyps, neoplasia, and cystine or ammonium urate stones, which are radiolucent, but is not ideal for evaluating the urethra (e.g., it cannot be used to evaluate most of the urethra of male cats); radiography with or without contrast should always be performed to identify urethral stones or plugs if present.

Although most cats with FIC do not have a UTI, a complete urinalysis (see ch. 72) should be performed at least once in cats with chronic LUTS (see ch. 330) and as explained above, cystoscopy may be useful to

exclude alternative diagnoses even though it is not helpful for the diagnosis of FIC (see ch. 108).

Treatment

Recent treatment advances for FIC reflect the perspective that FIC often represents a problem affecting the bladder rather than a bladder problem. If these cats have a sensitized SRS, then approaches that aim to reduce activation of the SRS are more likely to be effective than those that do not. Because environmental conditions are known to affect the behavior and health of animals,[95] particularly captive animals,[96] we focused on the effects of environmental enrichment (EE) for FIC by adapting approaches used in zoos and research facilities.[97] From this perspective, EE consists of creating conditions that permit the animal to feel safe, which means to sustain a perception of control that exceeds its perception of threat. These conditions include access to species-appropriate novelty, activity, and interactions with other animals (including humans). We operationalized these concepts as MEMO,[98,99] which recently were incorporated into professional EE guidelines.[100] The prognosis for FIC depends on the cat, the housing situation, and the ability and commitment of the client to implement MEMO. In my experience with cats with severe FIC,[66,67,84] implementation of effective EE leads to recovery without the need for pharmacotherapy or any special diet in nearly all patients.

Treatment for FIC includes consideration of acute and chronic approaches to the cat, the owner, and the environment. As mentioned, clinical signs of LUTS commonly resolve in most cats within a few days. Unless a concurrent UTI is documented, antibiotics are not warranted. Analgesic therapy may be appropriate for acute management of FIC (described below). Owners of otherwise healthy cats less than 10 years of age can be told that the most common cause of their cat's signs is FIC, offered diagnostic evaluations to rule out other diagnoses if they choose to do so, and MEMO to facilitate recovery. Cage enrichment is helpful for hospitalized cats, and recent guidelines[101] and recommendations[102] are available.

Effective communication determines MEMO treatment outcome.[98,103] When owners understand that their effective implementation of MEMO can decrease the severity and frequency of LUTS and signs of comorbid disorders in their cats, the prognosis is excellent.[66,67,84] MEMO consists of owner education about cats in general, FIC, effective resource management (food, water, rest areas, litter containers, etc.), and modification of the environment to reduce perceived threats and intercat conflict in multicat households. A variety of resource materials that can be recommended to clients is provided in the client handout.

A quadratic relationship exists between the environment and health, with problems occurring both in barren and chaotic situations,[77] so forms to facilitate evaluating the cat and its surroundings are available.[104,105] In addition, I prefer to use a "coaching" (adherence) as opposed to an "expert" (compliance) approach whenever possible to help the client do the change work of EE because clients perceive it to be in their interest.[106,107] Trained technicians also can carry out this work effectively and empathically.

When changes are suggested, cats are offered choices of resources to determine their preferences for food and feeding management, water and watering, litter container and substrate,[8] space, and form of interactions with people and other animals. MEMO also provides opportunities for play and interactions that are species-appropriate for the cat. In households with more than one cat, the number and locations of resources is increased to create a "house of plenty" to decrease competition for resources that might contribute to recurrence of signs of FIC related to intercat conflict.

Some cats are especially sensitive to changes in feeding schedule, owner work schedule, addition or removal of people or pets from the household, and the owner's emotions, so disruptions in their environment should be kept to a minimum, made gradually, and tailored to the cat's needs and limitations. While beyond the scope of this chapter, detailed guidance for environmental evaluation and implementation of MEMO is available that can be used to inform recommendations.[98-100]

A variety of aspects of nutrition have been considered for incorporation into treatment plans for cats with LUTS (see ch. 185); few have been demonstrated to be effective in cats with FIC.[108] For example, dilution of the urine has been proposed to reduce the risk of recurrence of signs in cats with FIC,[109] but clinical studies of FIC have found no effect of diet moisture content,[10] and both laboratory and clinical studies of MEMO for FIC have reported large reductions in recurrence of signs without dilution of the urine,[66,67] so any salutary effect must be modest.

Some veterinary diets are marketed for FIC. Attributes of these foods include variable combinations of increases in water content to reduce the urine specific gravity and changes in the amounts of minerals,

sodium chloride, omega-3 fatty acids, antioxidants, tryptophan, and alpha-casozepine. Unfortunately, no results of controlled clinical trials of any of the diets currently sold for cats with FIC are available in the peer-reviewed scientific literature. In a 2013 manufacturer-sponsored diet study abstract,[110] the recurrence rate for cats fed a test veterinary diet was comparable to that recorded in other studies,[10,56,66,67,93] whereas the recurrence rate for cats fed a test commercial diet was higher. Recommendations for EE were offered to all owners, but no group treated with EE alone was described, nor was a "usual care" group included. Regrettably, the composition of the veterinary diet currently commercially available is different from that of the diet tested, so the results will not be clinically relevant even if they are eventually published.

Tryptophan, an essential amino acid, has been added to some diets based on the idea that it would increase central serotonin concentrations, which would then exert an anxiolytic effect. Most studies of tryptophan's effects on mood are acute feeding studies, however, with very little, if any, evidence of long-term beneficial effects.[111] Moreover, dietary tryptophan may not exert this effect on serotonin in cats,[112] and even if it did, one would still need to demonstrate that this led to the desired clinical outcome in the target population, since other constituents of the diet can influence tryptophan availability. Diets also have been supplemented with alpha-casozepine, but to my knowledge, no studies of effects of these foods on cats with FIC have appeared in the peer-reviewed scientific literature.

Recommending a diet change seems most reasonable when either the owner or the cat does not like the diet currently fed. Some owners and cats prefer dry foods and may object to forced transition to canned foods, particularly when the diets are of little demonstrable therapeutic value. Attempts to alter the urine to minimize crystalluria in cats with nonobstructive FIC are not indicated. I am not aware of any published evidence supporting the idea that the common types of crystals in cat urine damage the urothelium or worsen LUTS in cats with FIC. If a diet change seems advisable, I recommend offering the new food at mealtime next to the usual food in a separate container so the cat can express its preference. If the cat chooses the new food, the old food can be removed.

Feeding management is another aspect of nutritional care to consider, since it can provide EE. Natural feline feeding behavior includes predatory activities such as stalking and pouncing. These may be simulated by hiding small amounts of food around the house or by putting food in a feeding device from which the cat has to extract individual pieces or move to release the food pieces (if such activity appeals to the cat). Opportunities to express species-typical prey behaviors are commonly used in captive felids to provide enrichment,[113-115] and, although not yet carefully studied in domestic cats, food puzzles might benefit some cats with FIC. Most cats also seem to prefer to eat individually in a quiet location where they will not be startled by other animals, sudden movement, or activity of an air duct or appliance that may begin operation unexpectedly.

A combination of a synthetic feline facial pheromone and valerian (Feliway; Ceva Sante Animale, Libourne, France) is marketed to exert a calming effect on cats, although a recent systematic review questioned its efficacy.[116] The product seems to benefit some cats, so I offer a trial of the electric room diffuser form of it to clients. One or more diffusers can be placed where the cat may be the most stressed: windows, doors, soiled furniture, or the litter container. The product can be used during or after implementation of MEMO if EE alone is found not to control signs sufficiently.

The most effective analgesic therapy for chronic visceral pain in cats is not known. We currently treat acute episodes or flares with oral transmucosal buprenorphine at 10 to 20 mcg/kg two to four times daily for up to 7 days, often combined with acepromazine (0.25 mg IM or 2.5 mg [injectable form given orally] q 8 h), for up to 4 days. Sustained-release formulations of buprenorphine that can provide up to 72 hours of therapeutic drug levels for pain relief following a single injection are available, but I am not aware of any reports of their use for FIC. Our approach has not been tested in controlled trials; it is only our clinical impression that it provides relief to affected cats. We provide analgesic therapy for up to 5 days and recommend further diagnostic evaluations if clinical signs do not significantly improve by then. Analgesics also can be dispensed for use if clinical signs recur prior to contacting the veterinarian.

Butorphanol also has been used, but its effects are not as long-lived or potent as those of buprenorphine[117]; fentanyl patches also have been used in rare cases in which bladder pain was assessed as severe. Anecdotal reports of the use of nonsteroidal anti-inflammatory drugs (NSAIDs), especially meloxicam and ketoprofen, abound, but no published studies of safety or effectiveness of these drugs for FIC currently are available to my knowledge. NSAIDs are licensed for use in cats for preemptive pain management, usually as a single treatment before anesthesia and surgery; chronic use can risk development of acute intrinsic kidney failure, especially if the cat is dehydrated at the time of administration. The FDA recently required the following statement to be added to the label for meloxicam use in cats, "Repeated use of meloxicam in cats has been

associated with acute renal failure and death. Do not administer additional injectable or oral meloxicam to cats. See Contraindications, Warnings, and Precautions for detailed information." Robenacoxib, a long-acting NSAID, recently has become available for use in cats; its effectiveness for cats with FIC has yet to be reported to my knowledge. Additionally, NSAIDs do not seem to provide relief for human beings with IC.[118]

A variety of other pharmacological approaches to treatment of FIC have been tried, including drugs to alter bladder/urethral contractility, to modify the bladder lining, and to alter central neurotransmitter profiles.[109] As with analgesics, effectiveness of most of these drugs has not been tested in controlled clinical trials. Moreover, little consideration has been given to the potential negative effects of chronic forced pilling on the cat, and as mentioned, resolution of clinical signs has been repeatedly demonstrated without the use of drug therapy.[10,66,67,110,119]

Notwithstanding the occasional anecdotal report, no clinical trials of drugs to alter bladder or urethral contractility in cats with FIC have been published to my knowledge, and this class of drug is not effective for humans with IC. Studies to date also have shown no benefit of oral glucosamine[93] or pentosan polysulfate supplementation by mouth[56] or subcutaneous injection[120] over that of placebo for FIC (or IC[55]). Two tricyclic antidepressants, amitriptyline and clomipramine, have been used to treat cats with severe FIC, although neither is specifically indicated for this purpose, and should be used with caution.[10,17,109,121]

Summary

The most common cause for LUTS in cats is FIC, which unfortunately remains a diagnosis of exclusion. Converging evidence from a variety of studies suggests that most cases of FIC are more likely to be a disorder affecting the bladder than a primary bladder disorder, which led to the "Pandora Syndrome" hypothesis.[4] Because FIC can be a chronic, frustrating disease, excellent client communication in conjunction with MEMO, analgesics, and possibly other pharmacologic agents can often provide sufficient EE to permit clinical recovery in both acute and chronic cases.

Beyond therapy, however, we veterinarians take an oath to use our scientific knowledge and skills to protect animal health and welfare and to prevent and relieve animal suffering. Given the documented effects of confinement on cats,[67,102,122,123] I advocate for implementation of effective EE as preventive health care for all cats, as necessary for their health and welfare as provision of satisfactory nutrition, appropriate vaccination, and parasite control.

CHAPTER 335

Urethral Diseases

Joseph W. Bartges

Urethral disease occurs commonly in dogs and cats, often in association with diseases of the urinary bladder. Clinical signs of urethral disease include pollakiuria, stranguria, periuria, hematuria (see ch. 47), obstruction of urine flow, or urinary incontinence (see ch. 46). Physical examination (see ch. 2) should include palpation of the perineal region, rectal examination (the pelvic urethra is palpable through the rectal wall running dorsal to the pelvic bones), and examination of the external genitalia. Urinalysis (see ch. 72) is important as it may contain evidence of infection or neoplasia. Imaging procedures such as survey abdominal radiography, contrast urethrocystography (see ch. 124), and cystoscopy (see ch. 108) may be required for diagnosis. Ultrasonographic (US) evaluation of the urethra is limited by the pelvis (see ch. 88).

Urethral Sphincter Mechanism Incompetence (USMI)

Degenerative USMI is the most common cause of urinary incontinence in dogs, occurring primarily in spayed females several years after ovariohysterectomy (see ch. 333).[1,2] Clinical signs include unconsciously leaving a puddle of urine wherever the dog lies, but while awake, urination is normal and incontinence is not present. Bacterial urinary tract infection (UTI) occurs commonly with incontinence and is often not associated with active urine sediment. UTI does worsen the urinary incontinence. Estrogenic or alpha-agonist agents, alone or in combination, are treatments typically employed. Dogs unresponsive to these medications can be managed with surgical injection of urethral bulking agents or placement of a hydraulic urethral occluder.[1,3-5]

Anatomic Congenital Urethral Disease

Ectopic Ureter

Definition

Ectopic ureters are included in this chapter because urinary incontinence is a result of their abnormal urethral or vaginal opening (see ch. 336). Normally, ureters enter the dorsolateral caudal surface of the bladder and empty into the trigone after a short intramural course. Ectopic ureter results from termination of one or both ureters at a site other than this and likely result from an embryologic abnormality of the mesonephric duct ureteral bud. Degree of ureteral bud deviation from the normal position determines the ectopic opening location. Ectopic ureters may be unilateral or bilateral, intramural or extramural. An extramural ectopic ureter bypasses insertion at the trigone and inserts distally in the urethra, vagina or vestibule in females, or ductus deferens in males. An intramural ectopic ureter inserts at the trigone but tunnels in the urethral wall to open distally. Variations of the intramural ectopic ureter include ureteral troughs, double ureteral openings, multiple fenestrated openings, and two intramural ureters opening in a single orifice.[6] Ectopic ureters may be associated with other congenital defects of the urogenital tract including agenesis, hypoplasia, or renal dysplasia; hydroureter; ureterocele; urachal remnants, pelvic bladder; vulvovaginal strictures; and persistent hymen.[7,8]

Signalment

Ectopic ureters (most often bilateral and intramural) are most commonly diagnosed in young female dogs (median age of 10 months).[8,9] Males with ectopic ureter are often slightly older (about 24 months) of age when diagnosed. It is presumed that many males are never diagnosed because they remain continent due to their urethral length and their external urethral sphincter.[9] Breeds reported to be at greater risk for ectopic ureter include the Siberian Husky, Labrador Retriever, Golden Retriever, Newfoundland, English Bulldog,

West Highland White Terrier, Fox Terrier, Skye Terrier, and Miniature and Toy Poodles.[8] A genetic basis may exist but is unproven in most cases. Cats are rarely diagnosed with ectopic ureter.

Clinical Signs and Physical Examination

Intermittent or continuous urinary incontinence since birth or weaning is the most frequently reported clinical sign in dogs with ectopic ureter. Most, however, also appear to void normally. Physical examination findings are often unremarkable, with the exception of moist or urine-stained hair in the perivulvar or preputial region. Urine scalding may cause secondary dermatitis, and owners may report frequent licking of the vulvar or preputial area. Some dogs have vulvovaginitis, a vulvovaginal stricture, or a persistent hymen that can be detected digitally or with vaginoscopy. About two-thirds of these dogs have a history of UTI.[6]

Diagnosis

Survey radiography should be performed to assess the size, shape, and location of kidneys and bladder. Excretory urography combined with pneumocystography, abdominal US, contrast urethrocystography with vesicoureteral reflux, fluoroscopy, or contrast-enhanced computed tomography (CT) may be used to diagnose ectopic ureter (Figure 335-1).[8,10] Urethrocystoscopy (see ch. 108) is excellent, especially when combined with other imaging modalities (E-Figure 335-2).[8] Dilation of the ectopic ureter is often, but not always, present.

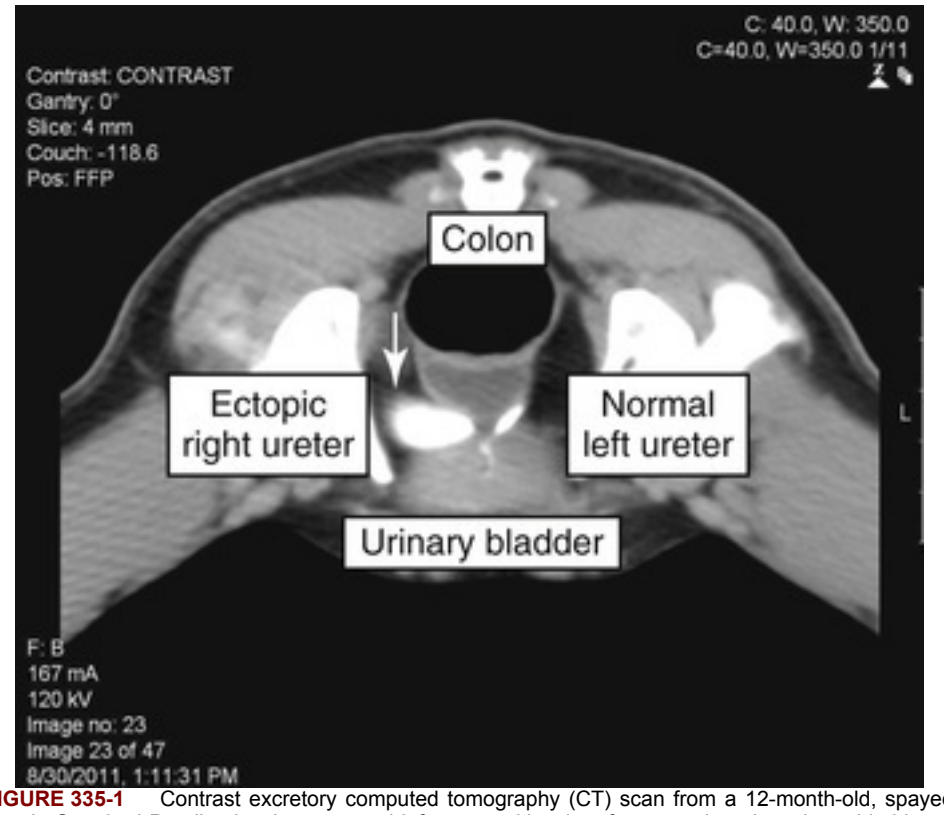

FIGURE 335-1 Contrast excretory computed tomography (CT) scan from a 12-month-old, spayed female Standard Poodle showing a normal left ureter with a jet of contrast into the urinary bladder at the trigone and a dilated right ureter that enters that urinary bladder at the trigone but tunnels distally.

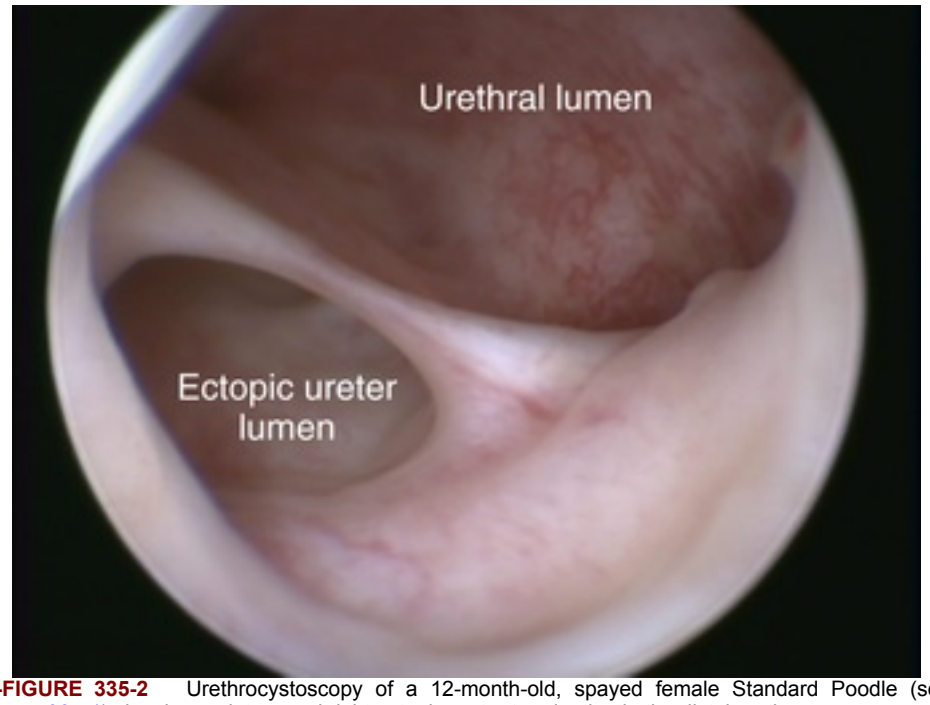


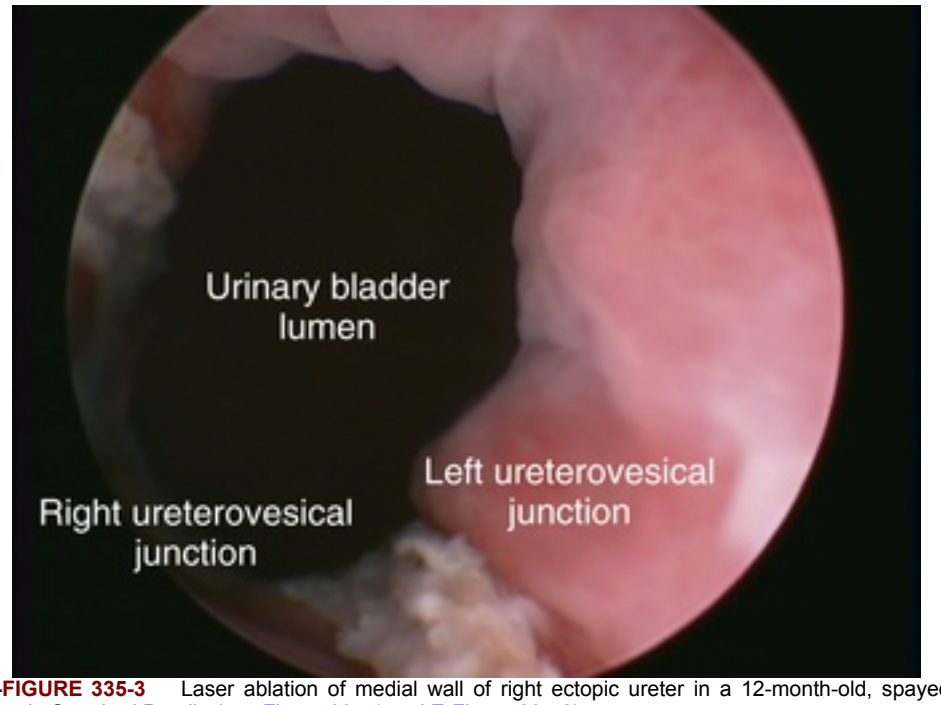
E-FIGURE 335-2 Urethrocystoscopy of a 12-month-old, spayed female Standard Poodle (see Figure 335-1) showing an intramural right ectopic ureter terminating in the distal urethra.

Treatment—Surgery

Some dogs may respond partially or completely to the drugs used for USMI. While medical management may help control urinary incontinence, surgical correction or laser ablation is preferred. An extramural ectopic ureter can be ligated at its distal end and reimplanted into the bladder between its apex and trigone (neoureterocystostomy). The bladder wall should be cultured or urine from the renal pelvis should be collected for culture at the time of surgery due to the frequency of bacterial UTI. Traditionally, intramural ectopic ureters are treated by ligation of the distal submucosal ureteral segment and creating a new ureteral opening in the trigone of the urinary bladder (neoureterostomy and urethral-trigonal reconstruction); however, incontinence persists in many (44-67%) because the intramural segment of ureter disrupts the functional anatomy of the internal urethral sphincter mechanism.[8,11,12]

Treatment—Laser

Transurethral laser ablation may be used to correct intramural ectopic ureters (see ch. 124). A rigid (in females) or flexible (in males) endoscope is inserted retrograde into the urethra; diagnostic urethrocystoscopy is performed. A catheter is inserted into the lumen of the ectopic ureter in order to protect the lateral urethral wall. A laser fiber, diode or preferably Holmium : YAG, is inserted through the operating channel of the cystoscope and used to transect the free wall of the ectopic ureter until the opening is as close as possible to the normal trigone anatomic location (E-Figure 335-3).[13-16] Incontinence may persist with intramural ectopic ureters because the proximal urethra and internal urethral sphincter mechanisms can be disrupted.[17] Following the laser procedure, it appears that dogs are more likely to be continent than after surgery. In dogs with a kidney that cannot be saved due to hydronephrosis or pyelonephritis, nephroureterectomy can be performed.



E-FIGURE 335-3 Laser ablation of medial wall of right ectopic ureter in a 12-month-old, spayed female Standard Poodle (see Figure 335-1 and E-Figure 335-2).

Urethral Aplasia and Hypoplasia

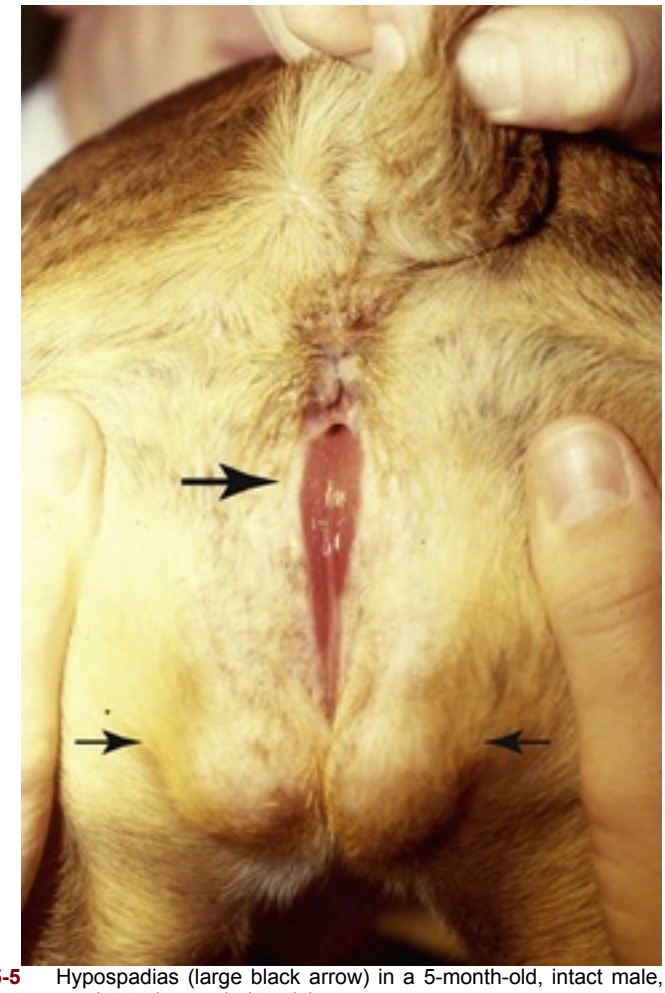
Urethral aplasia is a rare congenital anomaly characterized by complete absence of a patent urethra. Incontinence is associated with ectopic ureters.[18,19] Urethral hypoplasia has been described in immature female cats in association with juvenile-onset urinary incontinence (E-Figure 335-4).[20-22] Diagnosis is based on clinical signs and imaging studies. Radiographic features include urethral shortening and vaginal aplasia. Urethral hypoplasia may be associated with other congenital anomalies and bacterial UTI. Some dogs respond to sympathomimetic therapy. Surgical reconstruction of the bladder neck may improve or resolve clinical signs.[21,22]

E-FIGURE 335-4 Urethral hypoplasia in a 9-month-old, spayed female Rottweiler.

Epispadias and Hypospadias

Definitions

Epispadias is a congenital defect in the dorsal aspect of the distal urethra. Hypospadias is an anomalous ventral malposition of the urethral meatus.[23] Epispadias has been associated with exstrophy of the urinary bladder in an 8-month-old, female, English Bulldog.[24] Hypospadias is most commonly seen in males. The Boston Terrier and Dalmatian have been described as having increased risk (E-Figure 335-5).[23,25] It has been described in a Himalayan cat.[26] Additionally, it has been described in an East Greenland Male Sledge Dog after potential *in utero* exposure to 320 mcg/day organochlorine (128 pg TEQ/kg/day), 32-128 times the World Health Organization (WHO) guidelines and threshold levels for teratogen and reproductive effects.[27] The condition is rare, and etiology is unclear. The types are glandular, penile, scrotal, perineal, or anal, according to urethral opening location and can be classified as mild, moderate or severe. In the severe form, underdevelopment or absence of the penis, failure of fusion of the scrotum, and failure of the urethra to close in the perineal area may be seen. Other abnormalities associated with hypospadias include retained testicles, kidney agenesis, bone or anorectal defects, umbilical hernia, hydrocephalus, urinary incontinence and ascending UTI.[23,28] Chromosome analysis can be used to differentiate hypospadias from true hermaphroditism.[25]



E-FIGURE 335-5 Hypospadias (large black arrow) in a 5-month-old, intact male, English bulldog; the small black arrows point to descended testicles.

History, Physical Findings, Diagnosis and Treatment

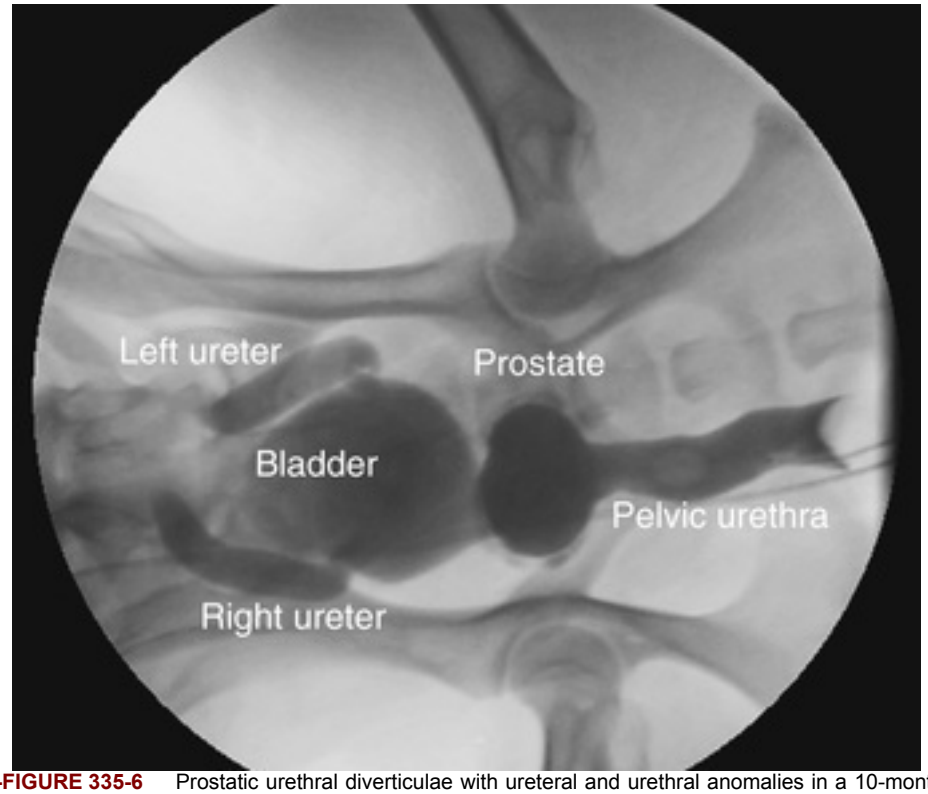
Affected dogs are diagnosed at various ages; some show no clinical signs whereas some present with urinary incontinence, periurethral dermatitis, or bacterial UTI.[28,30] Diagnosis is often based on physical examination. Affected male dogs have an abnormal ventral urethral meatus that may be located anywhere along the shaft of the penis, scrotum, or perineum, usually associated with malformation of the prepuce and/or penis.[28,29] Hypospadias has been described in female dogs in association with genetic intersex. Embryonically, hypospadias results from incomplete fusion of the urogenital fold. The presence of an *os penis* in male dogs precludes surgical reconstruction in most. Scrotal or perineal urethrostomy combined with castration and removal of vestigial preputial and penile tissues may be of cosmetic value. Shortening of the penis, amputation, and urethral reconstruction have been described.[31-34] One technique described significant reconstruction, urethrostomy, and partial penile amputation. This technique may be considered for glandular or penile hypospadias or after resecting the ventral aspect of the distal prepuce when inadequate tissue is present for a simple two-layer closure.[35]

Urethrogenital Malformations

Urethrogenital malformations are seen with intersex conditions, and pseudohermaphroditism is often associated with urinary incontinence.[36] Pseudohermaphrodites have gonads of one gender and external genitalia of the other.[37] It occurs in both sexes as a result of simultaneous development of müllerian duct derivatives (oviduct, uterus, and portions of the vagina) and masculinization of the urogenital sinus. The phenotype (appearance) depends on the degree of masculinization of the urogenital sinus. Incontinence likely results from retention of urine in anomalous communications between urethra and genital tract, which then

passively leak.[38] The condition develops early in life and may be accompanied by UTI.[38] Diagnosis is based on physical signs and imaging studies. Urinary incontinence may resolve with surgical correction.[36]

Prostatic urethral diverticulae have been described in male dogs in association with abnormally short and wide intrapelvic urethra, widened urinary bladder neck, and ureteral anomalies (E-Figures 335-6 and 335-7).[39] This seems similar to a condition described in an infant with congenital obstructive posterior urethral membrane, where a membrane extended proximally from the verumontanum toward the bladder neck. While this often results in chronic renal disease, a mild degree of obstruction and protective pressure pop-off mechanisms have been reported, resulting in dilation of the prostatic utricle.[40]



E-FIGURE 335-6 Prostatic urethral diverticulae with ureteral and urethral anomalies in a 10-month-old, castrated male Labrador Retriever. Ventrodorsal contrast urethrocystogram with ureteral reflux of contrast using fluoroscopy. Bilateral hydroureter is present and the ureters enter the urinary bladder through one vesicoureteral junction. The urinary bladder neck is nonexistent and there is post-prostatic urethral dilation.

E-FIGURE 335-7 Cystoscopic image of prostatic urethral diverticula in a 10-month-old, castrated male Labrador Retriever (see E-Figure 335-6). The prostatic median raphe is visible (*).

Urethral Duplication

Urethral duplication is an uncommon congenital anomaly only described in immature dogs.[41-45] Because of close association between embryonic development of the urogenital and gastrointestinal systems, urethral duplication is almost always accompanied by other duplication anomalies. The anomalies result from abnormal sagittal midline division and subsequent parallel development of the embryonic hindgut, cloaca, rectum, or urogenital sinus.[46] Associated anomalies depend on the stage at which dysmorphogenesis occurs. Physical examination may reveal anatomic abnormalities, urinary incontinence, or clinical signs associated with secondary bacterial UTI. Diagnosis is based on physical examination, imaging, and exploratory surgery. Urethral duplication may in some cases be amenable to surgical extirpation of the duplicated structure; however, surgical reconstruction has rarely been attempted with extensive duplication.

Ectopic Urethra

Ectopic urethra is characterized by abnormal position of the external urethral orifice. Embryonically, urethral ectopia results from anomalous morphogenesis of the urogenital sinus, paramesonephric ducts (müllerian ducts), or mesonephric ducts.[47] Clinical signs depend on the site of the urethral termination and other concurrent urogenital anomalies. Lifelong urinary incontinence was the predominant clinical feature in a 21-month-old female English Bulldog with unilateral ureteral ectopia and an ectopic urethra terminating in the distal vagina.[48] In contrast, a 2-month-old, female, domestic shorthair cat with ectopic urethra terminating in the ventral rectum did not have urinary incontinence but did void urine through the anus.[49]

Urethrorectal, Urethrovaginal, and Urethroperineal Fistulas and Urethral

Diverticula

Fistulas connecting the urethral lumen with the large bowel, vagina, and perineal region have been described in dogs and cats.[44,50-57] Congenital urethrorectal fistulas occur because of failure of separation of the fetal cloaca into the anterior urethrovesical segment and the posterior rectal segment by the urorectal septum, resulting in a permanent communication between the urethra and the rectum. Micropenis and midline vestibuloperineal fistula were described in two dogs with urinary incontinence considered to be intersexes (78XX karyotype).[58] It has also been described as an acquired disease due to prostatic abscessation in a dog but may occur due to traumatic, inflammatory, or neoplastic processes.[53,59] Males appear to be affected more frequently, and English Bulldogs appear to have a predilection for urethrorectal fistula.[59] Clinical signs are due to abnormal passage of urine from the fistula during urination. Additional signs may include diarrhea, perineal dermatitis, and signs associated with secondary bacterial UTI. Fistulas have been associated with infection-induced struvite urolithiasis.[51,53,55] Diagnosis is based on clinical signs and imaging studies (Figure 335-8). Treatment is surgical correction or urinary diversion. Conservative therapy (indwelling urinary catheter, low-residue diet, and antibiotics) was successful in a dog with a urethrorectal fistula secondary to a prostatic abscess.[53]

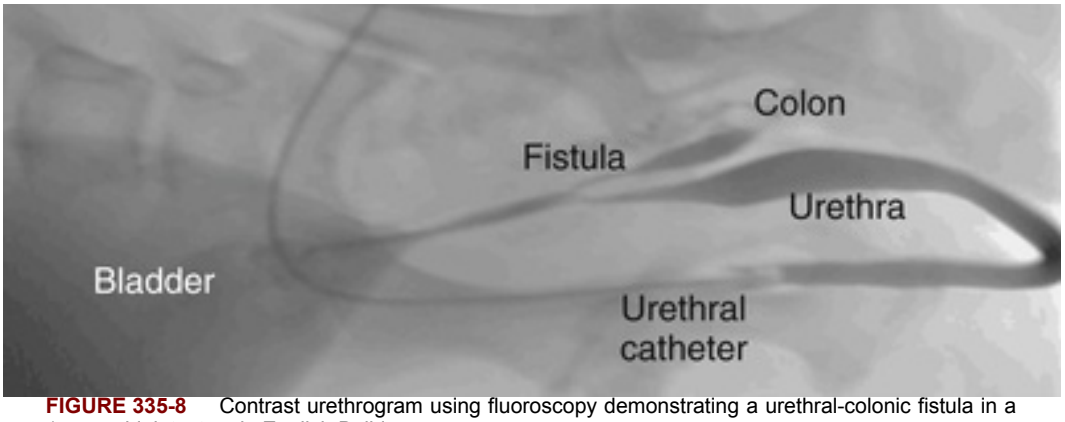


FIGURE 335-8 Contrast urethrogram using fluoroscopy demonstrating a urethral-colonic fistula in a 1-year-old, intact male English Bulldog.

Urethral Prolapse

Urethral prolapse occurs when the distal urethra protrudes through the urethral orifice of the penis. It appears as a red or purple mass at the tip of the penis and occurs in male dogs <5 years of age (Figure 335-9)[60]; English Bulldogs and Boston Terriers appear predisposed.[61-63] Urethral prolapse may not be associated with clinical signs or owners may only notice a red to purple "mass" at the tip of the penis during urination; however, it may be associated with dripping of blood, licking of the prepuce or penis, or signs of lower urinary tract disease (see ch. 44, 45, and 46). Diagnosis is based on physical examination; it must be differentiated from neoplasia. If urethral prolapse is associated with no to few signs, treatment may not be necessary.[64] Urethral prolapse is treated by attempting to manually reduce the prolapsed tissue; applying hypertonic saline may facilitate the attempt. A loose purse-string suture is then placed but recurrences are common. Surgical reduction or urethropexy are treatments of choice.[63]

FIGURE 335-9 Urethral prolapse in a 2-year-old, intact male English Bulldog.

Urethral Stricture and Hypoplasia

Congenital urethral strictures and hypoplasia have been described in young dogs and cats.[21,65] Clinical signs relate to partial or complete urethral obstruction with stricture or urinary incontinence with hypoplasia (see ch. 44-46). Systemic signs, bladder distention or rupture, overflow incontinence, secondary bacterial UTI, or hydronephrosis can follow outflow obstruction or incontinence with urethral hypoplasia. Urinary incontinence and bilateral hydroureter and hydronephrosis were observed in an 8-month-old, male, German Shepherd Dog with congenital midurethral stricture.[65] Treatment involves surgery. If the stricture occurs in the extrapelvic urethra, urethrostomy may be performed; if it occurs in the intrapelvic or intraabdominal urethra, then urethral resection and anastomosis or prepubic urethrostomy may be indicated.[66,67] Dilation of the urethral stricture may also be attempted with balloon or bougienage catheters. Urinary incontinence secondary to urethral hypoplasia may be treated surgically or with a hydraulic urethral occluder with variable success.[21]

Congenital Urinary Incontinence

Many congenital disorders are associated with urinary incontinence. In addition to those described in the preceding sections, spinal dysraphism (cleftlike malformations of the spine and spinal cord resulting from incomplete closure of the neural tube) is associated with urinary and fecal incontinence. Congenital USMI has been described in dogs and cats associated with urethral hypoplasia[21] or due to neurogenic abnormalities in pseudohermaphrodites[38]; however, ectopic ureter is most commonly associated with juvenile urinary incontinence.[8,14,68]

Metabolic Urethral Disease—Urethrolithiasis and Feline Matrix-Crystalline Urethral Plugs and Urethral Obstruction

Definitions

Obstructive uropathy refers to abnormalities in structure or function of the urinary tract caused by impairment of normal flow of urine and the resulting local and systemic effects of that impairment.[69,70] Impairment of flow through the urethra either due to physical obstruction (E-Figures 335-10 and 335-11 and Figure 335-12) or detrusor or urethral dysfunction causes signs. Although there are many causes of urethral obstruction, urolithiasis is the most common cause in dogs (see ch. 331) and crystalline-matrix urethral plugs and uroliths are most common in cats (see ch. 332). About 10-20% of cats with lower urinary tract signs have urolithiasis or urethral plugs. Struvite and calcium oxalate are the most common uroliths reported.[71] Most urethral plugs contain large quantities of matrix (mucoprotein containing mucus and inflammatory debris) with varying quantities of mineral. Crystals become trapped in the matrix. It is thought that the mucus is secreted by urinary bladder and urethral mucosal cells in response to an irritant or inflammatory stimulus. Matrix also contains sloughed tissue or blood with or without inflammatory cells. Matrix-crystalline plugs usually occur at the tip of the penis where the urethra narrows, but they can occur anywhere in the urethra.

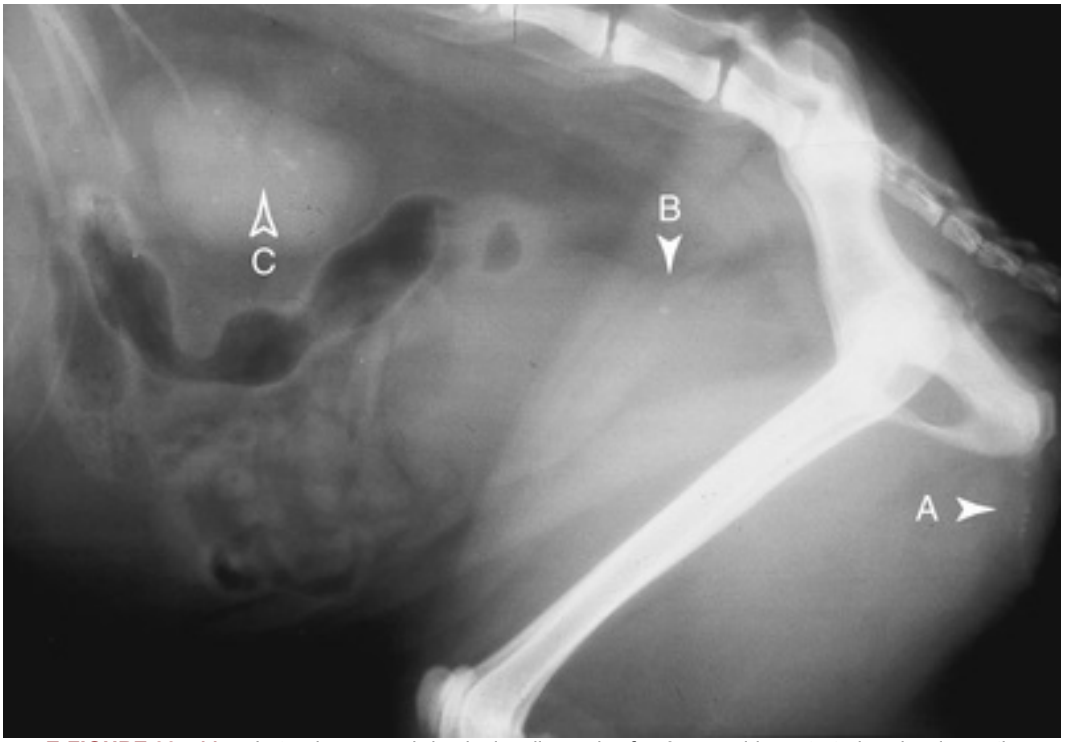
E-FIGURE 335-10 Lateral survey abdominal radiograph of a 4-year-old, intact male English Bulldog with urethral obstruction due to a cystine urolith (arrow); urocystoliths are also present.



E-FIGURE 335-11 Lateral survey abdominal radiograph of a 9-year-old, castrated male, domestic shorthaired cat with calcium oxalate urethroliths causing obstruction **(A),** cystolith **(B),** and nephroliths **(C).**

Clinical Consequences

Clinical consequences of urethral obstruction are often, but not always, associated with signs of uremia.

Partial or early outflow obstruction may not impair renal function sufficiently to cause uremia; however, clinical signs of uremia usually occur within 24 hours of complete urethral obstruction. As functional renal mass decreases or as intravesical, ureteral, and renal pressure increases, urine concentrating ability is lost. Increased renal tubular volume of urine and increased tubular pressure occur, causing azotemia and uremia. Early detection and removal of obstruction can result in prompt resolution of uremic signs, although renal abnormalities may persist for some time. Also, urethral obstruction may lead to detrusor atony, urethral injury, urethral and bladder mucosal damage, UTI, or urethral or bladder rupture.

Clinical Signs, Physical Examination, Laboratory Test Results

Signs of obstructive uropathy vary depending on several factors: degree of urine outflow impairment, duration of disease, and presence of bacterial UTI. Patients with urethral obstruction may or may not have preceding signs of lower urinary disease. They may only exhibit clinical signs localized to the lower urinary tract, such as dysuria, hematuria, pollakiuria, inability to pass urine, or pain (see ch. 44, 45, and 46). They may, however, exhibit polysystemic signs of uremia: vomiting, anorexia, obtundation. Owners may mistake animals with urethral obstruction as being constipated or having abdominal or back pain.

Physical examination may reveal a healthy dog or one that is extremely ill. A large painful bladder may be palpable. Bradycardia, hypothermia, pale mucous membranes with prolonged capillary refill time, hyperpnea, and halitosis may be present. The tip of the penis may be dark purple and swollen, and one or more uroliths may be palpated in the urethra. Rectal examination should be performed, when possible, to rule out a pelvic urethral urolith or obstruction from neoplasia or prostatic disease. Samples for complete blood count, serum biochemical analysis, urinalysis and urine culture should be collected. Cystocentesis may be performed successfully even with urethral obstruction, if care is taken to insert the needle gently, angling the tip toward the trigone while stabilizing the bladder (see ch. 105). When the pet is stable, survey abdominal radiography should be performed. Additional imaging such as ultrasound (see ch. 88), contrast urethrocystography, or urethrocystoscopy (see ch. 108) may be considered.

Treatment—Emergency Stabilization

Priorities of treating a patient with urethral obstruction depend on degree of obstruction and the patient's general health. If the animal is extremely depressed, oxygen should be administered (see ch. 131), an IV catheter placed (see ch. 75), and blood and urine samples obtained. Management of such emergencies, including fluid therapy and correcting electrolyte abnormalities, are fully reviewed in E-Box 335-1 and ch. 127, 129, 150, and 322. Once stabilized, the pet can be sedated or anesthetized in order to relieve the urethral obstruction. If the animal is severely depressed or unconscious, relieving the urethral obstruction may be possible without sedation or anesthesia. In some male dogs, passing a urinary catheter may be performed while the dog is awake and urethroliths retropulsed into the urinary bladder without sedation or anesthesia.

E-Box 335-1

Emergency Treatment for Patients with Urethral Obstruction

Fluid Therapy (see ch. 129)

Fluid therapy should be instituted with the rate based on physiologic status of the patient. Estimate the degree of dehydration and administer an isotonic replacement electrolyte solution over 6-12 hours if minimally dehydrated, over 4 hours if moderately dehydrated, and rapidly if shock is present. Rate of fluid therapy should be assessed and adjusted based on response to therapy including heart rate, electrocardiogram, respiratory rate, and thoracic auscultation. If bradyarrhythmia is present due to hyperkalemia, it should be treated aggressively (see below).

Hyperkalemia (see Section VII and ch. 309)

Clinical and experimental studies have shown that obstructive uropathy alters sodium, potassium, magnesium, phosphorus, and calcium metabolism.[72,73] Hyperkalemia is caused by acidemia, decreased renal excretion of potassium, and tissue catabolism. Alterations in P-R interval, S-T segment, and T waves on electrocardiograms are associated frequently with hyperkalemia. Dysrhythmias may also occur, including third-degree heart block and ventricular arrhythmias. Varying degrees of neuromuscular weakness and flaccid paralysis occur as a result of impaired impulse transmission. Serum

concentration of potassium approaching 10 mEq/L may be associated with bradycardia and cardiac arrest.

Immediate life-threatening arrhythmias due to hyperkalemia should be treated first. Treatment can include calcium gluconate (50-100 mg/kg IV over 2-3 minutes, monitor ECG) to counteract effect of hyperkalemia at the sinoatrial node, or measures to decrease serum potassium concentration: bicarbonate (1-2 mEq/kg IV), 10% dextrose infusion (4-10 mL/kg IV), insulin (0.1-0.25 IU/kg IV q 2-4 h), or dextrose and insulin infusion (0.5 IU/kg regular insulin + 4 mL of 50% dextrose/IU of insulin IV).

Metabolic Acidosis (see ch. 128)

Metabolic acidosis is often present in acute urethral obstruction; however, usually it is not severe enough (pH seldom < 7.0) to warrant specific treatment.

Hypocalcemia (see ch. 69)

Ionized hypocalcemia may occur in cats with urethral obstruction and it exacerbates the effects of hyperkalemia; it is treated with calcium gluconate (see above).[74]

Many protocols are available to facilitate relief of urethral obstruction including: morphine (0.1-0.3 mg/kg IM), butorphanol (0.2-0.4 mg/kg IV or IM), propofol (2-4 mg/kg IV), short-acting barbiturate (5 mg/kg IV), isoflurane anesthesia administered by mask, and ketamine (2.5-5 mg/kg IV) mixed with diazepam (0.125-0.25 mg/kg IV) or midazolam (0.125-0.25 mg/kg IV or IM) or acepromazine (0.05-0.1 mg/kg IV). Cystocentesis, if necessary, should be performed using a 22-gauge, 1 1/2-inch needle or a 22-gauge over-the-needle catheter attached to an IV extension set and three-way stopcock, to decompress the urinary bladder and collect samples. It is important to stabilize the needle or catheter in order to avoid further bladder damage and avoid bladder rupture and uroabdomen. Urethral unobstruction should be performed as soon as possible. In male cats, a urethral crystalline-matrix plug may be dislodged by massaging the distal penis between the thumb and forefinger and applying gentle pressure to the bladder (E-Figure 335-13). If the obstruction is not relieved, retrograde hydropropulsion should be performed.

E-FIGURE 335-13 Urethral plug dislodged from a 5-year-old, castrated male, domestic shorthaired cat by massaging the penile urethra and applying gentle pressure on the urinary bladder.

Relieving Feline Matrix-Crystalline Urethral Plugs (see ch. 107)

Once stabilized, the cat is usually placed on its side or back and the penis is extended from the preputial sheath by pulling it in a caudal-dorsal direction and straightening the urethra. The end of the penis and periurethral tissues are cleansed gently, the tip of a lubricated 3.5-French (Fr) polypropylene open-ended tomcat catheter is inserted gently into the external urethral orifice, and the lumen of the penile urethra flushed with 12 mL sterile solution (Video 335-1). This is often successful in flushing the obstructing material back into the bladder. Do not flush the urethra with lidocaine as it may become absorbed and can be toxic. Rectal massage of the pelvic urethra may help dislodge the plug.

Relieving Uroliths (see ch. 107)

Retropulsing Uroliths in Obstructed Male Dogs

Uroliths that cause urethral obstruction should be retropulsed into the urinary bladder using a dilute sterile lubricant solution made by mixing 1 part sterile lubricant with 1 part sterile water.[75] One can place 15 mL sterile lubricant in a 35-mL syringe and 15-20 mL of sterile fluid in a second 35-mL syringe. Attach syringes to the 3-way stopcock, squirt the sterile solution into the lubricant, and then pass the combination back and forth from one syringe to the other, several times. Alternatively, add sterile fluid to sterile lubricant in a syringe and let stand for 5 to 10 minutes. Anesthetize or sedate the dog or cat. Insert a red rubber catheter (5.0-8.0 Fr) in dogs or a polypropylene catheter (3.5-Fr) in cats to site of obstruction. Infuse sterile lubricant-fluid solution to lubricate the urethra. Sometimes, this is adequate to retropulse urethroliths into the urinary bladder.

If needed, attach a syringe with sterile fluid to the urethral catheter. Then, occlude the urethra proximally by rectal palpation, applying digital pressure to trap the urethra against the pelvic floor. At the same time, occlude the distal penile urethra and infuse sterile fluid under pressure. When the urethra is distended, release occlusion of the pelvic urethra. Often, as uroliths are retropulsed into the bladder, there is a "popping" sensation, and the person doing the rectal can often feel the uroliths move cranially. Uroliths that are amenable to this procedure include urate and cystine because of their smooth texture, most struvite, and some calcium oxalate, because of surface texture. This procedure will not work if uroliths are embedded in the urethral mucosa or if there is a stricture proximal to the urolith in the urethra. An alternative treatment for urethroliths is lithotripsy (see ch. 124).[76-79]

Female Dogs and Cats of Either Gender

Occasionally, female dogs and cats have urethral obstruction due to urolithiasis. Urethroliths are often palpable on rectal examination and may be retropulsed into the urinary bladder using a combination of urethral catheterization and flushing and digital moving of the urolith per rectum.

Indwelling Urinary Catheters (see ch. 106)

The decision for placing an indwelling, closed-system urinary catheter depends on difficulty in relieving the urethral obstruction, stream of urine obtained, amount of crystalline and/or gelatinous debris in the urine after copious flushing of the bladder, degree of bladder overdistention, likelihood of detrusor atony, degree of systemic illness, and cause of urethral obstruction. Administration of an alpha$_2$-receptor antagonist (prazosin or phenoxybenzamine) helps to decrease urethral spasm secondary to the catheter.[80,81] Depending on the cause of the urethral obstruction, definitive treatment and appropriate preventative measures should be undertaken.[82] Antibiotics should not be administered while an indwelling urinary catheter is present. While antibiotics decrease the incidence of bacterial UTI, when infections occur they exhibit a higher degree of antimicrobial resistance.[83] In one study of induced sterile cystitis in cats with indwelling urinary catheters, some cats receiving amoxicillin developed bacterial cystitis and at necropsy had positive bacterial cultures from kidney samples.[84]

Complications

Bacterial Infection

Bacterial infection may be present before urethral obstruction or be introduced as a consequence of procedures used to relieve obstruction (see ch. 330). Alkaline urine associated with infection by urease-producing microorganisms may predispose to struvite crystalluria and urolithiasis or to struvite-matrix plug formation. Infection is difficult to eradicate while urinary stasis exists. Signs of lower urinary tract infection

may persist after urethral obstruction is relieved. Outflow obstruction predisposes the upper tract to ascending bacterial infection due to vesicoureteral reflux.

Micturition Dysfunction

After a prolonged period of retaining urine, pets may have difficulty completely emptying the bladder (see ch. 333). This may be due to decreased bladder elasticity, damage to nerves, damage to contractile elements, or urethral edema/inflammation resulting in urethral spasm.[85] Detrusor atony or urethral swelling or spasm may persist for unpredictable periods, depending on the underlying disease and the amount of irreversible damage caused by urethral obstruction, and may impact survival.

Postobstructive Diuresis

Relief of urethral obstruction is accompanied by alterations in ability to modulate water and sodium balance. This postobstructive diuresis can be profound, can affect hydration status and electrolyte balance, and may require days of IV or SC fluids to avoid dehydration (see ch. 322). Measuring urine output and body weight after relieving urethral obstruction aids in determining necessary fluid therapy to maintain hydration.

Intrinsic Renal Failure

Although postrenal azotemia occurs more commonly than renal azotemia with urethral obstruction, primary renal failure may follow (see ch. 322). Factors that may contribute to renal failure include loss of renal parenchyma due to sustained increased intrarenal pressure, cytokine production by infiltrating leukocytes into renal parenchyma, electrolyte imbalances, fibrosis of damaged renal parenchyma, and ischemia due to dehydration associated with urethral obstruction and postobstructive diuresis.[86]

Death

Obstructive uropathy that persists for more than 24 hours usually results in postrenal uremia. The increased backpressure induced by obstruction impairs glomerular filtration, renal blood flow, and tubular function.[87] After obstructing the urethra of normal cats, death occurred in 3-6 days as a result of cardiopulmonary failure associated with fluid and electrolyte imbalances or acute oliguric/anuric renal failure.[73] Damage to the mucosal surface of the urinary bladder and presence of bacterial UTI shorten survival times.

Prognosis

Prognosis for animals with urethral obstruction is dependent upon its cause, ease with which it is relieved, and success of preventative therapy. In one study of 45 male cats with urethral obstruction, reobstruction due to uroliths or crystalline-matrix plugs occurred in about one-third, clinical signs recurred in about half, and euthanasia was performed in 20%.[88] The primary mineral component of feline matrix-crystalline urethral plugs is struvite; therefore, preventative measures should include dietary modification to prevent crystal reformation in these cats.

If the obstruction cannot be relieved, is recurrent despite appropriate treatment, or if penile trauma occurs during attempted relief of urethral obstruction, surgical urinary diversion (scrotal urethrostomy or perineal urethrostomy) should be considered.[89,90] Complications of scrotal urethrostomy in dogs are hemorrhage at time of surgery or stricture at the site afterward. Perineal urethrostomy in cats may be associated with stricture formation (E-Figure 335-14), urine leakage, or recurrent bacterial UTI.[89,91-93] For urethral obstruction due to neoplasia, urethral stents or cystostomy catheters may be used (see ch. 124).[94]

E-FIGURE 335-14 Urethral stricture at site of previous perineal urethrostomy in a 3-year-old, castrated male, domestic shorthaired cat.

Neoplastic Urethral Disease

Primary neoplasia of the urethra is uncommon in dogs and cats. Extension neoplasia into the urethra is seen with some bladder transitional cell carcinomas and some prostatic squamous cell carcinomas, but other neoplasms have been described.[95-104] Diagnosis is made by rectal palpation of the urethra, contrast urethrography, or cystoscopy (Figures 335-15 and 335-16). Treatment involves surgical removal or laser ablation and/or chemotherapy (see ch. 351); insertion of a urethral stent to relieve obstruction may also be done (Figure 335-17; see ch. 124).[105-107]

Idiopathic Urethral Disease—Reflex Dyssynergia

Definitions

During normal urine voiding, the detrusor contracts and the urethra relaxes. This results in the expulsion of urine. Reflex dyssynergia, also called *functional urethral obstruction* or *detrusor urethral dyssynergy,* occurs when there is a lack of coordinated detrusor contraction with urethral relaxation during voiding; the urethra either does not relax or it contracts before the bladder is empty (see ch. 333). Clinically, pets either attempt to urinate without success or initial urination results in a normal urine stream that stops even though the animal continues to attempt to urinate. Sometimes the normal stream will stop completely or will decrease to spurts or drips of urine. A cause for reflex dyssynergia is not identified in more than 50% of dogs. It can be associated with spinal lesions cranial to the second lumbar cord segment. Hypothesized lesions that could cause reflex dyssynergia include the reticulospinal tract, Oluf's nucleus, caudal mesenteric ganglion, or loss of inhibitor signals to the pudendal and hypogastric nerves.[108]

Signalment, Signs, Diagnosis

Reflex dyssynergia affects primarily middle-aged, large- and giant-breed male dogs, although female dogs and cats may be affected.[109-113] As mentioned, the animal postures to urinate and often produces a good initial stream that suddenly stops or becomes spurts or drips of urine despite continued attempts to urinate. Residual urinary bladder urine volume is large due to the functional urethral obstruction. Dogs should have less than 0.5 mL/kg residual urine volume after urination.[114] Urine leakage may occur after attempts to urinate cease, mimicking overflow incontinence. This occurs because the internal urethral sphincter hypertonicity is thought to be triggered by voiding. In chronic cases, bladder overdistention may result in some degree of detrusor atony resulting in large residual urine volume. Diagnosis is made by historical information and watching the animal void. Imaging studies may show a large urinary bladder after voiding, and contrast urethrography may show an inability to adequately dilate the proximal urethra or urethral spasm. Thorough neurological examination is important (see ch. 259), although most patients do not have

neurological deficits. The only clinical sign may be pain, e.g., cervical pain on manipulation.

Treatment

Treatment involves urethral relaxation and, occasionally, stimulation of bladder contraction. Alpha-blockers such as prazosin, tamsulosin, and phenoxybenzamine, decrease internal urethral sphincter smooth muscle tone. Relaxing external urethral sphincter skeletal muscle may be of help, using benzodiazepines or other relaxants (acepromazine, methocarbamol, dantrolene).[114-118] Clean intermittent urinary catheterization by owners at home may be necessary (see ch. 105 and 106). A cystostomy catheter may be used to prevent urinary bladder overdistention and, in refractory cases, a urethral stent may be inserted across the part of the urethra that is narrowed or has spasms based on contrast urethrography (see ch. 124).[109] Prognosis is generally fair to good; however, patients often require lifelong therapy and relapses occur. Prognosis is worse with detrusor atony and recurrent UTI.

Inflammatory/Infectious Urethral Disease

Urethritis refers to inflammation of the urethra. Inflammation may be primary or secondary to other diseases including trauma, urolithiasis, or neoplasia.[96,119] Urethritis often occurs with bacterial cystitis in dogs or idiopathic cystitis in cats. Inflammation occurs due to breakdown of the urothelial lining and may result in ulceration and erosion. Proliferative urethritis may occur secondary to chronic bacterial infection or immune-mediated disease. Granulomatous or lymphoplasmacytic urethritis causes epithelial hyperplasia, lymphocyte and plasma cell infiltration, and chronic bacterial infections.[120]

Clinical signs are consistent with lower urinary tract disease (see ch. 44-47). Diagnosis is made by rectal palpation of the urethra, contrast urethrography, or cystoscopy (E-Figures 335-18 and 335-19; see ch. 108). Biopsy of the urethra confirms the inflammation. Treatment includes antimicrobial therapy and, possibly, anti-inflammatory drugs if granulomatous urethritis is present. Anti-inflammatory therapy with prednisone (1 mg/kg PO q 24 h), cyclophosphamide (2.2 mg/kg PO q 24 h for 4 days per week), or piroxicam (0.3 mg/kg PO q 24 h) may be tried. For proliferative urethritis, anti-inflammatory therapy as described or immunosuppressive therapy (azathioprine 2 mg/kg PO q 24-48 h, or prednisone 2 mg/kg PO q 24 h) with concurrent antimicrobial therapy is recommended. If urethral obstruction is present, a cystostomy catheter may be required until regression of the inflammatory infiltration and urethral obstruction.[94]

E-FIGURE 335-18 Lateral abdominal contrast vaginourethrocystography in a 4-year-old, spayed female Chow-cross dog with granulomatous (lymphoplasmacytic) urethritis.

E-FIGURE 335-19 Granulomatous (lymphoplasmacytic) urethritis in a 6-year-old, spayed female Irish Setter dog secondary to chronic bacterial cystitis due to *Escherichia coli.*

Traumatic Urethral Disease

Urethral trauma may occur from blunt or penetrating injuries, especially from traumatic urinary catheterization (Figure 335-20).[121-124] Blunt vehicular trauma may damage the urethra due to pubic or os penis fractures. Iatrogenic urethral trauma during urinary catheterization may occur, especially when using a stiff polypropylene catheter (see ch. 105 and 106). Clinical signs relate to the lower urinary tract. Urine may collect SC or into the abdomen. Hematuria may be the only clinical sign. Diagnosis is made by contrast urethrography or cystoscopy. Treatment includes placement of an indwelling urinary catheter and surgical correction or urinary diversion.[121,122,125,126] Urethrostomy may be necessary if the urethra is not salvageable.

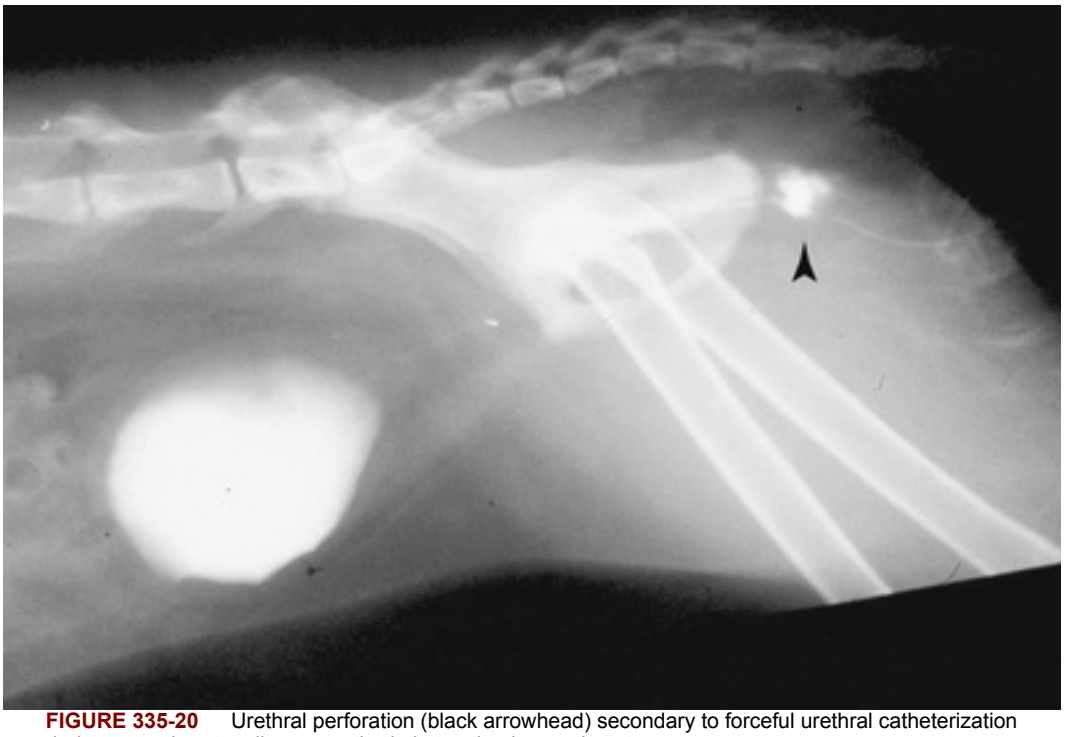

FIGURE 335-20 Urethral perforation (black arrowhead) secondary to forceful urethral catheterization during procedure to relieve a urethral obstruction in a male cat.

Urethral Stricture

Urethral stricture usually occurs secondary to urethral trauma, especially urinary catheterization in cats,[89,125] or surgery (see E-Figure 335-14).[127,128] Clinically, dogs and cats with urethral strictures strain to urinate, have hematuria, or are unable to urinate (see ch. 44-47). There is often a history of a traumatic or surgical event, although urethral stricture may occur secondary to a neoplastic process such as a transitional cell carcinoma. Diagnosis is made by visualization if the stricture is at the site of a previous urethrostomy procedure, by contrast urethrography, or cystoscopy (see ch. 108). Treatment includes surgical correction, dilation of the strictured area, or insertion of a urethral stent (see ch. 124).[89,90,106,127,129,130]

Urethral Foreign Bodies

Occasionally dogs or cats with clinical signs of lower urinary tract disease and/or urethral obstruction have a urethral foreign body. Among the foreign bodies reported are grass awns, lead pellets, a migrating popsicle stick resulting in struvite urolith formation, and a sewing needle–associated struvite urolith.[131-134] Indwelling urethral catheters may serve as a foreign body for clinical signs or obstruction (E-Figures 335-21 and 335-22) if the dog or cat chews the distal end of the catheter, resulting in retention of the proximal end within the urinary system. These may serve as a nidus for infection or encrustation (Figure 335-23 and E-Figure 335-24). Removal of the foreign body results in resolution of clinical signs as long as urethral stricture or detrusor atony has not occurred. Prevention of catheter-retained fragment foreign body involves ensuring the whole catheter is present when removed by the patient or by medical personnel.

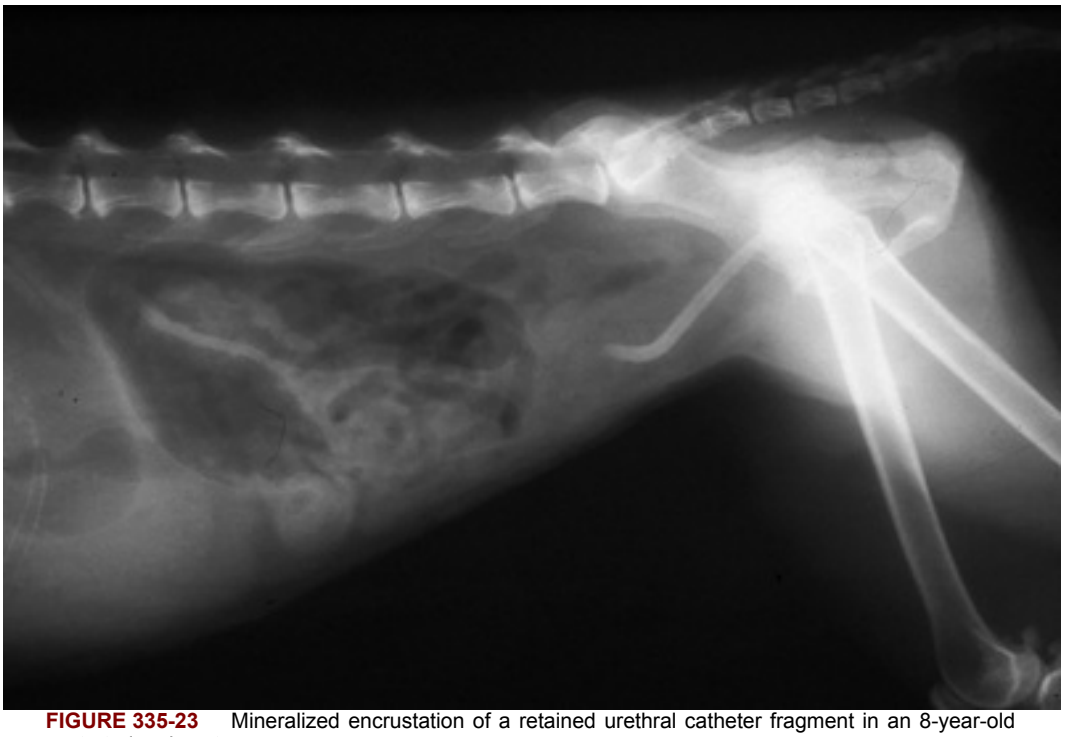

FIGURE 335-23 Mineralized encrustation of a retained urethral catheter fragment in an 8-year-old castrated male cat.

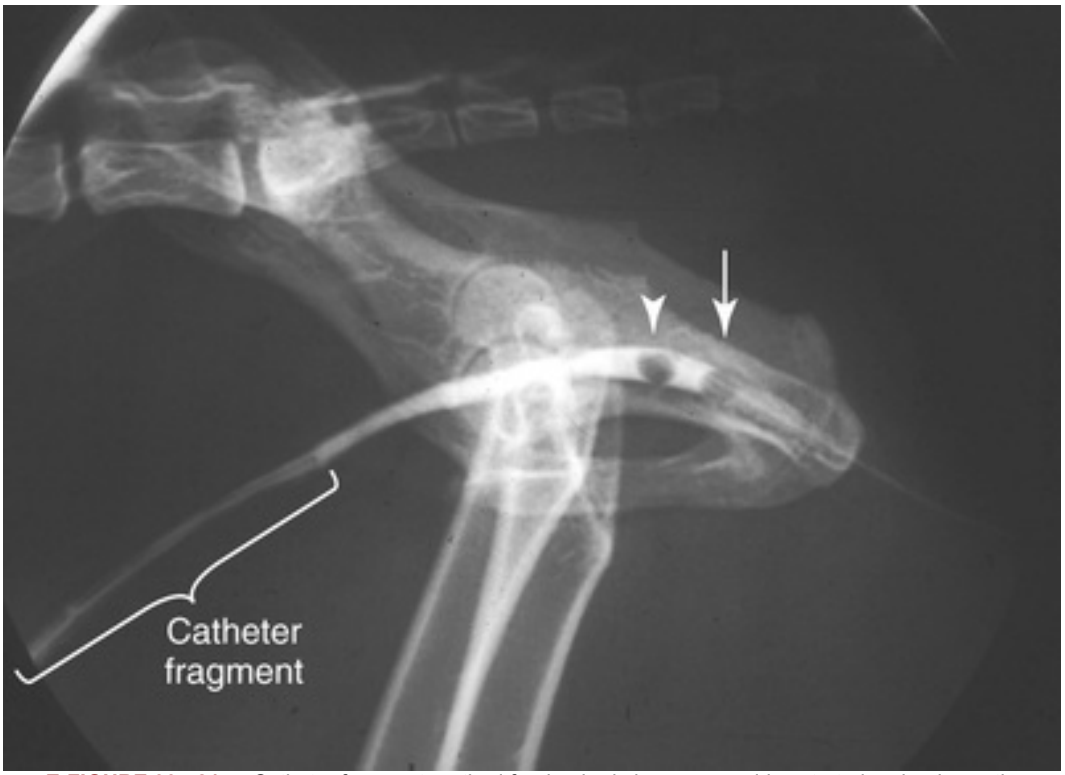

E-FIGURE 335-21 Catheter fragment urethral foreign body in a 5-year-old castrated male, domestic shorthaired cat with repeated urethral obstruction. The balloon of an angiographic catheter (white arrow) and an air bubble in the urethra (white arrowhead) are seen.

E-FIGURE 335-22 Catheter fragment foreign body from cat described in E-Figure 335-21.

E-FIGURE 335-24 Encrusted catheter fragment from patient in Figure 335-23.

CHAPTER 336

Congenital Diseases of the Lower Urinary Tract

John M. Kruger, Joseph W. Bartges, Elizabeth A. Ballegeer

Congenital urinary tract disorders occurring in young dogs and cats may result from heritable (genetic) or acquired processes that affect differentiation and growth of the developing urinary tract or from similar processes that eventually affect the structure or function of the mature urinary system. Formation of the urinary system depends on sequential and coordinated development and interaction of multiple embryonic tissues involving expression of over 400 regulatory genes.[1-6] Despite the extraordinary complexity of urinary system organogenesis, congenital anomalies of the urinary bladder and urethra are relatively infrequent causes of lower urinary tract disease.

Anomalies of the Ureterovesical Junction

Ectopic Ureters (Ureteral Ectasia)

Congenital ectopic ureters (EUs) are characterized by termination of one or both ureters at a site other than the craniolateral aspect of the bladder trigone.[7] Dysembryogenesis of the ureteral bud and failure of common excretory duct apoptosis during ureter transposition result in ectopic openings positioned along the path of ureteral migration (the so-called ectopic pathway).[8-11] EUs are classified according to the location of the anomalous opening relative to the bladder neck and the anatomic course of the anomalous ureter to its termination. *Intravesicular* EUs terminate caudal and medial to their normal position in the craniolateral aspect of the trigone but cranial to the bladder neck. *Extravesicular* EUs terminate caudal to the distal apex of the trigone in the bladder neck, urethra, uterus, or vagina.[8,9,12-14] *Intramural* EUs contact the bladder wall normally but course distally in the submucosa through the trigone before opening into the urethra or vagina (Figure 336-1).[7] Intramural EUs may also form ureteral troughs, develop multiple ureteral openings, or fail to develop a distal orifice.[15] *Extramural* EUs totally bypass the bladder before terminating in the urethra, vagina, or uterus (Figure 336-2). Female dogs appear to be affected more commonly than males; however; the prevalence of EUs in male dogs may be underestimated.[8,14,16-18] The majority of EUs in male and female dogs are intramural and bilateral.[8,9,14,19-21] EUs are considered very rare in cats. Only 31 cases of feline EU have been reported, of which 57% were males and 43% were females.[20,22-40] The vast majority of feline EUs are extramural with a similar prevalence of unilateral (55%) or bilateral (45%) malformations. The urethra is the most common site of termination in female dogs and cats. In male dogs, the majority of EUs terminate in the bladder neck or preprostatic urethra.[8] Because of the close relationship between metanephric duct system and development of the urogenital organs, EUs may be associated with other concurrent congenital anomalies such as renal ectopia, renal aplasia/hypoplasia, ureteroceles, urachal remnants, urinary bladder agenesis/hypoplasia, urethral agenesis or ectopia, urethral sphincter mechanism incompetence (see ch. 333), vestibulovaginal malformations, phimosis, and cryptorchidism.[41,42] Duplicated (double) ureters associated with ureteral ectopia, hydroureter, hydronephrosis, and urinary tract infection have also been reported in male and female dogs and in a male cat.[28,43,44]

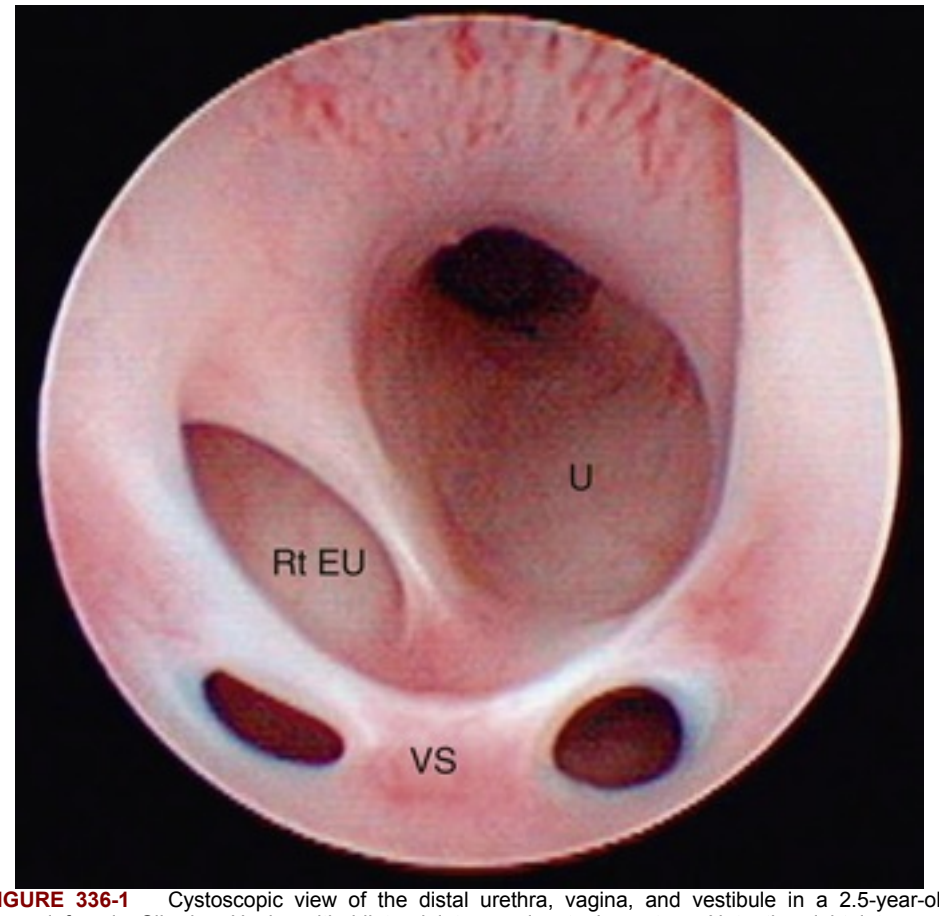

FIGURE 336-1 Cystoscopic view of the distal urethra, vagina, and vestibule in a 2.5-year-old spayed female Siberian Husky with bilateral intramural ectopic ureters. Note the right intramural ectopic ureter opening (Rt EU) in the distal urethra (U) and a persistent vaginal septum (VS).

FIGURE 336-2 A three-dimensional reconstructed image after positive contrast-enhanced CT excretory urography of a 10-year-old, castrated male, Siberian Husky with a 2-year history of urinary incontinence and bilateral extramural ectopic ureters. Note dilation of the right and left extramural ectopic ureters (denoted by an X), which enter the dorsal preprostatic urethra approximately 1 cm caudal to the vesicourethral junction. The white arrow depicts contrast medium in the proximal urethra traveling from a partially distended urinary bladder.

Epidemiologic studies in North America and Europe have identified an increased prevalence of EU in Border Terriers, Briards, English Bulldogs, Entlebucher Mountain Dogs, Fox Terriers, Golden Retrievers, Griffons, Labrador Retrievers, Miniature and Toy Poodles, Newfoundland dogs, Siberian Huskies, Skye Terriers, and West Highland White Terriers.[8,12,45-48] The high predilection in these breeds, observation of EU in closely related dogs, and results of pedigree analyses strongly suggest a hereditary basis for the disorder.[12,14,45,49] Recent population genetic studies have confirmed a hereditary basis for EUs in Entlebucher Mountain Dogs.[45] However, the specific mode of inheritance and genetic mutation(s) involved in EUs in this and other dog breeds have not been reported. Familial or breed predilections have not been identified in cats with EUs.[33]

Clinical signs vary, depending on site(s) of EU termination and presence of other concurrent urogenital abnormalities. Urinary incontinence is the predominant clinical sign in affected dogs and cats (see ch. 46). In most dogs, incontinence is often recognized shortly after weaning, and its severity may vary from continuous involuntary dribbling to intermittent incontinence associated with rest, excitement, or changes in body position. However, onset of urinary incontinence may be delayed in some dogs, especially males.[8,12,14,17,18,50] In addition, some affected male and female dogs and cats may remain continent.[8,12,14,40] Other clinical signs may include abdominal distention, discoloration of the periurethral hair, perivulvar dermatitis, and other lower urinary tract signs (e.g., pollakiuria and dysuria). Ureteral ectopia is frequently complicated by concurrent urinary tract infection in dogs (see ch. 330), whereas infection appears to be less common in affected cats.[15,30]

Although urinary incontinence in juvenile animals is highly suggestive of EU, other congenital and acquired causes of incontinence should be considered (see ch. 333).[3] Survey abdominal radiography and

ultrasonography allow assessment of the size, shape, and location of the kidneys, ureters, and urinary bladder. Administration of a diuretic (furosemide 1 mg/kg IV) during color Doppler ultrasonography may improve the sensitivity of this technique and permit phenotyping dogs as normal, intravesicular ectopic, or extravesicular ectopic (Video 336-1).[45,51-53] However, definitive diagnosis requires additional diagnostic methods, or combination of methods, including excretory urography (±pneumocystography), retrograde vaginography, urethrography, contrast-enhanced computerized tomography (CT), or urethrocystoscopy (see ch. 108).[8,9,12,42,53] Contrast-enhanced CT and urethrocystoscopy appear to be the most reliable methods of establishing a diagnosis, characterizing ureteral opening morphology, and identifying other concurrent urogenital anomalies (see Figures 336-1 and 336-2). Contrast-enhanced CT may have diagnostic advantages in male dogs, whereas urethrocystoscopy is considered the gold standard in female dogs.[8,9,12,53]

Treatment of urinary incontinence associated with EU requires correction of the anomalous ureteral opening(s) and management of any contributing comorbid conditions such as urethral sphincter mechanism incompetence. Surgical strategies employed for correction of EUs include transection and reimplanatation of the ureter (neoureterocystotomy), creation of a neostoma (*in situ* neoureterostomy), or complete removal of the kidney and its ureter (nephroureterectomy).[14,20,42,54] Over the past decade, transurethral cystoscopic-guided laser ablation of intramural EU has emerged as a minimally invasive alternative to surgical correction in dogs (see ch. 124).[18,19,21,55,56] With this technique, a holmium : YAG or diode laser is used to transect the free wall of the EU that is adjacent to urethral lumen, effectively transposing the ureteral opening into the urinary bladder (Video 336-2). Regardless of approach, residual postprocedure urinary incontinence is common, especially in female dogs, with residual incontinence rates ranging from 30% to 75%.[14,21] Interestingly, surgical or laser correction of EU in male dogs may be associated with more favorable outcomes.[8,14,18] Dogs with persistent postoperative incontinence may have concurrent urinary sphincter mechanism incompetence and may benefit from pharmacologic management with alpha-adrenergic agonists, transurethral bulking agent injections, or placement of an artificial urethral hydraulic occluder (see ch. 124).[57-64]

Ureteroceles

Ureteroceles are a congenital cystic dilation of the terminal submucosal segment of the distal ureter. *Orthoptic (simple) ureteroceles* are located at the trigone of the urinary bladder with the ureteral orifice in normal position. Ureteroceles accompanying ectopic ureters are classified as *ectopic ureteroceles.* Ureteroceles may be unilateral or bilateral and are usually ectopic.[8,14,65-67] Ureteroceles have been most commonly reported in female dogs but have also been reported in male dogs and a male cat.[14,20,47,65-72] Patients with orthoptic ureteroceles may be asymptomatic or may develop lower urinary tract signs (i.e., dysuria, stranguria, pollakiuria, and hematuria).[67,72-76] Patients with ectopic ureteroceles typically develop urinary incontinence. In addition, both orthoptic and ectopic ureteroceles are frequently associated with concurrent urinary tract infection and ipsilateral hydroureter, hydronephrosis, and renal dysfunction.[65-78] A diagnosis of ureterocele is based on excretory urography, contrast-enhanced CT, ultrasonography, urethrocystoscopy, or exploratory celiotomy and cystotomy.[42,53] Treatment of ureteroceles is directed at alleviating clinical signs by transurethral laser ureterocele ablation, ureterocelectomy, neoureterocystotomy, or ureteronephrectomy.[42,77]

Anomalies of the Urinary Bladder

Urinary Bladder Agenesis and Hypoplasia

Agenesis or hypoplasia of the urinary bladder results in diminished capacity for urine storage and presents as urinary incontinence.[17,30,79-81] Complete agenesis of the urinary bladder is rare but has been reported in a 4-month-old, female, mixed-breed dog with urinary incontinence.[79,80] Hypoplasia is more common in dogs and cats and may result from embryonic bladder maldevelopment or from conditions that limit adequate bladder filling during fetal development.[82] Ureteral ectopia is frequently associated with bladder hypoplasia, which may contribute to urinary incontinence after surgical correction.[17,30,81] Bladder capacity may increase substantially over a period of several months after correction of EU.[81,83]

Pelvic Bladder

Pelvic bladder refers to urinary bladders that have a blunt-shaped trigone, which is located in an intrapelvic location and associated with a shortened urethra.[84] Although some affected dogs are continent, other dogs with pelvic bladders have refractory incontinence without any other identifiable cause.[84-87] Pelvic bladder has also been associated with other concurrent lower urinary tract disorders.[84] A diagnosis of pelvic bladder is established by contrast radiography. Since the degree of bladder distention directly affects trigone position relative to the pelvic brim, adequate distention during contrast urethrocystography is necessary to assess bladder position. If pelvic bladder is associated with urinary incontinence, pharmacologic management with alpha-adrenergic agonists may be attempted (see ch. 333).[64] If urinary incontinence is refractory to medical therapy, then surgical interventions, injections of urethral bulking agents, or placement of an artificial urethral sphincter may be considered (see ch. 124).[59-63]

Exstrophy

Exstrophy refers to eversion of the urinary bladder, and often the intestines and external genitalia, through midline defects in the ventral abdominal wall.[88] This rare disorder has been reported in an 8-month-old, female, English Bulldog with urinary incontinence and pyelonephritis and in a cat.[89,90] Treatment involves reconstructive surgery.

Urinary Bladder Duplication

Complete and partial urinary bladder duplication with and without urethral duplication has been reported in young dogs and cats.[91-93] Clinical signs may include dysuria, stranguria, urinary incontinence, and abdominal distention. Diagnosis is made by physical examination and imaging studies. Treatment involves surgical correction; however, success depends on degree of malformation and presence of additional congenital anomalies.

Urachal Anomalies

Urachal anomalies occur commonly in dogs and cats. The urachus is a fetal connection allowing urine to pass between the developing urinary bladder and the placenta. It undergoes complete atrophy at birth. However, macroscopic or microscopic urachal remnants may persist as a patent urachus or as urachal cysts or diverticula.[94,95]

A patent urachus occurs when the urachal canal remains functionally patent, resulting in inappropriate urine loss through the umbilicus.[69,96-99] A patent urachus is often accompanied by omphalitis, ventral dermatitis, and urinary tract infections. Rarely, uroabdomen may occur when a patent urachus terminates in the abdominal cavity.[100] A urachal cyst may develop if the urachal epithelium in an isolated segment of a patent urachus continues to secrete fluid.[95]

A vesicourachal diverticulum occurs when a portion of the urachus located at the bladder vertex fails to close. Urachal remnants are microscopic lumens lined by transitional epithelium that are located at the bladder vertex.[95] Approximately 40% of bladders from 80 cats had microscopic diverticula in one study.[101] Congenital microscopic diverticula are usually clinically silent; however, macroscopic diverticula may develop in cats and dogs with microscopic urachal remnants following the onset of concurrent but unrelated acquired lower urinary tract disease (e.g., urinary tract infections, urolithiasis, or idiopathic cystitis).[102-105] Many macroscopic diverticula in cats disappear within 2 to 3 weeks following treatment of the acquired disease and resolution of clinical signs.[103,104] Congenital macroscopic vesicourachal diverticula are thought to be caused by urine outflow obstruction and develop before or shortly after birth. In a necropsy study of 50 dogs without signs of urinary tract disease, 30% of dogs had macroscopic vesicourachal diverticula.[102] Persistent macroscopic diverticula increase risk of bacterial urinary tract infection and associated clinical signs of lower urinary tract disease.[106]

Vesicourachal diverticula are best visualized by positive contrast urethrocystography, ultrasonography (see ch. 88), or cystoscopy (see ch. 108). Treatment of vesicourachal diverticula depends on their size, biological behavior, and association with clinical disease. Many macroscopic diverticula associated with active lower urinary tract disease regress with successful treatment of the acquired disease.[103,104] If diverticula persist after appropriate therapy and are associated with recurrent lower urinary tract disease, then diverticulectomy may

be warranted.[105]

Trigonal (Paraureteric) Diverticulum

Congenital bladder diverticula may also arise from the region of the trigone, presumably as a result of an inherent weakness in the bladder musculature and subsequent herniation of the bladder mucosa.[107] Putative congenital trigonal diverticula have been observed in two young German Shepherd Dogs presented for hematuria, dysuria, stranguria, and urinary tract infection.[108,109] Diagnosis of trigonal diverticula is established by positive contrast cystography, ultrasonography (see ch. 88), cystoscopy (see ch. 108), or exploratory laparotomy. Diverticulectomy is indicated to eliminate urine stasis and reduce risk of infection, urolithiasis, obstruction, and malignant transformation.

Colovesical Fistula and Uterine-Bladder Communication

Rarely, the urinary bladder may communicate with the colon or uterine horn.[32,33,110,111] Clinical manifestations include abnormal urination patterns (simultaneous passage of urine from the prepuce or vulva, and from the anus), urinary incontinence, lower urinary tract signs, and urinary tract infection. Treatment is limited to surgical correction.

Primary Urinary Bladder Neoplasia

Urinary bladder neoplasms are rare in immature dogs and cats.[112] Botryoid rhabdomyosarcoma has been observed in large-breed dogs younger than 18 months but can occur in other dogs.[113-122] Botryoid rhabdomyosarcomas are embryonic mesenchymal tumors arising from pluripotent stem cells originating from primitive urogenital ridge remnants. They are infiltrating tumors that project from the trigone into the bladder lumen as botryoid (resembling a cluster of grapes) masses.[115] Tumors may be associated with lower urinary tract signs, obstructive uropathy, and hypertrophic osteoarthropathy.[114,115] Treatment includes surgery with or without additional chemotherapy.[123,124] Metastases to local tissues (lymph nodes, mesentery, omentum, prostate) and distant organs (lung, liver, kidney, spleen) have been described with this tumor.[113,120,122]

Anomalies of the Urethra

Urethral Aplasia and Hypoplasia

Urethral aplasia is a rare congenital anomaly characterized by complete absence of a patent urethra. Incontinence occurs associated with ureteral ectopia.[69,125] Urethral hypoplasia has been described in immature female cats and is associated with juvenile-onset urinary incontinence.[30,126,127] Diagnosis is based on clinical signs and imaging studies. Radiographic features include urethral shortening and absence of a vagina. Urethral hypoplasia may be associated with other congenital anomalies and urinary tract infection. Affected animals may respond to alpha-adrenergic therapy; however, surgical reconstruction of the bladder neck may be required in some cases to improve or resolve clinical signs.[126,127]

Epispadias and Hypospadias

Epispadias refers to congenital defects in the dorsal aspect of the distal urethra, and hypospadias refers to anomalous ventral malposition of the urethral meatus.[128] Epispadias has been associated with exstrophy of the urinary bladder in an 8-month-old, female English Bulldog.[89] Hypospadias occurs more commonly and usually in male dogs; Boston Terriers and Dalmatians have been described as having an increased risk.[128-130] Hypospadias has been described in a Himalayan cat.[131] In affected male dogs, an abnormal ventral urethral meatus may be located anywhere along the shaft of the penis, scrotum, or perineum. It is usually associated with malformation of the prepuce and penis.[132,133] Hypospadias has been described in female dogs in associated with concurrent disorders of intersexuality. Affected dogs present at various ages and may be asymptomatic or have clinical signs of urinary incontinence, periurethral dermatitis, or urinary tract infection.[132,133] Diagnosis is often based on physical examination. The presence of an *os penis* in male dogs

precludes surgical reconstruction in most cases. Scrotal or perineal urethrostomy combined with castration and removal of vestigial preputial and penile tissues may be of cosmetic value. Shortening of the penis, amputation, and urethral reconstruction has also been described.[134-138]

Urethral Duplication

Urethral duplication is an uncommon congenital anomaly encountered in immature male and female dogs.[139-144] Because of the close association between embryonic development of the urogenital and gastrointestinal systems, urethral duplication is often accompanied by other duplication anomalies involving the descending colon, rectum, urinary bladder, vagina, vulva or penis. Examination of affected animals may reveal anatomic abnormalities, urinary incontinence, or clinical signs associated with secondary urinary tract infection. Diagnosis is based on physical examination, imaging studies, and exploratory surgery. Urethral duplication may in some cases be amenable to surgical extirpation or cyanoacrylate glue embolization of the duplicated structure.[139,144]

Ectopic Urethra

Ectopic urethra is characterized by abnormal position of the external urethral orifice. Clinical signs depend on the site of the termination of the abnormal urethra and other concurrent urogenital anomalies. Lifelong urinary incontinence was the predominant clinical feature in a 21-month-old female English Bulldog with unilateral ureteral ectopia and an ectopic urethra terminating in the distal vagina.[145] In contrast, a 2-month-old, female, domestic shorthair cat with an ectopic urethra terminating in the ventral rectum did not have urinary incontinence but did void urine through the anus.[33]

Urethrorectal, Urethrovaginal, and Urethroperineal Fistula

Congenital fistulas connecting the urethral lumen with the large bowel, vagina, and perineum have been described in dogs and cats.[79,142,146-152] Male dogs appear to be affected more frequently and English Bulldogs appear to have a predilection for urethrorectal fistula.[153] Clinical signs are due to abnormal passage of urine through the fistula during urination and may include diarrhea, perineal dermatitis, and signs associated with secondary urinary tract infections. Fistulas have been associated with infection-induced struvite urolithiasis.[79,149,151] Diagnosis is based on clinical signs and imaging studies. Treatment involves fistulectomy, surgical urinary diversion, and eradication of secondary urinary tract infections (see ch. 330).

Urethral Stricture

Presumed congenital urethral strictures have been described in young dogs and cats.[127,154,155] Clinical signs relate to partial or complete urethral obstruction and may include stranguria, pollakiuria, prolonged urination, bladder distention, overflow incontinence, hydroureter, and hydronephrosis. Urinary incontinence and bilateral hydroureter and hydronephrosis were observed in an 8-month-old, male, German Shepherd Dog with congenital midurethral stricture.[154] Extrapelvic urethral strictures may be managed by urethrostomy, whereas intrapelvic or intraabdominal urethral strictures may require urethral resection and anastomosis or prepubic urethrostomy.[156,157] Alternatively, urethral strictures may be managed by cystoscopic or fluoroscopic-guided balloon catheter dilation.[158-160]

Congenital Urethral Sphincter Incompetence

Congenital urethral sphincter mechanism incompetence has been described in dogs and cats and is often associated with other urogenital malformations (ureteral ectopia, urethral hypoplasia or aplasia, urethral dilation, and prostatic urethral diverticula).[30,42,60,127,161] However, in some sexually intact juvenile patients, congenital sphincter mechanism incompetence may occur in the absence of other concurrent urogenital anomalies. Although urinary incontinence may lessen or resolve with pharmacologic management, many patients require additional surgical intervention, injections of urethral bulking agents, or placement of an artificial urethral sphincter (see ch. 124).[57-64]

Urethrogenital Malformations

Urethrogenital malformations associated with diseases of intersexuality, especially pseudohermaphroditism, are often associated with urinary incontinence.[162-164] Pseudohermaphrodites have gonads of one sex and external genitalia resembling those of the opposite sex.[165] It occurs in both sexes as a result of simultaneous development of müllerian duct derivatives (oviduct, uterus, and portions of the vagina) and masculinization of the urogenital sinus. Appearance of the genitalia depends on the degree of masculinization of the urogenital sinus. Incontinence develops early in life and may be accompanied by urinary tract infection and other lower urinary tract signs. Urinary incontinence likely results from retention of urine in anomalous communications between the urethra and the genital tract and subsequent passive leakage.[166] Diagnosis is based on clinical signs and imaging studies. Urinary incontinence may resolve with surgical correction.[162]

CHAPTER 337

Prostatic Diseases

Michelle Anne Kutzler

Client Information Sheet: Prostatic Diseases

The most important prostatic diseases in dogs include benign prostatic hyperplasia (BPH), acute and chronic bacterial prostatitis, prostatic abscess, paraprostatic cysts, and prostatic neoplasia. The reported prevalence of each prostatic disease varies markedly between studies, depending on population age and neutering status. Reports likely are biased toward BPH and prostatitis in countries where dogs are seldom castrated and toward neoplasia in countries where castration is more common. Studies of dogs with clinical manifestations of prostatic disease certainly are not representative of their true prevalence, given the common occurrence of subclinical prostatic disease in dogs. A study focusing on dogs that died of diseases unrelated to the prostate indicated a 76% prevalence of subclinical prostatic disease.[1] Severe systemic manifestations suggestive of sepsis or inflammation should always raise a suspicion of acute bacterial prostatitis in intact male dogs. The possibility of prostatic disease should not be ruled out in neutered dogs, as castration increases the risk of prostatic neoplasia when compared with intact dogs.[2]

The anatomy and location of the feline prostate differs from dogs in that it lies at the cranial rim of the pelvis, midway between the root of the penis and the neck of the bladder. The prostate includes two lobes and covers the urethra only dorsally and laterally.[3] Based on this location, it seems reasonable to expect that, besides lower urinary tract signs, constipation and dyschezia could occur in toms as a result of partial large bowel obstruction by the enlarged prostate.[4]

Diseases of the prostate gland are extremely rare in cats and include chronic bacterial prostatitis, prostatic abscess, estrogen-induced squamous metaplasia, paraprostatic cysts, and neoplasia.[3,5-11] Despite the rarity of these diseases, diagnostic testing (e.g., cystocentesis for urine sediment exam and culture and sensitivity [see ch. 72], ultrasonography with fine needle aspirate or biopsy of the prostate as indicated [see ch. 88, 89, and 111]) should be performed if prostatic enlargement is identified. Prostatic disease should be included in the list of differential diagnoses for dyschezia or constipation in male cats, even in neutered animals.

Benign Prostatic Hyperplasia

Although normal prostatic growth is achieved by about 2 years of age, prostatic cells undergo ongoing hypertrophy and hyperplasia under the influence of androgens. Prostatic volume tends to increase with age and this process should be considered normal in intact male dogs. This spontaneous benign hyperplasia is observed both in dogs and in men. BPH has been reported to occur in 80% of intact dogs >5 years old and 95% of dogs >9 years old.[4,12] However, histologic evidence of BPH can be encountered as early as two years of age, with a reported prevalence of 16% at that age.[13] In addition, BPH seems to affect Scottish Terriers more severely than other breeds.[4]

Pathogenesis

Prostatic cell growth is under the influence of dihydrotestosterone (DHT) (and to a much lower extent testosterone), estradiol-17-beta, and many other local growth factors. Age-related changes in the androgen : estrogen ratio seem important for development of BPH. DHT represents the main mediator of BPH, promoting growth of stromal and glandular elements.[12,14-17] BPH can progress to cystic BPH as well as predispose dogs to chronic bacterial prostatitis that can progress to cystitis, epididymitis, and orchitis. Estradiol can induce cellular metaplasia of prostatic epithelial cells with glandular obstruction, retention of

prostatic fluid and blood, and formation of parenchymal cysts of varying size that might or might not communicate with the urethra.[18] Progressive secretory stasis and subsequent ductal occlusion result in the formation of multiple cavitary areas within the prostate gland. Parenchymal (intraprostatic) cysts typically communicate with the urethra, unlike paraprostatic cysts (see below).[15,19]

Diagnosis

Dogs with BPH have a symmetrically enlarged prostate that is moderately firm and not painful on rectal palpation. Most affected dogs show no overt clinical signs.[15,20] Prostate asymmetry can be palpated in dogs with prominent prostatic cysts, as often occurs with cystic BPH. Clinical signs occur mostly in advanced stages, when the enlarged prostate compresses the colon dorsally and dogs have problems defecating. Other signs include sanguineous discharge from the tip of the penis unrelated to urinating, hematuria, dysuria, hematospermia, and infertility. Since dogs with BPH are at increased risk of developing chronic bacterial prostatitis, clinical signs such as signs of caudal abdominal pain, stiff gait, reluctance to move, and severe systemic manifestations consistent with sepsis can dominate the clinical picture. Definitive diagnosis of BPH requires prostatic biopsy, although a presumptive diagnosis can be based on signalment, history, physical and rectal exam, and prostatic fluid examination (see ch. 111).[15] Seminal fluid from affected dogs contains blood with or without minimal mononuclear inflammation.[21] Quantitative bacterial culture should yield <100 bacteria per milliliter.[22] Abdominal ultrasound (see ch. 88) typically confirms the findings of the rectal exam and shows a mild diffuse hypo- or hyperechogenicity (Figure 337-1).[23,24] The sublumbar lymph nodes should not be enlarged in uncomplicated BPH. Fine needle aspiration (see ch. 89) and cytologic evaluation (see ch. 93) can reveal the typical characteristics of hypertrophied prostatic cells, which further increases the suspicion of BPH.[25] The suspicion of BPH can be confirmed with a therapeutic trial using androgen suppression. Options include osaterone acetate (Ypozane; available in U.S.) 0.25-0.5 mg/kg PO q 24 h for 7 days, which has been shown to decrease prostatic volume by ≈27% after 1 week and 40% after 2 weeks[26]; or medroxyprogesterone acetate (available in U.S.) 3-4 mg/kg SC single injection, which has been shown to eliminate clinical signs in 84% of dogs in 4-6 weeks, with 68% remaining free of signs for at least 10 months[27]; or deslorelin (Suprelorin; not available in U.S.) 4.7 mg/dog SC implant, which has been shown to decrease prostate size beginning after 22 days, being complete after 52 days.[28] It is difficult to justify a more invasive procedure like an aspiration or a biopsy when less invasive methods (ultrasonography and response to treatment) strongly support BPH.[15] It is important to realize that BPH is a common incidental finding in middle-aged to older dogs and this diagnosis should be interpreted with caution in dogs with moderate to severe clinical signs.

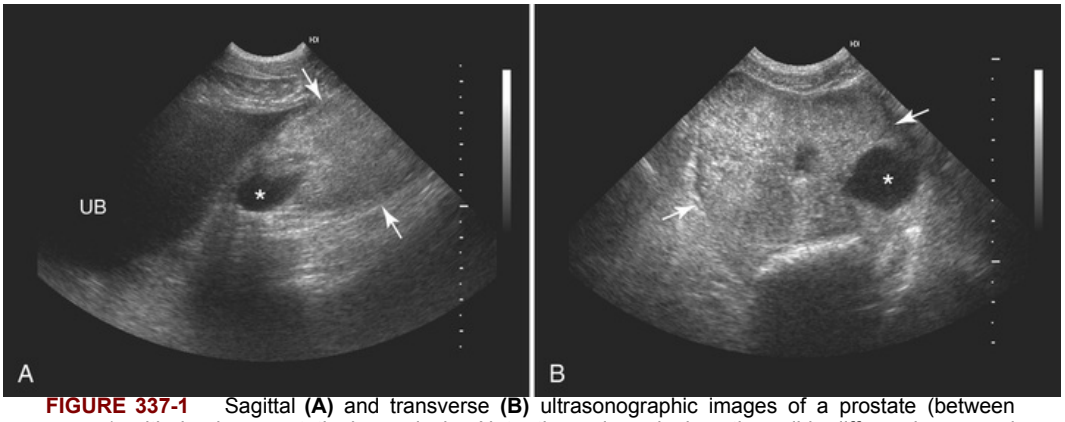

FIGURE 337-1 Sagittal **(A)** and transverse **(B)** ultrasonographic images of a prostate (between arrows) with benign prostatic hyperplasia. Note the enlarged size, the mild, diffuse, hypo- and hyperechogenicity, and the presence of an anechoic intraprostatic cyst (asterisk). The urinary bladder (UB) is to the left in the sagittal image.

Therapy

The goal of therapy for dogs with BPH is reducing prostatic size to alleviate clinical signs and to decrease the

risk of complications such as chronic bacterial prostatitis or prostatic abscess. *Castration* is the first choice treatment for most dogs. It causes rapid reduction in prostatic volume by 50% in 3 weeks and 75% in 3 months. Approximately 3 weeks after castration, involution of the prostate should be verified by rectal palpation or by ultrasound to rule out concurrent, previously masked neoplasia or abscessation. Reversible androgen suppression therapy should be considered for breeding dogs or older dogs with increased anesthetic risk. These forms of therapy are safe and practical, even for mid- to long-term treatment.

Finasteride (Proscar, Merck, 5 mg/dog [irrespective of body weight] PO q 24 h) is a 5-alpha-reductase inhibitor that blocks conversion of testosterone to its bioactive metabolite DHT. This treatment results in decrease in prostatic volume by 50-70% in 2-4 weeks via apoptosis.[29,30] Semen volume decreases without negative effect on semen quality.[31] Although DHT concentrations decrease, serum testosterone concentrations remain unchanged. Dogs, therefore, maintain libido and fertility, and they can be bred successfully.[32] Clinical signs associated with BPH begin to resolve after 1 week of therapy and most dogs have complete resolution of signs within 4 weeks.[31] The prostate will return to its enlarged BPH size within 8 weeks of discontinuing therapy. Therefore, treatment protocols either should be continuous for the remainder of the dog's reproductive life or should be used with a 6-weeks-on-and-6-weeks-off therapy schedule to be more affordable for owners. Regular physical exams including rectal palpation are recommended in these dogs.

Acute Bacterial Prostatitis

Acute prostatitis usually is a disease of mature, intact or recently-castrated dogs. It usually is the result of an ascending infection with normal aerobic urethral bacteria into a hyperplastic prostate gland,[3] although hematogenous infection can occur.[33] The most commonly identified bacterial organism in dogs is *Escherichia coli* (70%), followed by *Staphylococcus* spp., *Klebsiella* spp., *Proteus mirabilis, Mycoplasma canis, Pseudomonas aeruginosa, Enterobacter* spp., *Streptococcus* spp., *Pasteurella* spp., and *Haemophilus* spp.[12] Infections with anaerobic bacterial or fungal organisms have been reported rarely, including one dog with prostatic pythiosis.[33,34]

Diagnosis

Dogs with acute bacterial prostatitis typically present with signs of systemic disease such as depression, anorexia, vomiting, and fever, as well as more organ-specific signs including stranguria or tenesmus, signs of caudal abdominal pain, urethral/preputial discharge, and stiff or stilted gait. The prostate can feel normal in size and shape or it can be asymmetric with an irregular surface on rectal examination. The prostate almost always is painful on palpation.[23] Affected dogs often are severely ill. Blood work reflects systemic inflammation, including neutrophilia with a left shift and toxic changes. Urinalysis (see ch. 72) can be normal or show hematuria, pyuria, and bacteriuria. Urine collected by cystocentesis should be cultured, as prostatic secretions will flow retrograde into the bladder and results of urine and prostatic fluid cultures are highly correlated.[35] Imaging studies (either radiography or ultrasonography [see ch. 88]) for acute bacterial prostatitis will show prostatomegaly, which may not have been palpable per rectum. Ultrasound-guided fine needle aspiration or biopsy can provide samples of prostatic fluid or parenchyma for cytology and bacterial culture and sensitivity, but because of the risk of bacterial seeding along the needle tract, prostatic wash and brush sampling techniques are a safer alternative for obtaining these samples (see ch. 111).[15]

Therapy

The mainstay of treatment for acute bacterial prostatitis is appropriate antimicrobial therapy based on results of urine and/or prostatic fluid or parenchyma culture and sensitivity. Since the blood-prostate barrier is broken in acute bacterial prostatitis, this barrier should not be a major concern when selecting an antibiotic. However, it is recommended, when possible, to initiate therapy directly with an antibiotic that has good prostatic parenchymal penetration so that once the barrier is restored (following the acute phase of infection), antibiotics will not need to be changed.[23] The blood-prostate barrier prevents the diffusion of ionized drugs and of those with low lipid solubility or high protein binding.[16,36] Basic antibiotics with a pKa >7.0 (e.g., trimethoprim-sulfamethoxazole and chloramphenicol) diffuse easily from the blood to the prostatic parenchyma. As the pH of the normal canine prostatic fluid is typically acidic, the pH gradient between blood and prostate favors additional trapping of weakly basic drugs that are ionized in the acidic prostatic fluid.[12,37]

Fluoroquinolones are able to penetrate the prostate parenchyma well regardless of pH and are therefore a good choice for initial empirical antibiotic treatment while waiting for culture results.[38] At a dosage of 5 mg/kg PO q 12 h, enrofloxacin achieves prostatic fluid and parenchymal concentrations exceeding the minimum inhibitory concentration for most pathogens.[38] Antimicrobial therapy should continue for a prolonged period of time (i.e., 4-6 weeks) to reduce the likelihood of prostatic abscess formation. Urine and/or prostatic fluid should be re-cultured 2-3 weeks into treatment while the patient is still under therapy to confirm efficacy (culture is negative). Culture also should be repeated 1 to 3 weeks after cessation of antimicrobial therapy.

The potential impact of acute bacterial prostatitis should not be underestimated clinically since it can lead to sepsis, systemic inflammation, and multiple organ involvement (see ch. 132). Affected dogs should be monitored and treated, if needed, with intravenous (IV) fluids (see ch. 129), analgesics (see ch. 126 and 166), and supportive care. Following the acute phase of infection, castration may be performed as an adjunctive therapy in order to reduce prostatic size (and volume of infected tissue).[23] Castration is not recommended during the acute phase of infection, as scirrhous spermatic cords may form secondary to bacterial ascension.[39] Reversible androgen suppression therapy with finasteride should be used initially until the infection is controlled and a safe surgical castration is possible, or long-term (as described above) in cases of breeding males where castration is not desired.[12]

Prostatic Abscessation

Prostatic abscessation can occur secondary to acute bacterial prostatitis or following estrogen-induced squamous prostatic metaplasia from an infected cyst.[35,40,41]

Diagnosis

Clinical signs of prostatic abscessation are similar to those of acute bacterial prostatitis, including signs of systemic illness, lethargy, fever, pain on urination and defecation and caudal abdominal pain.[15] In addition to an inflammatory leukogram, affected dogs can have sepsis-induced hypoglycemia. Abscesses can be walled off and lose direct contact with the prostatic ductal system. Therefore, bacterial culture of prostatic fluid can yield false-negative results.[42] Ultrasound (see ch. 88) is important for diagnosis and it reveals one or more hypo- to anechoic cavitary lesions within the parenchyma of an enlarged, irregularly-outlined and asymmetrically-shaped prostate gland. A highly-skilled ultrasonographer can differentiate abscesses from uninfected cysts, cavitary neoplasias, or hematomas.[43] Hyperechoic focal areas suggestive of necrotic debris within an abscess can be observed.[39] Even though prostatic abscessation can present similarly to acute prostatitis clinically, it is important to make the correct diagnosis, as the treatment regimen differs.

Therapy

Prostatic abscessation requires a combination of drainage (see below) and appropriate antimicrobial treatment, as antibiotics alone will not successfully eliminate the infection. Local ischemia tends to hinder penetration of antibiotics into the abscess and, in contrast to acute bacterial prostatitis, the prostate-blood barrier commonly is intact.[39] Antibiotics that readily cross the intact prostate-blood barrier (e.g., enrofloxacin, trimethoprim-sulfonamide, chloramphenicol) should be chosen and administered for 6 weeks following drainage. The prostate should be reassessed by ultrasonography to confirm the abscess cavity is not refilling. Similar to the treatment of acute bacterial prostatitis, the prostatic fluid should be cultured both during treatment and 2-4 weeks after antimicrobial therapy is discontinued. Castration and/or reversible androgen suppression therapy should be employed to promote a more rapid resolution of bacterial infection.[44]

Abscesses must be drained either surgically or by ultrasound-guided percutaneous aspiration.[40,45] Ultrasound-guided, percutaneous drainage may be a useful alternative to surgical treatment if the cavitary lesions are well-circumscribed and neither concurrent systemic illness nor prostatic neoplasia is suspected. There is a potential risk for causing iatrogenic peritonitis during percutaneous aspiration.[39] Also, >50% of dogs that undergo aspiration of prostatic abscesses have experienced abscess recurrence.[45] Instillation of 95% ethanol into the drained abscess cavity was used successfully in a dog with recurrent disease.[40] Surgical drainage of a prostatic abscess should include omentalization or marsupialization with placement of a Penrose drain. In one study of 92 dogs with the latter technique, 22 dogs died or were euthanized in the

immediate perioperative period and only 33 dogs were reported to have good to excellent results.[46] Omentalization results in a lower rate of recurrence, lower mortality, and a lower incidence of urinary incontinence postoperatively compared with marsupialization, which is why omentalization is favored by surgeons.[39,47]

Chronic Bacterial Prostatitis

Chronic bacterial prostatic infections are more common than are acute bacterial infections. Both mainly affect mature intact dogs or those infected immediately prior to castration.[48] The prevalence of chronic bacterial prostatitis is difficult to estimate because up to 35% of dogs exhibit no clinical signs nor do they even have an inflammatory leukogram. One study reported a prevalence of 24% subclinical chronic prostatitis in dogs that died of diseases unrelated to the prostate.[1]

Diagnosis

The most common presenting complaint for chronic bacterial prostatitis is a recurrent urinary tract infection with persistence of the same pathogen in an otherwise healthy intact or recently-castrated dog. Infection persists in the prostate during short-term antimicrobial treatment and this leads to reinfection of the urinary tract once antimicrobial therapy is discontinued.[23,49] Other possible clinical signs include sanguineous urethral discharge independent of urination, as well as hematuria, hindlimb gait abnormalities, or discomfort when rising.[50] Less common owner observations are signs of testicular pain from ascending epididymitis, or infertility. Findings on rectal palpation of the prostate vary from normal for a mature, intact male dog to, less commonly, asymmetric, firm and irregular. The prostate usually is not painful on palpation and this may lead to the false assumption that prostatic disease can be excluded.[23] Prostatic fluid evaluation (see ch. 111) shows evidence of suppurative inflammation. In >70% of dogs with chronic bacterial prostatitis, prostatic fluid culture grows a single organism.[16,51] Fine needle aspirate and/or biopsy of the prostate can result in septic peritonitis (see ch. 279) secondary to needle-tract seeding, as has been reported with acute bacterial prostatitis. Radiographically, the prostate is usually normal. Mineralization can be present, but it is not specific and it is indistinguishable from neoplasia.[23] Ultrasonographic findings include a heterogeneous pattern of mixed echogenicity with a focal or diffuse increase in parenchymal echogenicity and hypo- to anechoic parenchymal cavities (Figure 337-2).[52,53] Sonographic shadowing can be seen with calcification, fibrosis, or gas.[23]

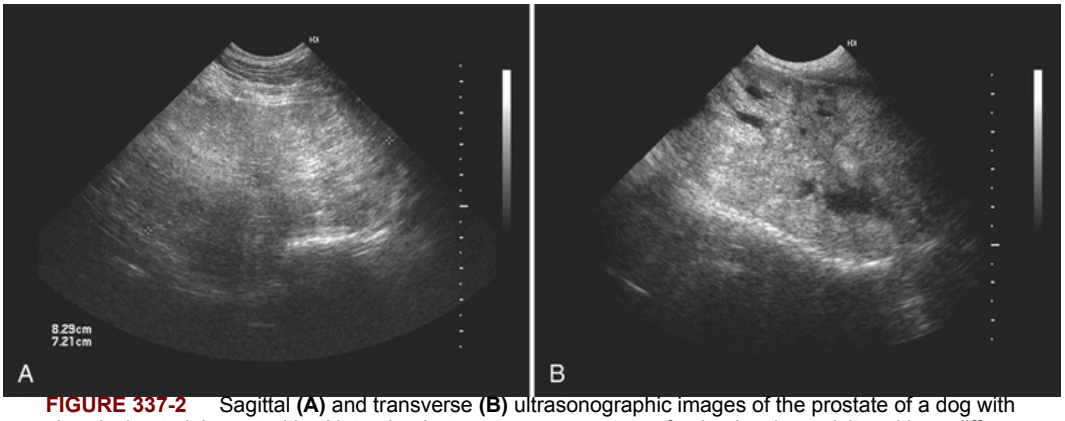

FIGURE 337-2 Sagittal **(A)** and transverse **(B)** ultrasonographic images of the prostate of a dog with chronic bacterial prostatitis. Note the heterogeneous pattern of mixed echogenicity with a diffuse increase in parenchymal echogenicity and hypo- to anechoic parenchymal cavities (intraprostatic cysts).

Therapy

Treatment of chronic bacterial prostatitis is similar to therapy for acute bacterial infections. Therefore, good antibiotic choices for chronic bacterial prostatitis include trimethoprim-sulfonamide for most aerobic bacterial

infections, fluoroquinolones against *Mycoplasma* spp., and chloramphenicol against anaerobes (see section on Acute Bacterial Prostatitis for complete explanation).[4,23,38] As with acute bacterial prostatitis, antimicrobial treatment should be based on culture and sensitivity and should be continued for a minimum of 4-6 weeks, regardless of earlier resolution of clinical signs.[36] When compared with intact control dogs, castration leads to significantly faster resolution of infection.[44,54] Antibiotics should be started 5-7 days prior to castration to reduce the risk of scirrhous cord formation.[15]

Paraprostatic Cysts

Paraprostatic cysts are fluid-filled remnants of the uterus masculinus, which, when present, are located outside the prostatic parenchyma.[55]

Diagnosis

Clinical signs are related to cyst size and can include dyschezia and dysuria from extraluminal compression on the colon or urethra, respectively. Urinary incontinence has been described in dogs where the cyst causes partial urethral obstruction with subsequent bladder overdistention.[43] Depending on their size, paraprostatic cysts may be suspected on abdominal palpation and they may be palpated as a mass within the pelvic canal on rectal exam.[55] They usually arise craniolaterally to the prostate and they tend to displace the bladder cranioventrally or dorsally and the colon and rectum dorsally on radiographs (Figure 337-3). Common histopathologic characteristics include connective or fibrous tissue wall, with or without an epithelial lining, and osseous metaplasia. Radiographic evidence of cyst mineralization is a frequent finding, occurring in 50% of dogs in one report.[55] Mineralized paraprostatic cysts have been discussed as a possible contributing factor in the development of perineal hernias in male dogs.[56] Ultrasonographically, paraprostatic cysts typically have hyperechoic rims and hypo- or anechoic contents, sometimes with septations.

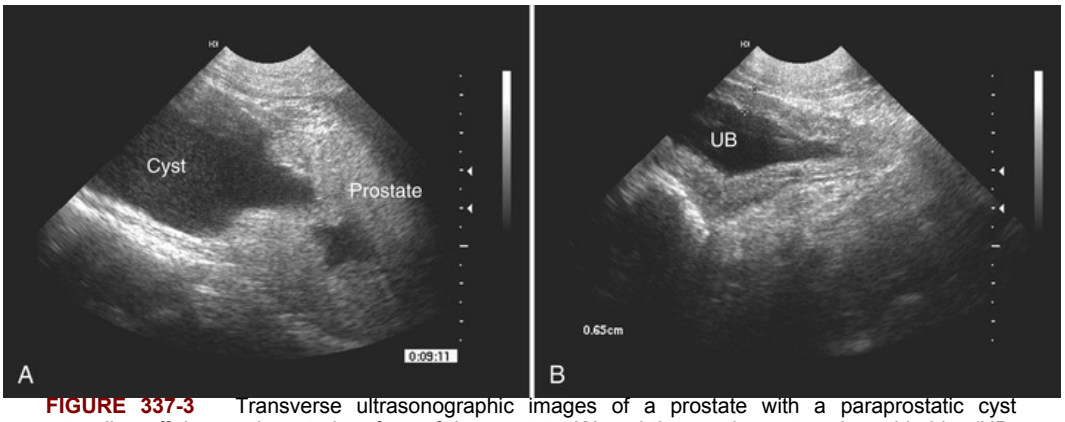

FIGURE 337-3 Transverse ultrasonographic images of a prostate with a paraprostatic cyst extending off the cranioventral surface of the prostate **(A)** and the nearly empty urinary bladder (UB; wall thickness of 0.65 cm is within normal limits for an empty bladder) present on the caudoventral surface of the prostate **(B).**

Therapy

While most paraprostatic cysts do not require any treatment because they are incidental findings, treatment for paraprostatic cysts that are causing clinical signs includes surgical debridement, omentalization, marsupialization and, if needed, placement of surgical drains.[39] Alternatives to surgical treatment include ultrasound-guided percutaneous drainage, which was associated with lower morbidity, lower costs, and improved outcome when compared to surgery in one study.[45]

Prostatic Neoplasia

Except for humans, dogs are the only species known to have a clinically significant incidence of prostatic

cancer. Both species share several similarities, and the dog serves as a model for human disease.[57,58] Adenocarcinoma is the most frequent prostatic neoplasm in dogs, but more than half exhibit intratumoral heterogeneity.[58] The tumor can arise from both glandular or ductal epithelial cells of the prostate or from the urothelium of the prostatic urethra, but in most cases, the precise cellular origin remains unknown.[59] The other common prostatic neoplasm in dogs is transitional cell carcinoma, derived from the prostatic urethra. Other tumors such as sarcomatoid carcinoma, primary and metastatic hemangiosarcoma, and lymphoma have been reported rarely[60-63] (see ch. 351).

Diagnosis

The specific diagnosis of canine prostatic neoplasms may be challenging, as many primary adenocarcinomas in the dog have morphologic and light microscopic features similar to those of transitional cell carcinoma.[59] Overall, canine prostate cancers are malignant epithelial neoplasms that often exhibit gland-like or acinar structures and are, therefore, usually classified as adenocarcinomas.[64] Most canine prostate cancers do not express androgen receptors and are hormonally independent, and, therefore, do not respond to androgen deprivation.[12,64] It is important to note that in dogs, castration significantly increases the risk of developing prostatic cancer. In a large multicenter retrospective study, the risk of developing prostatic transitional cell tumor was 8 times higher in castrated than in intact dogs, and it was 2.1 times higher for prostatic adenocarcinoma.[65] On a histologic level, it has been shown that castration leads to an increased occurrence of less-differentiated growth patterns in canine prostatic cancer.[57] Castration does not seem to initiate tumor development, but it favors tumor progression. This may be the result of supraphysiologic luteinizing hormone (LH) concentrations that persist for the dog's life following castration, as a result of the loss of testicular negative feedback. LH receptors are present within human prostatic epithelium[66] but have not been investigated in dog normal or neoplastic prostate tissue yet. Breed predispositions for prostate cancer include mixed-breed dogs, Shetland Sheepdogs, Scottish Terriers, Airedale Terriers, and Doberman Pinschers.[65]

Common clinical findings in dogs with prostatic neoplasms include dysuria, macroscopic hematuria, dyschezia, hindlimb pain, and ataxia.[64] In more advanced stages, clinical signs of paraneoplastic syndromes such as lethargy, anorexia, weight loss, and poor body condition are present. Dysuria can be due to concurrent prostatitis or to local invasion into the prostatic urethra, occasionally resulting in urethral obstruction. Pyuria and hematuria were found in 62% and 66%, respectively, of 24 dogs with prostate cancer.[67] Because of the aggressive nature of canine prostate cancer, most dogs are in advanced stages of disease when diagnosed. Often, there is extensive local invasion and widespread visceral metastases, with a prevalence up to 80% at the time of diagnosis.[67] The most common sites of metastasis are the sublumbar and iliac lymph nodes, lung, and bone (mostly the lumbar vertebrae and pelvis). Involvement of liver, kidney, spleen, and brain has been reported. The presence of neoplastic tissue in the urinary bladder is a common manifestation of local invasion by neoplastic cells, which also can be found in the prostatic lymphatics, perineural space, and pelvic musculature. In dogs, all prostate cancers are considered to be highly aggressive neoplasms with widespread metastatic tendency.

Diagnosis of prostatic neoplasia in dogs usually is based on history, clinical signs, prostatic imaging (see ch. 88), fluid analysis (see ch. 111), cytology (see ch. 93) and/or histopathology. Radiographic changes can include prostatomegaly, mineralization of the prostate, evidence of regional lymphadenomegaly, and possibly evidence of metastasis to the lungs and bones, especially to the lumbar vertebrae and pelvis. Ultrasound findings can include focal to diffuse hyperechoic areas, mineralization, and loss of normal prostatic contour (Figure 337-4).[15] Percutaneous, ultrasound-guided fine needle aspiration is a viable diagnostic tool for cytologic diagnosis of prostatic neoplasia (E-Figure 337-5).[68] However, there is a potential risk of needle-tract seeding into the abdominal wall.[69] This complication seems to be rare, but the possibility should not be neglected and the needle tract should be resected at surgery if possible. Prostatic wash is a valuable alternative to fine needle aspiration (see ch. 111).

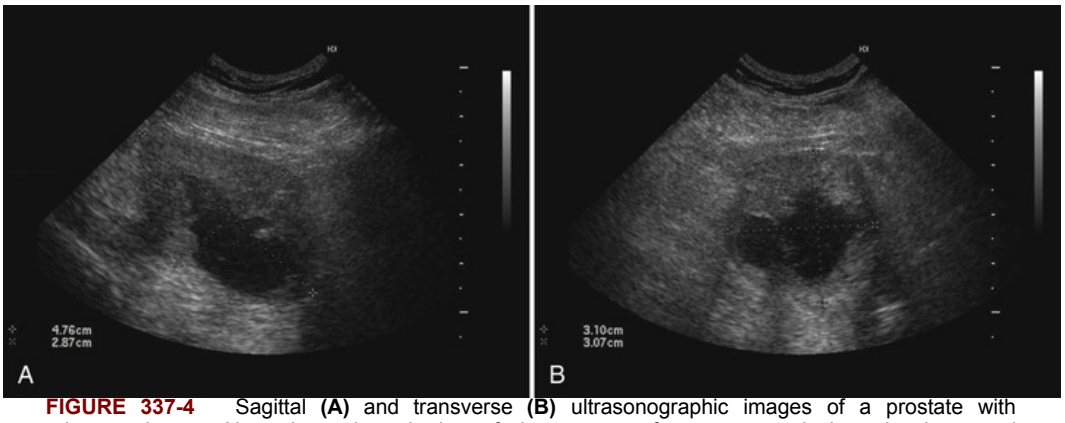

FIGURE 337-4 Sagittal **(A)** and transverse **(B)** ultrasonographic images of a prostate with adenocarcinoma. Note the enlarged size of the prostate for a castrated dog, the increased echogenicity, and presence of large, coalescing cysts with hypoechoic luminal contents. The ultrasonographic appearance of a prostatic abscess can be similar to that of a prostatic adenocarcinoma. The diagnosis should be confirmed by evaluation of a prostatic fluid sample and/or prostatic biopsy.

E-FIGURE 337-5 Ultrasonographic guidance during biopsy minimizes the risk of complications and maximizes the diagnostic value of the sample.

Therapy

In general, the survival for most dogs with clinical prostate cancer is short, often only ranging from weeks to months.[58] Since canine prostate cancer is aggressive and highly metastatic, ideally both local and systemic therapies are indicated. However, there is no widely accepted standard of care at present, and treatment options are limited and rather unrewarding.[64] Piroxicam, a nonsteroidal anti-inflammatory, can be administered at 0.3 mg/kg PO q 24 h, and has successfully reduced the size of various canine carcinomas.[70] A

combination of piroxicam with cisplatin (60 mg/m^2 IV q 21 d) has resulted in complete or partial remission in 71% of dogs with urinary bladder cancer, compared with no tumor remission with cisplatin treatment only (see ch. 351).[71] Radiation therapy did not improve survival significantly and its role in the treatment of canine prostatic neoplasia is unclear.

Other treatment options include palliative partial or total surgical prostatectomy.[72] However, such approaches are associated with serious risks of complications and they do not necessary prolong survival time.[64] Other palliative treatment options could be beneficial and include bisphosphonates to inhibit osteoclasts and help in the management of skeletal metastases (see ch. 352).[73] Inhibition of bone resorption relieves pain, reduces the risk of fracture, and controls paraneoplastic hypercalcemia.[64] Despite numerous attempts to improve treatment of prostatic cancer in dogs, the prognosis currently remains poor.

CHAPTER 338

The Hallmarks/Origin of Cancer

Chand Khanna, Amanda Foskett

There has been a recent explosion in our understanding of the biology of cancer that has led to a parallel explosion in our opportunities to better diagnose and treat cancer. Accordingly, it is now necessary for clinicians to have a sound understanding of the basic biology of cancer so as to best implement novel and conventional therapeutic options. It is also important to integrate this insight to appropriately consider the use of recently developed molecular tests for cancer and cancer progression.

In 2000, the Nobel laureates Hanahan and Weinberg proposed a model for understanding the complexity of cancer, referred to as the "hallmarks of cancer."[1]

An attractive component of this proposed model was a cohesive structure in which one could consider the complexity and growing number of molecular changes that have been identified in cancer cells, and how these events independently and collectively contribute to the formation of a cancer. Briefly, this model suggested that despite the large number of molecular alterations that have been associated with cancer, they all could be understood by their contribution to six critical features necessary for the development of a cancer. These critical features were described as the "hallmarks of cancer." A specific molecular alteration could contribute to cancer by providing a cell with one or more of these hallmarks; however, it is the acquisition of all of the hallmarks that yields the full cancer phenotype. The traits ("hallmarks") that the authors prioritized in the model are summarized in Figure 338-1.

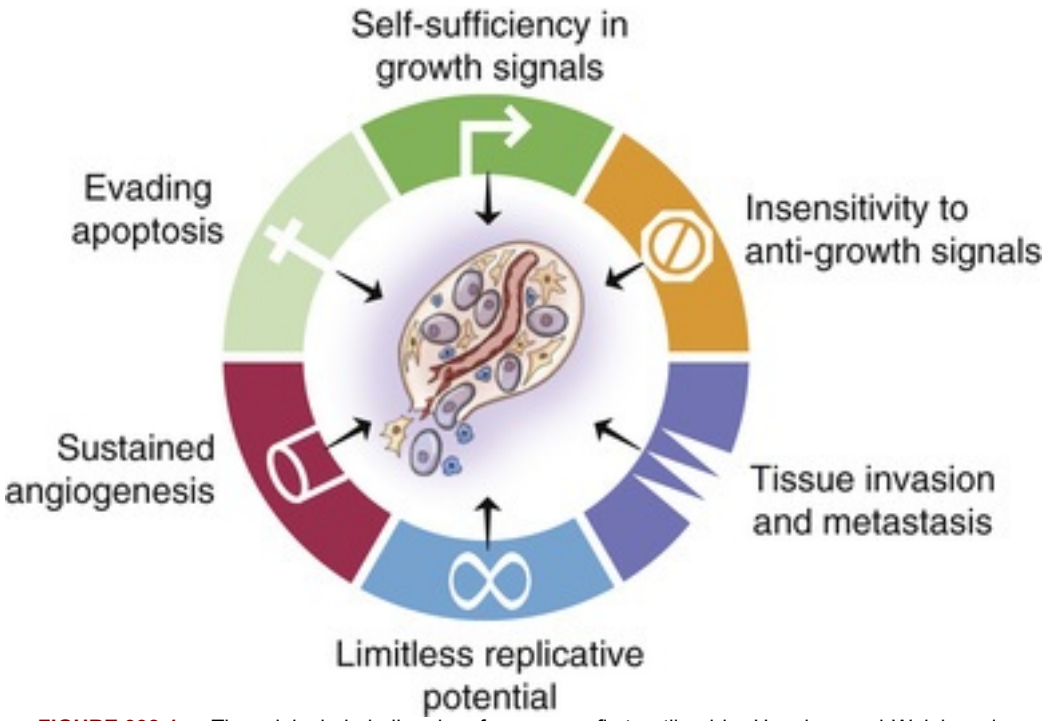

FIGURE 338-1 The original six hallmarks of cancer as first outlined by Hanahan and Weinberg in 2000. (From Hanahan D, Weinberg RA: The hallmarks of cancer. *Cell* 100[1]:57-70, 2000.)

An important clinical corollary of this model is that the effective treatment of a cancer should prioritize

cancer targets that are most needed to deliver a hallmark to a cell. In summary, this model allows the simplification of thousands of genes linked to the cancer phenotype to a simple set of six "hallmarks" that must be acquired in order to create cancer from a normal cell. Additionally, this model allows a focus on the fundamental features of cancer rather than on the specific functions of various molecular changes.

Ten years after the original publication of this model, a revision was proposed that refined the "hallmarks" through some clarity in the features of cancer progression and metastasis, and inclusion of "enabling features" of cancer.[2]

The use of this model allows the clinician to focus on the critical features of the cancer phenotype rather than a long list of genetic molecular alterations. Furthermore, it provides a simple framework to characterize the contributions made by various molecular alterations.

Cancer Is a Genetic Disease

It is clear from all points of evidence, that cancer is a genetic disease.[3,4] Indeed, related to the above discussion on the hallmarks of cancer, each of the six hallmarks required for a cancer can be delivered through alterations in genes. To say that cancer is a genetic disease does not suggest that cancer is a hereditary disease, although there are familial, and therefore hereditary, risks associated with cancer.[5]

The classical association between cancer and genetics involves a discussion of tumor promoting genes that become overactive, referred to as oncogenes, or the loss of genes that normally constrain one or more of the hallmarks of cancer, referred to as tumor suppressor genes. The activation of oncogenes occurs for a variety of reasons. Often, this involves a mutation or other structural change that activates the normal gene (a proto-oncogene) to become a cancer-associated oncogene. The gain of function seen in an oncogene is a dominant event, and therefore requires the alteration of only one of a gene's alleles.[6,7] Conversely, the loss of a tumor suppressor gene is recessive event, and therefore requires the loss of both alleles for the function of that tumor suppressor to be lost. Interestingly, it is the loss of a tumor suppressor gene, *P53,* that is believed to be the most common genetic alteration seen across human cancers. Not surprisingly, loss of P53 has also been described in a variety of veterinary cancers.[8-12] P53 is a member of a family of genes described as checkpoint genes. P53 and other checkpoint genes serve to "survey" the genetic landscape of a cell and determine if there has been sufficient DNA damage to warrant halting the division of the cell and its progress through the cell cycle (referring to a series of steps that allows the cell to undergo mitosis). Halting the division of the cell allows DNA repair mechanisms to repair the DNA damage identified in the cell. If the DNA damage is more significant, genes like P53 will not only halt the mitotic process, but will shift the cell into a pathway of programmed cell death (apoptosis). This allows elimination of this genetically altered cell, therefore preventing it from potentially contributing to a hallmark of cancer. Accordingly, the loss of P53 and its checkpoint function will eliminate the ability of cells to enter this suicide/death pathway, and therein increase the number of cells present with genetically altered landscapes. The loss of two alleles in a tumor suppressor gene which, as described, will contribute to a hallmark of cancer, often occurs as a result of a hereditary and sporadic ("second hit") event. In this scenario, the first loss of a tumor suppressor gene is a familial risk and the second loss is sporadic. The resultant loss of these two alleles, often described as "two hits," explains why there are families at increased risk for specific cancers. This was first described by Knudson in the familial and sporadic form of retinoblastoma in humans, which results from a two-hit loss of the retinoblastoma (Rb) tumor suppressor gene.[13]

Historically it was believed that the genetic alteration that results in the dysregulation of a specific gene occurred as an alteration in the nucleic acids that constitute that gene. It is now increasingly understood that these alterations in gene function can occur outside a specific change in the gene itself. This understanding is included in a large field of cancer biology referred to as epigenetics. Briefly, epigenetics largely refers to changes in the regulatory elements of a gene (namely the promoter or enhancer of the gene). Epigenetic alterations in gene function in fact can be a more common mechanism for cancer-associated gene dysregulation than structural changes in a gene (i.e., mutation). Interestingly, these epigenetic changes in gene function have been aligned closely with various environmental and other acquired risks for cancer.[14,15]

Telomerase and the Acquisition of Limitless Replicative Potential

The acquisition of limitless replicative potential is a hallmark of cancer. This hallmark has been closely associated with the telomere and telomerase. Telomeres are specialized DNA protein complexes that cap the ends of chromosomes and maintain genomic stability by preventing recombination or fusion with other

chromosomes. Each telomere consists of tandem repeats of TTAGGG and several telomere-related proteins. In normal cells, telomeres shorten with each cell division, referred to as telomeric attrition. Telomerase is a reverse transcriptase capable of making the terminal telomeric repeats, thus extending the telomere and compensating for attrition during cell division.[16] Very low levels are detected in normal somatic tissues; however, telomerase is found at high levels in germline and cancer cells, giving them long-term proliferative potential. Some cancer cells are capable of maintaining telomere length and surviving without telomerase.[17] In these instances, alternative mechanisms, referred to collectively as alternate lengthening of telomeres (ALTs), are used.[18,19] The mechanisms are not fully understood, but have uncovered novel therapeutic targets (i.e., ataxia telangiectasia and Rad3-related kinase [ATR]) that are being targeted in dogs by novel anticancer drugs.[20]

Tumor Progression and Metastasis

In order for cancer cells to spread from the primary tumor to distant secondary sites, individual cells and groups of cells must accomplish a number of discrete processes associated with the metastatic cascade. A detailed study of the metastatic cascade has now defined critical steps, which appear to be the most difficult for cancer cells to pass through successfully. These steps represent *unique periods of vulnerability* during which cellular stresses result in the death of the majority of cancer cells, and especially non-metastatic cells. These stresses appear to be highest as metastatic cells interact with the microenvironment at the secondary metastatic sites. It is only the minority of cancer cells that can adapt and survive these vulnerable states during the metastatic cascade. Indeed, the metastatic phenotype now can be defined by an ability of cells to adapt to stresses experienced during these vulnerable states.[21-23] An understanding of these stresses and the mechanisms by which cells overcome them could provide a new opportunity for the discovery and development of metastasis-specific therapies.

Metastasis is a multistep process that results in the dissemination of tumor cells from a primary site to distant secondary organs, and the eventual progression of disease at these secondary sites. Metastatic cancer cells are uniquely programmed to endure and overcome cellular stresses associated with each step in this process.

Based on studies of the metastatic phenotype of sarcoma cells in dogs, mice and humans, we believe that a common determinant of metastatic cancer cells is their ability to resist these stresses.[24] Starting with our study of the metastasis-associated protein ezrin, we have taken this cross-species (murine, canine, human) comparative approach to the study of metastasis as a means to develop an understanding of metastasis that can be translated rapidly to the clinic in the form of novel therapeutics.[24]

Recent and preliminary data now suggest the endoplasmic reticulum (ER) of highly metastatic cells as being distinct from that of low metastatic cells. Indeed, the ER response in highly metastatic cells seems to lead to a protective effect that is not seen in low metastatic cells.[25] These data suggest the ER and the ER responses in highly metastatic cells could serve as potential targets for novel antimetastatic therapy. Studies now are underway to screen and identify drugs that target the stress adaptation pathways of the ER and, in so doing, could be useful against metastatic progression.

Angiogenesis and the Tumor Microenvironment

Tumor vasculature and angiogenesis have been studied extensively, especially as a target for cancer therapy. Tumor angiogenesis refers to the formation of blood vessels within the tumor microenvironment through sprouting or intussusception of pre-existing blood vessels. This is in contrast to vasculogenesis, or formation of blood vessels *de novo*, during embryogenesis. The vasculature within and surrounding a tumor is of critical importance, as it supplies the nutrients, growth factors, metabolites, inflammatory mediators, and oxygen for primary tumor proliferation.[26] Tumor blood vessels also provide a means for tumor cells to enter the vasculature and spread to other parts of the body, and play a vital role in the metastatic cascade.

Normal angiogenesis occurs in all tissues and is of particular importance in embryogenesis and wound healing. Hypoxia is the primary physiologic stimulator in the development of vasculature. Hypoxia-sensing mechanisms in poorly perfused tissues induce new vessel formation to satisfy the metabolic requirements of cells in the hypoxic environment. Cells respond by secreting proangiogenic growth factors, including vascular endothelial growth factor (VEGF), platelet derived growth factor (PDGF) and basic fibroblast growth factor (bFGF), among others. Briefly, these factors induce endothelial cells from surrounding blood vessels to migrate towards the angiogenic stimulus and organize to form new vessels. Generation of a new blood

supply to these tissues eliminates the hypoxic stimulus, and VEGF production declines.[27]

The tumor microenvironment often does not abide by normal physiologic rules. Many cancer cells are capable of inducing angiogenesis in the absence of hypoxia. Multiple mechanisms have proven responsible for this phenomenon, including the overproduction of VEGF, and upregulation of other vascular stimulating cytokines. This phenotype has been associated with the activation of oncogenes, loss of function in a number of tumor-suppressor genes, and downregulation of angiogenic inhibiting mechanisms. The tumor microenvironment also lacks the normal barriers present in non-cancerous tissues. For example, the basement membrane and connective tissues often are compromised in malignant tissues, creating an altered tumor-vascular interface, which could influence metastatic potential, access to nutrients, and access to other mediators.[28]

In human medicine, a plethora of therapeutic agents has been developed to target various steps in the angiogenic pathway.[29,30] In veterinary medicine, small-molecular targeted therapies also have started to emerge on the market. Specifically, Palladia (toceranib) is a receptor tyrosine kinase (RTK) inhibitor developed to target c-kit in mast cell tumors. This drug also inhibits the RTKs of VEGF, and other proteins, involved in angiogenesis. Toceranib has known activity against a number of cancer types, independent of c-kit.[31] Indeed, many tumor types overexpress VEGF or PDGF, or have aberrant VEGF signaling, and reasonably could be targeted with this drug.[32]

The Cancer Stem Cell Hypothesis

It is recognized that within a cancer there is a variety of subpopulations, including those that account for the rapid recurrence of a cancer after initial response to therapy. The cancer stem cell hypothesis proposes that a small but definable population of cells within a tumor is able to self-renew and give rise to tumor cells both at the primary tumor site and sites of metastasis. Within this heterogeneous environment exists a small number of slowly dividing cells that differ from the rest of the cancer cell population that are resistant to conventional treatment. This population is proposed as the cause for recurrent disease despite initial response to treatment (e.g., chemotherapy, radiation, or surgery) or distant metastasis to other sites in the body later in disease progression.[33]

Clinically, cancer stem cells (CSCs) have become a prominent area of interest and research as a potential target for cancer treatment. CSCs were first pinpointed in acute myeloid leukemia (AML). These cells were identified by their ability to self-renew and repopulate the bone marrow of severe combined immunodeficient (SCID) mice following transplantation of human AML cells and administration of *in vivo* cytokine stimulation.[34] Later experiments identified a hierarchy among these populations, and discovered specific cell markers, present only on this small population of CSCs, that were capable of differentiating into blastic leukemic cells.[35] Various CSC markers now have been identified on a number of solid tumors including breast cancer,[36] colorectal,[37-39] pancreatic,[40] hepatocellular,[41] ovarian,[42] and prostatic cancers,[43] among many others including melanoma.[44] Specific markers identified in these tumor types have been associated with prognosis, metastatic rate, and response to treatment in human cancer patients, indicating that these CSCs could be a valid target for novel cancer therapy. Varying therapies targeting altered cellular pathways in the stem-cell population have shown promise *in vitro* and in some early clinical trials.[45,46] Immunotherapy also has been used for targeting cell surface markers unique to CSCs with varying efficacy in both the *in vitro* and *in vivo* settings[47] (see ch. 341).

Although new, targeted therapies towards CSCs are not yet common practice in veterinary medicine, this approach presents a new, exciting front that will likely benefit the veterinary patient in the future.

CHAPTER 339

Principles and Practice of Chemotherapy

Angela E. Frimberger, Antony S. Moore

Client Information Sheet: Chemotherapy Safety for Pet Owners

Chemotherapy is the principal modality used to treat systemic cancers such as hematologic malignancies and metastatic solid tumors.

Tumor Biology in Chemotherapy

A good understanding of tumor biology, discussed in detail in ch. 338, is necessary in planning chemotherapy.

Chemotherapy works best against a small tumor burden. As tumors grow, the growth fraction decreases, the cell cycle time increases, cellular heterogeneity increases (leading to a higher level of spontaneous resistance), and areas of poor perfusion increase. Thus, it may not be possible for chemotherapy drugs to be delivered to cancer cells at cytotoxic levels. In addition, because resistance to chemotherapy can occur through spontaneous mutations that occur with each cell division at a rate intrinsic to each tumor, the likelihood that mutations resulting in drug resistance have occurred is related to the number of cell divisions that have taken place. Finally, chemotherapeutic cytotoxicity follows fractional-kill kinetics. For example, if a particular dose of drug kills 4 logs of cells, then it will reduce a tumor of 10^{12} cells to 10^{8} cells and a tumor of 10^{10} cells to 10^{6} cells—either will appear clinically as a complete response because 10^{9} cells is usually the limit of clinical detection; however, the latter scenario is obviously preferable. Therefore, it is most advantageous to begin treatment with the smallest tumor, and in general, chemotherapy will be most active either after early detection or after a cytoreductive ("debulking") procedure such as surgery or radiation therapy.

Chemotherapy Strategies

In managing chemotherapy, communication between veterinarian and owner is essential. These communications must be both frank and compassionate. All options should be presented to owners without preconceptions of the owner's preferences.

A definitive diagnosis of tumor type, clinical stage of disease, and the patient's overall health are important both in establishing a prognosis and prescribing a treatment plan. The general health screen is necessary to detect other conditions that may affect life expectancy (i.e., other systemic disease), conditions that need to be resolved prior to starting chemotherapy (e.g., subclinical urinary tract infection), or conditions that need to be taken into account in planning chemotherapy (e.g., subclinical cardiac or renal disease).

Staging and General Health Evaluation

Every patient is an individual, and the metabolism and excretion of the drugs are individual, and every cancer is also an individual. The purposes of staging are to evaluate the extent of disease and to assess the pet's general health—this is important both to evaluate fitness for therapy and to screen for unrelated or secondary conditions that may require management before starting cancer therapy or may separately impact on the pet's overall prognosis. Staging often carries prognostic significance that may help the veterinarian and client make informed, rational decisions about the type of therapy. Most staging systems are based on assessment of three major components of the malignant process: the size of the primary tumor (T), lymph node metastasis (N), and distant metastasis (M).

Goal of Treatment

It is important to establish the goal of treatment at the outset because it often determines the course of therapy. The goal of chemotherapy in human oncology is usually to cure the patient; however, in veterinary medicine, palliation may sometimes be a more appropriate goal. A continuing, open dialogue will allow an owner to make an informed decision and will ultimately create a "team" approach to treatment of the pet's cancer.

Palliative Intent Treatment

Palliation is defined as improving quality of life, and possibly extending life, but without expectation of cure. Palliative treatment is often appropriate when the prognosis is poor and significant toxicity cannot be justified when only a short duration of survival is expected. For many older veterinary patients, the diagnosis of cancer is made at a time when other diseases may limit survival to a greater extent than does the cancer. For these animals, palliative care may be most appropriate, and the choice of chemotherapy must be weighed against the risk of toxicosis. It is rarely effective to begin treatment with palliative intent and then later to switch to a more aggressive approach. However, it is common to begin treatment with curative intent and then later switch to a palliative course.

Curative Intent Treatment

Cure is defined as eradication of all tumor cells resulting in a permanent disease-free state, and is an ideal although not always realistic outcome. The restriction on chemotherapy doses to keep side effects within an acceptable range means that cures are usually only possible in a small number of veterinary patients—for example, 15% of dogs with lymphoma and 20% of dogs with osteosarcoma, given standard of care therapy. For dogs and cats that are in good health and have no concurrent illnesses and when chemotherapy holds the possibility of prolonged control of their cancer with little risk of toxicosis, chemotherapy with curative intent may be undertaken.

Chemotherapy in Combination with Other Treatment Modalities

In veterinary oncology, primary chemotherapy (chemotherapy as the sole or main treatment) is usually reserved for hematopoietic tumors (lymphoma, leukemias, multiple myeloma). For dogs with metastatic solid tumors (carcinomas and sarcomas) chemotherapy alone is rarely curative and is better considered to be palliative.

Adjuvant chemotherapy is used after resection or radiation of a primary tumor, to slow the progress of metastatic disease or possibly to provide a cure. This is done in settings when the animal is at significant risk of recurrence or metastasis, but before disease progression is clinically detectable—for example, after amputation in dogs with osteosarcoma. Adjuvant chemotherapy is effective because it is used at the earliest stages of growth. When a primary tumor is resected, micrometastatic foci of tumors cells have a high growth fraction and a low number of resistant cells. The disadvantage of adjuvant chemotherapy is that patients cured with surgery are treated unnecessarily. For tumors such as osteosarcoma and hemangiosarcoma in dogs and mammary tumors in cats, this percentage of surgical cures is small, but for animals with other tumors, the decision of whether chemotherapy will be beneficial or not may be more difficult.

Neoadjuvant chemotherapy is used before localized treatment modalities such as surgery or radiation therapy, with the objective of reducing the size of the primary tumor and reducing the scope and side effects of other definitive treatment. *Chemoradiotherapy* refers to the use of chemotherapy drugs primarily as radiation sensitizers rather than for their direct antitumor effect.

Drug Classes and Combination Chemotherapy

Many standard of care treatment protocols use chemotherapy drug combinations. Understanding combination chemotherapy requires a knowledge of the common classes of drugs in use in veterinary oncology.

Alkylating agents (Table 339-1) create cross-links in DNA, causing strand breaks. An interesting feature of this class of drugs is the apparent lack of cross-resistance between different alkylating agents or with other classes of drugs.

TABLE 339-1

Commonly Used Alkylating Agents

DRUG	FORM	POTENTIAL SIDE EFFECTS	DOSAGE/REGIMEN
Cyclophosphamide (Cytoxan)	25, 50 mg tablets; 500 mg vials	Myelosuppression Hemorrhagic cystitis	250 mg/m^2 PO q 3 wk 200 mg/m^2 IV q 3 wk 50 mg/m^2 PO q 48 h
Chlorambucil (Leukeran)	2 mg tablets (refrigerate)	Mild but cumulative myelosuppression	6-8 mg/m^2 PO q 48 h 15 mg/m^2 PO daily for 4 days q 3 wk
Melphalan (Alkeran)	2 mg tablets (refrigerate)	Myelosuppression	1.5 mg/m2 PO daily for 10 days, then a 10-day "rest"
Lomustine (CCNU; Gleostine)	5, 10, 40, and 100 mg capsules	Myelosuppression, neutropenia, and delayed thrombocytopenia in dogs; delayed neutropenia in cats Irreversible renal and liver toxicosis (uncommon)	50-90 mg/m^2 PO q 4-6 wk (dogs) 50 mg/m^2 PO q 6 wk (cats)
Mechlorethamine (Mustargen)	10 mg vials	Myelosuppression Extravasation reaction	In MOPP: 3 mg/m2 IV weekly
Procarbazine (Matulane)	50 mg capsules	Nausea, anorexia, diarrhea Myelosuppression	50 mg/m2 PO daily for 14 days (dogs); 10 mg/cat PO daily for 14 days
Dacarbazine (DTIC)	200 mg vials	Myelosuppression Anorexia, vomiting, diarrhea	800 mg/m2 q 3-4 wk (dolasetron is used prior to treatment) IV slow infusion over 5-8 hours
Ifosfamide (Ifex)	1 g with mesna 1 g vials	Myelosuppression Hemorrhagic cystitis (must be given with mesna and diuresis protocol) Renal toxicosis in cats	375 mg/m^2 IV (dogs) 900 mg/m^2 IV (cats) Given q 3 wk in 0.9% NaCl with mesna

Antitumor antibiotics (anthracyclines) (Table 339-2) act by DNA intercalation, interfering with topoisomerases, and other mechanisms. These drugs usually exhibit cross-resistance with others in their class and with drugs in some other classes, particularly mitotic inhibitors, and they are substrates for the multidrug resistance (MDR) pump.

TABLE 339-2

Commonly Used Antitumor Antibiotics

DRUG	FORM	POTENTIAL SIDE EFFECTS	DOSAGE/REGIMEN
Doxorubicin (Adriamycin)	2 mg/mL 10, 20, 50, 200 mg vials	Myelosuppression Cumulative cardiotoxicosis Anorexia, vomiting, diarrhea Allergic reaction Extravasation reaction Renal toxicosis in cats	30 mg/m^2 IV (large dogs) 25 mg/m^2 or 1 mg/kg IV (cats and small dogs) Given q 2-3 wk (infusion rate should not exceed 2 mg/min)
Mitoxantrone (Novantrone)	10, 20 mg vials	Myelosuppression GI effects (uncommon)	5.5-6 mg/m^2 IV (dogs) 6.5 mg/m^2 IV (cats)

			Given q 3 wk
Dactinomycin (actinomycin D, Cosmegen)	0.5 mg vials	Myelosuppression Extravasation reaction Diarrhea, vomiting	0.5-1 mg/m^2 IV Requires slow infusion rate (not reported used in cats to date)
Bleomycin (Blenoxane)	15 U (15 mg) vials NOTE: 1 U (USP unit) corresponds to 1000 IU (International Units) corresponds to 1 mg potency. Note 1 mg potency is defined by bioassay and is not identical to 1 mg dry weight (1 mg dry weight according to USP corresponds to 1.5 to 2 mg potency).	In humans: allergic reaction, pulmonary fibrosis	0.3-0.5 U/kg IV or SC weekly

Mitotic inhibitors (Table 339-3) act to inhibit assembly (vinca alkaloids) or disassembly (paclitaxel) of the mitotic spindle.

TABLE 339-3

Commonly Used Mitotic Inhibitors

DRUG	FORM	POTENTIAL SIDE EFFECTS	DOSAGE/REGIMEN
Vincristine (Oncovin)	1 mg/mL	Mild myelosuppression (dosage related) Anorexia in cats, rarely dogs (dosage related) Peripheral neuropathy (rare) Extravasation reaction	0.5-0.75 mg/m2 IV weekly
Vinblastine (Velban)	10 mg vials	Myelosuppression Peripheral neuropathy (very rare) Extravasation reaction	3 mg/m^2 IV q 2 wk (dogs) 1.5-2 mg/m^2 IV q 2 wk (cats)
Vinorelbine (Navelbine)	10 mg vials	Myelosuppression Peripheral neuropathy (very rare) Possible renal toxicosis in cats Extravasation reaction	15-18 mg/m^2 IV q 2 wk (dogs) 11.5 mg/m^2 IV q 1 wk (cats)

Platinum compounds (Table 339-4) create cross-links in DNA. The mechanism of action is similar to that of alkylating agents, and no cross-resistance with other classes of chemotherapeutic drugs is seen.

TABLE 339-4

Platinums Used as Chemotherapeutic Agents

DRUG	FORM	POTENTIAL SIDE EFFECTS	DOSAGE/REGIMEN
Cisplatin (Platinol)	50 mg vials	Renal toxicosis Vomiting and (less commonly) diarrhea Mildly myelosuppressive Fatal pulmonary edema in cats	50-70 mg/m^2 IV with 0.9% saline diuresis q 3-4 wk DO NOT USE IN CATS
Carboplatin (Paraplatin)	50, 150, 450, 600 mg vials	Myelosuppression	250-300 mg/m^2 IV q 3-4 wk (dogs) 210-240 mg/m^2 IV q 4 wk (cats)

Antimetabolites are analogs of normal metabolites that are incorporated into DNA where they interfere with enzyme activity, transcription, or translation. These drugs often have significant toxicity with low efficacy at veterinary dosages and are not frequently used in veterinary oncology. Gemcitabine is finding more application in veterinary medicine; for this drug, the infusion rate and time are an extremely important determinant of the efficacy and side effects, and the optimal dosage and infusion schedule are still being determined.

An important new class of chemotherapeutics is the tyrosine kinase inhibitors (TKIs). This class is rapidly expanding in human oncology and also contains the first chemotherapeutics developed specifically for dogs. The two veterinary drugs in this class are toceranib (Palladia) and masitinib (Masivet). The label dosage of toceranib (3.25 mg/kg PO q 48 h) is now considered higher than clinically appropriate (2.5-2.75 mg/kg q 48 h or 3 times per week). Although these are exciting new drugs and administered orally, the potential for adverse effects is as real with this class of drugs as with other chemotherapeutics. Scheduled monitoring, dosage adjustments, and supportive care are equally important.

Tumor resistance to individual chemotherapy drugs is common even before treatment is started. Further, tumor cells acquire resistance rapidly after drug exposure because of their high mutation rate. Combination chemotherapy may overcome some resistance problems by affecting different metabolic pathways in cells that are resistant to other drugs in the combination. Although combination chemotherapy could potentially be more toxic to normal cells, patterns of toxicity vary between drugs (Table 339-5). Judicious scheduling of chemotherapeutic agents so that their toxicities do not overlap can improve tumor cell kill without compounding toxicity.

Chemotherapy protocol design is complex and requires detailed knowledge of the drugs and their effects. Each drug included must be at least partially effective against the target tumor as a single agent. When drugs are given in combination on the same day, it may be necessary to reduce the dosage of each individual drug to achieve higher total dose intensity (see to follow); however, care must be taken not to reduce the dosage of a highly effective drug to allow administration of a second, less effective drug. The drugs are then scheduled, taking into account both the mechanism of action and the toxicity profile of each, to expose the tumor to the highest possible number of agents and maximize dose intensity while minimizing toxicoses. The safest and most effective protocols are designed by veterinary oncologists.

To reduce the development of drug resistance, it is important not to administer drugs at subtherapeutic dosages; the highest dose intensity possible should be delivered. It is also important not to modify the planned doses or schedule in anticipation of toxicosis that has not occurred. For example, a dog that became neutropenic after receiving doxorubicin is not at increased risk for myelosuppression from other chemotherapeutics such as cyclophosphamide, so doses of other drugs should only be reduced if they cause toxicosis. Supportive care such as preventative antiemesis also reduces need for chemotherapy dose reductions. On the other hand, if tumor growth occurs, it is not good practice to continue the same treatment protocol at the same dosages. Instead, an alternative regimen of non–cross-resistant but effective drugs should be used.

TABLE 339-5

Myelosuppressive Potential of Some Commonly Used Chemotherapeutic Agents

HIGHLY MYELOSUPPRESSIVE	MODERATELY MYELOSUPPRESSIVE	MILDLY MYELOSUPPRESSIVE
Doxorubicin Lomustine (CCNU) Cyclophosphamide Carboplatin Vinblastine Mitoxantrone Vinorelbine	Vincristine (0.75 mg/m^2)* Chlorambucil Melphalan Methotrexate Cisplatin Hydroxyurea 5-Fluorouracil	Corticosteroids L-asparaginase* Vincristine (0.5 mg/m^2)* Bleomycin Streptozotocin

*However, the combination of vincristine and L-asparaginase can be highly myelosuppressive.

Chemotherapy Drug Choices

Published data on tumor sensitivity to chemotherapy are changing rapidly. Although good published data are available on dogs with the most common diseases, information on other malignancies often is unavailable or is based on small case series. In contrast, for rare tumors that uncommonly metastasize, it is difficult to demonstrate adjuvant efficacy for any chemotherapy. Even when studies are completed, publication may be delayed; and the best resources for veterinarians are veterinary oncologists, the Veterinary Cancer Society (www.vetcancersociety.org), and Internet literature databases, such as Medline or PubMed.

In addition to efficacy, and possibly more important, the final choice of a drug (or protocol) depends on

toxicities, an owner's tolerance for side effects, the treatment goals, the cost, and the veterinarian's level of comfort in delivering chemotherapy and supportive care.

Timing of Chemotherapy

Although it is tempting to think of chemotherapy protocols as a "recipe" for treating cancer, in fact they should be considered as a guide. Veterinary chemotherapy protocols are often simple, consisting of one or two chemotherapy agents given at an interval that minimizes the risk of toxicosis but maintains the highest possible dose intensity. However, lymphoma protocols are often complex, with many agents scheduled in combination (see ch. 344).

Chemotherapy Dosing

Because their desired effect is cytotoxicity, many chemotherapy drugs have narrow therapeutic margins; that is, the toxic dosage is close to the effective dosage. Therefore, it is important to be as accurate as possible when calculating doses. For some drugs, dosing is based on "metabolic body size" (body surface area [BSA, m^2]) rather than weight. Although imperfect, this is based on the generalization that smaller animals have a higher metabolic rate and therefore should receive a higher dose on a body weight basis. For some drugs (e.g., doxorubicin) dosing based on BSA is imperfect, and small dogs and cats should be dosed at lower rate than larger dogs. Until further guidelines are available, veterinarians should check the dosing basis for any drug to be used and use a BSA conversion table when metabolic dosing is indicated.

In human oncology, dosing may be tailored to the individual either by monitoring drug levels or based on patient characteristics. For example, the appropriate dose of carboplatin can be calculated from a formula based on the patient's glomerular filtration rate (GFR) and the desired area under the curve (AUC). This type of calculation is not usually done in veterinary oncology; however, similar principles are recognized: in patients with reduced GFR (increased serum creatinine concentrations) carboplatin dosing should be reduced.

Evidence in both human and veterinary oncology suggests that optimal dose intensity improves the outcome for patients treated with chemotherapy. Dose intensity is defined as mg/m^2 of drug per week of therapy and can be modified by adjusting the dosage, the intertreatment interval, or both.

Route of Administration

Most chemotherapeutic agents are delivered either intravenously (IV) or orally (PO). Less commonly, they are given subcutaneously (SC) or intramuscularly (IM). Other modes of administration are sometimes used. For most intravenous chemotherapy administrations, injection through a peripherally located over-the-needle catheter is safest, reducing the risk of extravasation even when a small volume is to be administered. For longer infusions (more than 30 minutes), a through-the-needle catheter is less likely to become dislodged.

When long infusions are required, either for timed drug delivery (such as gemcitabine) or for the saline diuresis that accompanies nephrotoxic drugs (such as cisplatin or streptozocin), an infusion pump is recommended to ensure continued diuresis and/or even delivery of the drug dose. Changes in either of these factors could affect efficacy and the risk of toxicosis.

Vascular access may become a problem in small dogs and cats receiving chemotherapy. Because the risk of extravasation is greater in these animals, a subcutaneous implantable vascular access port may ease timely drug delivery and reduce stress during administration of chemotherapy. Such a port may be maintained for the duration of therapy and then removed. The implantable vascular access port must be placed surgically, in a similar manner to a tunneled catheter, with a subcutaneous pocket for positioning of the port. Ports for veterinary use are available from Norfolk Vet Products, Skokie, Illinois (www.norfolkvetproducts.com).

Most oral medications are administered as tablets or capsules. Tablet formulations should not be split for personnel safety reasons, and because distribution of the drug may not be uniform throughout the tablet, or the tablet may be enteric coated (e.g., chlorambucil). For small animals, reformulation of oral medications into smaller capsule sizes by a reputable compounding pharmacy specially equipped for handling cytotoxics can be considered.

Cisplatin and carboplatin can be delivered to dogs as an intracavitary infusion into the pleural, pericardial, or peritoneal cavities; or intravesicularly (into the urinary bladder) for bladder tumors.

Intralesional chemotherapy usually involves suspension of a chemotherapeutic agent in a vehicle. The use of cisplatin, bleomycin or 5-fluorouracil in sterile sesame oil or bovine collagen matrix has been reported. The mixture is injected into a tumor, creating high drug exposure to tumor cells. This involves minimal systemic

drug levels, avoiding the risk of systemic toxicosis. Intralesional chemotherapy is used to treat only small, easily accessible tumors. In this method, great care must be taken to avoid exposure of personnel, because spillage occurs easily and drug may leak from the injection sites.

Topical administration is available (5-fluorouracil—dogs only) but is rarely used because of drug toxicity and risk of exposure to humans who either apply the medication or interact with the dog. Certain drugs can also be administered intraarterially or intrathecally for specific treatment protocols; however, this is rarely done in veterinary medicine.

Encapsulation in liposomes can reduce or alter the toxicity of some chemotherapy drugs. Conjugation of the liposome with polyethylene glycol reduces clearance by the reticuloendothelial system, producing "stealth" liposomes with greater circulating time. A liposome-encapsulated doxorubicin formulation has been reported to be less cardiotoxic in dogs and cats, but resulted in a new cutaneous toxicosis.

Metronomic Chemotherapy

Metronomic chemotherapy uses small doses of chemotherapy frequently (usually daily or every other day), in contrast to conventional chemotherapy which uses maximum tolerated doses at intervals of weeks. This administration schedule appears to result in a shift in the mechanism of action of the drugs from cytotoxic to antiangiogenic (mainly through targeting tumor endothelial cells) and immunomodulatory (mainly through inhibition of Tregs). Chemotherapy drugs chosen for metronomic use are usually oral, such as cyclophosphamide, chlorambucil and lomustine (CCNU). Most often, cyclooxygenase inhibitors are also included in combination to further increase the antiangiogenic and immunomodulatory effect. Metronomic chemotherapy has become popular in veterinary medicine because it is usually well tolerated, but its efficacy has not been well documented in most settings. Although the treatment is generally less costly in the short term compared to conventional chemotherapy, many animals will need the commercially available drug sizes reformulated for metronomic use and this can be costly. Additionally, metronomic chemotherapy is usually continued for a much longer time (up to years) so total costs can mount up over time.

Despite its popularity, most of the published literature on metronomic chemotherapy consists of relatively small retrospective studies, often in groups of dogs with mixed types of malignancies. Thus, data are difficult to interpret and promising preliminary results have yet to be followed by more conclusive evidence of efficacy in most settings. Occasional good tumor responses are seen, but the majority of the antitumor efficacy that has been reported consists of stable disease (however, it is fair to say that there are many situations in veterinary oncology where long-term stabilization of disease is indeed a significant clinical benefit).

Although metronomic chemotherapy is generally thought of as less toxic than conventional chemotherapy, there are still risks of toxicosis and careful monitoring is still important. Metronomic cyclophosphamide poses a real risk of urothelial toxicosis, just as conventionally dosed cyclophosphamide does; the authors find that administering furosemide with each dose of cyclophosphamide reduces this risk substantially although we still see it occasionally and we still monitor carefully for microscopic hematuria. Metronomic lomustine was reported to result in a 30% rate of discontinuation of therapy for toxicosis; therefore, this treatment approach should be used with caution. The nonsteroidal anti-inflammatory drug (NSAID) component of many metronomic protocols obviously can also be associated with toxicosis as with any NSAID (see ch. 164). Metronomic cyclophosphamide also appears to be fairly safe in most cats, although again the published evidence is in a small, mixed group of cats with relatively short follow-up.

In the authors' opinion, long-term metronomic cyclophosphamide chemotherapy is probably the best chemotherapeutic option for incompletely resected soft tissue sarcomas where complete excision and/or radiation is not possible. Metronomic chemotherapy can also be considered in other settings where the pet's owners decline conventional chemotherapy, surgery and/or radiotherapy, where conventional therapy has been tried and failed, or as "maintenance" following adjuvant conventional chemotherapy for particularly high-risk tumors. However, until further evidence is available, the authors suggest that metronomic chemotherapy be considered investigational and not considered first-line therapy in most settings. Finally, client safety must be carefully considered when considering chronic use of alkylating agents at home and clients must be reminded regularly not to become complacent with safety procedures.

Chemoprotection

The administration of a second drug specifically to reduce the host organ toxicity of a chemotherapy drug is termed *chemoprotection.* Chemoprotectants in use in human and veterinary oncology include mesna and dexrazoxane. Mesna reduces the risk of cystitis associated with ifosfamide and cyclophosphamide by binding

toxic metabolites in the urine. Dexrazoxane protects against doxorubicin-associated chronic cardiotoxicosis and reduces severity of doxorubicin-associated extravasation injury when used soon thereafter.

Supporting Animals Undergoing Chemotherapy

Adverse effects of chemotherapy are discussed in detail in ch. 343. Before chemotherapy is administered, drug dosages and toxicities, as well as the administration schedule, must be reviewed with the owner. After treatment, the pet should be monitored at home for signs of toxicosis. An algorithm for interpretation of post-chemotherapy neutrophil counts is found in Figure 339-1.

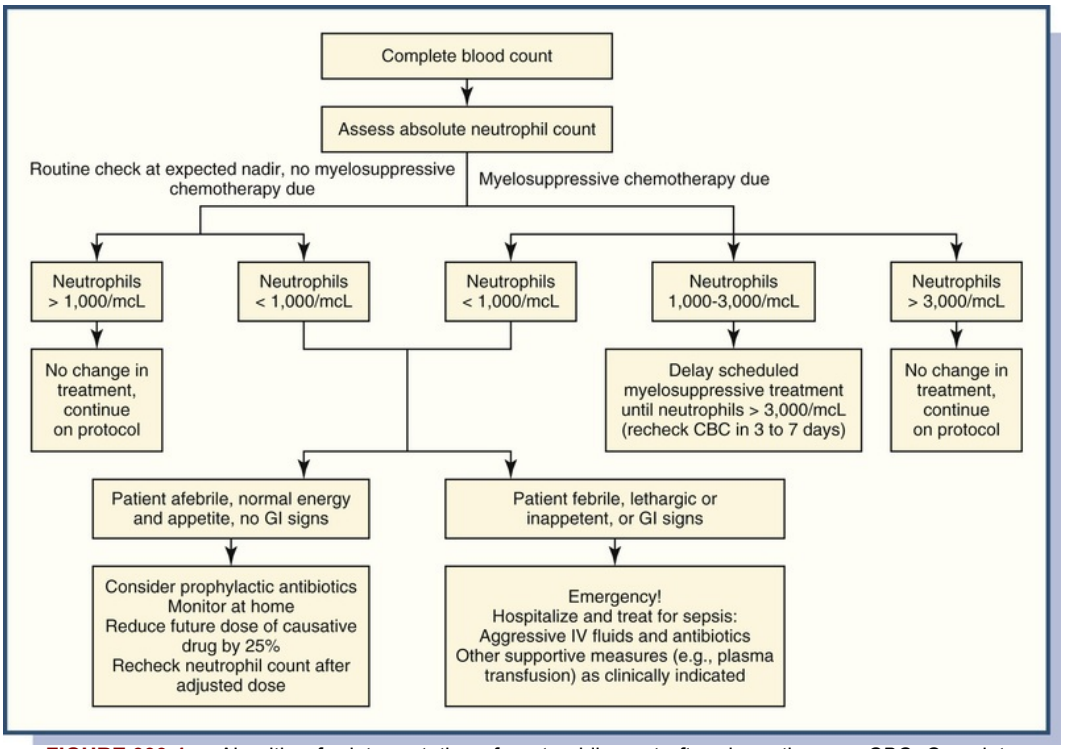

FIGURE 339-1 Algorithm for interpretation of neutrophil count after chemotherapy. *CBC*, Complete blood count; *GI*, gastrointestinal.

In order that pets maintain the highest quality of life, and that chemotherapy dosages be maintained at the highest level, the veterinarian should, whenever possible, use proactive supportive care to prevent or manage common toxicoses. Advances in the prevention and management of pain and nausea as well as organ-specific toxicoses such as cystitis will improve the veterinarian's ability to deliver adequate chemotherapy doses and provide high quality of life for pets with cancer.

Evaluating Treatment Response

To determine if a given treatment is effective, it is necessary to evaluate treatment response regularly. This is important to avoid unneeded expense, toxicosis and tumor progression that result from continuing to administer an ineffective drug. Clinicians can refer to Veterinary Cooperative Oncology Group criteria for measurement of both solid tumors and lymph nodes. The response to treatment can then be categorized as clinical remission/complete response (CR), partial response (PR), stable disease (SD), or progressive disease (PD). In the literature, *overall response rate (ORR)* refers to CR and PR combined. (Another term used in more recent literature, *clinical benefit*, refers to CR, PR and SD combined; while there are many clinical settings where SD is certainly beneficial, care needs to be taken when reading reports of treatment trials not to compare ORR to clinical benefit, as they are not equivalent).

Chemotherapy Drug Resistance

Resistance to chemotherapy may be either inherent or acquired. Drugs may be physically unable to reach tumors that are in sanctuary sites such as the central nervous system or that are poorly perfused. Tumor cells may inherently lack receptors for a drug or not be susceptible to the mechanism in some other way (e.g., cells that have asparagine synthetase will be resistant to L-asparaginase). Tumor cells may develop drug resistance spontaneously through mutation. With each cell division comes the risk of a resistance mutation; therefore the larger a tumor is (i.e., the more cell divisions it has undergone), the higher the likelihood that resistance will occur. Tumor cells can also develop drug resistance specifically. Exposure to sublethal drug concentrations can result in gene amplification of detoxifying proteins.

Although combination chemotherapy may circumvent individual drug resistance, it does not avoid the problem of cross-resistance to multiple unrelated chemotherapy drugs. The transmembrane pump protein (P-glycoprotein) is present at increased levels in some tumor cells, and both the level and prevalence increase with exposure to chemotherapy. This phenomenon of multiple drug resistance (MDR) occurs between anthracyclines, mitotic inhibitors, and others. However, alkylating agents are not substrates for the P-glycoprotein pump, and so they become the mainstay of treatment in patients that have this type of drug resistance.

Safe Chemotherapy Drug Handling

Most chemotherapeutic agents are both toxic and mutagenic. Because most are effective in the active phases of the cell cycle, toxicosis from chemotherapy is most common in tissues that are renewing and is usually related to drug dose. This has implications for the patient (toxicity and efficacy), as well as pet owner and veterinary staff safety in handling the drugs during administration and patient care. Precautions should be taken when handling chemotherapy drugs during any phase of preparation, administration and disposal of drugs or waste. Alkylating agents have been associated with the highest risks to handlers. Organ damage and increased risk of fetal loss have been reported in persons handling and administering chemotherapy with inadequate attention to personal safety.

The proper administration of chemotherapy has been covered in great detail by many authors. In brief, the regulations set by the U.S. Occupational Safety and Health Administration (OSHA) should be followed, and pet owners as well as all personnel coming in contact with chemotherapeutic agents should be protected to the best of the veterinarian's abilities. Some countries, and states, now have specific legislation for administering chemotherapy in veterinary practice. It is advisable to contact the relevant authority before making a treatment plan. A chemotherapy logbook, which includes identification of animals treated and the personnel involved in the treatments, should be maintained to track exposures. Information contained in the Material Data Safety Sheet (MSDS) for each drug covers specific health hazards, including carcinogenicity, primary routes of exposure, protective equipment, treatment of personnel acutely exposed, chemical activators, solubility, stability, volatility, and specific procedures to be undertaken in case of a spill. The MSDS should be requested with the initial shipment of any chemotherapeutic agent and should be kept on file in an easily accessible location. A spill kit (commercially available) should be maintained.

Ideally a vertical laminar flow biological safety cabinet should be used to prepare all chemotherapy drugs. Closed system drug delivery devices such as Equashield and PhaSeal (Video 339-1) are now available in small quantities suitable for veterinary practices and should be routinely used in handling cytotoxic drugs. All these items are usually available through distributors of chemotherapeutic agents. During parenteral administration, Luer-Lok syringes decrease the risk of drug leakage or spills. Chemotherapy vials should be stored in zip style bags, and if syringes containing chemotherapy are carried around the hospital they should be carried in zip style bags.

Risks to Pet Owners

A pet owner information sheet on chemotherapy safety should be provided. If owners are administering drugs orally at home, gloves and waste (zip style) bag should be provided. However, the primary concern is for people who are handling the drugs (mixing and administering), with less risk to those handling the feces and urine in hospital and at home.

Clear safety guidelines for pet owners handling bodily fluids of chemotherapy patients are still not entirely clear, and tend to err on the conservative side. A period of 24 to 72 hours is therefore a “best guess” as being beyond the major excretion of metabolites from a bolus injection. Drug and metabolite excretion in bodily fluids should be treated with respect but not panic. Most pet owners avoid contact with their pet's urine and feces as part of routine hygiene anyway; however, accidental one-time contact is no cause for alarm if

followed by normal washing. For drugs that are excreted in the urine, the pet should be encouraged to urinate on soil where urine will drain quickly, and any urine in other areas should be handled and disposed of as chemotherapy. Pregnant pet owners should consult their obstetrician before making a decision about having contact with their pet on chemotherapy, and should not handle any chemotherapeutic agents.

Principles and Practice of Radiation Oncology

Jessica Lawrence

Client Information Sheet: Radiation Therapy for Pets with Cancer

Introduction

Overview

Cancer is the leading natural cause of death in cats and dogs and its prevalence may be increasing.[1-3] *Cancer* is an umbrella term encompassing many diseases with various biological behaviors, standards of care and prognoses. Veterinarians are encouraged to be knowledgeable resources for clients and their pets. Radiation therapy began in the 19th century, following Roentgen's description of x-rays in 1895 and the discovery of radium by Marie and Pierre Curie in 1898.[4-6] *Radiation oncology* refers to the medical use of ionizing radiation as an integral part of cancer treatment by killing or controlling malignant cells. Radiation therapy is available in many facilities, both public and private.[7-9]

The primary purpose of radiation therapy is to provide local and/or loco-regional tumor control, although half body or total body irradiation is occasionally prescribed. Depending on the clinical situation, the primary intent of treatment is either palliative or definitive (potentially curative) and is commonly used in conjunction with surgery and/or systemic therapy. One of the most important challenges during radiation treatment is to target tumor tissue with tumoricidal doses while sparing normal tissue. Most of the advances in radiation oncology, including intensity modulated radiation therapy (IMRT), stereotactic radiation therapy (SRT), stereotactic radiosurgery (SRS), and image-guided radiation therapy (IGRT), focus on improving the ability to localize the tumor target, administer precisely aligned radiation beams, and spare normal structures to improve overall tolerability and outcome (Box 340-1). The two potential goals of radiation therapy include definitive intent ("curative" intent) radiation therapy and palliative radiation therapy. The aim of definitive intent radiation therapy is long-term control (sometimes cure) of a tumor. The aim of palliative intent radiation therapy is to ameliorate specific symptoms caused by a tumor (such as bleeding or pain) (Box 340-2).

Box 340-1

Common Radiation Terminology

Radiation terminology can be confusing and some terms inaccurately used as synonyms. Common terminology and abbreviations are provided below to improve the reader's understanding of commonly used terms.

- **Dose**—amount of radiation absorbed by the patient (Gray = Gy = 1 Joule/kg; the older term "rad" is not utilized).
- **Fraction**—individual administration of radiation.
- **Fractionation**—radiation dose is divided into fractions over the course of several days to weeks depending on the intent of treatment.
- **Radiation prescription**—particular dose and number of fractions prescribed to a tumor for a patient.
- **External beam radiation**—radiation delivered from outside the body by a machine that focuses high-energy photons at a tumor.
- **3-D Conformal radiation therapy (3D-CRT)**—conformal radiation therapy that is image-based and

improves radiation dose distribution across the tumor volume, which can limit the normal tissue involved.

- **Intensity-modulated radiation therapy (IMRT)**—improved radiation planning and delivery in which the intensity of the radiation beams aimed at the target volume vary over the treatment in order to improve conformity of the radiation dose distribution to tumor with a rapid fall-off in radiation dose to adjacent normal structures.
- **Image-guided radiation therapy (IGRT)**—imaging that occurs immediately prior to or during treatment in order to detect errors in patient and tumor positioning. IGRT provides a level of quality assurance, verifying that radiation beams will be precisely directed to the tumor volume.
- **Stereotactic radiosurgery (SRS)**—a single treatment involving a large fraction size (15-20 Gy), usually used to treat small well-delineated tumors.
- **Stereotactic radiation therapy (SRT)**—a small number of treatments (3-8) involving a large fraction size (10-20 Gy) used to treat small well-defined lesions.
- **Plesiotherapy**—"surface" radiation with limited penetration (2-3 mm), usually delivered by a strontium-90 (^{90}Sr) probe.
- **Brachytherapy**—short-distance radiation (commonly internal radiation), usually delivered through use of radioactive seeds.

Box 340-2

Radiation Therapy (RT) Protocol Summary

Definitive Intent RT Protocols

- Generally large number of fractions
- Low dose/fraction
- Expect acute side effects
- Generally more expensive
- Intent is to achieve long-term control ("curative") while limiting late toxicity
- Low risk of clinically significant late toxicity

Palliative Intent RT Protocols

- Smaller number of fractions
- High dose/fraction
- Few acute side effects
- Generally moderate expense to owner
- Intent is to improve quality of life (improve function, decreasing pain or bleeding)
- Higher risk of clinically significant late toxicity

Stereotactic RT Protocols

- Smaller number of fractions
- High dose/fraction but overall tumoricidal dose
- Decreased acute toxicity due to minimal normal tissue in the high dose region
- Reliant on image-guided positioning verification
- Expensive
- Intent may be palliation or long-term control while limiting normal tissue toxicity
- Clinical outcome data in dogs and cats are pending

General Considerations When Choosing Veterinary Patients for Radiation Therapy

Candidacy

Dogs and cats (and occasionally other species) should be evaluated carefully to ensure that they are good candidates for radiation treatment. Once the tumor type, biological behavior and extent of disease are known, the role of radiation therapy can be determined. Radiation therapy alone or in combination with surgery may be appropriate for managing patients with local or loco-regional disease. Adjuvant chemotherapy may be administered concurrent with radiation, depending on tumor type. Prospective planning is best approached as involving a team that includes the primary clinician, surgeon, medical oncologist, radiation oncologist and the owner. These are the decision makers in determining an optimal approach to managing a tumor. A viable treatment plan for one patient may not be suitable for another, even with a similar tumor.

Staging

Staging, determining the cancer's extent, is important to understand if localized disease is present when considering definitive intent radiation therapy. Diagnostic tests typically relate to the primary tumor type and may include complete blood count (CBC), biochemical profile, urinalysis, aspiration cytology of regional lymph nodes, thoracic and/or abdominal imaging, and advanced imaging. Computed tomography (CT) is one of the most useful tools for imaging tumors and is critical for computer-assisted radiation treatment planning. Magnetic resonance imaging (MRI) may be used for planning in some situations. Advanced imaging can allow initial subjective assessments regarding extent of disease, proximity of critical tissues near or in a potential treatment field, and which therapeutic options are reasonable and applicable. CT and/or MRI may not be indicated prior to radiation therapy if results will not change the therapy.

Client Education

With clients included on the team of decision makers, they should understand expense, frequency and anticipated duration of treatments. They should also be made aware of probability of adverse events and the projected outcomes. Radiation oncologists are able to define several aspects of radiation treatment, namely: (1) the indication for radiation therapy based on existing veterinary literature, (2) the goal of radiation therapy, (3) the target of radiation therapy (usually a localized disease pre- or postsurgery), (4) the type or technique of radiation treatment, (5) the planned dose and schedule of the radiation protocol, and (6) expected acute and late adverse events.

Basic Principles of Radiation Physics

See E-Box 340-3.

E-Box 340-3

Basic Principles of Radiation Physics

Overview and Radiation Sources

Radiation physics describes the manner in which radiation interacts with matter in order to induce an effect. Electromagnetic radiation can be considered moving packets of energy, or photons.[6] The amount of energy in each photon defines its position within the electromagnetic spectrum; for example, x-rays and gamma-rays contain more energy than ultraviolet (UV) light photons and are therefore at the higher end of the spectrum. Sufficiently energetic x-ray or gamma-ray photons may completely displace an electron from its orbit surrounding an atom when they interact with matter. All matter is composed of atoms and although the model of an atom has been updated, the simple Bohr model of an atom is sufficient for understanding the interactions of photons and atoms. An atom consists of a nucleus with one or more protons and neutrons held together by strong intranuclear forces, forming the positive charge of the atom, surrounded by a cloud of electrons held in place by electrostatic forces, which forms the negative charge.

How Does Radiation Interact with Tissue?

Radiation interacts with biological material by removing an orbiting electron, a process termed *ionization*.[10] External beam radiation uses a source of photons for therapy derived from either radioactive decay (^{60}Cobalt) or from man-made devices (linear accelerator) that create photons from fast electron streams striking a target. Ionizing radiation consists of both x-rays and gamma-rays: gamma-rays occur from radioactive decay while linear accelerators generate x-rays. Ionization events occur as photons and

particles travel through tissue and deposit their energy. The *gray* (Gy) is the term applied to the radiation dose that describes the quantity of energy deposited per mass of tissue, where 1 Gy is equal to 1 joule (J) of energy deposited per kilogram of tissue. The *centigray* (cGy) is often used to describe individual doses (fractions) of radiation (100 cGy = 1 Gy). The *rad* is a historical term used to describe radiation dose (1 rad = 1 cGy) and may appear in older radiation texts or journal articles.

A *photon* is any wave of energy traveling through space at the speed of light; the energy of the photon dictates its type of physical interaction with tissue. Low-energy photons used for diagnostic purposes are absorbed differentially in tissue, proportional to the cube power of the tissue's atomic number (density). This photoelectric effect results in densities typical of fat, soft tissues, and bone seen on diagnostic radiographs. The high-energy photons used for therapeutic purposes have physical interactions with tissue that occur predominantly via Compton scattering, related to tissue electron density. It minimizes differential absorption, providing uniform radiation dose deposition across a variety of tissues. With Compton scattering, photons interact with loosely bound electrons, giving their energy to the atom. Electrons are then ejected from the atom along with a second photon emitted in a different direction; both the electron and secondary photon can interact with additional tissue. Electrons are responsible for the effects of radiation as they can directly or indirectly damage biologic targets critical for cell survival.

Current Sources and Their Application

Ionizing radiation can be used to treat cancer. Radiation can be delivered by external beam units (linear accelerators, ^{60}Cobalt teletherapy, orthovoltage, charged particle accelerators) or by brachytherapy (^{125}Iodine, ^{192}Iridium, ^{103}Palladium). Low-energy x-ray beams in the range of 50-250 kiloelectron volts (KeV) deposit energy at or just below the skin surface. High-energy x-ray beams (>1 million electron volts or MeV) are less attenuated by the skin surface and deposit most of their energy at a greater depth in the body; thus, they are “skin sparing” energies. Charged particles such as electrons, protons, and heavy particles (carbon or argon ions) can be used for radiation therapy. Electron beams are used to treat tissues or tumors that require a uniform dose distribution from skin surface to a limited superficial depth. Particle beams such as protons are used for high-precision dose delivery at a particular depth in the body but are not commonly used in veterinary radiation oncology.

Medical radiation physics plays an integral role in the discipline of clinical radiation oncology, beyond identification and characterization of radiation dose and tissue distribution. It is also used for improving radiation therapy machines, development of three-dimensional (3D) treatment planning for identification of tumor target volumes, normal tissue dose, development of intensity-modulation and image-guided radiation therapies (IMRT, IGRT), particle therapy, improvement in immobilization techniques for improved reproducibility of treatment, and advancements in brachytherapy and hyperthermia.[5] All of these radiation physics developments have focused on improving radiation dose distribution across tumor volumes while decreasing normal tissue toxicity, which theoretically should improve local tumor control.

Radiation Therapy Machines

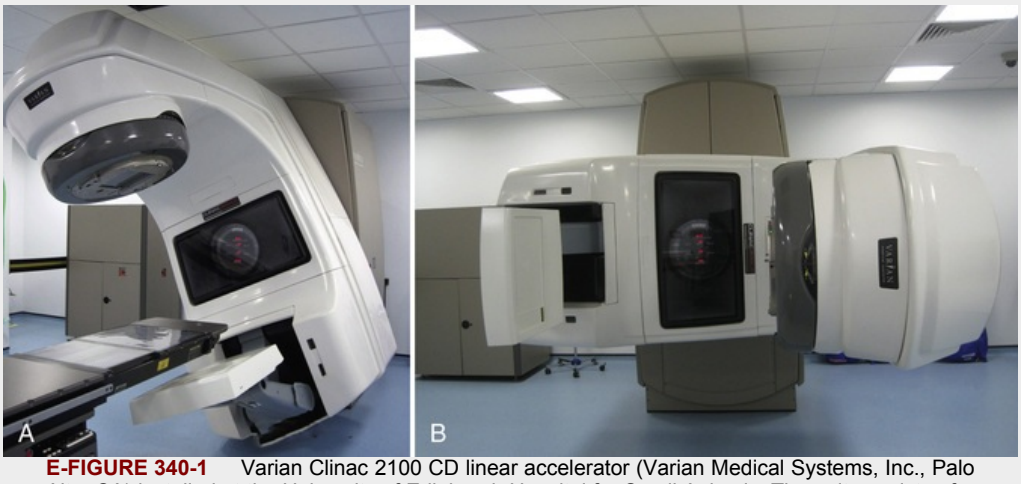
Ionizing radiation can be administered from different sources (external beam radiation therapy or teletherapy), through radioactive isotopes placed interstitially (brachytherapy), by surface therapy (plesiotherapy) or by systemic or intracavitary injection of radio-isotopes (^{131}Iodine or ^{153}Samarium). The most common form used in veterinary medicine is external beam radiation therapy. External beam units vary widely. Megavoltage external beam is most common, while orthovoltage units are used for certain conditions.

Orthovoltage machines produce lower energy (150-300 keV) x-rays and are considered relatively superficial in dose distribution. Its maximum energy is deposited at the surface of the skin with little penetration. There will be more attenuation by bone than soft tissue. Limited beam-modifiers can be used to attenuate or increase dose, such as wedges or blocks to limit normal tissue toxicity. Acute side effects with orthovoltage are often quite robust and late radiation effects administered to bone and skin may be dose-limiting.[11] Generally, orthovoltage therapy should be limited to small superficial tumors.

Megavoltage radiation has higher energy (>1 MeV), provides more uniform dose deposition within tissues, and has some skin-sparing properties. Because megavoltage machines require a specific depth of tissue (0.5 cm to 2.0 cm) to build the maximum dose, tissue-equivalent material (bolus) may be needed if the skin needs to be included in the treatment field. ^{60}Cobalt teletherapy units produce gamma-rays through radioactive decay to Nickel that have an average energy of 1.25 MeV. A ^{60}Cobalt source

measures approximately 2-3 cm so there is relatively large *penumbra* of treatment fields; the penumbra refers to the edges of the field where there is rapid dose fall-off. Because the energy produced by cobalt units is relatively low, there is only 0.5 cm of skin sparing; however, it is difficult to treat deep-seated tumors. One major disadvantage of ^{60}Cobalt teletherapy is that the radiation source is constantly decaying. This permits stable mechanics, but dose output constantly decreases and must be replaced every 5 years to avoid longer treatment times.

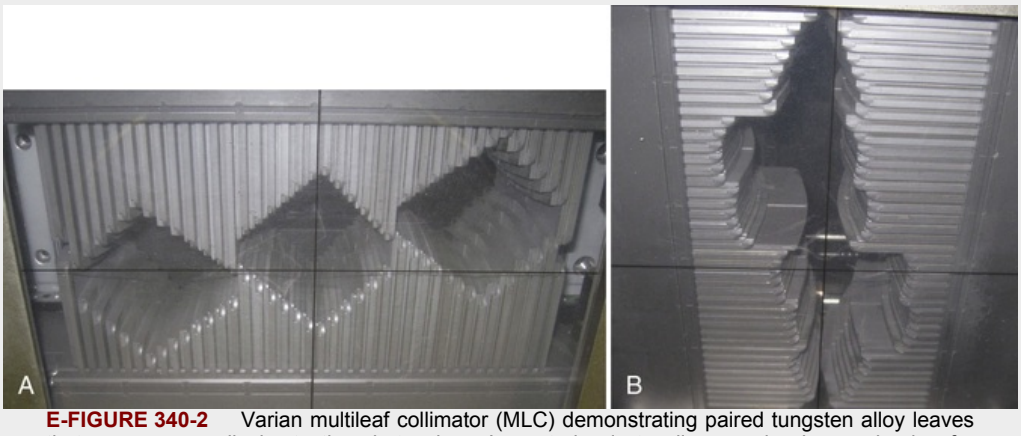
Linear accelerators are designed with various energy capabilities and produce x-rays ranging from 4-25 MeV in peak photon energies. In contrast to ^{60}Cobalt units, most linear accelerators have a high radiation output, and output can be manipulated manually if treatments need to be administered quickly. There is an even larger source-skin distance (100 cm versus 80 cm) so larger treatment fields can be used, and it affords the radiation technician more leniency when rotating the gantry (the head of the machine) around the patient. Linear accelerators have a small focal point, thus penumbra is small at the treatment field. As they are also megavoltage machines, linear accelerator degree of skin-sparing depends on the energy of the photons derived (approximately 1.5 cm for a 6 MeV photon beam). The depth of skin sparing increases with increasing photon energy. Field modifiers such as blocks, wedges, and beam spoilers may be used with both ^{60}Cobalt units and linear accelerators to improve dose distribution within the target region and reduce dose to normal tissues. Additionally, both are isocentric machines, meaning that the gantry head is capable of rotating 360 degrees around the patient to reduce patient re-positioning error and allow faster treatment delivery (E-Figure 340-1).



E-FIGURE 340-1 Varian Clinac 2100 CD linear accelerator (Varian Medical Systems, Inc., Palo Alto, CA) installed at the University of Edinburgh Hospital for Small Animals. The unit consists of a conventional multimodality linear accelerator with a retractable electronic portal imaging device (EPID) mounted perpendicular to the linear accelerator to permit assessment of patient positioning. **A,** Demonstrates the gantry head at 350 degrees to the table. **B,** Demonstrates the gantry head at 90 degrees.

Modern linear accelerators usually have multileaf collimators (MLCs), paired metal leaves that move in and out to create a desired field shape. They are ideal for complex and irregular treatment volumes (E-Figure 340-2). Although 3D conformal radiation therapy utilizes CT imaging to formulate a treatment plan, it does not always meet the needs of a particular shape unless a large number of beams are used and the target volume has a simple shape.[12,13] IMRT, by varying the MLC leaves during treatment, takes 3D conformal radiation therapy one step further by precisely shaping each beam or beamlet (subfields of each beam direction) to vary the photon fluence, therefore providing the optimal dose distribution for the radiation prescription.[12-14] Most current accelerators are also equipped with on-board imaging devices to aid with accurate patient positioning to ensure that a tumor is treated as indicated by the treatment plan. Imaging devices may vary from electronic portal imaging devices (EPIDs; see E-Figure 340-1) to mounted on-board kV CT units that allow precise registration (or image matching) of the patient's treatment position to the original optimal planning position. IGRT seeks to remove uncertainties associated with daily anatomical positioning by acquiring images of the patient immediately prior to beam delivery on the treatment machine. Images are then registered to the optimal position at planning and patient adjustments are made prior to treatment to verify the tumor position.[15-18] IGRT therefore

offers a level of quality assurance and verifies that radiation beams will be precisely directed to the target.



E-FIGURE 340-2 Varian multileaf collimator (MLC) demonstrating paired tungsten alloy leaves that move perpendicular to the photon beam's central axis to allow precise beam shaping for complex **(A)** and irregular **(B)** treatment volumes.

Many linear accelerators that are ≥6 MV are also capable of producing electrons that can be captured and used for therapy. Electrons are ideal for treating superficial tumors since they have rapid fall-off in dose with increasing depth of tissue. Electron therapy can spare critical structures deep to superficial lesions, such as an incompletely excised tumor located over the abdominal cavity. Various energy electron beams can be emitted, with the depth of tissue penetration dependent on electron energy. Because electrons scatter in air, an electron cone is used for collimation to the patient while a secondary cutout can be used to provide conformal treatment (E-Figure 340-3). Many superficial tumors in animals can be treated with electron therapy: incompletely excised soft tissue sarcoma, mast cell tumors, and injection site sarcomas.

E-FIGURE 340-3 Electron beam therapy is suitable for shallow tumors (<5 cm deep), such as tumors over the thoracic or abdominal wall. Electron cones are attached the head of the linear

accelerator and provide collimation to the animal's surface.

Biological Principles of Radiation Oncology

E-Box 340-4

Biologic Principles of Radiation Oncology

Overview

High-energy photons collide with orbiting electrons of biologic molecules in tissue, which leads to the ejection of electrons. Ejected electrons can directly damage biologic targets in close proximity of the atom; more commonly, electrons interact with water, since cells are comprised of 80% water, to produce highly reactive free radicals that damage the target (indirect damage). Tumor cell DNA is classically considered to be the principal target of therapeutic photons, although damage to cell membranes and blood vessels may also contribute to tumor control.[4-6] Alternative methods of radiation-induced cellular damage involve disruption of cellular homeostasis through various means such as protein modification, induction of stress response that alters the tumor microenvironment, vascular damage (at high doses of radiation), abscopal effects (antitumor immunity that affects responses distant from the primary tumor treated with radiation), and alterations in signal transduction.[4,5] Cell survival following radiation has been correlated to the residual level of double strand breaks within DNA, thus giving credence to the notion that DNA is the principal target.[4] Other DNA damage produced by ionizing radiation includes single strand breaks, base damage, sugar damage, and cross-links between DNA-DNA or DNA-protein.[4-6]

Linear Energy Transfer and Relative Biological Effectiveness

Ionizing radiation deposits energy along a track, linear energy transfer (LET), that leads to DNA damage and subsequent cell killing. Photons and electrons are considered low LET radiation because as they interact with tissue, electrons are set in motion. Those electrons are easily deflected, creating convoluted tracks. Protons and neutrons are considered high LET radiation; they are heavier particles that are more resistant to deflection and have straighter tracks through tissue.[4,6] The relative biological effectiveness (RBE) of different types of radiation is dependent on the LET and models exist to help predict tumor cell response.[4,6,19] The RBE formula is represented by the ratio of the standard radiation dose (usually 250 kV x-rays or ^{60}Cobalt) to the dose of test radiation that produces the same biologic effect. For example, 1 Gy of photons creates the same biologic effect as 1 Gy of electrons; however, 1 Gy of protons causes substantially more biological damage than 1 Gy of photons as the LET is much higher.

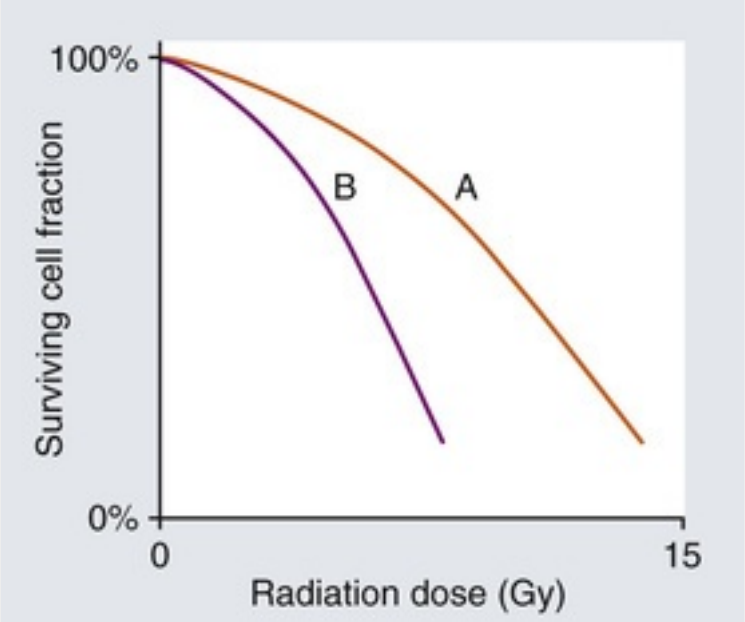
Energy deposited within tissue occurs randomly due to the nature of ionizing radiation interactions. Most ionization events do not cause DNA damage.[4,6,20,21] In most circumstances, large doses of low LET radiation (10-100 Gy) are required to significantly impact tumor cell growth and survival.[20,22] It has been estimated that approximately 10^5 ionizations can occur within the cell per Gy of absorbed low LET radiation dose, leading to approximately 1000 cross-links and base damages, 500-1000 single strand DNA breaks, and 25-50 double strand DNA breaks.[20] High LET radiation increases the number and severity of DNA lesions, which are more difficult for the cell to repair.[4]

Radiation Effects

Background

Inhibition of the continued reproductive ability of tumor cells is an important sequela of radiation treatment. Most cellular death following exposure to ionizing radiation results from chromosomal aberrations that ultimately leads to mitotic death or terminal growth arrest (similar to senescence), although lethally damaged cells may undergo senescence or interphase death (lymphocytes).[4] Many cells therefore do not demonstrate morphological evidence of radiation damage until cell division, at which time evidence of either apoptosis or necrosis may be present. The extent to which one mechanism of cell

death occurs versus another is dependent on cell type, radiation dose and the tumor microenvironment.[6] Cell survival following radiation is often described by the cell survival curve, which is an illustration of the relationship between radiation dose and cell kill (E-Figure 340-4). Radiation induces logarithmic cell kill, in which the probability of a critical target being damaged is proportional to dose. For example, a standard cell survival curve often demonstrates that a dose of 2 Gy kills approximately 50% of cells within a tumor. In a simplistic model where factors that increase or decrease cell kill are not included, the math suggests that a small tumor measuring 1 cm in diameter (containing 10^9 cells) will have 5×10^8 cells remaining after the first fraction and after 20 fractions of 2 Gy (40 Gy), 953 tumor cells would remain.[5] Radiation is therefore generally more effective on microscopic disease compared to macroscopic tumors, although there are exceptions depending on the intrinsic cell radiosensitivity (lymphoma). As most cells sustain mitotic or reproductive damage, measurable tumors often do not respond immediately but rather shrink after several weeks or months. For example, canine thyroid tumors treated with variable radiation therapy prescriptions have a time to maximal tumor reduction that varies from 6-24 months.[23-25]



E-FIGURE 340-4 A schematic of a cell survival curve following a single dose of radiation with low-LET radiation such as x-rays. Curve **A** has a wider shoulder region than curve **B,** suggesting that there is more reparable damage sustained by the cell population in **A** compared to the tumor population in **B.**

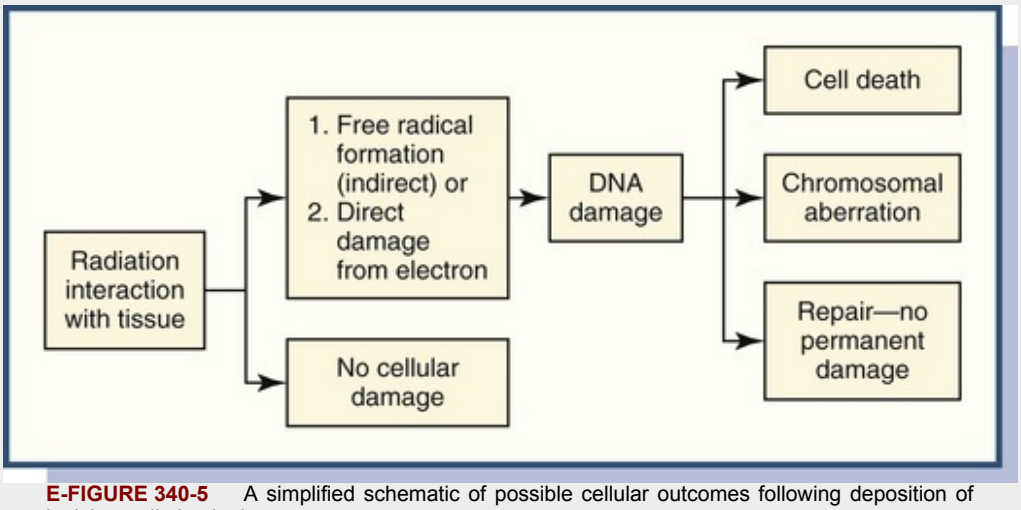
The "4 Rs"

Radiation biology is a subspecialty within radiation oncology. The focused is on tumor and normal tissue response to ionizing radiation to aid in developing safe and effective radiation protocols. The response of tumors (and normal tissue) to radiation has been predominantly characterized by factors that influence the ability of radiation to induce cell damage and each cell's ability to recover. Classically, the 4 "Rs" of radiobiology have been viewed as critical in determining the net response of tumors to radiation: repair, redistribution (reassortment), repopulation, and reoxygenation. Radiosensitivity has largely been incorporated as the fifth R as the intrinsic radiosensitivity of cells *in vitro* correlates to the responsiveness of tumors to radiation therapy in the clinic.[4,26-28] With the advent and increasing popularity of SRS and SRT, which involve one or a few large doses of radiation (8-30 Gy per fraction), respectively, researchers have re-evaluated the role of the 5 Rs of radiobiology. For most tumors, the concepts of the Rs still apply to SRS and SRT with the exception that antitumor immunity (abscopal effects) may be enhanced in some tumors by very large doses of radiation.[26,29]

Cellular Repair of Radiation Damage

Several consequences can occur within cells after DNA damage secondary to ionizing radiation. That damage is classified as lethal, sublethal, or potentially lethal, thus leading to a spectrum of tumor and

tissue responses from significant damage to no net cellular damage (E-Figure 340-5),[4,6] The repair of cellular damage between radiation doses is the major mechanism underlying observations that a larger total dose can be tolerated when the radiation dose is fractionated, or divided into smaller administrations, rather than administered all at once. The shoulder of a cell survival curve reflects the accumulation of sublethal damage that can be repaired if given adequate time (see E-Figure 340-4). Repair of sublethal damage increases cell survival before the subsequent fraction of radiation; this is important when normal tissue is within or near the radiation field. An increase in total dose to tumor is therefore required in order to provide the same degree of biological damage when a single dose of radiation is fractionated.[4] Most radiation damage is repaired within 6-24 hours of radiation administration. Double stranded DNA breaks appear to be the most challenging for repair as they are more likely to result in chromosomal or chromatid aberrations.[4,6,30,31] In mammalian cells, homologous recombination and non-homologous end joining both occur depending on the cell cycle phase.[4] Faulty repair of DNA strand breaks may lead to chromosomal aberrations which can result in cell lethality or in stable anomalies.[4,32,33]



E-FIGURE 340-5 A simplified schematic of possible cellular outcomes following deposition of ionizing radiation in tissue.

Redistribution and Cell Cycle Effects

Synthesis (S) is the cell cycle phase in which DNA synthesis occurs. The Gap 2 (G2) phase follows and mitosis (M) follows G2. Cells then enter the Gap 1 phase (G1) and can continue to S phase or enter a period in which cell division ceases (G0). The cell cycle phase at radiation influences inherent sensitivity or resistance to radiation. Cells within the late G1 to early S phase and G2 or M phases are most sensitive to radiation while cells in G1 and mid-late S phases are most resistant.[4] Cells that are not actively cycling (G0) tend to be more resistant. Cells that survive radiation tend to be synchronized in the more resistant phases of the cell cycle within a few hours; however, cells then cycle into more radiosensitive phases prior to the next fractionated dose of radiation.[4] Redistribution of cells into radiosensitive phases of the cell cycle is an important concept when considering concurrent chemotherapy treatment as drugs are typically chosen based on their ability to redistribute cells into G2 or M phase.

Repopulation

Following a dose of radiation, if surviving cells are given long intervals of time between treatments, the tumor population will increase due to replication. This process is termed *repopulation* and can affect cell survival in between fractions of radiation or over the course of a protocol. Accelerated repopulation may occur in some tumors, in which tumors appear to repopulate more rapidly than their initial growth rate.[4,30,34,35] Repopulation of tumor cells during a conventional course of fractionated radiation therapy is an important factor affecting the local control rate of rapidly growing tumors. This is the basis for the avoidance of treatment delays and for accelerated protocols in human oncology, where a prescribed radiation dose is "accelerated" and administered in a shorter period of time.

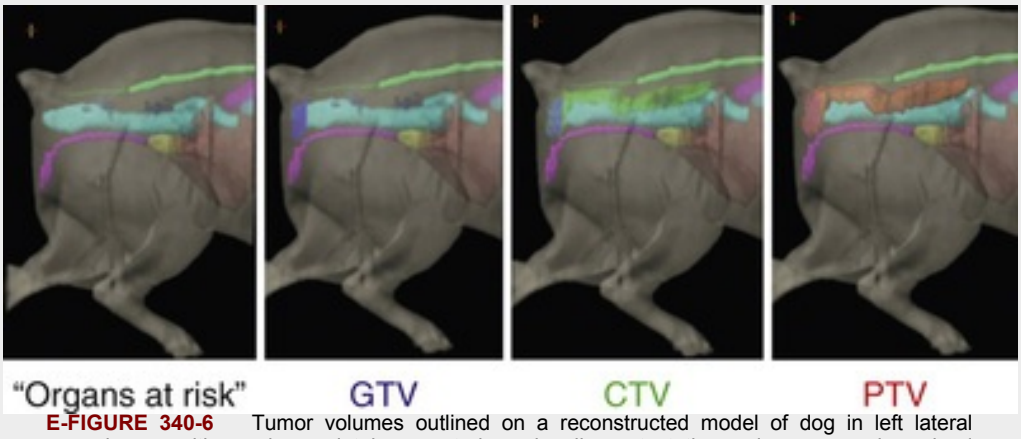
Reoxygenation

One of the most important influences the microenvironment has on tumor response to radiation is the presence or absence of oxygen at the time. Hypoxia is common in tumor tissues that grow rapidly, outgrow their blood supply, and cause abnormal angiogenesis. The biological effects of radiation on cells are enhanced by oxygen. Oxygen interacts with free radicals generated by radiation to "fix" DNA damage, resulting in damage that is very difficult to repair. For this effect, oxygen must be present at the time of radiation or within a few milliseconds.[4,33,36] Cells irradiated in the oxic conditions are approximately three times as sensitive as cells irradiated under hypoxic conditions. Chronic hypoxia, or diffusion-mediated hypoxia, develops due to the limited distance that oxygen can diffuse from a vessel before it is entirely consumed and represents a larger challenge than acute hypoxia, or transient and fluctuating hypoxia that results from intermittent tumor blood flow. Cells that are chronically hypoxic will reoxygenate only when their proximity to blood vessels increases; as tumors shrink with treatment, tumor oxygen levels increase. This is likely one of the most important advantages to fractionated radiation therapy.[26] Multiple strategies, including use of hypoxic cell sensitizers, hyperbaric oxygen, and erythropoietin, have attempted to improve oxygenation within tumor tissue. But, they have generally resulted in variable and minimal clinical improvement.[4,33,36-40]

Time, Dose, and Fractionation

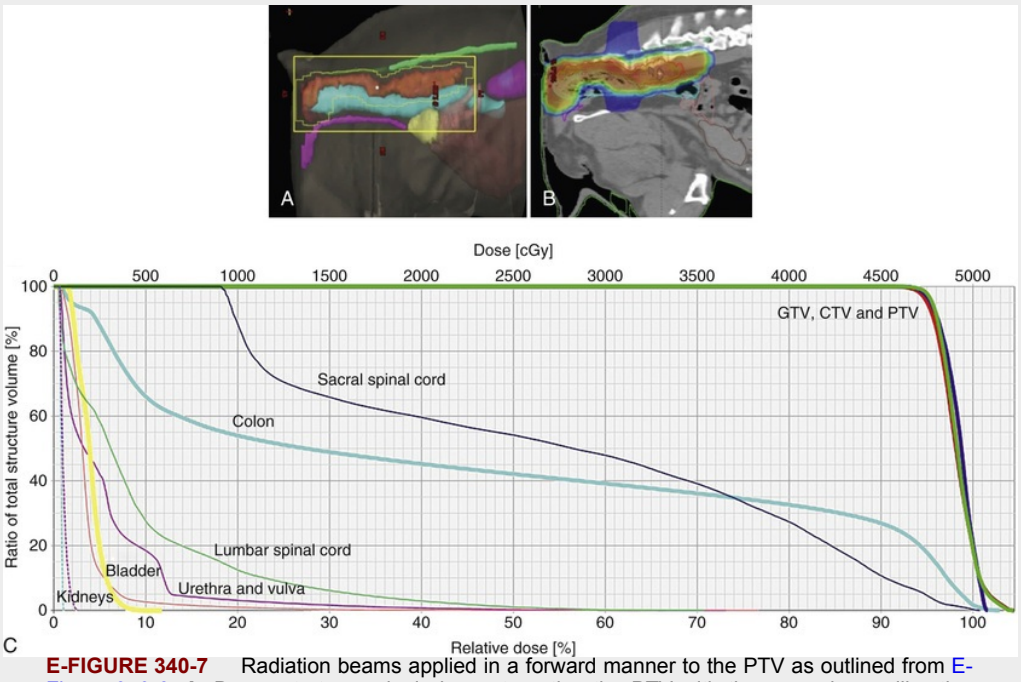
Factors that influence the effectiveness and tolerability of radiation include the overall dose of radiation prescribed, the dose given in each treatment fraction, and the time required for the protocol. Radiation oncologists recognized that higher total doses could be given to patients if the daily radiation dose was reduced into smaller fractions; this led to improved tumor response and decreased normal tissue damage. The primary goal of radiation therapy is to precisely target the tumor volume with tumoricidal doses of radiation while minimizing dose to surrounding normal structures. The overall dose and fractionation protocol is largely based on the particular tumor type and grade, adjacent normal tissue, the inherent radiosensitivity of the tumor cells, and clinical evidence (and sometimes clinical experience). Advanced imaging (often with CT alone but sometimes a registration of CT and MRI and/or positron emission tomography [PET]-CT) is commonly used for radiation treatment planning and aids in the delineation of tumor volumes and target structures for most non-extremity tumors.

Typically a radiation oncologist identifies and outlines three main tumor volumes as well as normal tissues (organs at risk [OAR]) within the data set used for planning. Tumor volumes include the gross tumor volume (GTV), the clinical target volume (CTV) that includes the GTV plus a margin to account for microscopic disease, and the planning target volume (PTV) that includes the CTV and an additional margin to account for intrinsic and extrinsic setup error (E-Figure 340-6). The radiation dose and fractionation protocol is typically prescribed to the PTV. Improved computerized treatment planning has improved ability to target tumor volume and reduce the radiation dose to normal structures (conformal radiation, E-Figure 340-7).



E-FIGURE 340-6 Tumor volumes outlined on a reconstructed model of dog in left lateral recumbency with an incompletely resected, regionally metastatic anal sac apocrine gland adenocarcinoma. Organs at risk outlined included the rectum (aqua), urethra and vulva (magenta), spleen (brown), spinal cord (green), bladder (yellow) and kidney (purple). The GTV represents the gross tumor volume, or visible tumor tissue; the CTV represents the clinical target volume that includes the GTV plus a margin to account for microscopic disease, and the PTV represents the planning target volume, which includes the CTV and a margin for intrafraction and interfraction motion. To illustrate the volumes, this dog's surgical scar was considered the GTV, while the CTV

included the GTV plus the visible draining sacral (hypogastric) and medial iliac lymph nodes. A standard margin of 3 mm was added to the CTV to create the PTV, to which radiation was prescribed.



E-FIGURE 340-7 Radiation beams applied in a forward manner to the PTV as outlined from E-Figure 340-6. **A,** Demonstrates a single beam targeting the PTV with the secondary collimation achieving conformation via the leaves of the multileaf collimator. **B,** Illustrates the dose in color wash, with the prescribed dose in orange. Lower radiation dose is represented by the cooler colors (green and blue). **C,** Illustrates a dose volume histogram, highlighting the high dose to the tumor volumes and lower dose to normal structures.

In veterinary medicine, current conventional prescriptions for definitive intent radiation therapy consists of 15-20 fractions of 2.5-4 Gy per fraction administered daily to total doses of 42-63 Gy.[8,9,30] Palliative intent radiation protocols vary but generally include higher doses per fraction (4-9 Gy) given less frequently to lower overall doses (20-32 Gy).[8,9] Fractionation was designed to exploit the Rs of radiobiology; specifically, to avoid repair and repopulation but allow reoxygenation and redistribution into sensitive phases of the cell cycle within tumor tissue over the treatment duration. Accelerated fractionation, hyperfractionation, and hypofractionation are altered schemes used in some definitive intent protocols to improve local control. The goal of accelerated fractionation is to complete radiation before tumor cells begin accelerated repopulation. The goal of hyperfractionation is to deliver smaller doses per fraction but a higher overall dose of radiation. Hyperfractionated protocols often include modest acceleration. Hypofractionation involves the administration of a larger dose per fraction but a smaller number of fractions; this is somewhat similar to a palliative protocol but with IGRT and SRT may provide good or superior tumor control for some tumor types.[33] SRT and SRS involve a small number of treatments (1-8) to a small but visible tumor target with rapid dose fall-off to adjacent structures. Both techniques require image guidance and verification to ensure proper patient and target position in order to acquire the advantage of having minimal normal tissue included in the high dose region. This allows a "conformal avoidance" approach in that ablative doses of radiation can be administered without significant concern for radiation damage to normal tissue.

Clinical Radiation Therapy

Practical Aspects of Veterinary Radiation Administration

When a veterinary patient undergoes radiation therapy, it is important that prospective planning develop an optimal therapy and determine a method for reproducible and verified patient positioning. In this manner,

radiation can be administered to the targeted tumor volume. Advanced treatment planning and administration, such as IGRT and SRT, rely on the patient being positioned properly for delivery of each radiation fraction. Decreasing margins of the PTV are successful if proper positioning is confirmed prior to each treatment.

Unlike in human radiation oncology, pets are anesthetized for treatment planning as well as for each radiation treatment in order to ensure reproducible and prolonged positioning for treatment. Most anesthesia protocols utilize rapid acting anesthetic agents to permit quick recovery. Typical radiation patients are anesthetized for 60-90 minutes for the first treatment, but only 10-15 minutes for subsequent treatments. Positioning devices, such as immobilization mattresses, face masks, bite blocks, and foam wedges, are often used to create a patient-specific setup position that can be replicated for each treatment (Figure 340-8). Not all tumors require extensive planning, but generally when normal structures are in close proximity to the target, 3D treatment planning (usually via CT for tissue density information) aids in reducing normal tissue toxicity. Tumors of the extremity, which are located away from critical tissues, rarely require 3D planning unless preoperative radiation therapy is performed or if there is concern about the postoperative tumor extent.

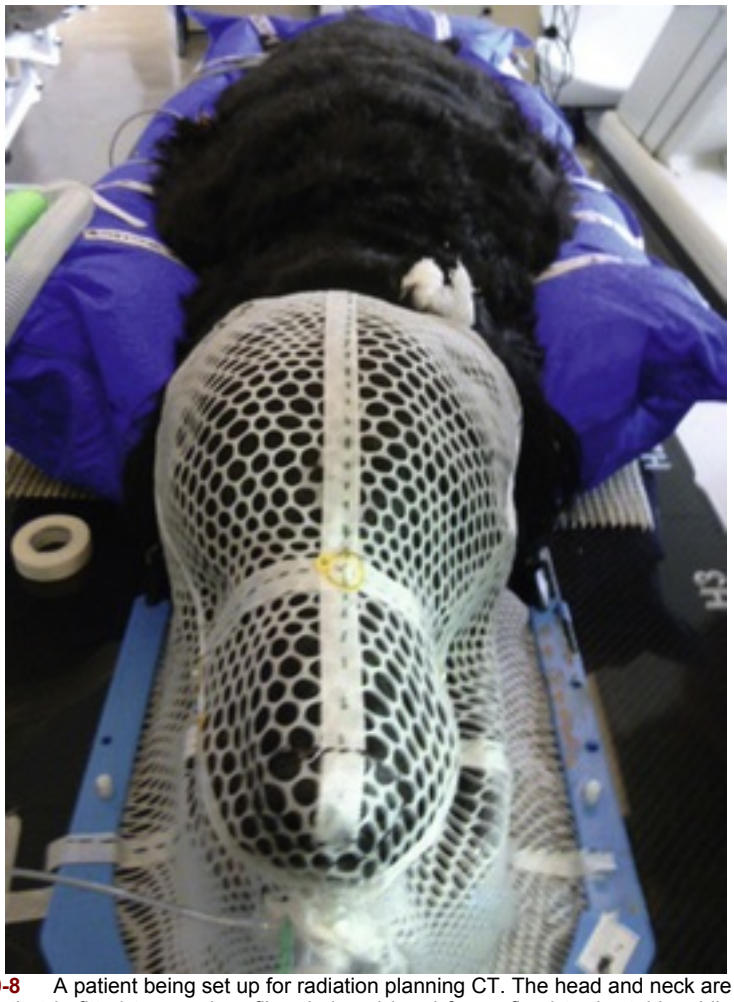


FIGURE 340-8 A patient being set up for radiation planning CT. The head and neck are resting on a plastic insert that is fitted to a carbon fiber–indexed head frame fixed to the table while the body is immobilized in a vacuum lock mattress. An acrylic face mask is used to conform to and secure the head to the head rest and frame. Laser alignment is used to aid in positioning between CT and radiation therapy.

Tissue Toxicities

Fractionating Therapy

There is often concern regarding radiation-induced toxicity within the treated volume. It is important that

thorough discussions take place among all involved prior to starting radiation therapy. Treatment toxicity depends on the fractionation schedule, time over which radiation occurs, and the type and volume of normal tissues within a radiation field. As radiation does not discriminate between cell types, both tumor and normal tissue react similarly. However, therapeutic radiation, fractionation and delivery technique employed attempt, in part, to exploit the difference in repair capabilities of normal and tumor tissues. Tumor cells typically have impaired repair mechanisms and an increased number of cells in the cell cycle by nature of their increased proliferative rates. Normal tissue in the radiation field is "dose-limiting" with respect to the maximum dose that can be safely administered. Dose per fraction, treatment schedule, and total dose affect normal tissue tolerance.

Tissue structure is important because fractionating radiation reduces toxicity to normal tissues and may improve the overall response of a tumor as compared with giving a small number of fractions but a high dose per fraction. Radiation administered once or twice a day allows normal cells to repair but does not provide enough time for repair of tumor cells. This allows cumulative damage to develop within the tumor exposed to repeated fractions.[4] The probability of tumor control is always weighted against the probability of complications. At lower doses of radiation, the probability of complications is low and provides a moderate chance of tumor control whereas increasing the dose gains a higher chance of tumor control but with a higher risk for normal tissue complications (Figure 340-9).

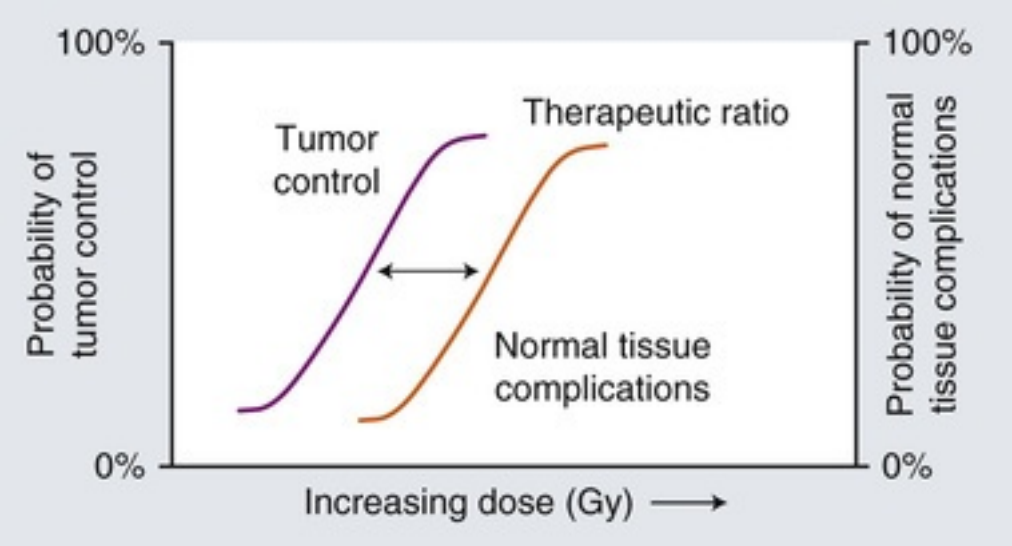

FIGURE 340-9 Therapeutic ratio described for radiation therapy, in which the probability of tumor control is weighted against the probability of normal tissue complications. At lower doses of radiation, the probability of complications is low but with a moderate probability of tumor control. Increasing the dose may gain a higher chance of tumor control but at the cost of a higher risk for normal tissue complications.

Acute Radiation Toxicity

Acute radiation toxicity is typically reversible, self-limiting, occurs during or shortly after therapy, and effects are confined to the irradiated area. Rapidly proliferating tissues such as epithelium, mucosa, and tumor are most affected acutely. Acutely affected tissues tend to heal within 2-4 weeks (Figure 340-10). Discomfort is expected in the short-term and acute toxicity is often unpleasant for both the owner and pet. Acute toxicities are predominantly dependent on the total dose of radiation administered (the higher the dose, the greater the toxicity) but also on the duration and frequency of treatment (shorter overall treatment time increases toxicity) and the fraction size (the higher the fraction size, the greater the toxicity). Concurrent chemotherapy administered in conjunction with radiation may increase acute radiation toxicity. Guidelines on culpable drugs in veterinary oncology are not available.[41] Acute effects are self-limiting and heal in most cases without medical intervention, although analgesia is important in managing radiation patients.

FIGURE 340-10 Acute radiation toxicity in a dog with a stage IV nasal carcinoma treated with definitive intent radiation therapy. **A,** Acute moist desquamation in the irradiated field at the end of treatment. **B,** Acute oral mucositis of the tongue, which was within the irradiated field. **C,** Healing desquamation 2 weeks post radiation therapy. **D,** Fully healed acute radiation adverse effects 16 months post radiation therapy.

For unexpected severe acute toxicity, standard surgical wound management may be used to ensure the site remains clean and protected. Little has been published regarding optimal methods to manage veterinary patients undergoing radiation therapy and there are no evidence-based consensus guidelines for radiation oncology.[42] In a survey of North American veterinary radiation facilities, about 75% used oral antibiotics and oral analgesics to manage radiation induced dermatitis. But, there were many opinions regarding treatment strategies.[42] The team must employ methods to avoid further trauma from licking, scratching or rubbing at the radiation site. For oral lesions, soft food, oral rinses and occasionally antibiotics (with oral coverage) are

used. Given our heightened awareness of antimicrobial resistance, in part due to the widespread indiscriminate use of broad-spectrum oral antibiotics, efforts should be made to determine if alternative methods are useful in the management of radiation toxicity.[43-45]

Late Adverse Effects

"Late" radiation adverse effects typically occur ≥6 months after completing therapy. Effects seen are determined by the structures within the irradiated field. Late radiation adverse effects typically develop in slowly proliferating or non-renewing tissues such as heart, lung, kidneys, nerve, bone, and muscle. Late effects, directly related to unexpected, severe, acute side effects that do not adequately recover, are also seen. These non-renewing tissues are dose-limiting. Thus, prescribed tumor dose should keep the probability of clinically relevant late effects at <5%. Late tissue damage is progressive and irreparable in most cases and results from vascular damage, chronic inflammation, fibrosis, necrosis, and loss of normal tissue stem cells. The most common late effects are cosmetic, but clinically relevant toxicity such as osteoradionecrosis or secondary tumor formation can occur if long-term survival (>3-5 years) follows radiation therapy (Figure 340-11).[11] Likelihood of late radiation effects depends on the fraction size (the greater the fraction size, the greater probability of late toxicity). The overall dose prescribed is also important. Because late radiation effects are generally irreversible, effort is made to avoid their development (Table 340-1).

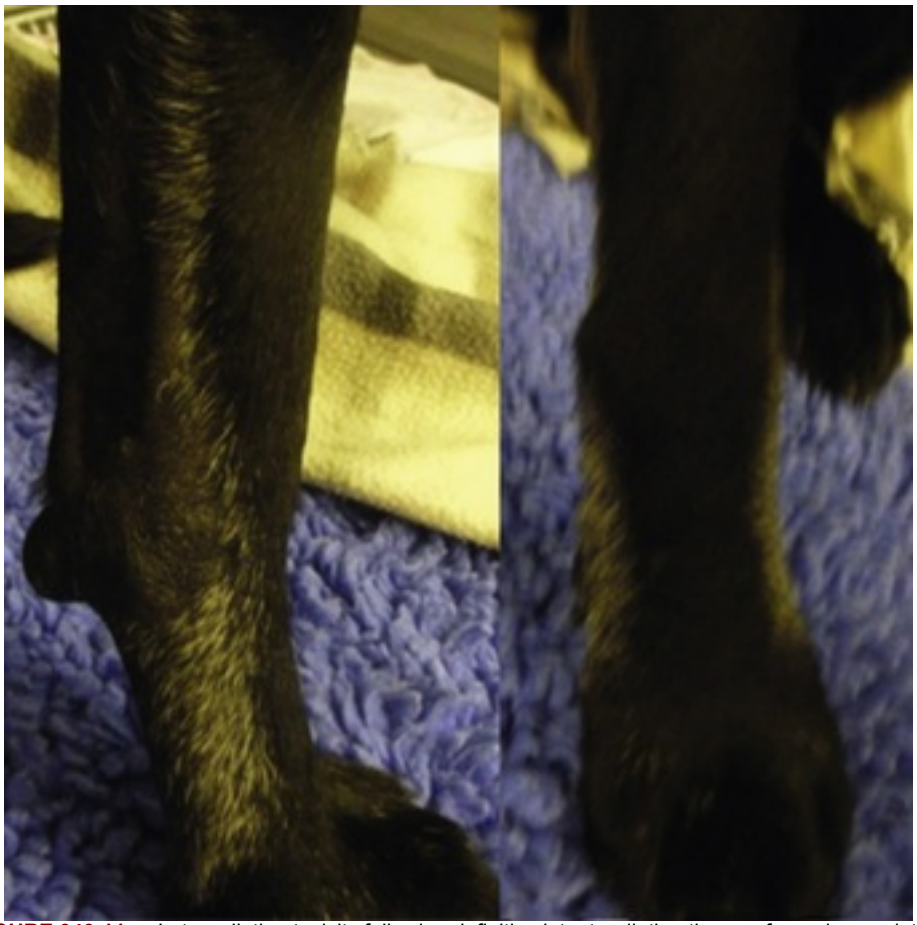

FIGURE 340-11 Late radiation toxicity following definitive intent radiation therapy for an incompletely excised soft tissue sarcoma. The radiation field is outlined along the lateral and caudal aspect of the limb by alopecia and leukotrichia, where the dorsal aspect of the distal limb was spared to permit lymphatic drainage.

TABLE 340-1

Radiation-Induced Toxicities That Can Occur in the Dog and Cat

SKIN	ACUTE RADIATION TOXICITY	LATE RADIATION TOXICITY
Skin and subcutis	Moist desquamation Alopecia	Fibrosis and contraction Non-healing ulcer Leukotrichia Alopecia Secondary tumor (sarcoma)
Extremity	Nail or pad slough	Neuropathy Muscle fibrosis and contraction
Spinal cord	Delayed "acute" transient myelopathy (rare)	Myelopathy Infarction Radiculopathy (lower motor neuron syndrome)
Cervical region	Pharyngitis Esophagitis Tracheitis	Hypothyroidism Esophageal stricture
Oral cavity	Mucositis	Periodontal disease Xerostomia (dry mouth)
Nasal cavity	Mucositis Nasal discharge	Chronic rhinitis (nasal discharge)
GI tract	Gastritis, enteritis or gastroenteritis Colitis/anusitis	Stricture
Eye	Blepharitis/blepharospasm Conjunctivitis Corneal ulceration Keratitis Uveitis	Cataract Keratoconjunctivitis sicca (KCS) Retinal changes Blindness
Brain	Encephalopathy (rare) Edema (rare) Systemic effects: lethargy, nausea, vomiting (rare)	Encephalopathy Infarction/hemorrhage
Bone		Osteoradionecrosis Secondary tumor formation (sarcoma)
Kidney	Acute nephropathy	Fibrosis leading to nephropathy

Palliative versus Definitive Protocols (see Box 340-2)

Factors dictating likelihood of late toxicity help in choosing between definitive and palliative radiation protocols. It is common to recommend definitive intent radiation protocols for pets with a good prognosis and high likelihood of survival beyond 6 months. The dose given each day in this type of protocol is lower in order to "protect" normal tissue from developing significant late toxicities that could negatively impact quality of life. Palliative protocols are typically reserved for animals with a poor prognosis. The goals of palliative therapy are to alleviate pain associated with the tumor, decrease the size of any mass causing obstruction (a laryngeal mass or compressive medial iliac lymph node), and to otherwise alleviate debilitating signs of cancer (bleeding from a large ulcerated oral mass).

Palliative radiation therapy is not intended to prolong survival, although it may do so indirectly. Rather, it is prescribed to improve quality of life. There are many different protocols for palliative radiation. They often involve radiation administered once or twice weekly for 3-4 doses or 4-5 total doses are administered daily. Because the dose of radiation is higher for each fraction, if pets do well with treatment and survive greater than 6-12 months following treatment, there is a higher likelihood of clinically relevant late toxicity (Figure 340-12). SRS and SRT utilize modest hypofractionation but the techniques involve precise delivery of a highly conformal radiation to a small target, minimizing the amount of normal tissue within the prescribed high radiation dose region.[5] Clinical data in dogs and cats are limited. Such radiation has been employed for solid tumors: brain, canine osteosarcoma, feline injection site sarcoma, and canine nasal tumors.[46-52]

FIGURE 340-12 Clinically relevant late radiation toxicity in a dog treated with palliative radiation therapy for a solitary epitheliotropic mandibular gingival lymphoma. Osteosarcoma (arrow) developed within the radiation site 4 years following treatment for lymphoma; following mandibulectomy, there was no evidence of lymphoma in the histologic sections.

Adjuvant Radiation Therapy

Overview

Because cell killing follows exponential kinetics, larger tumors require higher doses of radiation to induce a complete response. Indeed, several studies have demonstrated an inverse relationship between the likelihood of tumor control following radiation therapy and tumor size for canine mast cell tumors, soft tissue sarcomas, pituitary tumors, and oral tumors, and feline nasal planum squamous cell carcinomas and oral squamous cell carcinomas.[53-59] Radiation tends to be most useful in microscopic disease due to the nature of solid tumor growth (Gompertzian growth) and double strand DNA breaks in tumor cells being the target of therapy. There are exceptions, but radiation therapy is considered most effective in the postoperative setting for most tumors in animals, when surgical margins are incomplete or narrow and there is risk of tumor recurrence (Figure 340-13).

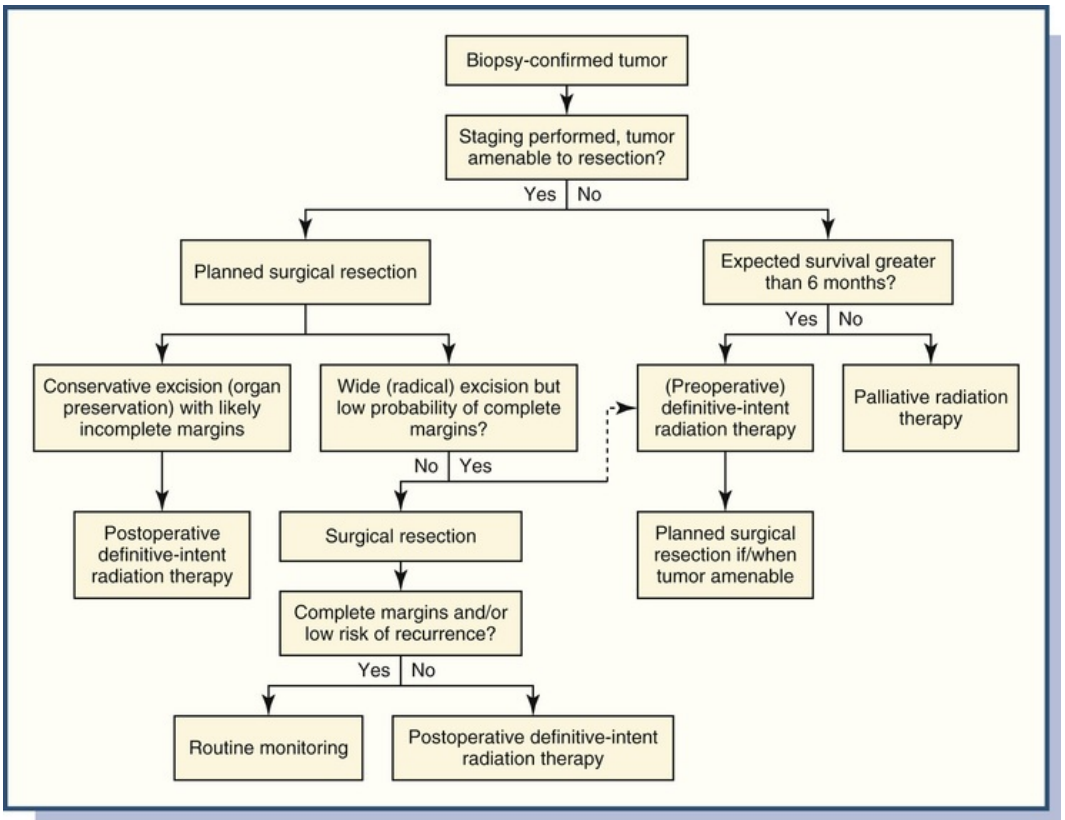

FIGURE 340-13 Algorithm for the role of radiation therapy in the management of veterinary cancer patients. Tumor histology, clinical characteristics, staging and other factors will influence the decision to pursue definitive radiation therapy. Palliative radiation is generally considered for patients with advanced cancer.

In most cases, radiation therapy begins 10-20 days after surgery, allowing tissue time to heal. The radiation field then includes all areas potentially contaminated by the surgical approach and areas likely to contain microscopic disease. Advantages of postoperative radiation therapy include: surgical staging permits tailoring of radiation target volumes and doses; radiation is most effective at achieving long-term control when targeting microscopic disease; there is no negative impact on post-surgical wound healing (although this is rare in companion animals); and there is no delay in surgery, which may have a psychological benefit for people with cancer (and potentially pet owners).

Advantages and Disadvantages of Surgery Preceding Radiation

Surgical staging is generally considered one of the best methods of determining true tumor extent, as samples are submitted for histologic evaluation after removal. The surgeon therefore has a critical role when postoperative radiation therapy is planned. Prior to surgical resection, it is often helpful to determine if placement of radiopaque clips or markers is useful to identify surgical excision borders. Use of markers can aid in postoperative tumor volume delineation (GTV and CTV) to be targeted. This improves ability to exclude normal tissue.[60] Potential disadvantages of postoperative radiation therapy include the volume of normal tissue irradiated is larger after surgery, especially if the surgical scar does not relate well to the tumor bed; there may be increased risk of tumor cell dissemination at surgery; there may be alteration in the blood supply to residual tumor cells, creating a more hypoxic and radio-resistant environment, thus necessitating higher overall dose; if there are surgical complications with wound healing, the time to start of radiation may be delayed.

Preoperative Radiation Therapy

Pre-operative radiation therapy is often recommended for large tumors when it is not known whether a tumor can be safely and completely excised, i.e., canine thyroid tumors or feline injection site sarcomas.[23-25,51,61-63] Radiation therapy is often prescribed for a 3-4 week protocol which is then followed by a 2-4 week period in which any acute toxicities are permitted to heal prior to surgery. Possible advantages of performing

preoperative radiation therapy include using less radiation, perhaps because there has been no alteration in vasculature by surgical manipulation; a smaller treatment field is treated as the tumor volume and target volumes can be better defined; there is no delay in the start of radiation; and the extent of surgery may be slightly less depending on the response to treatment.

Potential disadvantages of preoperative radiation therapy include the lack of initial surgical staging, which may limit radiation therapy planning; a potential deleterious effect on post-surgical wound healing (although this is not well recognized in veterinary medicine even in cases where surgery is performed months following radiation therapy); and hypoxic regions in measurable bulky tumors may inhibit good cellular responses to radiation. Cats with injection site sarcomas often have extensive and highly infiltrative disease at the time of presentation, thus preoperative radiation therapy plays a major role in decreasing potential late radiation effects by permitting a lower overall dose to be prescribed to a smaller treatment volume. For unresectable tumors, preoperative radiation therapy may create a smaller tumor (downstaging) more amenable to excision. The decision to undertake preoperative versus postoperative radiation therapy should be a team decision.

Chemotherapy and Radiation Therapy

Chemotherapy may be administered concurrently with radiation due to the biologic behavior of some tumors, their underlying tumor histology, or as a radio-sensitizer. The extent to which chemotherapy drugs synergize with radiation is extremely variable. In people, some interact strongly (doxorubicin) and others show no obvious synergy (cytosine arabinoside). Efforts to evaluate chemotherapy drugs such as carboplatin and gemcitabine as radiation sensitizers for dogs and cats have been disappointing.[64,65] While many animals tolerate concurrent chemotherapy and radiation therapy or tyrosine kinase inhibitors and radiation therapy, it is important to monitor for unexpected hematologic, gastrointestinal, or radiation adverse events.[41,64,66,67]

Common Tumor Types Treated with Radiation Therapy in Veterinary Oncology

Many tumors are responsive to radiation; however, the overall response tends to be variable and dependent on the signalment, tumor histology, location, grade, and/or stage of disease. It is always important to remember that normal critical structures adjacent to the radiation field limit the amount of radiation that can be administered; occasionally doses must be modified to avoid significant injury. A general guide for tumor types that are responsive to radiation is provided in E-Table 340-2. Radiation therapy may be used for other tumor types as well, such as solitary plasma cell tumors, solitary lymphoma, salivary gland tumors, distal urinary tract tumors, thymomas, and histiocytic sarcomas, depending on the clinical picture. Palliative radiation therapy can be employed for most tumors as well in an effort to improve dysfunction or pain. For tumors that have positive responses to radiation therapy, re-irradiation may be a viable option but is dependent on the initial radiation protocol, the overall dose and fractionation schedule and normal tissues in close proximity to the recurrent or progressive tumor. Given advances in therapeutic radiation technology, it is likely that the role of radiation therapy in the management of veterinary cancer patients will become increasingly important and integrated into multimodality approaches.

E-TABLE 340-2

Common Tumor Types in Dogs and Cats Treated with Radiation Therapy

TUMOR	TREATMENT TYPE	RESPONSE TO RADIATION	TOXICITIES*	OUTCOME/COMMENTS
Oral Tumors—Dogs				
Oral ameloblastoma[68,69]	Definitive intent† radiation therapy only	Excellent	*Acute:* oral mucositis, moist desquamation *Late:* leukotrichia, alopecia and lichenification of skin within the irradiated site; risk of periodontal disease, osteoradionecrosis,	Median survival: 4 years

			carcinogenesis	
Oral fibrosarcoma[54,70,71]	Definitive intent radiation therapy following incomplete resection[54,70,71]	Fair to good	*Acute:* oral mucositis (can be severe), moist desquamation *Late:* leukotrichia, alopecia and lichenification of skin within the irradiated site; risk of periodontal disease, osteoradionecrosis, carcinogenesis	Median survival: 1.5 years
	Definitive intent radiation therapy only[72]	Fair	*Acute:* oral mucositis (can be severe), moist desquamation *Late:* leukotrichia, alopecia and lichenification of skin within the irradiated site; risk of periodontal disease, osteoradionecrosis, carcinogenesis	Median survival: 11 months
	Palliative intent radiation therapy[72]	Good	*Acute:* minimal due to palliative approach *Late:* leukotrichia, alopecia and lichenification of skin within the irradiated site; risk of periodontal disease, osteoradionecrosis, carcinogenesis	Median survival: 4-10 months
Oral melanoma[54,55,65,73]	Coarse-fraction (palliative) radiation therapy with or without surgery and/or chemotherapy	Fair to good	*Acute:* minimal due to palliative type protocol *Late:* leukotrichia, alopecia and lichenification of skin within the irradiated site; moderate to high risk of periodontal disease, osteoradionecrosis and carcinogenesis if long-term survival achieved	Median survival: 7-10 months Size is prognostic for outcome. Location, stage and histologic criteria may be prognostic for outcome. Radiation offers good local control but death is often due to metastatic disease
Oral (non-tonsillar) squamous cell carcinoma[54,74,75]	Definitive intent radiation therapy only or in conjunction with surgery	Good	*Acute:* oral mucositis (can be severe), moist desquamation	Median survival: 8 months-1.2 years
			Late: leukotrichia, alopecia and lichenification of skin within the irradiated site; risk of periodontal disease, osteoradionecrosis, carcinogenesis	Size and location are prognostic for outcome.
Tonsillar oral squamous cell carcinoma[76,77]	Palliative radiation therapy often in conjunction with surgery and chemotherapy	Fair to good	*Acute:* minimal due to palliative type protocol	Median survival: 6 months Fair to good local control but death typically due to progressive lymph node or lung metastasis
			Late: leukotrichia, alopecia and lichenification of skin within the irradiated site; low risk due to short survival time	

Oral Tumors—Cats				
Oral squamous cell carcinoma[53,78-82]	Accelerated hypofractionated radiation therapy[53,78,79]	Fair	*Acute:* mucositis, moist desquamation	Median survival: 6 months Progression-free survival: 4.5 months
			Late: leukotrichia, alopecia; low risk due to short survival	Size was prognostic for outcome
	Palliative or various hypofractionated radiation therapy with or without surgery[80,81]	Poor to fair	*Acute:* mucositis, moist desquamation	Median survival: 2-6 months
			Late: low risk due to short survival	Mandibular location associated with improved outcome
	Definitive intent radiation therapy[82]	Poor to fair	*Acute:* mucositis, moist desquamation, inappetence *Late:* leukotrichia, alopecia, lichenification; low risk for significant effects due to short survival	Median survival: 3-6 months
Nasal Tumors—Dogs				
Nasal carcinomas and sarcomas[17,47,83-91]	Definitive intent radiation therapy (conformal radiation therapy and IMRT)[17,86,87,89,91]	Good	*Acute:* oral mucositis, rhinitis, moist desquamation, blepharospasm, conjunctivitis, uveitis *Late:* cataracts, keratoconjunctivitis sicca, blindness, chronic rhinitis, periodontal disease	Median survival: 8-19 months IMRT is associated with dramatically reduced radiation adverse effects. Poorly differentiated carcinomas or squamous cell carcinoma may carry worse prognosis Stage IV nasal tumors with extension through the cribriform plate carry a worse prognosis. Median survival: 6 months.
	Palliative radiation therapy (conformal radiation therapy, SRT)[47,83-85,88,90,91]	Good	*Acute:* oral mucositis, rhinitis, blepharospasm, conjunctivitis, uveitis *Late:* cataracts, keratoconjunctivitis sicca, blindness, osteoradionecrosis and fistula formation, chronic rhinitis, periodontal disease if long-term survival is achieved	Median survival: 6-10 months Epistaxis may be negatively associated with outcome. SRT may yield higher risk of late toxicity.
	Re-irradiation with palliative radiation therapy following local failure[87]	Good	*Acute:* oral mucositis, rhinitis, blepharospasm, conjunctivitis, uveitis *Late:* cataracts, keratoconjunctivitis sicca, blindness, osteoradionecrosis and fistula formation, chronic	Median progression-free survival: 9 months from reirradiation Note: high risk of late toxicity due to prolonged survival and high overall dose to normal tissues

			rhinitis, periodontal disease	
Nasal Tumors—Cats				
Nasal carcinoma92-94	Definitive intent hypofractionated radiation therapy94	Good	*Acute:* oral mucositis, rhinitis, blepharospasm, conjunctivitis, uveitis *Late:* cataracts, keratoconjunctivitis sicca, chronic rhinitis, periodontal disease	Median survival: 11 months Range in survival: 1 month-3 years
	Palliative hypofractionated radiation therapy92,94	Good	*Acute:* mucositis, moist desquamation, conjunctivitis *Late:* cataracts, keratoconjunctivitis sicca, chronic rhinitis, osteoradionecrosis, periodontal disease; higher risk of late toxicity	Median survival: 12 months
Nasal lymphoma95-97	Definitive intent radiation therapy alone96	Excellent	*Acute:* oral mucositis, rhinitis, blepharospasm, conjunctivitis, uveitis *Late:* cataracts, keratoconjunctivitis sicca, chronic rhinitis, periodontal disease	Median survival: 1.5-3 years
	Definitive intent radiation therapy with multidrug chemotherapy96,97	Excellent	(As above)	Median survival: 1.5 years
	Palliative hypofractionated radiation therapy95,96	Good	*Acute:* oral mucositis, rhinitis, blepharospasm, conjunctivitis, uveitis *Late:* cataracts, keratoconjunctivitis sicca, ocular atrophy, chronic rhinitis, secondary tumor formation, periodontal disease	Median survival: 1-1.2 years
Skin/Subcutaneous Tumors—Dogs				
Mast cell tumor58,98-104	Definitive intent radiation following incomplete resection with or without chemotherapy98-104	Excellent	*Acute:* moist desquamation, rarely ulceration *Late:* leukotrichia, alopecia, lichenification, fibrosis, osteoradionecrosis, secondary tumor formation	Median survival: 2-6.8 years Median progression-free survival: 2.7-3.4 years Survival linked to grade and stage of mast cell tumor. Chemotherapy is typically administered for tumors at high risk for metastasis.
	Definitive radiation alone58	Good	*Acute:* moist desquamation, rarely ulceration *Late:* leukotrichia, alopecia, lichenification, fibrosis	Median survival: 1.5 years Size is prognostic for outcome
Soft tissue sarcoma57,70,105-108	Definitive intent radiation therapy following incomplete	Excellent	*Acute:* moist desquamation, rarely ulceration *Late:* leukotrichia, alopecia,	Median survival: > 5.4 years 5-year survival rate: 78%

	resection70,107		lichenification, fibrosis, osteoradionecrosis, secondary tumor formation	
	Definitive intent radiation therapy alone57	Fair	*Acute:* moist desquamation, rarely ulceration *Late:* leukotrichia, alopecia, lichenification, fibrosis	1-year tumor control rate: 67% 2-year tumor control rate: 33%
	Palliative radiation therapy105,106,108	Good	*Acute:* rare due to palliative approach *Late:* leukotrichia, alopecia, lichenification, fibrosis, higher risk of osteoradionecrosis, secondary tumor formation if long-term control achieved	Response rates: 50-87%
Ceruminous gland adenocarcinoma109,110	Definitive intent following incomplete resection	Good to excellent	*Acute:* moist desquamation, rarely ulceration of the ear canal, secondary otitis externa or interna, temporary deafness *Late:* leukotrichia, alopecia, lichenification, fibrosis, chronic otitis externa and/or interna, tympanosclerosis	Mean tumor control: 3.2 years 1-year tumor control rate: 56%
Thyroid carcinoma23-25,111	Definitive intent radiation therapy only24,111	Good to excellent	*Acute:* moist desquamation, esophagitis, tracheitis, caudal oral mucositis *Late:* leukotrichia, alopecia, lichenification, fibrosis, esophageal stricture and regurgitation, tracheal stricture and/or cough, hypothyroidism, osteoradionecrosis, secondary tumor formation	Response rates: >75% Median survival: 2.1-3.8 years When considering post-radiation surgical resection, the time to maximum response can vary from 6-22 months
	Hypofractionated (palliative) radiation therapy23,25	Good	As above, with higher probability of late effects such as esophageal stricture	Median survival: 1.8 years
Anal sac apocrine gland adenocarcinoma112	Definitive intent following surgical resection to primary tumor bed and locoregional lymph nodes	Good to excellent	*Acute:* colitis, anusitis, moist desquamation of the skin *Late:* leukotrichia, alopecia, lichenification, fibrosis, rectal stricture	Median survival: 1.5 years The probability of late toxicity to pelvis is highly dependent on fraction size protocol
Skin/Subcutaneous Tumors—Cats				
Injection site sarcoma (vaccine associated sarcoma)51,61-63,113-115	Definitive intent radiation therapy following incomplete resection61,63,113,114	Good	*Acute:* moist desquamation, other effects possible depending on anatomic tumor location *Late:* leukotrichia, alopecia, lichenification, fibrosis, other effects possible depending on anatomic tumor location	Median survival: 1.9-3.5 years Disease-free interval: 1.1-1.3 years

	Preoperative definitive intent radiation therapy[62,114,115]	Good	As above but lower volume of tissue developing acute toxicity and at risk for late toxicity	Median survival: 1.6-2.1 years Median disease-free interval: 1.1-1.7 years
	Stereotactic radiation therapy (palliative)[51]	Good	*Acute:* skin erythema and dry desquamation *Late:* dependent on normal tissue irradiated	Margin status is prognostic for outcome
Brain Tumors—Dogs				
Various tumors: intra-axial, extra-axial[116-118]	Definitive intent radiation therapy[116,117]	Fair to good	*Acute:* minimal; possible skin desquamation, oral mucositis, ocular effects, acute cerebral edema, altered mentation *Late:* fibrosis, necrosis, seizures, altered behavior	Median survival: 8 months-1.9 years
	Stereotactic radiation surgery[118]		As above with fewer acute side effects	Median survival: 1.1 years
Meningioma[119,120]	Definitive intent radiation therapy following incomplete resection	Good	*Acute:* minimal; possible skin desquamation, oral mucositis, ocular effects, acute cerebral edema, altered mentation *Late:* fibrosis, necrosis, seizures, altered behavior	Median survival: 1.4 years
Pituitary tumors[56,121-123]	Definitive intent radiation therapy	Good	*Acute:* minimal; possible skin desquamation, oral mucositis, ocular effects, acute cerebral edema, altered mentation *Late:* fibrosis, necrosis, seizures, altered behavior	Median survival: 1- >2 years
Brain Tumors—Cats				
Pituitary tumors[52,124,125]	Definitive intent radiation therapy	Good to excellent	*Acute:* minimal; possible skin desquamation, oral mucositis, ocular effects, acute cerebral edema, altered mentation *Late:* fibrosis, necrosis, seizures, altered behavior	Median survival: 1.5-2.1 years Median survival for all cause mortality (tumor-related median survival not reached)
Bone Tumors—Dogs				
Osteosarcoma[48,49,126-129]	Palliative intent radiation therapy with or without systemic therapy[126-129]	Fair to good	*Acute:* erythema, dry desquamation (appendicular), mucositis (axial) *Late:* leukotrichia, alopecia, lichenification, fibrosis of soft tissues, osteoradionecrosis, fracture if prolonged survival achieved	Response rate for pain relief: 50-83% Median response duration: 1.5-2.5 months Median survival time: 4 months
	Stereotactic radiosurgery for limb-spare in conjunction with chemotherapy[48,49]	Fair to good	As above with potentially higher risk of late toxicity	Median survival: 10-12 months

*Note that acute and late toxicities are heavily dependent on the treatment site, radiation protocol and type of radiation therapy prescribed

and administered; therefore general information on potential toxicities is provided.

†Definitive intent radiation therapy was defined as radiation therapy administered with the intent of long-term control.

IMRT, Intensity-modulated radiation therapy; *SRT,* stereotactic radiation therapy.

CHAPTER 341

Cancer Immunotherapy

Barbara J. Biller

Client Information Sheet: Cancer Immunotherapy

Introduction

Of the treatment modalities available to treat cancer, immunotherapy has the greatest potential to specifically target tumors and spare normal tissues. It is also unique in its ability to provide a long-term memory response that could prevent tumor recurrence. Much of cancer research traditionally has been focused on understanding properties of the tumor cell itself, such as aberrant cell signaling, immortalization and activation of invasion, and metastasis. More recently, there has been a growing awareness of the importance of the host and the tumor microenvironment in shaping cancer progression (see ch. 338); among the most critical of these factors are the immune system and its response to cancer.

The idea that the immune system can control cancer is not a new one. In 1909, Ehrlich suggested cancer might occur at an "overwhelming frequency" if not for the function of the patient's immune system.[1] In the 1960s, Burnet proposed that lymphocytes were constantly patrolling normal tissues and eliminating abnormal cells through a process he termed *immune surveillance.*[1,2] Burnet's theory was not widely accepted until the 1990s, when tumor-associated antigens and tumor-specific lymphocytes were first identified in human cancer patients. Now it is recognized that nearly every known innate and adaptive immune effector mechanism participates to some degree in tumor recognition and control or, conversely, in helping tumors avoid detection.

Overview of Tumor Immunology

The dual role of the immune system in protecting against tumor development and promoting tumor growth is illustrated by the phenomenon of *immunoediting.* During this process, the phenotype of neoplastic cells evolves to escape detection by the host immune system. Immunoediting can be characterized by three distinct phases. During the initial phase of immunosurveillance (also known as elimination), transformed cells are recognized and destroyed through a combination of innate and adaptive immune responses (reviewed in Box 341-1). The few cells that manage to survive enter an equilibrium phase in which there is a dynamic balance between tumor cell destruction and survival. In the final escape phase, however, constant immune pressure and the genetic instability of the tumor promote the expansion of a population of poorly immunogenic and potently immunosuppressive tumor cells that are well-equipped to evade further detection.[3]

Box 341-1

Principal Immune Cells Involved in Stimulation and/or Inhibition of Antitumor Immune Responses

Response Type

Innate

Dendritic cell (DC)

- Initiate adaptive immune responses through antigen presentation and T-cell activation; some subsets are immunosuppressive in the tumor microenvironment

Tumor-associated neutrophil (TAN)

- May recruit Treg and support tumor angiogenesis

Macrophage
- Very efficient phagocytes

M1
- Help activate T-cell mediated antitumor responses

M2
- Produce immunosuppressive cytokines and facilitate tumor evasion

Myeloid-derived suppressor cell (MDSC)
- Direct and indirect inhibition of T-cell immune responses; recruit Treg

Natural killer (NK) cell
- Perforin-dependent, direct killing of tumor cells recognized as "non-self"

Adaptive: Cellular

Cytotoxic T lymphocyte (CTL, CD8+ effector)
- Direct killing through activation and recognition of tumor antigens

CD8+ memory
- Recalled to protect against relapsing or metastatic disease

Helper T lymphocyte (T_h)
- Aid (T_h1) or inhibit (T_h2, T_h17) CTL function depending on tumor microenvironment

CD4+ T_h (T_h1, T_h2, T_h17)

Regulatory T lymphocyte (Treg)
- Indirect and direct effects; recruited to inhibit other immune effectors such as CTLs and DCs

Adaptive: Humoral

Antibody-mediated (Direct)
- Recognize tumor cells and induce apoptosis

Complement dependent (Indirect)
- Forms membrane attack complex that leads to tumor cell cytotoxicosis

Immune escape occurs through multiple complex mechanisms that can be divided into two broad categories. The first involves selection for tumor cells with features of reduced recognition (such as the absence of strong tumor antigens or loss of major histocompatibility complex molecules) and an increased ability to survive. The second mechanism is the development of an immunosuppressive tumor microenvironment dominated by the production of inhibitory cytokines (transforming growth factor-beta [TGF-beta] and interleukin [IL]-10) and the recruitment of immunoregulatory immune cells such as regulatory T cells (Tregs) and myeloid-derived suppressor cells (MDSCs). Together, these changes create a tumor microenvironment that facilitates tumor progression rather than detection.

Recognition of the impact of cancer immunoediting is leading to improvements in the efficacy of immune based therapies, many of which are likely to become more widely available to the veterinary profession over the coming years. This chapter highlights some of the most promising therapies under evaluation in veterinary clinical trials or already used in practice. The chapter reviews immune therapies that stimulate immunity in general (nonspecific tumor immunotherapy) as well as some of the tumor-specific approaches such as tumor vaccines and monoclonal antibodies (Figure 341-1).

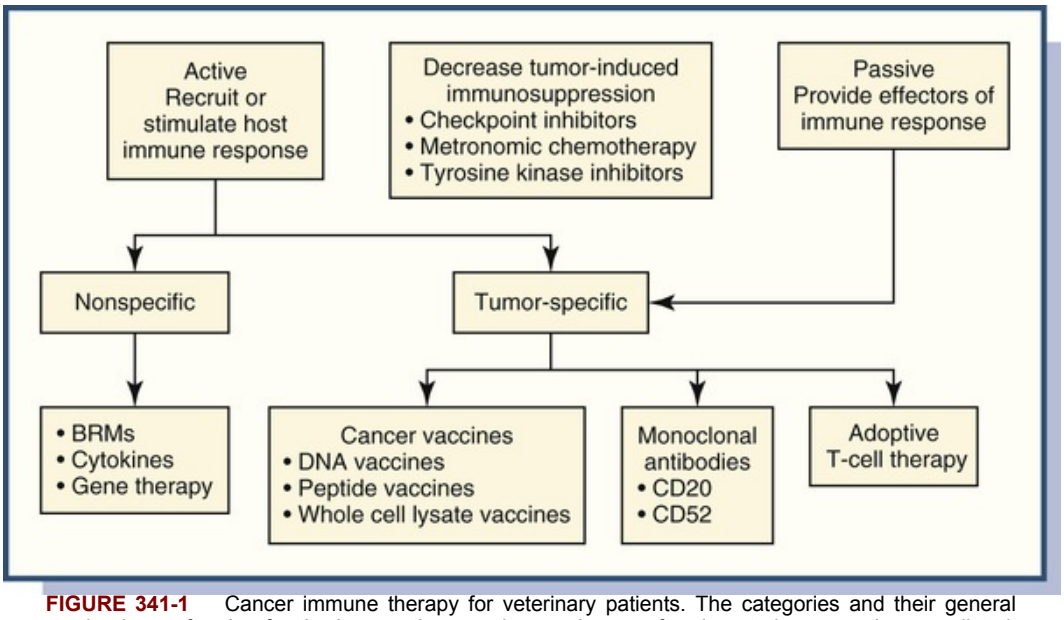

FIGURE 341-1 Cancer immune therapy for veterinary patients. The categories and their general mechanisms of action for the immunotherapeutics used most often in veterinary oncology are listed. Each is grouped according to the overall goal of therapy. *BRMs*, Biologic response modifiers.

Nonspecific Tumor Immunotherapy

The goal of nonspecific immunotherapy is to engage the innate and adaptive arms of the immune response in the recognition and destruction of neoplastic cells. In general, better stimulation of innate immunity (mediated primarily by dendritic cells and macrophages) results in more effective T- and B-cell mediated adaptive immune responses.

Bacillus of Calmette and Guérin (BCG)

One of the best-studied forms of nonspecific therapy is the biologic response modifier (BRM) known as BCG (bacillus of Calmette and Guérin), a modified strain of *Mycobacterium bovis* initially developed as a vaccine for tuberculosis in the early 20th century. Direct contact of BCG with malignant cells elicits production of multiple inflammatory cytokines including interferon (IFN)-gamma, IFN-alpha, IL-2, IL-6, IL-12 and tumor necrosis factor (TNF)-alpha.[4] This proinflammatory response attracts and activates neutrophils, macrophages, and cytotoxic T-lymphocytes, triggering destruction of tumor cells and induction of long-lived memory T-lymphocytes.[5]

Infusion of BCG into the bladder is one of the most effective forms of therapy for urogenital transitional cell carcinoma in people.[5] Although BCG has been instilled into the canine bladder and is well-tolerated at low doses, it is not effective in the treatment of canine transitional cell carcinoma (TCC), which typically presents as much more invasive disease in dogs compared to humans.[6,7] BCG has also been combined with human chorionic gonadotropin and administered subcutaneously to treat mast cell tumors in dogs, where it was found to be as effective as single-agent vinblastine chemotherapy with fewer side-effects in one randomized clinical trial.[8] Other studies evaluating the administration of BCG in dogs either alone or in combination with other therapies for mammary carcinoma, osteosarcoma, and lymphoma have not demonstrated a therapeutic benefit.[9-11]

Liposome-Encapsulated Muramyl Tripeptide (L-MTP-PE)

Muramyl dipeptide (MDP) is an immunostimulatory component of the BCG cell wall modified by addition of a peptide and incorporation into liposomal membranes to result in L-MTP-PE, a pharmaceutical product efficiently taken up by monocytes and macrophages that stimulates a cascade of innate and adaptive antitumor immune responses in the host.[12] Based on clinical studies in dogs with osteosarcoma, hemangiosarcoma, melanoma, and mammary adenocarcinoma, L-MTP-PE was moved into clinical trials in

humans (mostly children) with osteosarcoma.[13-15] A phase III prospective randomized trial showed significant reduction in the risk of death from osteosarcoma when L-MTP-PE was added to systemic chemotherapy for the treatment of localized disease.[15] Patients with metastatic or recurrent disease also had a decreased risk of further recurrence and death when L-MTP-PE was included in the treatment strategy. Also known as mifamurtide, L-MTP-PE was licensed by the European Medical Association in 2009 as an adjunct to chemotherapy in children with localized osteosarcoma. Mifamurtide has orphan drug status in the United States, but is not currently available to veterinarians. If this situation changes, it is likely that the drug initially will be cost-prohibitive but may prove to be a valuable nonspecific immunotherapeutic for dogs with osteosarcoma and other malignancies.

Cytokine and Gene Therapy

Cytokines with immunostimulatory properties, including IL-2, IL-12 and IL-15, IFN-gamma, and TNF-alpha, also are of interest as tumor-nonspecific immunotherapies. While each has been at least preliminarily assessed in veterinary patients, IL-12 appears most promising because it can be effectively targeted to tumor tissues, thus avoiding the toxicoses associated with systemic cytokine administration. In a clinical investigation of dogs with malignant melanoma, IL-12 was linked to an antibody targeting necrotic tumor regions and administered SC. This strategy resulted in minimal serious toxic effects as well as encouraging immunologic and clinical activity (about a 50% overall response rate).[16]

Another way to deliver cytokines is through gene therapy, in which host cells are transfected or transduced to express specific recombinant proteins of interest. For example, the IL-12 gene can be targeted specifically to tumor cells, triggering a locally immunostimulatory environment. This approach could be particularly useful in controlling large tumors including fibrosarcoma, squamous cell carcinoma, and malignant melanoma, as evidenced by several recent studies investigating efficacy in cats, dogs, and horses, respectively.[17-20]

Tumor-Specific Immunotherapy

Through a variety of approaches, the objective of tumor-specific immunotherapy is to elicit an antitumor immune response that results in clinical regression of a tumor or its metastases. Unlike cytotoxic chemotherapy, which induces rapid tumor cell death, clinical responses depend on the development of adaptive immune responses that can take several months or more to appear. Furthermore, it is becoming increasingly evident that a measurable cell-mediated or humoral antitumor immune response does not necessarily correlate with tumor regression. The observation of "mixed responses" is another frequent problem in assessing outcome; this phenomenon is characterized by the differential response of metastases within different tissues of the same patient. Factors such as these pose significant challenges to the design of clinical trials evaluating tumor-specific immunotherapy, especially in terms of determining efficacy and making comparisons between trials. To address some of these obstacles, specific immune-related response criteria are currently being evaluated alongside the more traditional RECIST (Response Evaluation Criteria in Solid Tumors) methods to more comprehensively capture a variety of clinical response patterns and standardize evaluation of various immunologic endpoints.[21,22] With these caveats in mind, the rest of this chapter will focus on cancer vaccines and monoclonal antibodies, two forms of tumor-specific immunotherapy with particular relevance to veterinary oncology.

Cancer Vaccines

As outlined in Figure 341-1, there are several methods by which anticancer vaccines can be generated, including those that deliver specific tumor antigens against a defined target (DNA and peptide vaccines) and those that provide exposure to a range of potential tumor-associated antigens that are usually not known (whole cell tumor lysate vaccines). While each approach has pros and cons in terms of vaccine preparation and the quality of the immune response evoked, cancer vaccines are versatile and can be engineered to boost key aspects of the immune response or to target specific tumor types or even antigens common to a spectrum of malignancies.

The only cancer vaccine currently commercially available for veterinary patients is Oncept (Merial Ltd, Duluth, MN), which is a xenogeneic nucleic acid vaccine containing the DNA sequence encoding human tyrosinase. Tyrosinase is an intracellular glycoprotein essential for melanin synthesis that is overexpressed in the majority of canine melanocytic tumors.[23,24] Early work demonstrated evidence of immunologic and clinical activity in dogs with malignant melanoma of the oral cavity and digit, leading to the vaccine's

licensure in 2010 for use in stage II and III oral canine malignant melanoma.[25-28] However, more recently, studies have reported conflicting outcomes, with some showing improved outcome in Oncept-vaccinated versus unvaccinated dogs while others have not.[29-31] Although better clarification of Oncept's effectiveness awaits investigation in larger randomized clinical trials, introduction of a cancer vaccine specifically for dogs is an exciting step towards improving the availability of immunotherapy for veterinary cancer patients.

There is a variety of other tumor vaccine strategies under clinical investigation in veterinary oncology. One of the most intriguing is the use of attenuated *Listeria monocytogenes*, genetically modified to express specific tumor antigens. When the vaccine construct is administered systemically, the *Listeria* organism infects the patient's myeloid cells, which then induces expression of the desired antigen by the neoplastic cells. This approach shows promise in mouse tumor models and is currently being explored using the tumor antigen HER2/*neu* as the target in canine osteosarcoma.[32-34]

Monoclonal Antibodies

Some of the most significant advances in the treatment of human cancers have been brought about by the use of therapeutic monoclonal antibodies (MAbs) that selectively target malignant cells. There is a growing number of MAbs that are being used to treat human patients with non-Hodgkin's lymphoma and carcinoma of the breast, prostate, and colon.[35] Many therapeutic MAbs are unconjugated and act by binding to specific targets on the surface of malignant cells to induce apoptosis. Apoptosis occurs through direct and indirect effects; the indirect effects typically are mediated by the activation of secondary immune effector mechanisms, such as antibody dependent cell-mediated cytotoxicity (ADCC) or the complement cascade. MAbs also can be linked to toxins, radioisotopes, or chemotherapy agents to induce tumor cell death or they can be used for abrogating tumor-induced immunosuppression (e.g., by blockade of CTLA-4 or PD-1, which limit T-cell mediated antitumor immune responses).

Although MAbs are not yet commercially available for use in veterinary patients, several are under investigation in clinical trials. Preliminary data showed that addition of an anti-CD20 MAb (Aratana Therapeutics) to CHOP or doxorubicin chemotherapy improved survival compared to dogs treated with chemotherapy alone.[36,37] Another MAb targeting the T-cell antigen CD52 (Aratana Therapeutics) has undergone evaluation in dogs with T-cell lymphoma; efficacy has not yet been reported. NV-01 (NexVet), a MAb that blocks nerve growth factor signaling, recently has been tested in clinical trials for dogs with osteoarthritis. In addition to its efficacy as an analgesic, NV-01 was found to decrease bone pain in dogs with osteosarcoma.[38] NV-01 appears promising for managing chronic bone and joint pain of various causes, either as a stand-alone therapy or combined with other medications. It is anticipated that these and other MAbs will be more widely available over the next couple of years.

Challenges for the Future

This chapter provides a brief overview of cancer immunotherapy, focusing on the strategies used most often for veterinary patients. There are other approaches not covered here, such as adoptive T-cell therapy or the administration of oncolytic viruses, which also hold promise and are actively being explored. No matter the approach employed, the success of cancer immunotherapy will depend on the continued development of therapies targeting tumor-induced immunosuppression. The recent U.S. Food and Drug Administration approval of the immune checkpoint inhibitors ipilimumab and nivolumab, which are MAbs targeting CTLA-4 and PD-1, respectively, illustrates the growing awareness of this need.

Investigations of the immunomodulatory properties of tyrosine kinase inhibitors (e.g., toceranib phosphate) and of metronomic chemotherapy are further examples of efforts to alleviate immunosuppression. In dogs with a variety of tumors, administration of either toceranib or low daily dosages of cyclophosphamide is associated with a reduction in circulating Treg numbers.[39,40] Similarly, liposomal preparations of the chemotherapy agent clodronate may be helpful in reducing canine MDSCs via the drug's effects on tumor-associated macrophages.[41]

Despite the challenges ahead, the potential to improve the outcome for people and animals with cancer using novel immune therapies is significant. Veterinarians are in a unique and critically important position to contribute to this effort through their work with companion animals as both cancer patients and translational models. As our understanding of the tumor microenvironment and our ability to target it rapidly improve, the use of anticancer immunotherapy in the clinic likely will become as commonplace as other modalities such as radiation therapy and chemotherapy.

CHAPTER 342

Molecular Targeted Therapy

Cheryl London

Introduction

Advances in molecular biology, DNA sequencing and bioinformatics have resulted in a much more detailed characterization of how key cellular processes are dysregulated in cancer cells. In particular, understanding the contribution of proteins that normally play essential roles in regulating cell survival, growth, differentiation and migration to tumor biology has helped to establish a framework for the development of novel therapies to disrupt tumor growth. Targets relevant for therapeutic intervention included kinases, transcription factors, proteins that block apoptosis, heat shock proteins and regulators of nuclear export, among others. The two most common approaches for targeting aberrant cellular proteins are monoclonal antibodies and small molecule inhibitors. While antibodies primarily are directed at cell surface proteins, small molecule inhibitors can impact proteins on the cell surface, in the cytoplasm and in the nucleus. Several small molecule inhibitors have been approved for the treatment of human cancers and many more are undergoing clinical testing. In veterinary medicine, the use of small molecule inhibitors is more recent, with just two inhibitors, toceranib (Palladia) and masitinib (Kinavet) approved or conditionally approved by the U.S. Food and Drug Administration (FDA) for use in dogs.[1,2] This chapter discusses the current status of small molecule inhibitors in veterinary clinical oncology.

Toceranib (Palladia)

Toceranib phosphate is an orally bioavailable small molecule inhibitor that blocks a variety of cell surface receptor tyrosine kinases (RTKs) by acting as a reversible competitive inhibitor of adenosine triphosphate (ATP) binding, preventing phosphorylation and subsequent downstream signaling. The inhibitory profile of toceranib includes the RTKs VEGFR2, PDGFRbeta, and KIT.[2-5] Toceranib is very closely related to sunitinib (Sutent) that blocks the activity of VEGFR2/3, PDGFRalpha/beta, KIT, CSF1R, FLT-3, and RET.[6] While it was initially developed as an anti-angiogenic agent, toceranib's broad target profile results in direct anti-tumor activity as well. It is also evident that toceranib has immunomodulatory properties in dogs with cancer through modulation of regulatory T cells (Tregs) further contributing to its effects against several tumor types in dogs.

Phase 1 Clinical Trial

Toceranib initially was studied in a phase 1 clinical trial in 57 dogs with a variety of cancers.[3] Objective responses were noted in 16 dogs (6 complete responses [CR] and 10 partial responses [PR]) with stable disease (SD) in an additional 15 dogs for an overall biological activity of 54%. Based on the known involvement of KIT dysregulation in canine mast cell tumors (MCTs), the highest response rate was observed in this disease setting, with 10/11 dogs with KIT mutations exhibiting clinical benefit. The maximum tolerated dosage (MTD) was established as 3.25 mg/kg PO q 48 h and the adverse event profile was found to be primarily gastrointestinal (GI) in nature including loss of appetite, diarrhea, and less commonly vomiting.

Pivotal Field Study

A placebo-controlled randomized clinical field study of toceranib subsequently was performed in dogs with non-resectable Grade 2 and 3 MCTs.[2] The response rate for all 145 dogs that received toceranib in this trial was 42.8% (21 CR, 41 PR) with an additional 16 dogs experiencing SD for an overall biological activity of 60%. Dogs whose MCT had mutations in KIT were twice as likely to respond to toceranib as those without, and

dogs without lymph node metastasis had a higher response rate than those with involvement. These data formed the basis for the subsequent FDA approval of toceranib in 2009 for the treatment of dogs with MCTs.

Off-Label Activity

Following its approval, toceranib was used off label to treat a variety of tumors in dogs. A retrospective analysis captured this off-label use and clinical benefit (CR, PR, or SD) was observed in 63/85 (74%) of dogs with solid tumors including: anal sac adenocarcinoma (28/32; 8 PR, 20 SD), metastatic osteosarcoma (11/23; 1 PR, 10 SD), thyroid carcinoma (12/15; 4 PR, 8 SD), head and neck carcinoma (7/8; 1 CR, 5 PR, 1 SD), and nasal carcinoma (5/7; 1 CR, 4 SD).[7] The median dosage of toceranib used was 2.8 mg/kg PO; 58.7% of dogs were given drug three times a week (Monday/Wednesday/Friday [M/W/F]), and 74.6% received treatment for 4 months or longer.

Activity also has been reported in lymphangiosarcoma[8] and chronic monocytic leukemia[9] with several other anecdotal reports in individual tumor types not yet published. This indicates that toceranib could have broad anti-tumor activity in dogs.

Combination Therapies

Piroxicam, a nonsteroidal anti-inflammatory mixed cyclooxygenase (COX)-1/COX-2 inhibitor, has shown activity in the treatment of carcinomas and often is included in metronomic chemotherapy regimens. A phase 1 trial was performed in dogs with cancer to establish the safety of toceranib/piroxicam co-administration.[10] Several anti-tumor responses were observed and the combination of standard oral dosages of both drugs (toceranib 3.25 mg/kg PO q 48 h, piroxicam 0.3 mg/kg PO q 24 h) was found generally to be safe. However, the dogs were not monitored to assess whether GI side effects occurred after long-term administration. Therefore, piroxicam often is administered q 48 h alternating with the toceranib to help reduce the risk of GI toxicosis.

To assess whether vinblastine and toceranib could be combined effectively, a phase 1 clinical trial was performed in dogs with MCT.[11] The dose-limiting toxicosis for the toceranib/vinblastine combination was found to be neutropenia, and the MTD of vinblastine was 1.6 mg/m^2 every other week when administered with toceranib at 3.25 mg/kg PO q 48 h. Despite the reduction in vinblastine, the objective response rate was 71%, suggesting that there is additive or synergistic activity when the drugs are given in combination.

To determine whether the combination of radiation and toceranib would be of benefit in MCTs, dogs with non-resectable tumors received prednisone, omeprazole, diphenhydramine, and toceranib at 2.75 mg/kg on M/W/F for 1 week prior to receiving coarse fractionated radiation therapy.[12] The objective response rate was 76.4% (58.8% CR, 17.6% PR) and the median survival time was not reached with a median follow-up of 374 days and no reported enhancement of radiation toxicoses. These data indicate that combined radiation/toceranib has significant clinical benefit in dogs with non-resectable MCTs. The combination of radiation and toceranib also appears to benefit dogs with nasal carcinoma. Dogs receiving 10 fractions of radiation (total dose 42 Gy; see ch. 340) with toceranib had a median survival time of 615 days compared to 371 days for a similarly treated historical control that did not get toceranib.[13]

Immunomodulatory Properties

Low-dosage cyclophosphamide often is used in metronomic treatment regimens to alter the local microenvironment through modulation of angiogenesis and reduction in the number of immunosuppressive Tregs. To assess the effects of toceranib on immune function, dogs with cancer received drug q 48 h for 2 weeks, at which time low-dosage cyclophosphamide was added to the treatment regimen.[14] Toceranib significantly reduced the number and percentage of Tregs in the peripheral blood of treated dogs, with a concomitant increase in interferon (IFN)-gamma serum concentrations. These data indicate that toceranib can have efficacy in metronomic therapy regimens.

Toceranib in Microscopic Metastatic Disease

The activity of toceranib has been evaluated in the microscopic metastatic disease setting. In one study, dogs with appendicular osteosarcoma underwent amputation followed by carboplatin chemotherapy, then were randomized to receive either toceranib/piroxicam/cyclophosphamide or piroxicam/cyclophosphamide (controls).[15] There was no difference in progression-free survival or overall survival, and these did not differ

significantly from historical data regarding dogs that underwent amputation and were treated with carboplatin alone. In a second study, dogs with stage 1 or 2 splenic hemangiosarcoma underwent splenectomy and were treated with doxorubicin.[16] If deemed free of disease after chemotherapy, they went on to receive toceranib. When compared to a historical control group that received doxorubicin alone, there was no improvement in progression-free survival or overall survival. These data indicate that toceranib likely has no benefit in the setting of microscopic metastatic disease in the absence of a known tumor driver (i.e., mutant KIT in MCTs).

Current Dosage Recommendations

Evidence now exists that good biologic activity occurs when doses are initiated below the 3.25 mg/kg MTD and that alternative dosing schedules are effective. In a study of dogs with solid tumors, dosages of toceranib ranging from 2.4-2.9 mg/kg PO q 48 h were associated with drug exposure considered sufficient for target inhibition, resulting in modulation of a key pharmacodynamic marker consistent with VEGFR signaling inhibition.[17] Importantly, the lower dosages were associated with a substantially reduced adverse event profile compared to 3.25 mg/kg. Both PR and CR were documented and 35/40 dogs remained on toceranib for an average duration of 4 months.[17] Data generated from the retrospective analysis of toceranib use in solid tumors found that the three times a week dosing schedule may be better tolerated by some dogs, particularly when toceranib is combined with other therapeutics, such as nonsteroidal anti-inflammatory drugs.

Masitinib and Imatinib

Masitinib mesylate (Kinavet), conditionally approved in 2010, blocks the activity of KIT, PDGFR and the cytoplasmic kinase Lyn. A large placebo-controlled clinical trial was performed in >200 dogs with MCTs in which masitinib significantly improved time to progression compared to placebo, and outcome was improved in dogs with MCTs possessing KIT mutations.[1] Subsequent follow-up of patients treated with masitinib for 2 years identified an increased number of patients with long-term disease control compared to those treated with placebo (40% versus 15% alive at 2 years).[18] A retrospective analysis of dogs with MCT treated with masitinib showed a response rate of approximately 50%.[19] Although the number of dogs evaluated in this study was small and there were varying disease presentations, this study suggests that biologic activity of masitinib is likely to be higher in the setting of primary rather than relapsed disease. Masitinib has also been reported to have activity against T-cell lymphoma in dogs, although no formal clinical trials have been undertaken in this disease setting.

There have been no specific studies of imatinib mesylate (Gleevec) in veterinary medicine, although a few reports have been published regarding its use in both dogs and cats. In these, imatinib was well tolerated, and objective anti-tumor responses were observed in dogs with MCTs carrying both mutant and wild-type KIT.[20-22] Responses also have been observed in cats with MCT that have KIT mutations.[23,24]

Management of Adverse Events Associated With Toceranib and Masitinib

Nearly all small molecule inhibitors induce adverse events; as underlying co-morbidities may contribute to these effects, efforts should be made to increase the health status of dogs prior to their use. For both toceranib and masitinib, the most common side effects relate to the GI tract, including loss of appetite, diarrhea and occasionally vomiting (see ch. 343).[1-3,17,19] The administration of a gastric acid suppressant, particularly omeprazole, may be beneficial in mitigating the risk of GI ulceration, especially in the setting of MCTs. Inappetence is a relatively common side-effect and typically responds to standard anti-nausea therapies (metoclopramide, ondansetron, maropitant; see ch. 39) or low-dose prednisone. With respect to diarrhea, metronidazole and/or loperamide along with probiotics are often useful. Both protein losing nephropathy (PLN; see ch. 325) and systemic hypertension (see ch. 157) have been associated with toceranib administration. The PLN is generally mild to moderate and effectively managed with enalapril/benazepril and/or dose reduction. Similarly, the hypertension can be typically managed with amlodipine. Masitinib is reported to induce PLN, although a much more serious and sometimes fatal condition of protein loss can occur in rare cases.[19,25] Other toxicoses including hepatotoxicosis, neutropenia and anemia have been observed, although these occur infrequently. Drug holiday, dose reduction and schedule modification represent extremely useful tools for managing these toxicoses.

Additional Molecular Targets

While kinases have represented the most common target for therapeutic intervention, several other proteins are critical for cancer cell growth and survival. The heat shock protein HSP90 is responsible for folding several client proteins, many of which are oncogenes (KIT, MET, BRAF, AKT). HSP90 inhibitors block protein folding, resulting in protein degradation and tumor cell death. The HSP90 inhibitor STA-1474 showed good activity in dogs with a variety of solid tumors, particularly MCTs, in a phase 1 study.[26] A subsequent regimen-finding study in dogs with MCTs showed that 2-day consecutive dosing was most effective at inducing objective responses and providing sustained KIT downregulation (London et al, unpublished). Exportin 1 (XPO1)[27] is the sole nuclear exporter of several major tumor suppressor and growth regulatory proteins.[28,29] Its expression is upregulated in hematologic malignancies and solid tumors, often correlating with a poor prognosis. KPT-335 (verdinexor), an orally bioavailable small molecule XPO1 inhibitor, has shown activity in dogs with T and B cell lymphoma in phase 1 and 2 clinical trials.[30] Verdinexor is undergoing clinical development for treatment of canine lymphoma.

Histone deacetylase (HDAC) enzymes remove acetyl groups from histone proteins and regulate gene transcription.[31] HDAC inhibitors (HDACi) can alter the expression of epigenetically silenced genes and thereby inhibit tumor progression.[32,33] The anti-epileptic drug valproic acid is an HDACi that has activity in several tumor models.[34-36] In a phase 1 trial, valproic acid was given prior to doxorubicin in dogs with cancer.[37] Objective responses were observed and a few occurred in traditionally anthracycline-resistant tumors; importantly, the combination was safe and well tolerated. Lastly, RV1001 is a novel orally bioavailable small molecule inhibitor of phosphatidylinositol-3-kinase delta (PI3Kdelta), a cellular signaling protein known to contribute to tumor growth. RV1001 has activity against PI3Kdelta at low nanomolar concentrations, with effects on beta and gamma isoforms at low micromolar concentrations. A phase 1 clinical trial of RV1001 in dogs with naive or relapsed T or B cell lymphoma revealed excellent activity, with an objective response rate of 62% (3 CR, 10 PR).[38] Inhibition of pAKT was demonstrated in tumor samples within 2 hours of RV1001 dosing, showing rapid target modulation. RV1001 is undergoing further development for the treatment of canine lymphoma.

Summary

The development of small molecule inhibitors targeting key proteins that drive tumor growth and survival has transformed human cancer therapy. Such agents are only beginning to impact veterinary oncology with the availability of toceranib and masitinib, although more are likely to become available in the near future. The combination of small molecule inhibitors with standard chemotherapy and radiation therapy likely will markedly enhance treatment outcomes for veterinary patients in the future.

CHAPTER 343

Complications of Anticancer Therapy

Louis-Philippe de Lorimier, Craig A. Clifford

Client Information Sheet: Side Effects and Complications of Anticancer Drugs

Introduction

Traditionally, because of the mere objective to kill as many cancer cells as possible with each dose administered, the dosage of conventional cytotoxic agents has been based on the concept of maximum tolerated dose (MTD) rather than the standard pharmokinetic/pharmodynamic (PK/PD) modeling (see ch. 160).[1] With this concept, some side effects will be expected and accepted ("tolerated" by the patient) when dosing below the MTD, and what is considered tolerated is determined based on the severity (grading) of the observed side effects.[2] When using anticancer therapy, the potential benefits should always outweigh the risks, but even with a thorough knowledge of the common side effects, it is rarely possible to accurately predict how an individual will react to a specific drug until it has been administered (i.e., the patient's own MTD is unknown). Most anticancer drugs have dosage ranges that will vary depending on the condition treated, the presence of co-morbidities, the age of the patient, the pre-treatment blood test results (organ function), the species to be treated, the breed of the patient, and the user's experience.

Most cytotoxic drugs are dosed on a mg/m^2 basis, the calculation based on body surface area (BSA) being presumably a more appropriate predictor of drug pharmacokinetics. However, the limitations of this approach have been demonstrated and dosing pets based on BSA may result in overdosing smaller patients (<10-15 kg), and possibly underdosing very large dogs.[3,4] For this reason, certain chemotherapy drugs may be best dosed on a mg/kg basis in smaller patients, such as the commonly used carboplatin and doxorubicin.

Corticosteroids are arguably the class of anticancer drugs with the most consistent side effect profile, polyuria/polydipsia (PU/PD) being the most noticeable one negatively impacting both the patients' and owners' quality of life.

New therapeutic classes of anticancer drugs are emerging (e.g., tyrosine kinase inhibitors, therapeutic vaccines, monoclonal antibodies) and the MTD concept may not be best suited to establish the appropriate dosage with these novel oncology treatments. For some of these newer drugs, *in vivo* "target inhibition" can be studied to help determine optimal dosing, which may be well below the MTD in some cases.[5] The common complications and side effects of anticancer therapy are generally classified by system, and a common terminology criteria and grading scheme has been established.[2] An expression that has long been used to describe the most common complications was "a BAG of side effects," which stood for Bone marrow (suppression), Alopecia, and Gastrointestinal. It is obvious that other systems can be affected.

Myelosuppression

Traditional cytotoxic chemotherapy agents are myelosuppressive by nature, since they affect rapidly dividing cells. The enzyme L-asparaginase is an exception amongst traditional anticancer agents, in that it is generally not myelosuppressive in and of itself. Typically, conventional chemotherapy drugs may cause various degrees of neutropenia and/or thrombocytopenia, since neutrophils and platelets have short bone marrow transit times and circulating half-lives. With red blood cells having longer bone marrow transit time and circulating half-life, a resulting anemia from chemotherapy may nevertheless happen in certain individuals, especially over the course of longer multi-agent protocols. The severity of cytopenias is graded from 1 to 4 (E-Table 343-1).[2]

E-TABLE 343-1

Grading of Cytopenias from Anticancer Therapy

ADVERSE EVENT	GRADE 1	GRADE 2	GRADE 3	GRADE 4
Neutropenia	1.5 k/mcL to <LLN	1.0-1.499 k/mcL	0.5-0.999 k/mcL	<0.499 k/mcL
Thrombocytopenia	100 k/mcL to <LLN	50-99 k/mcL	25-49 k/mcL	<25 k/mcL
Anemia (PCV)				
Dogs	30% to <LLN	20-30%	15-20%	<15%
Cats	25% to <LLN	20-25%	15-20%	<15%

LLN, Lower limit of normal; *PCV*, packed cell volume.

Adapted from the VCOG-CTCAE grading system.[2]

With lymphoma, certain cytopenias may be encountered at diagnosis, before any therapy is started, especially anemia (often non-regenerative anemia of chronic disease) and thrombocytopenia (often with an immune-mediated component, or resulting from bone marrow infiltration). Anemia and thrombocytopenia are also common with visceral hemangiosarcoma at diagnosis; the regenerative anemia, from internal blood loss and microangiopathy, and the thrombocytopenia, resulting from consumption and destruction, both generally resolve following surgery (i.e., splenectomy) and before initiation of chemotherapy.

With high grade lymphomas and acute leukemias, myelophthisis may occur and lead to more pronounced cytopenias at diagnosis or following chemotherapy. This is a situation where L-asparaginase and corticosteroids might be best used initially, owing to their lack of myelosuppressive effects.

The nadir, or low point in the cell count following treatment, varies between chemotherapy drugs. Most often, it occurs around 6-8 days following the administration of the commonly used cytotoxic drugs including the vinca alkaloids (vincristine, vinblastine, vinorelbine), doxorubicin, mitoxantrone, and high-dose pulse alkylators (cyclophosphamide, lomustine in dogs). Carboplatin causes a nadir that manifests closer to 14 days post-treatment in dogs, and around 14 to more than 25 days in cats.[6,7] Lomustine is also unpredictable in cats, with nadirs happening between 7 to 28 days following administration, depending on the individual and the dosage used.[8]

Even though all cytotoxic agents may result in neutropenia, depending on the dosage used, the drugs most commonly associated with clinically significant neutropenias in dogs and cats include carboplatin, doxorubicin, lomustine, mitoxantrone, vinblastine, and vinorelbine. Vincristine and cyclophosphamide have often been said to be less myelosuppressive; however, both can result in severe (grade 4) neutropenia when used at the higher end of the dosage range, or in individuals that may be intrinsically more sensitive.[9] A more pronounced neutropenia may be observed when vincristine is co-administered with L-asparaginase. Importantly, dogs with the mutation of the ABCB1-1delta (MDR-1) gene are known to be at higher risk of side effects from various drugs and many chemotherapeutic agents including vinca alkaloids (vincristine, vinblastine, vinorelbine), doxorubicin, mitoxantrone, taxanes, and dactinomycin.[10,11] The breeds most commonly affected with the mutation include the Collie (rough or smooth), Australian Shepherd (miniature or standard), McNab, Silken Windhound, Long-haired Whippet, Shetland Sheepdog, and German Shepherd to name a few.[12] For complete and updated lists of breeds at risk and problem drugs, or for information on the genetic testing, visit the Washington State University Veterinary Clinical Pharmacology Laboratory website (http://vcpl.vetmed.wsu.edu/). Dogs of the previously mentioned breeds should be tested to determine their mutation status, and dose reductions of problem chemotherapy drugs are required for affected individuals. Interestingly, ABCB1-1delta mutations were recently described in cats, and may also affect chemotherapy and other drugs sensitivity in the affected feline patients.[13]

A complete blood cell (CBC) count should be performed prior to administering a pulsed dose of a cytotoxic agent to any patient. Generally speaking, a potentially myelosuppressive drug will not be administered if the neutrophil count is below 2,000/mcL or if the platelet count is below 75,000/mcL. When cytopenias are present that prevent the safe administration of chemotherapy, treatment should be delayed by 2 to 7 days, and a CBC repeated. When delays are necessary, the number of days should be based on the cell lineage in question (e.g., shorter duration with neutropenia, since the bone marrow transit time is shorter).

Because of reasons discussed above, CBCs should also be repeated 7 days and occasionally 14 days after

therapy as well, to monitor and document the nadir. An increased risk of systemic infection (neutropenic sepsis) is present with neutrophil counts below 1,000/mcL. Prophylactic oral antibacterial therapy is generally recommended in neutropenic patients that do not demonstrate clinical signs of illness (i.e., fever, lethargy), and common choices include trimethoprim/sulfamethoxazole (15-30 mg/kg PO q 12 h), amoxicillin/clavulanic acid (13-15 mg/kg PO q 12 h), and cephalexin (22-25 mg/kg PO q 12 h). Owners should be instructed to monitor their animal at home (general attitude, appetite, body temperature). In a vast majority of cases, the neutropenia will resolve within 2 to 5 days in dogs, and a rebound neutrophilic leukocytosis is often observed following marrow recovery. Episodes of neutropenia in cats may take longer to recover (7 to >14 days), especially following lomustine and carboplatin therapy. After a severe neutropenic episode (<1,000/mcL), dosage of the causative agent should be reduced by 10-20% on subsequent treatments, so as to reduce the risk of serious complications. It is important to know that neutropenia, being an indicator of the MTD being reached or approached, may be associated with a better prognosis (remission duration and survival times) in dogs and in people with lymphoma.[14] Trying to completely avoid any neutropenic episode at all cost ultimately may be detrimental to the patient and favor early resistance and relapse.

Cytotoxic drugs affecting both the gastrointestinal tract and bone marrow may be more likely to result in neutropenic septic episodes, likely because of an increased risk of bacterial translocation from the gastrointestinal tract. Two studies demonstrated that risk factors for the development of sepsis in dogs following chemotherapy included lower body weight, the diagnosis of lymphoma, and the administration of doxorubicin or vincristine.[15,16]

Severe neutropenic episodes resulting in clinical signs of illness, typically including fever, lethargy and anorexia, are to be treated aggressively with the patients hospitalized and monitored more intensively to prevent sepsis. This includes more comprehensive monitoring of blood glucose, lactate levels, electrolytes, as well as closer monitoring of patient parameters such as blood pressure (see ch. 99), temperature, etc. Supportive therapy for sepsis should be undertaken (see ch. 132). Digestive signs should be treated when present (see below), as are other findings on the biochemical profile (e.g., electrolyte imbalances) or complementary tests. Blood cultures would logically be optimal but are rarely necessary or rewarding knowing that most neutropenic septic episodes respond rapidly and completely with aggressive empirical therapy, marrow recovery being the most crucial element.

The use of colony stimulating factors (e.g., rhG-CSF) is controversial and of questionable benefit to most patients, since high endogenous levels of canine G-CSF are likely present during the neutropenic episode. Furthermore, a recent study demonstrated that dogs receiving rhG-CSF for neutropenic septic episodes were at higher risk for longer hospital stays and in-hospital mortality.[16] In most patients with uncomplicated episodes of neutropenic sepsis, the fever abates rapidly, within hours after supportive therapy is begun, and the patient released home, away from the risk of nosocomial infections. A study on 70 canine cases of chemotherapy-induced neutropenic septic episodes reported a mortality rate of 8.5%.[16]

Cats appear to develop true neutropenic sepsis much less commonly than do dogs, even though the nadirs are often prolonged in this species.

Transient thrombocytopenia often follows cytotoxic chemotherapy administration. This is most commonly observed with carboplatin, lomustine, dacarbazine, melphalan, dactinomycin, cytosine arabinoside and doxorubicin. Clinical signs are rarely observed with platelet counts above 25,000/mcL, but patients with severe thrombocytopenia should be monitored for ecchymoses, petechiae, and bleeding (gastrointestinal, gingival, epistaxis) and avoid trauma. Certain alkylating agents may cause cumulative, sometimes not completely reversible thrombocytopenia following chronic administration, including lomustine, melphalan and chlorambucil.[17] Regular CBCs should be monitored and the drug discontinued if a trend is observed or if the platelet count falls below 100,000-125,000/mcL. The use of thrombopoietic agents is controversial and poorly documented at present.

Two orally administered tyrosine kinases, toceranib phosphate (Palladia) and masitinib mesylate (Kinavet-CA1, Masivet), were developed and marketed to treat canine mast cell tumors. Even though they are not considered to be truly myelosuppressive like traditional cytotoxic agents, cytopenias may be observed with both veterinary-approved kinase inhibitors, secondary to growth signal inhibition, including neutropenia, thrombocytopenia, and anemia.[18-21] Most often, these cytopenias will be mild and reversible but may occasionally be severe enough to warrant a treatment delay (drug holiday), until the cell counts return to normal.

Dermatologic Complications

Alopecia, Changes in Pigmentation

Chemotherapy-induced alopecia is a common complication in people and, though it is a cosmetic side effect, it bears an important negative psychological impact for many patients. The loss of hair following chemotherapy is less of a problem in veterinary oncology, but certain canine breeds with continuously growing hair may shed more than usual or truly become partially or completely alopecic. More commonly affected breeds include the Maltese, Bichon Frisé, Poodles, certain Terrier breeds, Shih Tzu, and Old English Sheepdog. This side effect does not negatively impact their quality of life, and is reversible once treatment is discontinued (Figure 343-1). Cats may occasionally lose whiskers or facial hair (most typically) while undergoing chemotherapy.

FIGURE 343-1 Chemotherapy-induced alopecia in a Shih Tzu treated for lymphoma.

Transient pigmentation alterations, most often depigmentation, have been reported in dogs treated with toceranib phosphate (Palladia), especially affecting the nose, footpads, lips, and less commonly the entire hair coat.[19] This complication, like alopecia, appears to be purely cosmetic and does not negatively impact the quality of life. It may be stem from the KIT protein inhibition, negatively impacting the skin melanocytes, and resolves upon discontinuation of the drug.

Extravasation

Certain chemotherapy drugs are irritants when administered perivenously, and include the platinum drugs (carboplatin and cisplatin), dacarbazine, mitoxantrone, and the taxanes. The local reaction with extravasation of irritants is mild to moderate and includes some degree of discomfort, erythema, crusting, and edema. True vesicants include the vinca alkaloids (vincristine, vinblastine, vinorelbine), anthracyclines (doxorubicin, epirubicin), dactinomycin, and mechlorethamine, and cause much more serious tissue damage when extravasated.

It is better to prevent extravasation injuries than to treat them after they occur. Using a vein that has not been used for >48 hours and installing a long catheter with a "clean stick" technique (see ch. 75) just before chemotherapy administration reduces the risks. Fluid pumps should be avoided, and simple gravity or manual syringe pushing favored. Minimal bandaging is recommended during chemotherapy administration, so as to see the catheter site and point of dermal entry as much as possible. If or when an extravasation of chemotherapy is observed, chemotherapy administration should be immediately discontinued, and negative pressure applied to the catheter to remove as much as possible of the agent at the site of perivenous leakage. Negative pressure should then be applied as the catheter is gently removed. Occlusive bandaging should be

avoided.

For extravasation of vinca alkaloids (vincristine, vinblastine, vinorelbine), it is recommended to apply warm compresses, for 15-20 minutes duration, four times a day, for 2-3 days. Some recommend instilling sterile saline (5-10 mL) around the site of leakage, to dilute the vesicant in local tissues. Others mention topical administration of dimethyl sulfoxide (DMSO), sometimes mixed with a corticosteroid, after heat application but these approaches are of arguable efficacy. The local infiltration of hyaluronidase has been described and may help reduce the severity of local tissue damage from vinca alkaloids, but the erratic availability of the drug makes it difficult to use consistently.[22] In general, vinca extravasation results in mild to moderate tissue damage, less commonly severe, and completely heals over 2-3 weeks without permanent consequences (Figures 343-2, *A-D*).

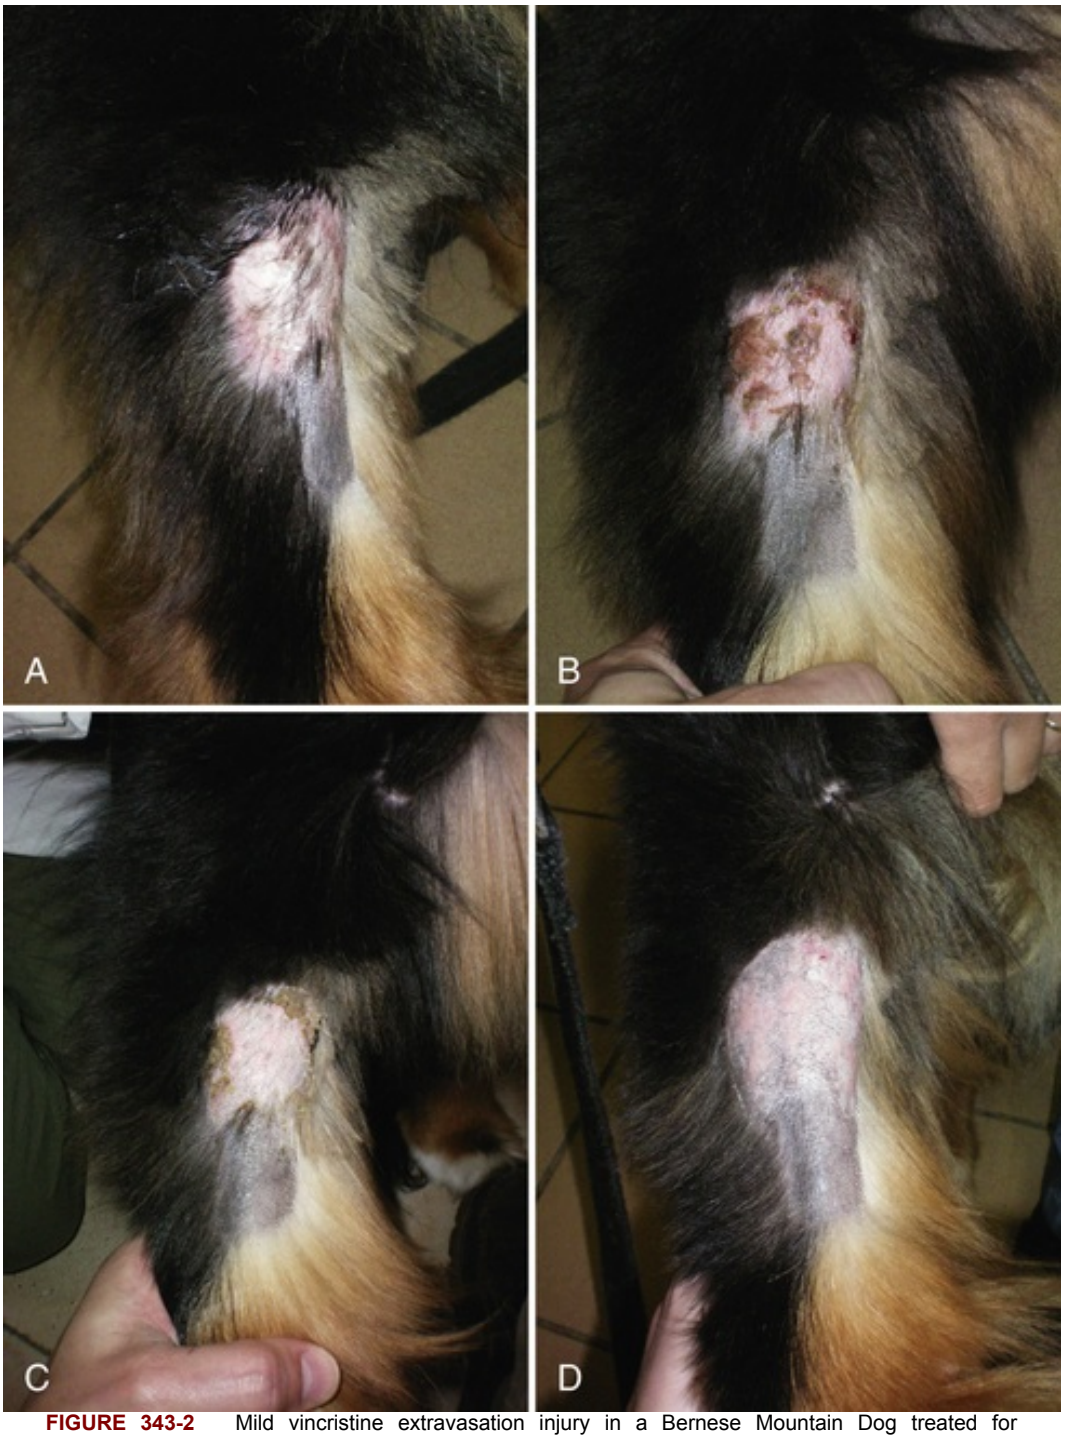

FIGURE 343-2 Mild vincristine extravasation injury in a Bernese Mountain Dog treated for

lymphoma, demonstrating progression of the lesion at days 5 **(A)** and 10 **(B),** and then improvement on days 13 **(C)** and 17 **(D).**

More serious, extravasation of doxorubicin, epirubicin or dactinomycin can result in very severe local tissue damage, sometimes progressing to dissecting necrosis in the deep tissues eventually requiring debridement surgery or, when damage appears irreversible, limb amputation (Figure 343-3). Contrary to the approach of extravasated vinca alkaloids, cold compresses on the site of injury are recommended with extravasation of these agents, for 15-20 minutes duration, four times a day, for 2-3 days. Again, the application of topical DMSO is of dubious benefit, but the timely intravenous administration of dexrazoxane, an iron chelator, may help markedly reduce and sometimes completely prevent the extent of local tissue damage.[23,24] Dexrazoxane is dosed at 10 times the dosage of doxorubicin (e.g., 300 mg/m^2 if the dog received 30 mg/m^2 of doxorubicin) and administered intravenously as soon as possible after the extravasation has occurred, and then ideally repeated 24 and 48 hours later. In rat studies, a benefit was observed when utilized within a 6-hour window of the extravasation.

FIGURE 343-3 Severe extravasation injury in a Rottweiler with osteosarcoma treated with doxorubicin 12 days prior.

Mechlorethamine extravasations can be treated with a 2.5% solution of sodium thiosulfate, a sulfur group donor, injected directly into the tissues at the extravasation site (same volume as the volume of mechlorethamine administered).

In all cases of extravasation, adequate analgesia should be provided with nonsteroidal anti-inflammatory drugs or corticosteroids (see ch. 164), and adjuvant analgesic drugs (including antihistamines) as needed (see ch. 126 and 166). Occasionally, antibiotics may be beneficial when secondary bacterial infections are confirmed or suspected. Importantly, self-trauma should always be prevented (e.g., Elizabethan collar).

Palmar-Plantar Erythrodysesthesia (PPES)

Also known as the "hand-foot syndrome" in people, PPES is a frequent dermatologic toxicosis associated with the intravenous administration of liposomal doxorubicin in dogs and cats.[25-29] It may present as discomfort, erythema, alopecia, and ulceration in the axilla, inguinal area, and skin surrounding the footpads in dogs, and as focal alopecia on the chin and limbs in cats.[25-29] Though PPES is self-limiting, the discomfort may be severe enough to warrant treatment delays or discontinuation. The co-administration of oral pyridoxine (vitamin B_6; 50 mg PO q 8 h) markedly reduces the severity of PPES lesions in dogs.[26]

Gastrointestinal Complications

Gastrointestinal (GI) side effects from anticancer therapy are often the most feared by human cancer patients and owners of cancer-bearing pets, and for good reasons as they always negatively impact the quality of life. The toxicosis may result from direct damage to the rapidly dividing cells of the intestinal crypts, or from a stimulation of the chemoreceptor trigger zone (CTZ), in the medulla oblongata, via neurotransmitters such as serotonin and substance P binding to 5-HT_3 and NK_1 receptors, respectively. Vomiting from stimulation of the CTZ is an acute phenomenon, often occurring within 24 hours of drug administration, and the chemotherapy agents most commonly at fault include cisplatin (by far the most emetogenic), dacarbazine, streptozotocin, doxorubicin, and mechlorethamine. Anorexia, nausea, vomiting, and diarrhea caused by toxicosis affecting immature enterocytes generally occurs 1 to 5 days following administration, and the drugs most at risk of causing clinical signs include doxorubicin, epirubicin, dactinomycin, mitoxantrone, dacarbazine, vinca alkaloids, and taxanes. The tyrosine kinase inhibitors, toceranib and masitinib, may cause direct GI irritation resulting in anorexia, nausea, vomiting, diarrhea, or hematochezia. NSAIDs are commonly used in cancer-bearing pets for analgesia and for their known anticancer effects. The potential for GI irritation exists, and may be amplified when the non-selective drug piroxicam is combined with certain cytotoxic chemotherapy agents.[30,31] The severity of GI side effects is graded from 1 to 4 (E-Table 343-2).

E-TABLE 343-2

Grading of Gastrointestinal Side Effects from Anticancer Therapy

ADVERSE EVENT	GRADE 1	GRADE 2	GRADE 3	GRADE 4
Anorexia	Coaxing or dietary changes required to maintain appetite	Oral intake altered ≤3 days w/o weight loss; appetite stimulants may be indicated	>3 days duration; significant weight loss (≥10%) or malnutrition; IV fluids, tube feeding or forcefeeding indicated	Life-threatening consequences; TPN indicated; >5 days duration
Nausea	Loss of appetite w/o alteration in eating habits	Salivation or "smacking of lips" <3 days, grade 2 anorexia	Salivation or "smacking of lips" 3-5 days, grade 3 anorexia	Salivation or "smacking of lips" >5 days, grade 4 anorexia
Vomiting	<3 episodes in 24 h, medical intervention not needed	3-10 episodes in 24 h; <5 episodes/day for ≤48 h; parenteral fluids (IV or SC) indicated ≤48 h; medications indicated	Multiple episodes >48 h and IV fluids or PPN/TPN indicated >48 h	Life threatening (e.g., hemodynamic collapse)
Diarrhea	Increase of up to 2 stools/day over baseline; no increase in frequency but consistency decreased over baseline	Increase of 3-6 stools/day over baseline; medications indicated; parenteral fluids (IV or SC) indicated ≤48 h; not interfering with ADL	Increase of >6 stools/day over baseline; incontinence >48 h; IV fluids >48 h; hospitalization; interfering with ADL	Life threatening (e.g., hemodynamic collapse)

ADL, Activities of daily living (eating, sleeping, defecating and urinating); *PPN*, partial parenteral nutrition; *TPN*, total parenteral nutrition.

Adapted from the VCOG-CTCAE grading system.[2]

Vincristine, via a neurotoxic effect on enteric motor function, may cause temporary ileus (dogs and cats)

and occasionally constipation (cats) in the days following administration. Abdominal discomfort, anorexia, nausea or vomiting may occur as a result, and patients may benefit from treatment with the prokinetic drug metoclopramide (0.3-0.5 mg/kg SC, PO q 8 h). In cancer-bearing pets not tolerating vincristine because of its effects on intestinal motility, replacing it with vinblastine may be a valid option.[31]

Chemotherapy-induced anorexia can be approached by offering more palatable foods, and pharmacologic appetite stimulation may also be used when necessary (see ch. 23). Commonly used drugs include cyproheptadine (dogs: 0.2 mg/kg PO q 12-24 h; cats: 2-4 mg PO q 12-24 h) and mirtazapine (dogs: 0.5 mg/kg PO q 24 h; cats: 0.5 mg/kg PO q 24-72 h).[33] Corticosteroids are generally not considered great choices for appetite stimulation because of their catabolic effects, but may be used at low dosage (e.g., prednisone at 0.5 mg/kg PO q 24 h, dexamethasone at 0.05 mg/kg PO q 24 h) and for short term use if not contraindicated. Oxazepam and megestrol acetate have been used on occasion for appetite stimulation in pets, the latter being a common choice in people with cancer cachexia, but are seldom recommended for this use nowadays. Low-dose intravenous propofol was shown to significantly increase food consumption in healthy dogs without causing excessive sedation, but the desired effect did not last long enough (15 minutes) to make it clinically useful.[34] A novel veterinary approved appetite stimulant, capromorelin, will soon become available as an option for anorexic pets. Nausea is a common underlying cause of anorexia, and may lead to vomiting when severe enough. Educating owners on how to recognize nausea in their pet is crucial. Signs of nausea may include loss of appetite, hypersalivation, licking the lips, turning the head when offered food, and vomiting. Offering more palatable foods to a nauseated animal may worsen the nausea and is not recommended. Treating actual or suspected nausea is crucial, even when no vomiting is reported, and may help improve the appetite. The drugs recommended to treat nausea are roughly the same as the ones used for vomiting (see below, and ch. 39).

Mild vomiting (<3 episodes/24 h) may be approached by food restriction for 12-24 hours, followed by gradual introduction of frequent small meals of a bland diet. If vomiting occurs when the stomach is empty (e.g., morning), gastric acid-suppressing drugs may be beneficial and include famotidine (0.5-1 mg/kg IV or PO q 12 h) and omeprazole (0.5-1 mg/kg PO q 24 h). With moderate vomiting, the use of antiemetics is warranted, and supportive therapy with parenteral crystalloids becomes indicated in more severe cases. The centrally acting antiemetic maropitant, a neurokinin 1 (NK_1) receptor inhibitor, is approved for use in dogs to prevent vomiting associated with cisplatin, and was also shown to be effective at reducing vomiting following doxorubicin administration.[35-37] Maropitant can be used both in dogs (1 mg/kg IV, SC q 24 h; 2 mg/kg PO q 24 h) and cats (1 mg/kg IV, SC, PO q 24 h).[35-38] Other antiemetics include metoclopramide, the $5\text{-}HT_3$ antagonists ondansetron (0.5-1 mg/kg IV, PO q 12-24 h) and dolasetron (0.5-1 mg/kg SC, IV q 12-24 h), and prochlorperazine (0.1-0.5 mg/kg IV, IM, SC q 8 h; 0.5-1 mg/kg PO q 8-12 h). Though antacids do not have direct antiemetic effects, their use may be beneficial to patients with severe nausea and vomiting. Severe vomiting requires supportive fluid therapy, and monitoring of chemistry profiles including electrolytes and acid-base status. Parenteral nutrition may also be required in more severe cases. Dosage reduction (10-20%) and a preventive approach should be implemented for subsequent administration of anticancer drugs that resulted in moderate to severe vomiting. A change of protocol may be required in more severe cases.

When treating macroscopic mast cell tumors, some of the GI clinical signs may result from hyperhistaminemia and hyperacidity following spontaneous degranulation or as a result of cytotoxic therapy.[39,40] High histamine levels, via the binding to H2-receptors on parietal cells, result in excessive secretion of hydrochloric acid, low gastric pH, and gastric irritation.

Mild diarrhea or soft stools can be approached with the feeding of a bland, highly digestible diet. With more severe chemotherapy-induced diarrhea, loperamide (0.1 mg/kg PO q 8-12 h) can be used in non-MDR-1 mutant dogs.[41,42] The antibiotics metronidazole (15 mg/kg PO q 12 h) and tylosin (10-20 mg/kg PO q 12 h) are also common choices. The use of naturally occurring clay to treat chemotherapy-induced diarrhea has also been shown to be beneficial.[43] Probiotics are now routinely used in clinics to treat acute or chronic diarrhea, and can be combined with other antidiarrheal therapies (see ch. 40, 167, and 178). A study evaluating the effect of maropitant to prevent vomiting from doxorubicin, serendipitously found that it also significantly reduced the frequency and severity of diarrhea in treated dogs, when compared to placebo.[37] Another placebo-controlled study evaluated the prophylactic use of trimethoprim-sulfadiazine (TMS) in dogs treated with doxorubicin for osteosarcoma and lymphoma.[44] The treated dogs (TMS group) had a significantly reduced hospitalization rate, and lower frequency and severity of GI toxicosis when compared to the placebo group.[44]

Mild GI toxicoses do not require dosage modifications. Moderate to severe toxicoses may require

hospitalization for supportive and symptomatic therapy, and should lead to subsequent dosage reductions of 10-25% or change in protocols, in addition to more aggressive prophylactic therapy (antiemetic, antidiarrheals).

Lethargy

Perhaps one of the most common and underreported side effects of anticancer therapy in pets, mild lethargy is generally self-limiting. Drugs most commonly associated with some degree of fatigue in the days following treatment are often also myelosuppressive and include doxorubicin, carboplatin, and lomustine, to name the most common only.

It is important to distinguish fatigue as a temporary and reversible side effect of therapy from lethargy secondary to nausea, anemia, pain, or tumor progression, as these underlying causes should be specifically addressed but chemotherapy-induced lethargy itself generally does not require intervention. Following a first dose of vincristine administered to a chemo naïve lymphoma patient, it is not rare to observe some self-limiting mild lethargy of short duration (generally 2-3 days) while billions of lymphoma cells are rapidly dying, resulting in significant energy consumption by large numbers of activated macrophages. A few weeks later, the same patient, receiving a second and identical dose of vincristine with a lymphoma that is now in partial remission (much smaller tumor burden), may not experience any fatigue.

When lethargy is moderate to severe, additional diagnostic tests should be performed to rule out cytopenias, disease progression, or concurrent disorders. Extreme lethargy in the 24-48 hours following aggressive chemotherapy administered to a chemo naïve lymphoma or lymphoblastic leukemia patient with a large disease burden could be secondary to the uncommon acute tumor lysis syndrome (ATLS; see ch. 344).

Cardiac Toxicosis

Cardiac toxicosis from chemotherapy is uncommon, but well described in pets and mainly associated with doxorubicin. Other drugs (e.g., mitoxantrone, epirubicin) were developed hoping for a similar efficacy profile but reduced risk of cardiotoxicosis. Also, it was demonstrated in dogs that a liposomal form of doxorubicin results in a much lower risk of cumulative cardiotoxicosis.[45]

There are two types of doxorubicin-induced cardiotoxicosis: acute or cumulative. Acute toxicosis presents as transient ventricular arrhythmias occurring during intravenous infusion, secondary to the spontaneous release of histamine and catecholamines, and generally does not bear clinical significance. The more serious cumulative cardiotoxicosis is the result of permanent damage to the cardiomyocytes, specifically oxidative injury to the sarcoplasmic reticulum, leading to reduced contractility, with or without arrhythmias, and to irreversible congestive heart failure (see ch. 247 and 252).

In dogs with no underlying myocardial disease, the risk of permanent cardiotoxicosis rises with cumulative doses above 180-240 mg/m^2. The risk/benefit ratio must be taken into account when treating dogs with underlying myocardial disease or with cumulative doses exceeding 240 mg/m^2. Options then include the use of a less cardiotoxic agent, or the co-administration of intravenous dexrazoxane (dosed at 10 times the doxorubicin dosage), an iron chelator known to reduce the risk of cardiotoxicosis from doxorubicin in dogs and people.[46,47]

Hepatotoxicosis

Lomustine (CCNU) is known to be hepatotoxic in dogs, and serum alanine aminotransferase (ALT), an indicator of hepatocellular damage, increases in up to 86% of treated dogs.[48-54] This hepatotoxicosis is cumulative and often irreversible. Acute liver failure may also rarely occur following a single treatment. In addition to pre-treatment CBC, the ALT should be monitored before each dose of lomustine and elevations of more than three times the upper normal limit should suffice to delay or discontinue treatment, unless the benefits of continued therapy clearly outweigh the risks. A prospective randomized clinical trial evaluated the co-administration of hepatoprotectants, combining S-adenosylmethionine and silybin, to lomustine in cancer-bearing dogs.[54] A reduced rate and severity of liver enzyme elevations was observed in dogs receiving the hepatoprotectants, when compared to dogs treated with lomustine alone.[54] In another study, dogs treated with lomustine were given the nutraceutical alpha-lipoic acid as a hepatoprotectant, but conclusions could not be made regarding the efficacy of this approach, owing to the lack of controls.[55] As a general rule, the concurrent use of hepatoprotectants is recommended in dogs receiving lomustine. Hepatotoxicosis in cats

receiving lomustine appears to be much less common.[56] The severity of liver enzyme and bilirubin elevations is graded from 1 to 4 (E-Table 343-3).

E-TABLE 343-3

Grading of Liver- and Kidney-Related Elevations from Anticancer Therapy

ALTERED SERUM BIOCHEMICAL PARAMETER	GRADE 1	GRADE 2	GRADE 3	GRADE 4
ALP				
Dogs	>ULN to 2.5 × ULN	>2.5-5.0 × ULN, transient (<2 wks)	>5-20 × ULN	>20 × ULN
Cats	>ULN to 1.25 × ULN	>1.25-1.5 × ULN, transient (<2 wks)	>1.5-2.0 × ULN	>2 × ULN
ALT				
Dogs	>ULN to 1.5 × ULN	>1.5-4.0 × ULN, transient (<2 wks)	>4.0-10 × ULN	>10 × ULN
Cats	>ULN to 1.25 × ULN	>1.25-1.5 × ULN, transient (<2 wks)	>1.5-2.0 × ULN	>2 × ULN
Bilirubin	>ULN to 1.5 × ULN	1.5-3.0 × ULN	3-10 × ULN	>10 × ULN
BUN	>1 to 1.5 × baseline; >ULN to 1.5 × ULN	>1.5 to 3 × baseline; >1.5 to 2.0 × ULN	>3 × baseline; >2.0-3 × ULN	>3 × ULN
Creatinine				

ALP, Alkaline phosphatase; *ALT*, alanine aminotransferase; *BUN*, blood urea nitrogen; *ULN*, upper limit of normal reference range.

Adapted from the VCOG-CTCAE grading system.[2]

Elevations in serum ALT are also reported to occur with the administration of streptozotocin to dogs with insulinoma.[57]

Vincristine is not hepatotoxic but, like other chemotherapy agents, is mainly eliminated via biliary excretion. In patients with marked cholestasis, as can be seen occasionally with hepatic infiltration by lymphoma, vincristine should temporarily be avoided or used at lower dosages in light of an increased risk of toxicosis resulting from a prolonged circulating half-life.

Even though they may not be considered true hepatotoxicoses, elevations of the corticosteroid-induced alkaline phosphatase and vacuolar hepatopathy are commonly associated with the use of corticosteroids in dogs, cancer-bearing or not (see ch. 285). Mild to moderate reversible liver enzyme elevations are also reported relatively commonly with the veterinary-approved tyrosine kinase inhibitors, toceranib and masitinib, and monitoring is indicated with chronic therapy.[19,58]

Neurologic Toxicosis

Neurologic toxicosis is uncommon in veterinary cancer patients when compared to people. Vincristine is known to cause GI signs in pets (ileus, constipation in cats) from its neurotoxic effect on enteric motor function, but very rarely a peripheral neuropathy similar to the dose-limiting toxicity observed in people.[59] The risk of central neurotoxicosis from vincristine, normally extremely low, may be higher in dogs homozygous for the ABCB1-1delta mutation.[60]

The antimetabolite 5-fluorouracil (5-FU) rarely causes clinically significant signs of neurotoxicosis in dogs when used at the standard dosage (150 mg/m^2 IV).[61] It is, however, extremely neurotoxic with accidental exposures to higher doses in dogs, and 5-FU is absolutely contraindicated in cats owing to a fatal neurotoxicity in this species.[62,63]

The alkylator chlorambucil, especially when used as a high-dose pulse regimen, may rarely cause reversible myoclonus and seizures in cats and dogs.[64,65] Chlorambucil is known to cause neurotoxic effects in the form of mood alterations and seizures in people as well.[66,67]

Mechlorethamine rarely causes reversible diminished hearing or hearing loss in people, and anecdotal reports of partially reversible hearing loss have been observed in cats.[68]

Urinary Tract Toxicosis

Nephrotoxicosis

Certain chemotherapy drugs are known nephrotoxicants requiring intense saline diuresis to reduce the risk of kidney disease in pets. These include cisplatin (dogs only), ifosfamide (dogs and cats), and streptozotocin (dogs).[57,69-71] Cancer-bearing pets with known or suspected kidney disease should not be treated with these drugs, owing to a high risk/benefit ratio. The close monitoring or renal parameters is advised, and their administration should be discontinued if creatinine elevations are observed. The severity of BUN and creatinine elevations is graded from 1 to 4 (see E-Table 343-3).

Doxorubicin has been described as a potential nephrotoxicant in cats, especially when administered at the dosage commonly used in dogs.[72] It has been demonstrated that the drug can be safely administered to cats at a dosage of 22-25 mg/m^2, and that the very low dosage recommended (1 mg/kg) following the initial toxicity study may have been too much of a dose reduction.[73] Renal parameters should be monitored in cats treated with doxorubicin, and prudence is recommended. In addition to the previously mentioned hepatotoxicity, lomustine (CCNU) may also be a potential nephrotoxicant in dogs, whether it is administered with a high-dose pulse or low-dose metronomic protocol.[53,74]

NSAIDs, including piroxicam and many veterinary approved molecules, are known for their nephrotoxic potential independent of their cyclooxygenase (COX)-2 selectivity. They are commonly administered to cancer-bearing pets, both for their analgesic and potential anticancer properties. Caution should be observed and regular monitoring performed, especially when combining their use to other potential nephrotoxicants, with chronic use, or when patients have questionable or decreased renal function. The combination of NSAIDs with cisplatin is simply too toxic and should be discouraged.[75-77]

The bisphosphonates are a class of drugs used in cancer patients for their inhibitory effect on osteoclasts, which is beneficial in the treatment of osteolytic bone pain and hypercalcemia. They are generally very well tolerated but both pamidronate and zoledronate, two potent and clinically useful intravenous aminobisphosphonates, showed the potential for nephrotoxicosis in preclinical toxicology studies. Clinical studies in cancer-bearing dogs showed that they could be safely administered to dogs and cats, alone or combined with other anticancer therapies.[78-85] The duration of infusion appears to play a role in their nephrotoxicity, and pamidronate (dogs: 1-2 mg/kg IV; cats: 1-1.5 mg/kg IV) should be administered over 2 hours, while zoledronate (dogs: 0.15-0.25 mg/kg; cats: 0.15-0.2 mg/kg) requires a shorter 15-minute infusion, both in 0.9% saline.[78-85]

The tyrosine kinase inhibitor masitinib mesylate has been shown to cause a protein-losing nephropathy (PLN) in up to 10% of treated pets, resulting in severe proteinuria in some cases.[20,21,86] Renal parameters, serum albumin, urinalyses and urine protein/creatinine ratios must be monitored, and the administration of the drug discontinued with progressive proteinuria. This drug-induced PLN is apparently reversible in most cases if identified early and the causative agent is removed.[20,21,86]

Carboplatin, unlike cisplatin, is not nephrotoxic at the clinically useful dosage. Studies in cats confirmed that, optimally, dosage would be individualized and based on glomerular filtration rate and area under the curve.[87-89]

Urothelial Toxicosis

Sterile hemorrhagic cystitis (SHC) is a well-recognized complication of cyclophosphamide and ifosfamide administration, direct urothelial irritation being chiefly caused by acrolein, an inactive metabolite. The risk of SHC in dogs may vary depending on the protocol of cyclophosphamide administration and cumulative doses, and the co-administration of furosemide or the thiol-based compound mesna was shown to significantly reduce this risk.[90-94] Cats may be at lower risk of developing SHC, but caution should be used when predisposing factors are present, including feline idiopathic cystitis.

If the use of mesna may not be mandatory with standard dosing of cyclophosphamide in dogs, it is recommended with ifosfamide or with high-dose (myeloablative) cyclophosphamide, as both would otherwise result in a high rate of serious SHC.[70,71,95-97] Ifosfamide, as previously mentioned, also requires saline diuresis to reduce the risk of nephrotoxicosis.

Various treatment strategies have been described anecdotally for SHC. It is imperative first and foremost to discontinue administration of the causative agent indefinitely, and to confirm SHC by ruling out other differentials (urinary tract infection, crystalluria, bladder tumor, etc.).

The signs of SHC generally tend to abate once the cause has been removed, but may take weeks or months to do so with severe cases. Early detection, when microscopic hematuria is confirmed without detectable clinical signs followed by discontinuation may improve the chances of mild, rapidly resolving SHC.

Symptomatic therapy is most typically used with SHC, and often includes the use of NSAIDs, to control discomfort and inflammation, and oxybutynin (dogs: 0.2-0.3 mg/kg PO q 8-12 h) to reduce the severity of muscle spasms. Some advocate the use of polysulfated glycosaminoglycan (Adequan) or pentosan polysulfate (Cartrophen Vet), so as to help restore the protective layer of the urinary bladder mucosa. Adjuvant analgesics may be required with more severe cases, and drugs anecdotally used to treat idiopathic cystitis (see ch. 334) may be useful, including amitriptyline (1-2 mg/kg PO q 12-24 h) and gabapentin (8-15 mg/kg PO q 8-12 h). In rare, more extreme and refractory cases, surgery may be required in the form of debridement or partial cystectomy. A medical treatment that has been described for such severe cases is the instillation of diluted formalin in the bladder, a procedure that resulted in improvement of the clinical signs in the few reported cases.[98,99]

Hypersensitivity Reactions (see ch. 137)

Hypersensitivity reactions are not common, but are well recognized with the administration of a handful of chemotherapeutic agents. A true type I, IgE-mediated anaphylactic reaction may occur following the administration of L-asparaginase, the risk being higher with increasing dose numbers. It is recommended to never administer L-asparaginase intravenously, the intramuscular or subcutaneous route being favored in dogs and cats, respectively, and to pre-treat with diphenhydramine (1-2 mg/kg IM or SC) 15 minutes prior to administration.

Doxorubicin may cause an anaphylactoid reaction, with accompanying hypotension and tachycardia, resulting from spontaneous histamine release by mast cells via a non-IgE mediated mechanism.[100] This histamine release, also a cause of cardiac arrhythmias, may be more pronounced with faster administration, hence the general recommendation to deliver as a short 15-30 minutes infusion. When following this recommendation, pre-treatment with diphenhydramine or dexamethasone may not always be required.

Finally, certain chemotherapy agents may be associated with relatively severe cutaneous hypersensitivity reactions in pets, mediated by their inert vehicles. The reactions include pruritus, flushing, urticaria, and facial swelling.[101-103] They were reported with both paclitaxel (cats and dogs) and etoposide (dogs) owing to their carriers, Cremophor EL and polysorbate-80, respectively, and the reactions occurred despite aggressive premedication.[100-103] Newer formulations or methods of administration may help minimize the risk of such reactions, including micellar incorporation of paclitaxel, or the use of the subcutaneous route.[104-106]

Specific and Uncommon Toxicoses

Cisplatin administered intravenously to cats causes severe, fatal pulmonary edema, and is therefore absolutely contraindicated, apart from the occasional low-dose intralesional use.

Pulmonary fibrosis can be a complication associated with high cumulative doses of bleomycin in dogs, but is an uncommon clinical concern in practice.[107] In cats, pulmonary hypertension and fibrosis may result from high cumulative doses of lomustine.[108] Pulmonary fibrosis may also be an uncommon complication in dogs treated with the novel chemotherapy agent rabacfosadine (VDC-1101), under evaluation to become FDA approved for the treatment of canine lymphoma.[109]

Streptozotocin is a chemotherapy agent that is especially toxic to the pancreatic beta-cells, and is used only to treat insulinoma in people and dogs. An expected potential complication is diabetes mellitus, from complete beta-cell ablation, and was observed in 42% of treated dogs in a recent prospective study.[57]

Pancreatitis has been reported to occur in a low percentage of dogs treated with toceranib phosphate.[19] The cause-effect relationship or underlying mechanism has not been established. Appropriate diagnostic tests are recommended when a dog receiving toceranib phosphate has clinical signs compatible with possible pancreatitis.

Lameness, most likely from muscular cramps, has been associated with the use of toceranib phosphate in dogs.[19] The lameness is most typically mild and weight-bearing, and resolves with a short (1-2 doses) drug holiday and an appropriate analgesic approach. Interestingly, the lameness rarely recurs upon re-initiation of

toceranib administration.

CHAPTER 344

Hematopoietic Tumors

David M. Vail

Client Information Sheet: Hematopoietic Tumors

Lymphoma

Lymphoma is the most common hematopoietic tumor affecting dogs and cats and is defined as a proliferation of malignant lymphoid cells affecting primarily the lymph nodes or solid visceral organs, such as the liver or spleen. Lymphoma is a loose categorization of a broad and varied group of several cancer subtypes arising from lymphoid cells. Subcategorization of the various types of lymphoma in dogs and cats is becoming more generally available and ultimately may allow more accurate prognostication and more individualized therapy.

Etiology

The etiology of lymphoma in companion animals is poorly understood. Several etiologic factors have been investigated including genetic and molecular,[1-31] infectious,[32-42] environmental[43-54] and immunologic factors.[55-61] While several genetic and molecular aberrations have been documented in dogs and cats, the clinical and therapeutic relevance of these factors are currently investigational and are therefore beyond the scope of the current chapter and the interested reader is referred to original manuscripts listed. Although certain uncommon varieties of lymphoma in cats have been directly and indirectly associated with feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV), respectively, no strong evidence exists for a retroviral etiology in dogs. Impaired immune function, including immunosuppressive therapy (e.g., renal transplant therapy) has been implicated in both dogs and cats, as has the presence of chronic inflammatory disease such as atopic dermatitis and cutaneous lymphoma. Additionally, an association between gastric *Helicobacter* infection and gastric mucosa associated lymphoid tissue (MALT) lymphoma in cats[62] and perhaps the dog[34] is suggested in one study and since this is a recognized syndrome in people, warrants further investigation.

Classification

Several classification schemes for lymphoma have been evaluated, including those based on anatomic site, World Health Organization (WHO) clinical staging (Table 344-1), histologic/cytologic/immune-phenotype, and genotype.

TABLE 344-1

World Health Organization Clinical Staging for Domestic Animals with Lymphoma

STAGE	CRITERIA
I	Single lymph node
II	Multiple lymph nodes in a regional area
III	Generalized lymphadenopathy
IV	Liver and/or spleen involvement (with or without stage III)

V	Bone marrow or blood involvement and/or any nonlymphoid organ (with or without stages I to IV)
Substage a	Without clinical signs of disease
Substage b	With clinical signs of disease

World Health Organization: *TNM classification of tumors in domestic animals*, Geneva, 1980, World Health Organization.

Canine Classification

In the dog, 80% to 85% of cases are of the multicentric peripheral nodal anatomic type and present as WHO stage III or IV. Alimentary (≈7%), cutaneous (≈6%), mediastinal (≈3%) and miscellaneous extranodal sites (central nervous system [CNS], bone, heart, nasal cavity, and primary ocular locations) are less frequently encountered. As previously mentioned, lymphoma is really a catch-all term for a varied group of several cancer subtypes arising from lymphoid cells. Recent advances in flow-cytometric, histopathologic, immunophenotypic and genotypic characterizations are just now beginning to provide us with data that may subcategorize this disease into prognostically important groups that may ultimately result in more personalized treatment recommendations. The most commonly applied histologic classification scheme is the WHO scheme based on immunophenotype and histologic phenotype.[63] Most cases (≈80%) equate to intermediate or high-grade non-Hodgkin's lymphoma in humans. Most canine lymphoma is of the B-cell immunophenotype, with approximately 25% to 30% being of T-cell derivation. Applying WHO classification, Valli et al. reported the 5 most common lymphoma subtypes in dogs (representing approximately 80% of cases) in decreasing order of frequency as diffuse large B-cell lymphoma (DLBCL), peripheral T-cell lymphoma not otherwise specified, nodal T-zone lymphoma, T lymphoblastic lymphoma, and marginal zone lymphoma.[64] DLBCL can be further classified into the prognostically distinct germinal center and post-germinal center subtypes by gene expression profiling.[23] Diagnosis/classification of clinical specimens by flow-cytometric and histopathologic methods for the purposes of prognoses and treatment will be discussed subsequently. Indolent forms of lymphoma (e.g., T zone, marginal zone) also exist.[63-69]

Feline Classification

Most lymphomas in cats are currently classified by anatomic site and whether they represent small cell/low grade indolent forms versus large cell/intermediate grade phenotypes. The overall prevalence of lymphoma in cats appears to be increasing and the increased prevalence appears due to an increase in the number and relative frequency of the alimentary (and in particular the intestinal) anatomic form of lymphoma in the species.[70-78] The typical signalment for cats with lymphoma cannot be uniformly stated as it varies widely based on anatomic site and FeLV status and therefore will be discussed individually under site-specific discussions and in Table 344-2.[35,79-86] In general, Siamese cats appear overrepresented and within the Siamese breed, there appears to be a predisposition for a mediastinal form that is not FeLV-associated and represents a younger population (median of 3 years).[87] Two distinct forms of lymphoma in cats bear special mention. Large granular lymphocyte lymphoma, a granulated, round cell tumor, usually involves the intestinal tract and abdominal viscera, with systemic involvement being the norm.[88-91] Affected cats are generally FeLV/FIV negative, and a preponderance of CD3+/CD8+ T-cell or NK-cell immunophenotype suggests a small intestinal intraepithelial origin. A second distinct class in cats resembling human Hodgkin's disease also has been characterized.[92-94] This form typically involves solitary or regional nodes of the head and neck and tumors are immunophenotypically classified as T-cell rich, B-cell lymphoma. Histologically, lymph nodes can be effaced by either nodular or diffuse small to blastic lymphocytes with characteristic bizarre or multinucleated cells (Reed-Sternberg-like cells). No association with FeLV or FIV has been documented.

TABLE 344-2

General Characteristics of the Most Commonly Encountered Anatomic Forms of Lymphoma in Cats*

ANATOMIC FORM†	RELATIVE FREQUENCY‡	MEDIAN AGE (YRS)	FELV ANTIGENEMIC	B-CELL	T-CELL	GENERAL PROGNOSIS
Alimentary/gastrointestinal§						
Small cell/low-grade	Common	13	Rare	Rare	Common	Good

Intermediate/large cell	Moderate	10	Rare	Common	Rare	Poor
Nasal	Uncommon	9.5	Rare	Common	Uncommon	Good
Mediastinal	Uncommon	2-4	Common	Uncommon	Common	Poor-Fair
Peripheral nodal	Uncommon	7	Uncommon	Moderate	Moderate	Fair-Poor
Laryngeal/tracheal	Uncommon	9	Rare	ID	ID	Good-Fair
Renal	Rare	9	Rare	Common	Uncommon	Poor-Fair
CNS	Rare	4-10	Rare	ID	ID	Poor
Cutaneous	Rare	10-13	Rare	Rare	Common	Fair
Hepatic (pure)	Rare	12	Rare	Uncommon	Common	Poor

*Data may include overlap or mixing of sites and represents the "post-FeLV era."

†As the primary site of presentation, rather than extension or progression.

‡Common = >50% of clinical presentations; Moderate = 20-50 % of clinical presentations; Uncommon = 5-20% of clinical presentation; Rare = <5% of clinical presentations.

§Includes those reported as "intra-abdominal" where intestinal is a documented component.

CNS, Central nervous system; *FeLV*, feline leukemia virus; *ID*, insufficient data.

Clinical Presentation and Signs

Canine Multicentric Nodal Lymphoma

Lymphoma affects primarily middle-aged to older dogs. No sex predilection is observed, and many different breeds are represented. The prevalence of certain immunophenotypes of lymphoma in dogs varies by breed.[16] Most cases present as relatively healthy dogs (substage a) with incidental generalized lymphadenopathy (Figure 344-1). In dogs with substage b disease, clinical signs are nonspecific and can include inappetence, weight loss, and lethargy. Paraneoplastic hypercalcemia (see ch. 352) may result in presentation for polyuria and polydipsia (see ch. 45). In stage V disease, if bone marrow involvement is marked, peripheral cytopenias may result in presentations reflecting neutropenic sepsis, thrombocytopenic hemorrhage, or anemia.

FIGURE 344-1 Generalized lymphadenopathy in an Italian greyhound with lymphoma (mandibular nodes pictured).

Canine Lymphoma of Other Sites

The presentation and associated clinical signs of lymphoma reflect the anatomic form present in each individual case. *Alimentary forms* may present with signs specific to the gastrointestinal tract (e.g., vomiting [see ch. 39], diarrhea [see ch. 40], weight loss [see ch. 19], inappetence [see ch. 23]). Mediastinal forms may present with respiratory signs (dyspnea [see ch. 28], muffled heart sounds) or with precaval syndrome characterized by pitting edema (see ch. 18) of the head, neck, and forelimbs secondary to tumor compression of the cranial vena cava (Figure 344-2). Nearly half of cases with mediastinal lymphoma are associated with paraneoplastic hypercalcemia,[95] resulting in polydipsia and polyuria as a presenting complaint.

FIGURE 344-2 Precaval syndrome in a dog with mediastinal lymphoma. Pitting edema of the head and neck are noted.

Cutaneous lymphoma has been called the "great imitator" because of its propensity to present in many varying forms. Single or multiple cutaneous lesions can occur, which may appear as mild, eczematous plaques or more impressive nodular tumors (Figure 344-3). Lesions may or may not be pruritic and can occur anywhere on the skin and in the oral cavity.

FIGURE 344-3 Cutaneous T-cell lymphoma (mycosis fungoides) in a dog.

Miscellaneous sites of lymphoma result in signs attributable to the location (i.e., lameness for bone lesions, neurologic compromise for CNS lymphoma).

Feline Lymphoma

No sex predilections have been consistently identified; however, the Siamese breed may be overrepresented.[87] In general, cats are more likely than dogs to present with clinical illness; ≥75% present with substage b signs, reflecting in part the high frequency of gastrointestinal involvement. Cats with alimentary lymphoma or large granular lymphocyte lymphoma present with varying degrees of weight loss (see ch. 19), unkempt hair coat, inappetence (see ch. 23), chronic diarrhea (see ch. 40), and vomiting (see ch. 39). Cats with mediastinal disease are often in severe respiratory distress (see ch. 139) secondary to an intrathoracic mass or the presence of significant pleural effusion (see ch. 244). Cats with renal lymphoma may present with polyuria/polydipsia secondary to renal failure. In the case of nasal lymphoma, sneezing (see ch. 27), chronic serosanguineous nasal discharge, exophthalmos, and facial deformity are common presentations. Cats with CNS lymphoma can present with constitutional signs (anorexia, lethargy) and signs referring to intracranial lesions, spinal lesions, or both. Cats with FeLV-associated lymphoma are more likely to present with anemia. Cats with Hodgkin's-like disease often present with a solitary enlarged mandibular or cervical node and are otherwise clinically healthy (substage a).

Diagnosis

For dogs suspected of having lymphoma, the diagnostic evaluation should include a thorough physical examination, complete blood count (CBC), serum biochemical profile and urinalysis. Optimally, ionized calcium should be measured. Ultimately, obtaining tissue and/or cytologic specimens for a definitive diagnosis is essential.

Physical Examination

A thorough physical examination should include palpation of all assessable lymph nodes and a digital rectal examination in the dog (see ch. 2). Mucous membranes should be evaluated for pallor or petechiae indicative of anemia or thrombocytopenia secondary to myelophthisis and for evidence of major organ failure, including the presence of icterus or uremic ulcers. Abdominal palpation may reveal organomegaly, intestinal wall thickening, or mesenteric lymphadenopathy. The presence of a mediastinal mass and/or pleural effusion may be suspected based on thoracic compression in cats and auscultation in both dogs and cats. An ophthalmic examination (see ch. 11) reveals abnormalities (e.g., uveitis, retinal hemorrhage, ocular

infiltration) in approximately one third to one half of dogs and cats with lymphoma.[96,97]

Hematologic Abnormalities

Hematologic abnormalities occur in the majority of cases. Anemia, when present, is usually normocytic, normochromic, and nonregenerative, reflecting anemia of chronic disease. Regenerative anemias may reflect concomitant blood loss or hemolysis. Cats with FeLV-associated disease may have a macrocytic anemia. If significant myelophthisis is present, the anemia may be accompanied by thrombocytopenia and leukopenia. Circulating atypical lymphocytes may be indicative of bone marrow involvement and leukemia. Hypoproteinemia is more commonly observed in animals with alimentary lymphoma.

Bone marrow aspiration cytology is recommended for staging due to the prognostic significance of marked marrow involvement (see ch. 92); it is also recommended for cases in which lymphoma is suspected but is not documented by assessment of peripheral nodes.

Serum Biochemical Abnormalities

Approximately 15% of dogs with lymphoma (40% of dogs with mediastinal involvement) are hypercalcemic (see ch. 297), often owing to the ectopic production of parathyroid hormone-related peptide (see ch. 352).[95,98] In cases of hypercalcemia of unknown origin, lymphoma should always be considered high on the differential disease list. In addition, the presence of hypercalcemia can serve as a marker for response to therapy. Elevations in blood urea nitrogen and serum creatinine may occur secondary to renal infiltration with tumor, hypercalcemic nephrosis, or dehydration. Liver-specific enzyme or bilirubin elevations may result from hepatic parenchymal infiltration. Serum globulin elevations, usually monoclonal, occur infrequently with B-cell lymphoma.

Retroviral Status

In the cat, retroviral screening (i.e., FeLV [see ch. 223] and FIV [see ch. 222]) is important from diagnostic, prognostic, and husbandry standpoints. The relative frequency of FeLV associations is presented in Table 344-2.

Imaging

Imaging (radiographic, ultrasonographic, computed tomography [CT], positron emission tomography [PET], PET/CT) may be important for diagnosis (especially in cases lacking peripheral lymphadenopathy) and to characterize treatment response. Imaging is equally important for clinical staging (i.e., determining the extent of disease), as results may significantly affect the overall prognosis and alter the caregiver's willingness to pursue therapy. Abnormalities on thoracic radiographs may include evidence of pulmonary infiltrates and thoracic lymphadenomegaly (Figure 344-4). Abdominal radiographs or ultrasound may reveal evidence of abdominal lymphadenopathy and/or spleen and liver involvement. Abdominal ultrasound (see ch. 88) is most important when intestinal lymphoma is suspected in the absence of peripheral lymphadenopathy. Additional imaging, including contrast studies of the gastrointestinal tract, CT, PET/CT, MR or myelographic studies of the CNS, and skeletal radiographic/scintigraphy surveys are reserved for cases in which involvement of the appropriate anatomic site is suspected. PET/CT represents the standard of care for staging and monitoring response in people with lymphoma; however, a lack of widespread availability precludes its routine use in veterinary oncology.[99-102] In the author's practice, unless clinical signs attributable to the abdomen exist, for typical cases of canine peripheral nodal lymphoma, imaging is limited to thoracic radiographs, as there is no prognostic difference between dogs with stage III and stage IV disease (i.e., liver/spleen involvement); however, the presence of cranial mediastinal lymphadenopathy is of prognostic significance.

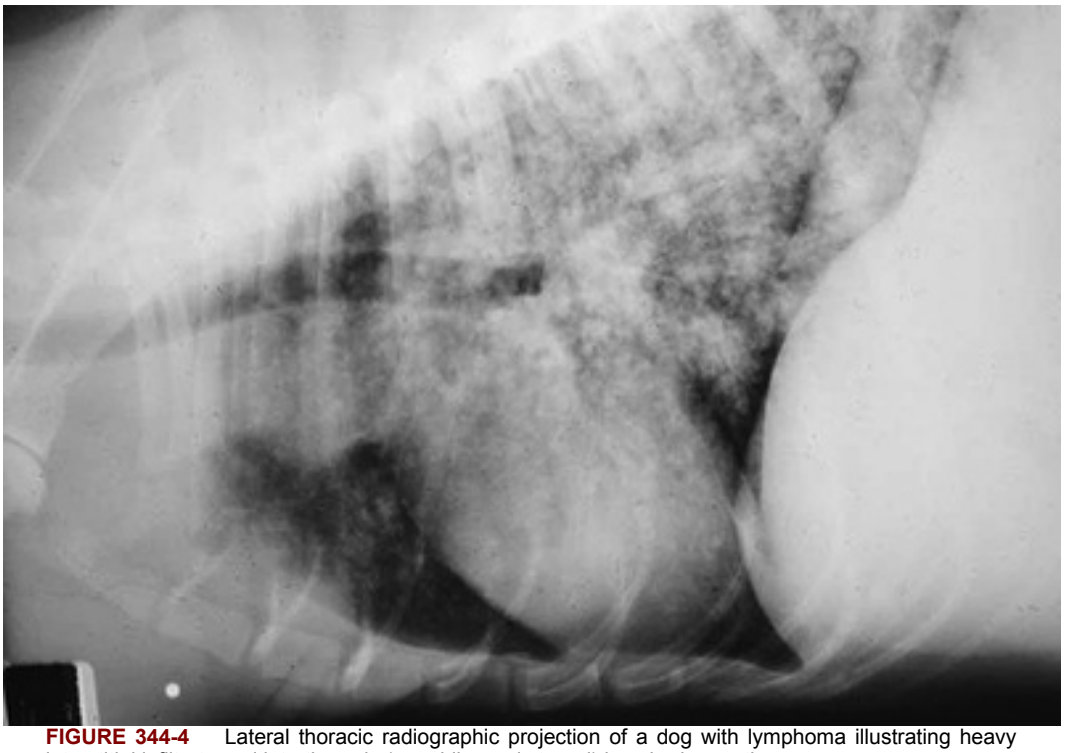

FIGURE 344-4 Lateral thoracic radiographic projection of a dog with lymphoma illustrating heavy interstitial infiltrate and intrathoracic (e.g., hilar and sternal) lymphadenopathy.

Cytologic and Histopathologic Diagnosis

In the author's opinion, a combination of histopathologic (Tru-Cut, wedge, whole node) and flow-cytometric assessment of needle aspirates should be the standard of care for diagnosis of nodal lymphoma (see ch. 95).[68,103-105] This allows accurate subtyping, provides a growing body of prognostic information and ultimately may result in treatment protocols tailored more specifically to the subtype encountered. While fine needle aspirate (FNA) cytologic assessment by a clinical pathologist is often adequate to make a diagnosis of lymphoma in dogs, clinically important subtyping is not possible with cytology alone. The predominance of a homogenous population of immature lymphoid cells is suggestive of lymphoma (Figure 344-5), although several small cell and indolent nodular variants exist and histological/immunophenotypic assessment of these less common forms is recommended.

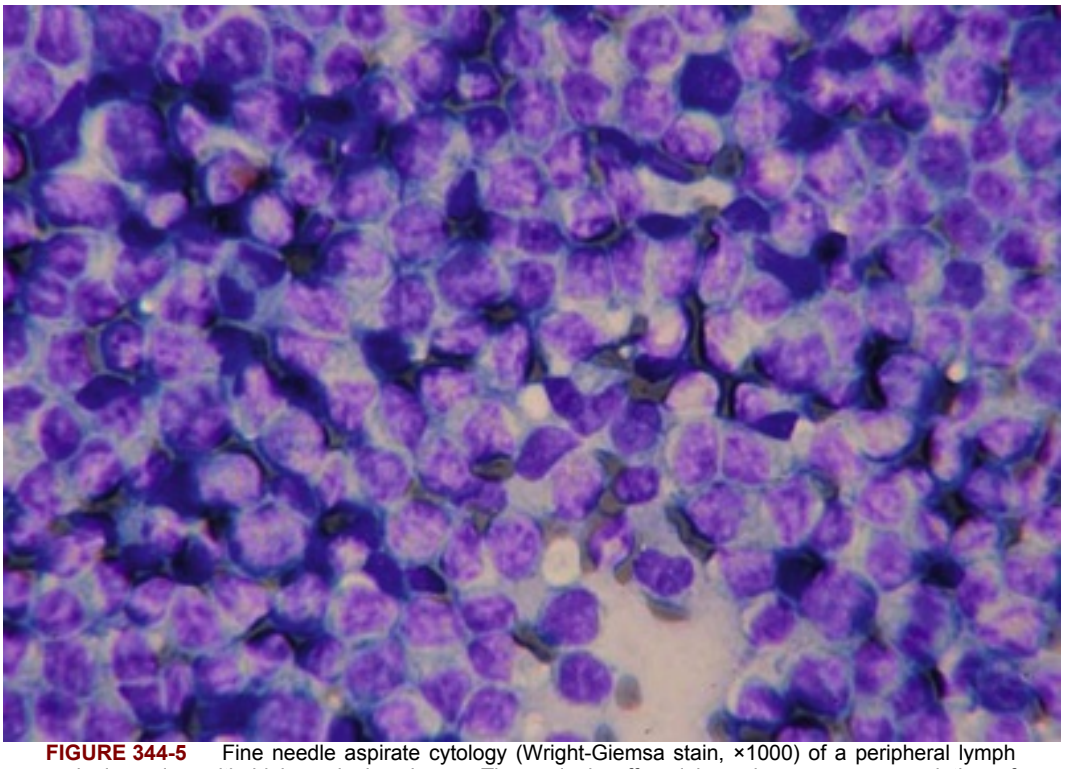

FIGURE 344-5 Fine needle aspirate cytology (Wright-Giemsa stain, ×1000) of a peripheral lymph node in a dog with high-grade lymphoma. The node is effaced by a homogenous population of immature lymphoid cells.

Additional site-specific cytologic or histologic assessments may be warranted when extranodal forms are suspected. Thoracocentesis (see ch. 102) followed by cytologic/flow-cytometric evaluation of pleural fluid is often diagnostic in cats with mediastinal lymphoma, but is less likely to be of value in dogs with effusions secondary to mediastinal involvement. Conversely, cerebrospinal fluid (CSF) analysis (see ch. 115) is more commonly helpful in dogs than cats with CNS lymphoma because the more common spinal form in cats is generally extradural.[106-108] In cats suspected of having CNS lymphoma, bone marrow (see ch. 92) and renal (see ch. 321) involvement are often present, and cytologic assessment of these organs is generally more easily attainable than from CNS sites.

For gastrointestinal lymphoma, controversy still exists as to the diagnostic sensitivity of endoscopically derived biopsy versus full thickness surgical biopsies; the former (see ch. 113) remains the gold standard; however, the latter is gaining more favor as techniques advance.[70-74,109,110] This is particularly germane for indolent gastrointestinal lymphoma which represents the most common form of lymphoma in cats but is rare in dogs. Advanced diagnostic techniques (e.g., flow cytometry, polymerase chain reaction [PCR] for antigen receptor rearrangement [PARR]) may be necessary in these instances. For cats and dogs having intermediate or high-grade gastrointestinal lymphoma, often abdominal lymphadenopathy, measurable intestinal/gastric masses or other abdominal organ involvement allows a less invasive definitive diagnostic approach whereby aspirate cytology or ultrasound guided core biopsies can be diagnostic without the need for laparotomy/laparoscopic intestinal derived biopsy.

Advanced Diagnostic Techniques

Besides their role in confirming a diagnosis of lymphoma, histologic and cytologic samples can be analyzed by various histochemical, immunohistochemical and flow-cytometric techniques to determine the immunophenotype (e.g., B, T, null cell, major histocompatibility complex [MHC] expression), cell size, tumor proliferation rate (e.g., Ki-67, proliferating cell nuclear antigen [PCNA], argyrophilic nucleolar organizer regions [AgNOR]), and subtype (high-, intermediate-, or low-grade/indolent tumors) as well as the presence or absence of an ever increasing number of molecular markers under investigation for prognostic, predictive, and therapeutic potential.[68,103-105,111-113] Several laboratories now offer routine advanced immunophenotypic analysis of samples with an ever increasing panel of immunophenotypic markers (e.g., B, T, MHC class, etc.) that provide the clinician and the client more accurate prognostic information; this author currently utilizes

Colorado State University's Clinical Immunology Laboratory for such analysis (http://csu-cvmbs.colostate.edu/academics/mip/ci-lab/Pages/default.aspx). As more samples are analyzed and correlated with outcome assessments following treatment, therapy recommendations aimed at specific lymphoma subtypes and indeed, individual patients will become available to veterinary patients, as is the standard in people.

In uncommon circumstances, routine cytologic and histologic assessments of tissues or cellular fluids are inadequate to confirm even a nonspecific diagnosis of lymphoma. When suspicious solid tissues, circulating lymphocytes, and effusive samples include a mixed-cell population or do not entirely discriminate malignant from benign reactive proliferations, assays of cellular clonality may be helpful in addition to flow-cytometric analysis.[103,114,115] Clonality is the hallmark of malignancy; that is, the malignant cell population theoretically should be derived from expansion of a single malignant clone characterized by a particular DNA region unique to that tumor. For example, in a dog with T-cell lymphoma all the malignant cells should contain the same DNA sequence for the variable region of the T-cell receptor gene. Likewise, a dog with B-cell lymphoma should have malignant cells with identical DNA sequences in the variable region of the immunoglobulin receptor gene. Conversely, in benign reactive lymphocytosis the cells are polyclonal for their antigen receptors. Polymerase chain reaction technology is used to amplify the variable regions of the T-cell and immunoglobulin receptor genes to detect clonality. Such assays are approximately 70% to 90% sensitive in the dog and less so in the cat. False-negative (e.g., null cell populations, incorrect PCR primers) and false-positive (e.g., ehrlichiosis and Lyme disease) rates of approximately 5% can occur. In these cases, a diagnosis should be made only after considering the results of all diagnostic evaluations, including histologic/cytologic evaluation, immunophenotyping, and clonality studies in conjunction with the signalment and physical findings. In general, for samples suspicious for but not diagnostic for lymphoma, flow-cytometric analysis is superior to PARR analysis; however, the performance of both may be preferable.

Molecular and proteomic analysis of DNA and serum biomarkers, respectively, are currently being investigated for their diagnostic and prognostic utility.[116-123] These molecular techniques, while helpful for diagnosis, could also have utility in defining more accurate clinical stage, determining treatment response and relapse and so-called molecular remission rates and minimal residual disease levels.

Differential Diagnosis

The differential diagnoses for lymphoma, which vary with the anatomic form of the disease, are presented in Table 344-3.

TABLE 344-3

Common Differential Diagnoses for Lymphoma

ANATOMIC FORM	DIFFERENTIAL LIST
Generalized	Disseminated infections lymphadenopathy (e.g., bacterial, viral, rickettsial, parasitic, and fungal) Immune-mediated disorders (e.g., lupus, polyarthritis, vasculitis, dermatopathy) Other hematopoietic tumors (e.g., leukemia, multiple myeloma, malignant or systemic histiocytosis) Tumors metastatic to nodes In cats, many benign reactive hyperplastic syndromes (see text)
Alimentary	Infiltrative enteritis (e.g., lymphocytic, plasmacytic enteritis) Nonlymphoid intestinal neoplasms Granulomatous enteritis Granulated round cell tumors in cats Gastrointestinal mast cell tumors in cats
Cutaneous	Infectious dermatitis (e.g., advanced pyoderma) Immune-mediated dermatitis (e.g., pemphigus) Other cutaneous neoplasms
Mediastinal	Thymoma Heart base tumor (chemodectoma) Ectopic thyroid tumor Pulmonary lymphomatoid granulomatosis Granulomatous disease (e.g., hilar lymphadenopathy)

Therapy

Untreated dogs and cats live an average of 4 to 6 weeks once a diagnosis of intermediate or high-grade lymphoma has been established, although significant variations can exist depending on location and subtype. In general, lymphoma is a systemic disease and requires a systemic approach to therapy (i.e., chemotherapy, immunotherapy). In cases of solitary nodal or extranodal lymphoma, local therapy involving either surgery or radiation may be indicated.

Systemic Chemotherapy in Dogs with Intermediate and High-Grade Lymphoma

The management of lymphoma initially is quite gratifying in both species, as response rates approach 90% in dogs and 70% in cats treated with multiagent chemotherapeutic approaches. Importantly, client perception of their pets' experiences during chemotherapy are generally positive, and the vast majority of clients feel that treatment is worthwhile and results in improvements in their companions' well-being and overall quality of life.[124-126] Unfortunately, most animals eventually succumb to relapse of chemotherapy-resistant, disseminated disease. Many chemotherapy protocols for dogs with lymphoma have been published and previously reviewed,[127,128] reflecting our inability to achieve cure in the majority of cases. Several factors should be considered and discussed with caregivers when choosing a protocol for a particular situation. These factors include the cost, time commitment, efficacy, toxicity, and experience of the clinician with the protocols in question. In general, more complex combination chemotherapy protocols are more expensive, more time-consuming (i.e., requiring repeated office visits and closer monitoring), and more likely to result in adverse events than are simpler, single agent protocols. However, as a general rule, more complex combination protocols initially result in longer remission and survival durations than do single agent protocols. Most complex combination protocols are modifications of "CHOP," a protocol initially designed for human oncologic use. The CHOP protocol represents combinations of cyclophosphamide (C), doxorubicin (hydroxydaunorubicin [H]), vincristine (Oncovin [O]), and prednisone (P). In the 1990s, large multi-institutional randomized clinical trials in people with intermediate and high-grade lymphomas established that more complex protocols or protocols did *not* result in enhanced efficacy and indeed, resulted in greater frequency of adverse events.[129] For this reason, CHOP remains the standard chemotherapy protocol for most intermediate and high-grade lymphoma in people. While large randomized trials have not been performed in dogs, it appears that regardless of which CHOP-based protocol is used, the overall median remission and survival times are approximately 8 and 12 months, respectively.[127,128] Approximately 20% to 25% of treated dogs are alive 2 years after initiation of these protocols. Response rates and the length of response vary, depending on the presence or absence of prognostic factors discussed subsequently. Historically, lymphoma treatment protocols began with an intensive induction phase, during which drugs are given weekly; this was followed by a maintenance phase, during which treatment intervals are slowly spread out and the drugs are given less frequently. More current treatment protocols have abandoned the use of a maintenance phase, as most data now show no benefit from their inclusion.[130-137] In general, shorter chemotherapy protocols are associated with similar response rates and first remission durations achieved with longer maintenance-containing protocols and have the advantage of less time on chemotherapy and less associated expense and adverse events. Additionally, overall survival lengths are not different once reinduction or rescue protocols are factored in. For peripheral nodal lymphoma, by convention, remission status is assessed according to the Veterinary Cooperative Oncology Group (VCOG) response evaluation criteria v1.0.[138] This simple and easily applied evaluation takes into account our inability to achieve true molecular complete remissions or cures and allows more accurate comparison of response following different protocols. The CHOP-based combination induction protocol used most often by the author is presented in Table 344-4.

TABLE 344-4

University of Wisconsin–Madison Combination Chemotherapy Protocol for Dogs with Lymphoma

TREATMENT WEEK	DRUG, DOSAGE, ROUTE	TREATMENT WEEK	DRUG, DOSAGE, ROUTE
1	Vincristine: 0.5-0.7 mg/m^2 IV Prednisone: 2 mg/kg PO q 24 h × 7 days	11	Vincristine: 0.5-0.7 mg/m2 IV

2	Cyclophosphamide: 250 mg/m^2 IV/PO Furosemide: 1 mg/kg IV* Prednisone: 1.5 mg/kg PO q 24 h × 7 days	12	Cyclophosphamide: 250 mg/m^2 IV/PO Furosemide: 1 mg/kg IV
3	Vincristine: 0.5-0.7 mg/m^2 IV Prednisone: 1 mg/kg PO q 24 h × 7 days	13	Vincristine: 0.5-0.7 mg/m2 IV
4	Doxorubicin: 30 mg/m^2 IV PO Prednisone: 0.5 mg/kg PO q 24 h × 7 days	14	Doxorubicin: 30 mg/m2 IV
6	Vincristine: 0.5-0.7 mg/m2 IV	16	Vincristine: 0.5-0.7 mg/m2 IV
7	Cyclophosphamide: 250 mg/m^2 IV/PO Furosemide: 1 mg/kg IV	17	Cyclophosphamide: 250 mg/m^2 IV/PO Furosemide: 1 mg/kg IV
8	Vincristine: 0.5-0.7 mg/m2 IV	18	Vincristine: 0.5-0.7 mg/m2 IV
9†	Doxorubicin: 30 mg/m2 IV	19‡	Doxorubicin: 30 mg/m2 IV

*Furosemide is given concurrently with cyclophosphamide to decrease the incidence of sterile hemorrhagic cystitis.

†If the patient is in complete remission at week 9, treatment continues to week 11.

‡If the patient is in complete remission at week 19, therapy is discontinued and the dog is rechecked monthly for recurrence.

Note: A complete blood count (CBC) should be performed before each chemotherapy treatment. If the neutrophil count is less than 2000 cells/mcL, the clinician should wait 5 to 7 days and then repeat the CBC; the drug is administered if the neutrophil count has risen above the 2000 cells/mcL cutoff.

Doxorubicin (30 mg/m^2 IV q 3 weeks for five treatments) along with oral prednisone remains the most effective and commonly used single agent cytotoxic chemotherapy protocol for dogs with lymphoma.[139-142] Approximately 70% of cases will respond, with median remission and survival durations of approximately 5 and 7 months, respectively. This single agent protocol is less time-consuming, less expensive, and requires fewer hospital visits. If clients choose to employ only oral medications, lomustine (CCNU; 70 mg/m^2 PO q 3 weeks) or cyclophosphamide (250-300 mg/m^2, PO or IV, q 2-3 weeks) and prednisone therapy can be used, although response rates and durations are less than those achieved with doxorubicin.[143]

If financial or other client concerns preclude the use of more aggressive systemic chemotherapy, prednisone therapy (2 mg/kg PO q 24 h) often results in short-lived remissions of approximately 1 to 2 months. It is advisable to inform clients that if they should decide to pursue more aggressive therapy at a later date, dogs with prior prednisone therapy are more likely to develop drug-resistant disease and to experience shorter remission and survival durations when subsequent chemotherapy protocols are attempted.[144-146] Modifications in chemotherapy dosage and/or frequency may be necessary under conditions of excess adverse events (AEs) (see ch. 343). In the absence of clinically significant AEs, in particular when a lack of expected neutrophil nadir is observed, dose increases are also warranted as this may imply inadequate dosing based on an individual patient's pharmacogenetics. Breeds at risk for abnormalities in P-glycoprotein drug transport (e.g., Collies, Shetland Sheepdogs, herding breeds) that predict risk for chemotherapy induced AEs should undergo MDR1 gene mutation analysis prior to using MDR1 substrate agents.[147]

When hypercalcemia is present, if the dog has substage a disease and is eating and drinking, ancillary therapy for hypercalcemia is usually unnecessary as chemotherapy results in normalization of serum calcium within a few days. If the animal is ill, azotemic, or showing significant signs attributable to hypercalcemia, therapy directed specifically at hypercalcemia (see ch. 69 and 297) concurrent with the initiation of systemic chemotherapy is warranted.

Systemic Chemotherapy in Cats with Intermediate and High-Grade Lymphoma

Several combination chemotherapy protocols for cats have been reported and reviewed previously.[148-150] The addition of doxorubicin to COP-based protocols (C, cyclophosphamide; O, Oncovin [vincristine]; P, prednisolone) appears superior to COP alone in the cat. However, in some studies, cats receiving COP experienced remission and survival durations comparable to cats treated with CHOP protocols.[151,152] In contrast to dogs, doxorubicin does not appear to be as effective a single agent therapy for feline lymphoma. In general, cats with intermediate or high-grade lymphoma do not enjoy as high a response rate or as long remission and survival durations as dogs with intermediate or high-grade lymphoma. Complete response

rates vary between 50% and 80%, and overall median remission and survival durations are approximately 4-6 and 6-8 months, respectively. However, a significant proportion of cats (30% to 40%) that achieve a complete response with combination chemotherapy enjoy more durable overall remission and survival times (i.e., 2 years) than that seen in dogs. The modified CHOP-based protocol preferred by the author for cats is presented in Table 344-5.

TABLE 344-5

University of Wisconsin–Madison Combination Chemotherapy Protocol for Cats with Lymphoma

TREATMENT WEEK	DRUG, DOSAGE, ROUTE	TREATMENT WEEK	DRUG, DOSAGE, ROUTE
1	Vincristine: 0.5-0.7 mg/m^2 IV L-asparaginase: 400 U/kg SC Prednisolone: 2 mg/kg PO q 24 h × 14 days	11	Vincristine: 0.5-0.7 mg/m2 IV
2	Cyclophosphamide: 200 mg/m^2 IV/PO Prednisolone: 2 mg/kg PO q 24 h (continued)	13†	Cyclophosphamide: 200 mg/m2 IV/PO
3	Vincristine: 0.5-0.7 mg/m^2 IV Prednisolone: 1 mg/kg PO q 24 h × 7 days	15	Vincristine: 0.5-0.7 mg/m2 IV
4	Doxorubicin: 25 mg/m^2 IV Prednisolone: 1 mg/kg PO q 48 h*	17	Doxorubicin: 25 mg/m2 IV
6	Vincristine: 0.5-0.7 mg/m2 IV	19	Vincristine: 0.5-0.7 mg/m2 IV
7†	Cyclophosphamide: 200 mg/m2 IV/PO	21†	Cyclophosphamide: 200 mg/m2 IV/PO
8	Vincristine: 0.5-0.7 mg/m2 IV	23	Vincristine: 0.5-0.7 mg/m2 IV
9‡	Doxorubicin: 25 mg/m2 IV	25§	Doxorubicin: 25 mg/m2 IV

*Prednisolone (1 mg/kg PO) is continued every other day from this point on.

†If renal or CNS lymphoma is present, substitute cytosine arabinoside (600 mg/m^2 SC q 12 h over 2 days) at these treatments.

‡If the patient is in complete remission at week 9, continue to week 11.

§If the patient is in complete remission at week 25, therapy is discontinued and the cat is rechecked monthly for recurrence.

Note: A complete blood count (CBC) should be performed before each chemotherapy treatment. If the neutrophil count is less than 1500 cells/mcL, the clinician should wait 5 to 7 days and then repeat the CBC; the drug is administered if the neutrophil count has risen above the 1500 cell/mcL cutoff.

Reinduction or Rescue Therapy

Ultimately, most dogs and cats with intermediate and high-grade lymphoma successfully treated with induction chemotherapy relapse with a more drug-resistant form. At the first recurrence, if >2 months has occurred between cessation of chemotherapy and relapse, it is recommended that *reinduction* be attempted by repeating the induction protocol that was initially successful. While the likelihood of a response is high at reinduction, the length of the response is generally shorter than seen with the initial therapy.[153] If reinduction fails, if the patient does not respond to initial induction, or relapses during initial induction, then so-called *rescue* agents or rescue protocols are used. These drugs or drug combinations typically are not found in the standard CHOP protocol and are withheld for use in drug-resistant cases. A number of single agent and multiagent rescue protocols have been reported and reviewed in the veterinary literature.[138,148,154,155] Overall rescue response rates of 40% to 90% are reported; however, responses are usually not durable, with median responses of 1.5 to 2.5 months being typical, regardless of the complexity of the protocol. The sequential application of several different rescue protocols can result in several months of extended survival with acceptable quality of life.

Immunotherapy for Lymphoma (also see ch. 341)

The most significant advancement in treating non-Hodgkin's lymphoma (NHL) in people in the last 2 decades

has been the development of monoclonal antibody therapies that are combined with standard CHOP protocols (e.g., R-CHOP, for rituximab-CHOP). This anti-human CD20 monoclonal antibody has significantly increased both progression free and overall survival in people with NHL when compared to CHOP alone.[156] Monoclonal antibody therapy has become the standard of care (in combination with chemotherapy) for several hematopoietic tumors in people (e.g., NHL, chronic lymphocytic leukemia, cutaneous lymphoma, gamma delta T-cell lymphoma). In veterinary oncology, national multicenter randomized trials are ongoing to determine the therapeutic efficacy of monoclonal antibody therapies against both canine B-cell (caninized anti-CD20; Aratana AT-004) and canine T-cell (caninized anti-CD52; Aratana AT-005) lymphoma that have received full USDA license approval. While safety has been established for these two agents, only preliminary (abstract form) efficacy data are available at the time of this writing and represent a reasonable but not complete expectation of anti-tumor activity. Once these trials (combining monoclonal and standard chemotherapy) have been completed and the results subject to rigorous peer review the true efficacy of these products will be known. It is hoped that these and potentially other[157] monoclonal antibody therapies in development will similarly revolutionize the treatment of NHL in dogs.

Investigations are also currently underway regarding the development of other immunologic therapies, including anti-lymphoma vaccines and bone marrow or stem cell transplant techniques following bone marrow ablative therapies.[158,159] Currently these are investigational in scope.

Radiation Therapy for Lymphoma

Radiation therapy for lymphoma is generally limited to cases where solitary anatomic sites are present without systemic involvement or in investigational trials utilizing whole or half body radiation protocols in combination with chemotherapy (see ch. 340).[160-168]

Therapy—Indolent (Low-Grade) Lymphoma

Indolent lymphomas include a varied group of tumors that are uncommon in dogs[63-69] but represent the most common form in cats (feline indolent gastrointestinal lymphoma).[70-79] Dogs with indolent lymphoma (e.g., marginal zone, mantel cell, T-zone lymphoma) generally experience prolonged survivals, often in the absence of chemotherapy. Dogs with indolent lymphoma may be devoid of clinical signs beyond nodal or splenic enlargement and despite their tumors being less responsive to chemotherapy, enjoy long-term survival. Owing to the less common nature of the indolent lymphomas in dogs, treatment recommendations are not well established. Initially, a decision is made whether to treat based on the presence of clinical signs effecting quality of life, presence of organomegaly or clinically significant cytopenias secondary to myelophthisis. In such cases, therapy usually is initiated with either single agent chlorambucil (20 mg/m^2 PO q 2 weeks) or cyclophosphamide (250 mg/m^2 PO q 2-3 weeks) with prednisone. In dogs with indolent lymphoma confined to the spleen or a solitary node, splenectomy or nodal extirpation without adjuvant chemotherapy often provides long-term control, with many living normal lifespans and dying of diseases other than their indolent lymphoma.

Cats with low-grade *small cell* alimentary lymphoma (i.e., gastrointestinal, hepatic) are best treated with a less aggressive chemotherapy protocol such as oral chlorambucil (20 mg/m^2 PO q 2 weeks) and prednisolone. Median survival times of approximately 2-3 years can be expected.

Therapy for Extranodal Lymphoma

If extranodal involvement is part of a more generalized or multicentric disease process, the systemic therapies previously discussed should be instituted. Conversely, if the extranodal site is solitary, local therapy without institution of systemic chemotherapy may be pursued. In these cases, strict adherence to staging diagnostics (i.e., bone marrow evaluation, radiographic/ultrasonographic, CT, or PET/CT imaging) is warranted to ensure localized disease. Local surgery and/or radiotherapy is often effective, and while systemic lymphoma may ultimately occur months to years later, it is the author's opinion that systemic therapy may be withheld until systemic disease has been documented.

In cases in which CNS involvement is part of a more generalized process, penetration of chemotherapeutic drugs through the blood-brain barrier (BBB) may be a concern. In standard CHOP protocols, only prednisone consistently penetrates the BBB. The addition of cytosine arabinoside, which achieves therapeutic CSF levels, to a CHOP-based protocol has been recommended; however, evidence of its activity in this setting is lacking. L-asparaginase, while not crossing the BBB, will exert its action (asparagine depletion) in the CSF. Radiation

therapy can also be effective, directed either to the entire neural axis (multifocal CNS lymphoma) or to specific CNS locations (solitary central or spinal lymphoma). Cytoreductive surgery has been attempted in a small number of cases of extradural lymphoma, with mixed results.

Cutaneous lymphoma in solitary sites may be effectively treated with local surgery or radiation therapy, but the likelihood of ultimate systemic involvement is high. Multiple cutaneous lesions are more commonly encountered (see Figure 344-3), and systemic therapy is necessary. In general, cutaneous lymphoma is less responsive to chemotherapy than multicentric lymphoma, however clinical signs can wax and wane considerably over time and long term outcomes may occur. First line therapy for dogs with cutaneous lymphoma currently includes lomustine (CCNU, 50-70 mg/m^2 PO q 3 weeks) and prednisone with response rates of approximately 80% and median response durations of 3 months.[169,170] Other chemotherapeutics with reported activity include Doxil (a liposome-encapsulated form of doxorubicin), L-asparaginase, dacarbazine, topical nitrogen mustard, and standard CHOP-based protocols. Monoclonal antibody therapy (anti-CD52) is effective in people for cutaneous T-cell lymphoma and data are currently being collected on cases treated with the caninized monoclonal (Aratana, AT-005) to determine its efficacy in dogs.

Cats with nasal lymphoma without concurrent systemic therapy can also be treated with local radiation therapy and generally enjoy long-term survival.[171-173]

Prognosis

Prognostic Factors in Dogs

A list of factors known or suspected to affect remission rates and/or remission and survival durations in dogs with lymphoma is presented in Table 344-6.[63-79,122,123,174-186] The three factors that most consistently correlate with prognosis in dogs are the immunophenotype/flow cytometric characteristics, histologic subtype and the WHO substage. Dogs with T-cell lymphoma generally have significantly shorter remission and survival durations; however, indolent T-zone lymphomas enjoy the longest survivals.

TABLE 344-6

Prognostic Factors for Lymphoma in Dogs[63-79,122,123,174-186]

FACTOR	STRONG ASSOCIATION	MODEST ASSOCIATION REQUIRING FURTHER INVESTIGATION	COMMENTS
WHO clinical stage		X	Stage I/II: favorable. Stage V with significant bone marrow involvement—unfavorable.
WHO clinical substage	X		Substage—b (clinically ill): associated with decreased survival.
Histopathology	X		High-grade/medium grade: associated with high response rate but reduced survival. The indolent lymphomas generally experience prolonged survivals, often in the absence of systemic therapy.
Immunophenotype/flow cytometric characteristics	X		T-cell phenotype associated with reduced survival. Low MHCII expression on B-cells associated with reduced survival.
Flow cytometric characteristics of peripheral blood	X		This includes combined size and immunophenotypic analysis.
Sex		X	Some studies suggest females have a favorable prognosis.
Anemia	X		
Molecular assessment of minimal residual		X	Likely to become much more important when more "curative" therapeutic approaches are developed and

disease (e.g., PARR)			instituted.
Measures of proliferation		X	Contradictory reports exist.
Prolonged steroid pretreatment	X		Most reports suggest previous steroid use shortens response durations; however, length of exposure necessary is unknown.
P-glycoprotein expression (drug resistance factors)		X	May be associated with poor response rates and shortened remissions.
Cranial mediastinal lymphadenopathy	X		Large compilation of cases reports shorter remission and survival durations.
Anatomic location	X		Leukemia, diffuse cutaneous and alimentary, hepatosplenic forms associated with unfavorable prognosis.
Chemotherapy induced hematologic toxicosis		X	Dogs experiencing grade III/IV neutropenia have prolonged first remission durations.

MHC, Major histocompatibility complex; *PARR*, polymerase chain reaction (PCR) for antigen receptor rearrangement.

Prognostic Factors in Cats

Factors most strongly associated with a more positive prognosis in cats appear to be presence of indolent lymphoma, complete response to therapy (which unfortunately cannot be determined prior to treatment), negative retroviral status, early clinical stage, anatomic site and perhaps the addition of doxorubicin to the treatment protocol.[71,75,81-83,87,88,90] In general, FeLV-negative cats that achieve a complete response on CHOP-based protocols have a high likelihood of long-term survival, with approximately 35% alive at 1.5 years after diagnosis. Cats with alimentary small cell lymphoma have the best overall prognosis with median survivals of 2 years or longer following therapy. Cats with nasal lymphoma have a fair prognosis as radiation therapy (or chemotherapy, if radiation therapy is not available) results in median survivals of 1.5 years. Little is known about the clinical course of Hodgkin's-like lymphoma in cats; following surgical extirpation of the affected node, recurrence may take months, and response to chemotherapy varies. Large granular lymphoma in cats appears to have a more aggressive and less responsive course.

Lymphoid Leukemia

Leukemia is defined as a proliferation of neoplastic cells in the bone marrow. The malignant cells may or may not be present in the peripheral blood circulation. Categorization of lymphoid leukemia into acute lymphoblastic leukemia (ALL) and chronic lymphocytic leukemia (CLL) is important from a diagnostic, prognostic, and therapeutic standpoint (Figure 344-6).[103,186-193] Flow cytometric analysis of immunophenotypic markers (see earlier sections) is particularly helpful.

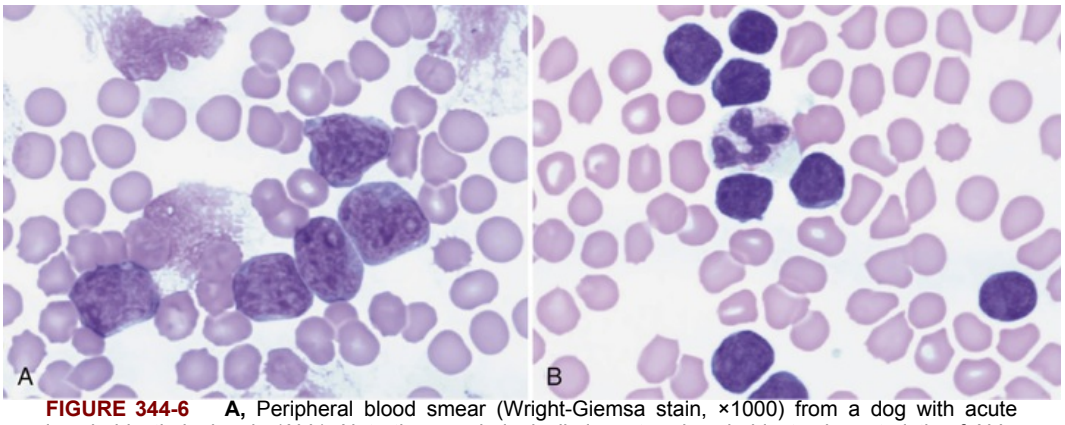

FIGURE 344-6 **A,** Peripheral blood smear (Wright-Giemsa stain, ×1000) from a dog with acute lymphoblastic leukemia (ALL). Note the morphologically immature lymphoblasts characteristic of ALL. **B,** Peripheral blood smear (Wright-Giemsa stain, ×1000) of a dog with chronic lymphocytic leukemia (CLL). Note the morphologically mature lymphocytes characteristic of CLL. (Courtesy Dr. Karen Young, University of Wisconsin-Madison.)

Acute Lymphoblastic Leukemia (ALL)

ALL is characterized by proliferations of morphologically immature lymphoblasts in the bone marrow and may be confused with multicentric stage V lymphoma (i.e., secondary bone marrow infiltration). The clinical course of ALL is rapid, progressive, and poorly responsive to therapy, although some immunophenotypic subclassifications are associated with better overall prognoses. Cats with ALL are younger and are often FeLV antigenemic. Presentations are nonspecific and may include lethargy, weight loss, intermittent pyrexia, hepatosplenomegaly, nonspecific abdominal pain, and neurologic signs. Most animals are anemic, and varying degrees of thrombocytopenia and leukopenia are present. Diagnosis is suggested by marked lymphoblast proliferation in the bone marrow or peripheral blood. Bone marrow aspirate or core biopsy (see ch. 92) and a CBC are usually all that are required for diagnosis of acute leukemia; however, immature forms can be difficult to classify beyond a blast form and flow-cytometric immunophenotype is employed to confirm. Aspiration cytology of lymph node (see ch. 95) and involved organs (see ch. 89) and confirmation of retroviral status in cats may be contributory. Approximately 10% of cases are classified as "aleukemic" leukemia because bone marrow infiltration is present but peripherally circulating lymphoblasts are absent. ALL may be further differentiated clinically from stage V multicentric lymphoma by its more rapid progression, lack of significant lymphadenopathy, poor chemo responsiveness and CD34+ immunophenotype. The prognosis is poor for dogs and cats with ALL. Remission durations are short and survival times of more than a few months are rare. It remains to be seen what role, if any, the new monoclonal antibody therapies will play in the treatment of lymphoid leukemia.

Chronic Lymphocytic Leukemia (CLL)

CLL is characterized by the proliferation of phenotypically mature lymphocytes rather than lymphoblasts. The majority of CLL cases in dogs and cats are of the T-cell lineage with dogs being primarily CD8+ T cells, many of which show a granular lymphocytic morphology.[147] CLL occurs in older dogs and cats presenting with nonspecific signs including lethargy, organomegaly, pyrexia, polyuria/polydipsia, hemorrhage (from thrombocytopenia), intermittent lameness, and collapse. However, asymptomatic lymphocytosis may be detected on routine geriatric or preanesthetic screening in some animals. Peripheral lymphocytosis can range from 10,000 to ≥300,000/mcL. Anemia, thrombocytopenia and neutropenia may be present secondary to myelophthisis. No association with FeLV infection has been documented in the cat. Unlike ALL, CLL often has a protracted course and is initially highly responsive to chemotherapy. Treatment is not initiated unless significant clinical signs, organomegaly, or peripheral cytopenias (anemia, neutropenia, thrombocytopenia) are present that affect the animal's quality of life. CLL cases have been followed for many months without the necessity for therapy. If therapy is indicated, chlorambucil (dogs: 0.2 mg/kg PO q 24 h for 10 days, then 0.1 mg/kg/day; cats: 2 mg/cat PO q 48 h: alternatively, 20 mg/m^2 PO q 2 weeks) is combined with daily or every other day prednisone. The majority of animals respond and enjoy good quality of life, with a median survival time of approximately 1 to 1.5 years. While prognosis is good in the short term, eventually CLL becomes resistant to therapy or progresses to ALL. While anti-CD52 monoclonal antibody is approved for use in people with CLL, the new canonized monoclonal antibody therapies have not been evaluated for CLL in dogs.

Nonlymphoid Leukemias and Myeloproliferative Disorders

Myeloproliferative disorders (MPDs) are defined as a group of rare nonlymphoid bone marrow cell disorders in which proliferation of one, several, or all marrow cell lines occurs. The disorders may represent preneoplastic or neoplastic conditions that may have a benign or malignant course. With few exceptions (e.g., see Polycythemia Vera, ch. 200), the veterinary literature on MPDs is sparse at best and is composed almost entirely of single case reports. MPDs are classified first on the basis of the derivation of the cell in question and second on the degree of cellular differentiation. If the proliferating cell population is phenotypically well differentiated, the disorder is classified as chronic; if immature or poorly differentiated, the disease is classified as acute. Table 344-7 lists possible MPDs variants reported in companion animal species. Because pluripotent bone marrow stem cells are involved, one MPD may evolve into another, and more than one cell line is involved in the same disorder.

TABLE 344-7

Myeloproliferative Disorders Possible in Dogs and Cats

CLASSIFICATION	CELL LINEAGE
Acute Myeloproliferative Disorders	
Acute myelogenous leukemia (AML)	Myeloblasts
Acute myelomonocytic leukemia (AMML)	Myeloblasts/monoblasts
Acute monocytic leukemia (AmoL)	Monoblasts
Acute megakaryoblastic leukemia (AmkL)	Megakaryoblasts
Erythroleukemia	Erythroblasts
Chronic Myeloproliferative Disorders	
Chronic myelogenous leukemia (CML)	Neutrophils, late precursors
Primary thrombocythemia	Platelets
Basophilic leukemia	Basophils and precursors
Eosinophilic leukemia	Eosinophils and precursors
Polycythemia vera	Erythrocytes

Animals with a chronic MPD may have no clinical signs until organ involvement or bone marrow myelophthisis results in clinical signs which are generally nonspecific and can include organomegaly, pallor, sepsis, and hemorrhage from thrombocytopenia. Most MPDs have been associated with FeLV infection in cats.

The diagnosis of MPD is based on demonstration of the proliferating cell line in the absence of nonneoplastic diseases associated with bone marrow hyperplasia or hypoplasia. Differential diagnoses therefore include chronic inflammatory diseases (e.g., ehrlichiosis), multicentric lymphoma, estrogen toxicity, lead poisoning and, in the case of essential or primary thrombocytosis, iron deficiency. Because many of the acute MPDs are poorly differentiated and/or represent combinations of cell lineages, light microscopic morphology is often insufficient and flow cytometric and histochemical analysis is ultimately necessary for precise classification. A complete listing of available tests is beyond the scope of the present chapter; these have been reviewed elsewhere.[191,193,194]

The acute MPDs are poorly responsive to single agent or combination chemotherapy protocols and the prognosis is grave. If chemotherapy is pursued, aggressive supportive therapy is necessary and to address cytopenias secondary to myelophthisis. Chronic MPDs carry a guarded prognosis; however, initial durable responses to therapy are more likely. Therapy is not required until clinical signs or significant peripheral cytopenia develops. Hydroxyurea has occasionally resulted in partial remission of several types of chronic MPD, particularly polycythemia vera, essential thrombocythemia, basophilic leukemia, and chronic myelogenous leukemia (CML). In dogs with CML, hydroxyurea is administered at an initial dosage of 20 to 25 mg/kg given PO q 12 h. This dosage is continued until the leukocyte count drops to less than 20,000 cells/mcL, at which time the dosage is reduced to 10 to 15 mg/kg q 24 h or switched to 50 mg/kg PO once every 2 to 3 weeks. A common side effect of hydroxyurea therapy in dogs is onychomadesis (sloughing of the claw or toenail). Ultimately, many of the chronic MPDs shift into a terminal phase or blast crisis, in which a fatal acute leukemic phase is observed. Tyrosine kinase receptor inhibitors (e.g., toceranib, masitinib) have not been thoroughly evaluated for the MPDs but may be considered.

Polycythemia vera (PV) (see ch. 57 and 200) is defined as an abnormal proliferation of erythroid precursors in the bone marrow; this occurs independent of erythropoietin (EP), and the cells follow a normal, orderly pattern of maturation.[150,151] The result is an abnormally elevated packed cell volume, erythroid count, and blood hemoglobin level. PV must be differentiated from so-called relative polycythemia or secondary polycythemia. Middle-aged dogs and cats are typically affected, presenting with varied signs including hyperemic mucous membranes, injected scleral and retinal vessels, weakness, exercise intolerance, frank hemorrhage (epistaxis, hematuria, melena), neurologic signs (dementia, seizures, paralysis, ataxia), and occasional splenomegaly. Cardiac or renal compromise may also be present. The majority of signs reported occur secondary to hyperviscosity syndrome, discussed in the plasma cell tumor portion of this chapter. The diagnosis is made by documentation of significant erythrocytosis (60% to 75% hematocrit) with normal to decreased serum EP levels and the absence of conditions associated with relative or secondary polycythemia. Thoracic and abdominal radiographs, thoracic and abdominal ultrasound, arterial blood gas determinations,

bone marrow aspirate testing, and serum EP levels should be procured to rule out differentials. Erythroid hyperplasia with relatively normal patterns of maturation is found on bone marrow cytology. Therapy involves reduction of red blood cell mass (phlebotomy;15 to 20 cc/kg body weight and reinfusion of the patient's plasma) and suppression of erythroid production in the bone marrow.[150,151] To suppress erythrocyte production, the use of radioactive phosphorus (^{32}P) or, more commonly available, chemotherapy (e.g., hydroxyurea, melphalan, cyclophosphamide, busulfan) have been used with mixed results.

Myeloma-Related Disorders

Myeloma-related disorders (MRD) arise when a cell of the plasma cell or immunoglobulin-producing B-lymphocyte precursor lineage transforms and proliferates to form a neoplastic population of similar cells. This population in most instances is monoclonal, producing a homogenous immunoglobulin although biclonal and polyclonal MRD neoplasms exist. MRDs include multiple myeloma (MM), IgM (Waldenstrom's) macroglobulinemia, solitary plasmacytoma (including solitary osseous plasmacytoma and extramedullary plasmacytoma [EMP]), and immunoglobulin secreting lymphomas and leukemias (including plasma cell leukemia). Multiple myeloma is the most important MRD based on incidence and severity. There exists some discordance and blurring of the distinction between MM and multicentric EMP in cats.

Multiple Myeloma

MM represents 8% of all canine hematopoietic tumors but is relatively rare in the cat.[195-202] In MM, the M-component may represent any class of immunoglobulin or only a portion of the molecule, such as the light-chain (Bence Jones protein) or heavy chain (heavy chain disease) of the molecule. Feline myeloma/MRD, while involving the bone marrow in the majority of cases, appears to involve extramedullary sites (e.g., skin, abdominal viscera) more commonly than in dogs.[198,200-202,204] The etiology of MM is for the most part unknown. Genetic predispositions, molecular alterations (e.g., TKI receptor abnormalities), viral infections, chronic immune stimulation, and exposure to carcinogens have all been suggested as contributing factors. MM has not been associated with either FeLV or FIV infection.

Pathophysiology

A wide array of pathologic abnormalities and related clinical syndromes can occur as a result of tumor infiltration of various organ systems, the presence of high levels of circulating M-component, or a combination thereof. Hyperviscosity syndrome (HVS) represents one of a constellation of clinicopathologic abnormalities resulting from increased serum viscosity. The magnitude of HVS is related to the type, size, shape, and concentration of the M-component in the blood. It is more common with IgM macroglobulinemia owing to its high molecular weight.[203] HVS can result in bleeding diathesis, neurologic signs (e.g., dementia, depression, seizure activity, coma; see ch. 260), ophthalmic abnormalities (e.g., dilated/tortuous retinal vessels, retinal hemorrhage, retinal detachment; see ch. 11), and increased cardiac workload with subsequent cardiomyopathy or congestive failure. These consequences are thought to be a result of sludging of blood in small vessels, ineffective delivery of oxygen and nutrients, and coagulation abnormalities. HVS is less common in cats.[204] Renal disease is present in 30% to 50% of dogs with MM as a result of Bence Jones (light chain) proteinuria, tumor infiltration into renal tissue, hypercalcemia, amyloidosis, diminished perfusion secondary to HVS, dehydration, or ascending urinary tract infection. Hypercalcemia occurs in 15% to 20% of dogs with MM and results primarily from the production of osteoclast-activating factor, other cytokines, or circulating N-terminal parathyroid hormone-related protein by neoplastic cells (see ch. 352). Hypercalcemia is rare in cats with MM.

Susceptibility to infection and immunodeficiency are often the ultimate causes of death in animals with MM. Normal immunoglobulin levels can be severely depressed, and leukopenias may be present secondary to marrow infiltration (myelophthisis). A normocytic, normochromic, nonregenerative anemia is encountered in approximately two thirds of dogs. This can result from myelophthisis, blood loss from coagulation disorders, anemia of chronic disease, or increased erythrocyte destruction secondary to high serum viscosity. Similar factors may lead to thrombocytopenia and leukopenia in 25% to 30% of affected dogs. Bleeding diathesis can result from one or a combination of events. M-components may interfere with coagulation including inhibition of platelet aggregation and the release of platelet factor-3, adsorption of minor clotting proteins, generation of abnormal fibrin polymerization, production of heparin-like anticoagulants, and a functional decrease in calcium.

Clinical Presentation

MM occurs in aged dogs and cats, with no breed or sex predilection. Clinical signs are variable due to the wide range of pathologic effects possible and may be present up to 1 year prior to diagnosis. In the dog, the most common clinical signs in decreasing order of frequency are lethargy and weakness, lameness as a result of bone destruction, hemorrhage (see ch. 135), polyuria/polydipsia (see ch. 45), and neurologic deficits (see ch. 259 and 260). Bleeding diathesis is usually represented by epistaxis and gingival bleeding (see ch. 29). CNS signs may include dementia, seizure activity, and deficiencies in midbrain or brainstem localizing reflexes secondary to HVS or extreme hypercalcemia. Signs reflective of transverse myelopathies secondary to vertebral column infiltration, pathologic fracture, or extradural mass compression can also occur (see ch. 267). In the cat, anorexia and weight loss are the most common clinical signs.[198,200-202,204] Lameness may be present due to bone lesions and hepatosplenomegaly is more commonly seen than in dogs. Epistaxis, pleural (see ch. 244) and peritoneal (see ch. 17) hemorrhagic effusions, retinal hemorrhage, and central neurologic signs have been reported. Polydipsia and polyuria can occur secondary to renal disease, and dehydration may develop.

Diagnosis

The diagnosis of MM usually follows demonstration of bone marrow plasmacytosis and serum or urine myeloma proteins (M-component), as well as detection of osteolytic bone lesions and/or other sites of visceral organ involvement. In the absence of osteolytic bone lesions or overt visceral organ involvement, a diagnosis can be made if marrow plasmacytosis is associated with a progressive increase in the M-component. All animals suspected of plasma cell tumors should receive a CBC, platelet count, serum biochemistry profile, and urinalysis. Serum electrophoresis and immunoelectrophoresis are performed to detect a monoclonal gammopathy (Figure 344-7) and to categorize the isotype of immunoglobulin involved. In early publications, the M-component was usually of the IgG or IgA class in nearly equal incidence in dogs,[195] however in the author's experience, the vast majority of dogs present with IgA disease.[205] In the cat, MM is usually associated with IgG elevations; only a few cases of IgA or IgM gammopathies have been reported.[198,200-202,204] Rarely, cryoglobulinemia is observed in dogs and cats with MM. Cryoglobulins are paraproteins that are insoluble at temperatures below 37° C and require blood collection and clotting to be performed at 37° C before serum separation. If Bence Jones proteinuria is suspected, heat precipitation and electrophoresis of urine are necessary, as commercial urine dipstick methods are not capable of this determination. "Nonsecretory" varieties of MM have been reported rarely in dogs.

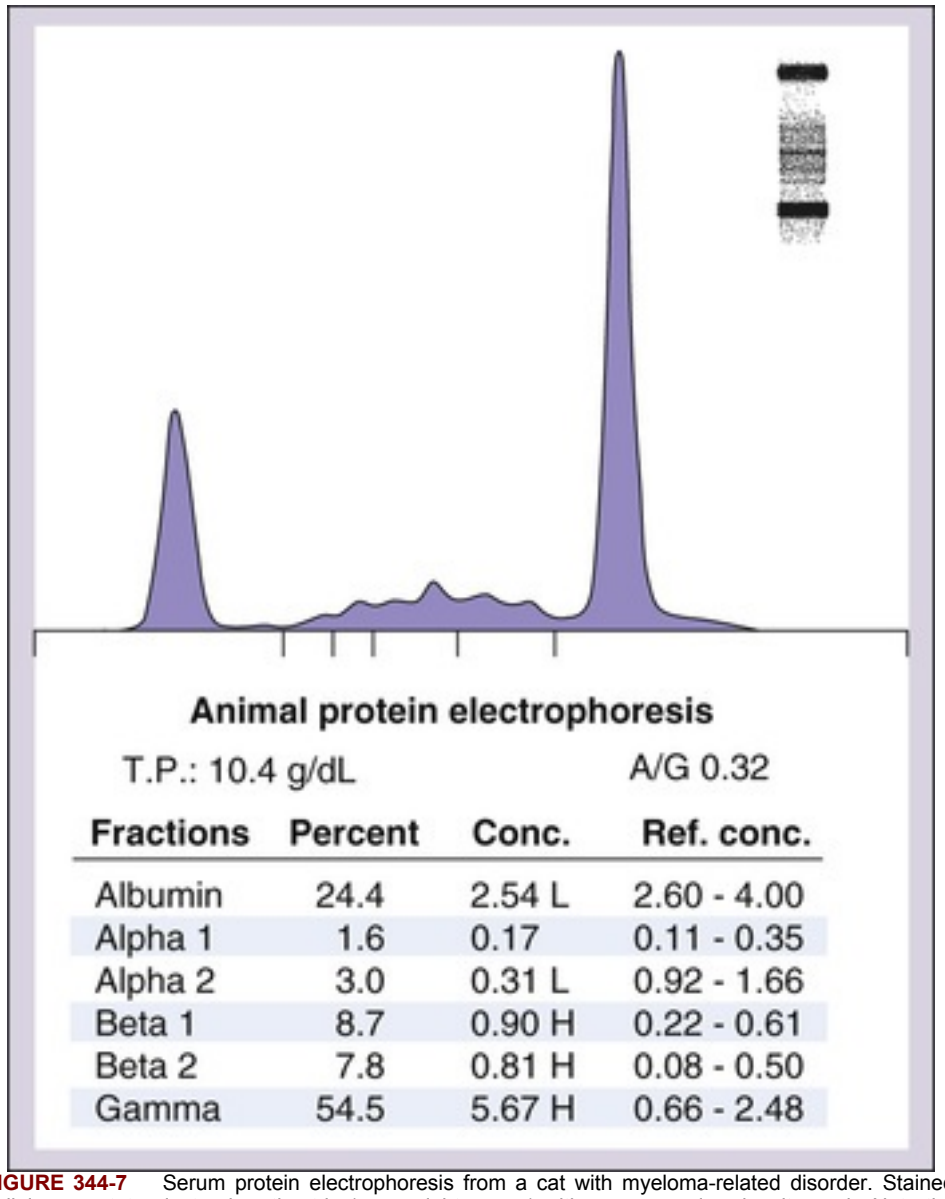

FIGURE 344-7 Serum protein electrophoresis from a cat with myeloma-related disorder. Stained cellulose acetate electrophoretic strip (upper right corner) with accompanying densitograph. Note the large M-component spike (representing an IgG monoclonal gammopathy) present in the gamma region. (Courtesy Dr. Frances Moore, Marshfield Laboratories, Marshfield, WI.)

Definitive diagnosis usually requires a bone marrow aspirate or core biopsy. Normal marrow contains less than 5% plasma cells, whereas myelomatous marrow often greatly exceeds this level. Malignant plasma cells can have a varied microscopic appearance, ranging from that of normal plasma cells to early stages of differentiation.

Skeletal survey radiographs are recommended to determine the presence and extent of osteolytic lesions, which may have diagnostic, prognostic, and therapeutic implications. Rarely, biopsy of osteolytic lesions (i.e., Jamshidi core biopsy) is necessary for diagnosis. Bone lesions may be isolated, discrete lesions (including pathologic fractures; Figure 344-8) or diffuse osteopenias.

FIGURE 344-8 A radiograph of lateral thoracic vertebrae in a dog with multiple myeloma showing multiple expansile, lytic lesions and pathologic fractures in the axial skeleton, most apparent in the spinous processes of the vertebrae and in a collapse fracture of the T3 vertebral body.

Approximately 25% to 75% of dogs with MM have evidence of bony lysis or diffuse osteoporosis. Bones engaged in active hematopoiesis are more commonly affected (e.g., vertebrae, ribs, pelvis, skull, and proximal long bones). Skeletal lesions are present in as few as 8% and as many as 68% of affected cats.[198,200-202,204] In macroglobulinemia, malignant cells often infiltrate the spleen, liver, and lymphoid tissue rather than bone, although bone involvement is occasionally seen.

If clinical evidence of hemorrhage is present, coagulation assessment (e.g., platelet count, prothrombin time [PT], and partial thromboplastin time [PTT]) and serum viscosity measurements should be undertaken. Nearly half of these patients have abnormal PT and PTT values. All animals should undergo a careful funduscopic examination; abnormalities may include retinal hemorrhage, venous dilatation with sacculation and tortuosity, retinal detachment, and blindness.

Differential Diagnosis

Other disease syndromes can be associated with monoclonal gammopathies including lymphoid tumors (lymphoma, CLL, and ALL), chronic infections (e.g., ehrlichiosis, Leishmaniasis, feline infectious peritonitis [FIP]), and monoclonal gammopathy of unknown significance (MGUS). MGUS (i.e., benign, essential, or idiopathic monoclonal gammopathy) is a benign monoclonal gammopathy not associated with osteolysis, bone marrow infiltration, or Bence Jones proteinuria.

Treatment

Initial Therapy of Multiple Myeloma

Therapy is directed at both the tumor cell mass and the secondary systemic effects. Chemotherapy is highly effective at reducing the myeloma cell burden, relieving bone pain, initiating skeletal healing, and reducing levels of serum immunoglobulins. It significantly extends both the quality and length of most patients' lives. Complete elimination of neoplastic myeloma cells is rarely achieved, however, and eventual relapse is to be expected.

Melphalan in combination with prednisone is the treatment of choice. In the dog, melphalan (0.1 mg/kg PO q 24 h) is given for 10 days then reduced (0.05 mg/kg q 24 h) and continued indefinitely. Prednisone

(0.5 mg/kg PO q 24 h) for 10 days is then reduced to 0.5 mg/kg PO every other day. Therapy continues until clinical relapse occurs or myelosuppression necessitates a dose reduction. The most clinically significant toxicity of melphalan is myelosuppression, particularly thrombocytopenia. CBCs should be performed biweekly for 2 months after initiation of therapy and monthly thereafter. If significant myelosuppression occurs, reduction of the dosage or the treatment frequency may be necessary. An alternative pulse-dosing regimen for melphalan (7 mg/m^2 PO q 24 h for 5 consecutive days out of every 21 days) has been used successfully at the University of Wisconsin in a small number of cases in which myelosuppression limited more conventional continuous low-dose therapy. Melphalan and prednisone therapy has also been used in cats with MRD although results are less rewarding. A cyclophosphamide, vincristine and prednisone combination has also been used in cats.

Cyclophosphamide can be used as an alternate alkylating agent, sometimes in combination with melphalan; however, no evidence exists to suggest superiority. In the author's practice, cyclophosphamide (250 mg/m^2) is limited to cases presenting with severe hypercalcemia or widespread systemic involvement, in which a faster acting alkylating agent may be beneficial. Cyclophosphamide is given IV once at the same time as oral melphalan therapy is started. Chlorambucil (0.2 mg/kg PO q 24 h) has been used for IgM macroglobulinemia in dogs.

Evaluation of Response to Therapy

Response is based on improvement in clinical signs, clinicopathologic parameters, and radiographic improvement of skeletal lesions. Improvement in bone pain, lameness, lethargy, and anorexia should be evident within 3 to 4 weeks. Objective laboratory improvement, including a reduction in serum immunoglobulin levels or Bence Jones proteinuria, is usually noted within 3 to 8 weeks.[205] Radiographic improvement in osteolytic bone lesions may take months, and resolution may only be partial. As previously discussed, complete resolution of MM rarely occurs, and a good response is defined as a reduction in measured M-component to at least 50% of pretreatment values. For routine follow-up, quantitation of serum immunoglobulins or measurement of urine Bence Jones proteins are performed monthly until a good response is noted and then every 2 to 3 months. Repeat bone marrow aspiration is performed if warranted and PARR analysis can be used to confirm molecular remissions.[205]

Therapy Directed at Complications of Multiple Myeloma

Long-term control of complications, including hypercalcemia, HVS, bleeding diathesis, renal disease, immunosuppression, and pathologic skeletal fractures, depends on control of the tumor mass. However, therapy directed more specifically at these complications may be indicated in the short term. If hypercalcemia is marked and significant clinical signs exist, standard therapies are indicated (see ch. 69). Moderate hypercalcemia typically resolves in 2 to 3 days of initiation of chemotherapy.

HVS is best treated in the short term by plasmapheresis. Bleeding diathesis usually resolves along with HVS; however, platelet-rich transfusions may be necessary with thrombocytopenia.

Renal impairment may necessitate aggressive fluid therapy. Careful attention to secondary urinary tract infections and appropriate antimicrobial therapy is indicated. Pathologic fractures of weight-bearing long bones and vertebrae may require immediate intervention in conjunction with systemic chemotherapy. Orthopedic fracture stabilization is undertaken and may be followed with radiotherapy. Inhibition of osteoclast activity with bisphosphonate drugs have been used with mixed results to reduce incidence/severity of skeletal complications.[206,207]

Rescue Therapy

At relapse or in cases initially resistant to melphalan, rescue therapy may be attempted. A combination of doxorubicin (30 mg/m^2 IV every 21 days), vincristine (0.7 mg/m^2 IV on days 8 and 15 of the cycle), and dexamethasone sodium phosphate (0.5 mg/kg IV on days 1, 8 and 15) administered in 21-day cycles has been employed by this author. Most dogs initially respond to rescue; however, the duration tends to be short-lived. High-dose cyclophosphamide and liposome-encapsulated doxorubicin have also been used for rescue.[208] Bone marrow ablative therapy and marrow or stem-cell rescue, thalidomide (and other antiangiogenic therapies), bortezomib (a proteasome inhibitor), arsenic trioxide, the bisphosphonates, VDC-1011 and other molecular targeting therapies have been utilized; however, their use in veterinary species is limited or completely absent at present.[205] A dog with melphalan-resistant MM achieved a partial response to tyrosine kinase inhibitor therapy (toceranib) that was maintained for 6 months.[209]

Prognosis

The prognosis for dogs with MM is good for initial control and a return to good quality of life. In 60 dogs with MM, >90% achieved a complete or partial remission with melphalan and prednisone.[195] Long-term survival is the norm, with a median of 540 days reported. Hypercalcemia, Bence Jones proteinuria, and extensive bony lysis are negative prognostic factors in the dog. The long-term prognosis is poor, owing to drug-resistant recurrence.

The prognosis for multicentric MRD in the cat is not as favorable as in the dog because remission durations are generally 2-4 months; however, occasional long-term survival has been reported.[198,200-202,204]

Solitary Plasmacytoma

Solitary collections of monoclonal plasmacytic tumors can originate in bone or soft tissues and are referred to as solitary osseous plasmacytoma (SOP) and extramedullary plasmacytoma (EMP), respectively. The majority of SOPs eventually progress to systemic MM.[172,173] Solitary cutaneous EMP, including oral cavity EMP, is typically a benign disorder in dogs.[174-180] Conversely, the natural behavior of noncutaneous EMP appears more aggressive. Gastrointestinal EMPs have been reported to involve the esophagus, stomach, and small and large intestine or colon.[181-185] Metastasis to associated lymph nodes is common, although bone marrow involvement and monoclonal gammopathies are less common. Colorectal forms progress slowly and may be cured with excision.[185] Few reports exist in cats and while some are controlled with surgical excision, widespread systemic involvement is more likely.[155-158,186-191]

Clinical Signs

Clinical signs associated with solitary plasmacytoma relate to the location. SOP usually is associated with pain and lameness if the appendicular skeleton is affected or with neurologic signs if vertebral bodies are involved. Cutaneous EMP usually has a benign course, whereas gastrointestinal EMP presents with nonspecific signs that suggest alimentary involvement.

Diagnosis

The diagnosis of SOP and EMP requires cytology or tissue biopsy. Thorough staging of SOP and noncutaneous EMP with bone marrow aspirate, serum electrophoresis, and skeletal survey radiographs is important to ensure disease is confined prior to initiation of therapy. In poorly differentiated solitary plasmacytic tumors, immunohistochemical (e.g., MUM1) may be helpful in confirming a diagnosis.[190,192-194] PCR techniques can also be used to determine clonality.

Therapy

Animals with solitary plasma cell tumors may be treated with local therapy (e.g., surgery and/or radiation therapy) in the absence of systemic chemotherapy provided thorough clinical staging does not reveal systemic involvement. Dogs with noncutaneous SOP and EMP may eventually develop systemic MRD. Systemic dissemination may not occur for many months to years beyond diagnosis in humans and no benefit from initiation of systemic chemotherapy prior to the documentation of subsequent systemic involvement is observed. Long-term follow-up of patients with solitary plasmacytoma is indicated to detect both recurrence of disease and systemic spread.

CHAPTER 345

Tumors of the Skin

Kenneth M. Rassnick

Client Information Sheet: Tumors of the Skin

The skin is the most common site of occurrence for neoplasms in the dog and the second most common site in the cat. Subcutaneous (SC) and cutaneous tumors together account for >1/3 of all canine tumors. Approximately 20% to 30% are histologically malignant.[1] Mast cell tumors, perianal (sebaceous) adenomas, lipomas, sebaceous gland adenomas, histiocytomas, trichoblastomas (formerly classified as basal cell tumors), squamous cell carcinomas, melanomas, fibrosarcomas, hemangiopericytomas, and papillomas are the most common histologic types of canine tumors.[1-4] Skin and SC tissues account for ≈1/4 of all tumors in the cat, and 50% to 65% are histologically malignant.[1,2,5] The histologic appearance of malignancy does not necessarily correlate with the tendency to metastasize. The most common skin tumors in cats include basal cell tumors, mast cell tumors, squamous cell carcinomas, fibrosarcomas, melanomas, and hemangiomas.[2,5,6]

Tumors of the skin and subcutis can be broadly classified histologically according to tissue of origin: epithelial, mesenchymal, round cell, or melanocytic (Box 345-1). They can be classified further according to cell of origin, when sufficient differentiation is present. This chapter focuses on tumors of epithelial origin, melanocytic tumors, and certain round cell tumors.

Box 345-1

Common Skin and Subcutaneous Tumors

Epithelial Tumors

Papilloma
Intracutaneous cornifying epithelioma
Squamous cell carcinoma
Basal cell tumors (basal cell epithelioma)
Trichoepithelioma
Follicular stem cell carcinoma
Pilomatricoma
Trichoblastoma
Sebaceous gland tumors
Hepatoid gland tumors (perianal gland tumors)
Sweat gland tumors (apocrine gland tumors)
Ceruminous gland tumors
Anal sac apocrine gland tumors

Mesenchymal Tumors

Soft-tissue sarcomas (see ch. 346)

Round Cell Tumors

Plasmacytoma
Mast cell tumor (see ch. 349)
Lymphoma (see ch. 344)
Histiocytoma (see ch. 350)

Transmissible venereal tumor (see ch. 351)

Melanocytic Tumors

Melanoma

General Approach

History and Physical Examination

Because lesions and masses involving the skin are easily seen, they are common reasons for owners to seek veterinary care. General history taking should include duration and rate of tumor growth, change in appearance over time, response to previous treatments, and related medical problems. Benign tumors are more likely to have a history of slow growth over months to years. In contrast, malignant tumors tend to be rapidly-growing and -changing in appearance. All tumors should be accurately reported in the medical record (location, diagrams/photographs, caliper measurements). The record also should include gross appearance (color, alopecia, ulceration), consistency (firm, soft), borders (circumscribed, infiltrative), and attachments to underlying tissues (fixed, movable). Most benign skin tumors are well-circumscribed and freely movable. In contrast, malignant skin tumors often are fixed to underlying structures and have ill-defined margins. As part of the patient's complete physical examination, lymph nodes draining a skin mass should always be thoroughly evaluated.

Diagnostics

General

The key to the appropriate management of skin tumors is a specific diagnosis. Often, diagnosis and characterization of a skin mass should be done before surgical excision, so the clinician can plan an appropriate surgical approach; make decisions about the need for adjuvant radiation therapy, chemotherapy, or immunotherapy; and discuss realistic outcomes of therapy and prognosis with clients. Figure 346-2 shows a general approach to the diagnosis of superficial masses using fine needle aspiration (FNA) and biopsy.

Routine hematologic and biochemical analyses rarely are helpful in the diagnosis of cutaneous masses; however, some skin tumors might be associated with paraneoplastic complications (see ch. 352). Screening blood tests are recommended before a definitive procedure is planned.

Radiographs of the thorax are required in the staging of malignant skin tumors, and abdominal ultrasound can be useful to assess potential sites of metastases for some tumors. For tumors that attach deeply to underlying tissues, radiographs, computed tomography (CT), or magnetic resonance imaging (MRI) can help delineate tumor borders prior to surgical excision.

Enlarged lymph nodes should always be evaluated cytologically or histologically (see ch. 95). For some tumors (mast cell tumors, melanomas), metastases might be present in lymph nodes that are palpably normal; therefore, lymph node evaluation should be a routine part of the evaluation of an animal with a cutaneous mass.

Fine Needle Aspiration

Fine needle aspiration (see ch. 86) for cytologic assessment (see ch. 87) is easy and quick to perform, and often provides information about the neoplastic cell type.[7] It is most useful in the diagnosis of round cell tumors (mast cell tumors, cutaneous lymphoma, histiocytoma) and for identifying benign skin tumors or papules, nodules, and masses that are nonneoplastic. When cytologic results are nondiagnostic, a biopsy should be performed. Likewise, when a cytologic diagnosis of neoplasia is obtained, a biopsy should always be done to confirm the diagnosis and assess important prognostic information, such as the degree of differentiation or the tumor grade, a description of vessel invasion, and an evaluation of tissue margins[8] when the biopsy is excisional.

Biopsy

A number of biopsy techniques can be used (see ch. 86). Incisional, needle core, or punch biopsies are indicated for large, infiltrative masses or for tumors in a difficult area for reconstruction, such as extremities and perineal or periocular regions. For superficial exophytic lesions, shave biopsies done with a scalpel blade might be adequate. For small, movable dermal masses, excisional biopsy can be both diagnostic and

therapeutic. Even when the diagnosis is known before biopsy, histopathologic assessment of the final specimen is essential because it might provide information for treatment planning.

For nonexcisional biopsies, the site should be in an area that can easily be included in a definitive resection or radiation field. As a general rule, all biopsy incisions on extremities should be longitudinal along the axis of the limb. Injection of local anesthetics into cutaneous and SC tumors should be avoided due to tissue distortion. The biopsy should be taken deeply enough to avoid superficial necrotic tissue and surrounding inflammation. The biopsy procedure should never disrupt tissue planes. Drain placement should be avoided, because it allows neoplastic cells in draining fluid to contact all tissues through which the drain is placed.

An ideal histologic specimen includes the junction of the tumor with adjacent normal tissue. Samples <1×1 mm usually are inadequate, but 1×5 mm needle core samples can be adequate. Samples that fall apart in formalin are often blood, mucus, or necrotic material and are usually nondiagnostic. Large biopsy samples or multiple specimens from different areas of the tumor, collected through the same incision, can improve the likelihood of an accurate diagnosis. Cautery instruments should not be used during the biopsy procedure; cautery for hemostasis can be used once the sample has been removed. Surgical diode lasers often make suboptimal samples; carbon dioxide lasers cause less thermal injury, but still might render small samples nondiagnostic.[9] Finally, formalin fixation can cause marked tissue contraction.[10] Applying India ink or other dyes to all cut surfaces of tumors before formalin fixation helps the pathologist distinguish surgical margins from preparation artifacts.

Epithelial Tumors

Papilloma

Cutaneous papillomas are benign proliferations of the epidermis and are common in the dog but relatively rare in cats. Grossly, they are whitish or gray, pedunculated or cauliflower-like masses and are often referred to as *warts* or *verrucae.* Both viral and nonviral forms exist.[11,12] Papillomaviruses are DNA viruses and are species-specific; causality was not proven in a case report of cutaneous papilloma in a cat from which a human papillomavirus was amplified.[13] Papillomaviruses can survive for >2 months at 4° to 8° C and for 6 hours at 37° C.[14] They can be transmitted by direct and indirect (e.g., fomite) contact. In general, papillomavirus infection occurs in damaged skin, and incubation times vary from 1 to 2 months.[14]

Cutaneous papillomas occur in older dogs, and single or multiple lesions can be seen. They most commonly occur on the head, eyelids, and paws and are not associated with papillomavirus. Canine oral papillomatosis is a contagious disease of viral origin that often affects young or immunocompromised dogs (see ch. 228 and 272).[15] Cutaneous inverted papillomas, cup-shaped lesions seen in young dogs, are also caused by infection with a papillomavirus. They occur on the ventral abdomen and inguinal region.[16] Rare cases of multiple, pigmented plaques, or papular papillomas, have been reported in dogs.[17] Pugs appear to be predisposed to these pigmented plaques, and the disease is related to a novel papillomavirus.[18] Finally, progression of viral papilloma into carcinoma might rarely occur in some dogs.[11,12]

In cats, most solitary cutaneous papillomas are not caused by papillomavirus. In contrast, papillomas that occur on the ventral tongue in cats are generally viral in origin, as are multiple cutaneous papillomas. These viral papillomas might be precursors to feline multicentric squamous cell carcinoma, or Bowen disease (see Feline Squamous Cell Carcinoma, below).[19]

Surgical excision of solitary cutaneous papillomas is curative. Canine oral papillomatosis usually undergoes spontaneous regression within 3 months, and the dog is then immune to reinfection.[14] Immunocompromised animals or those treated with immunosuppressive therapies, such as corticosteroids, might suffer from persistent papillomavirus infections and lesions.[15,20] Autogenous vaccines (to induce regression) have been used, and current attempts aim to create prophylactic and therapeutic recombinant vaccines.[21] Oral administration of retinoids has been reported to be effective for canine inverted papillomas.[22] Interferon or azithromycin might be effective in the treatment of severe oral or cutaneous viral papillomatosis.[23,24]

Intracutaneous Cornifying Epithelioma (Infundibular Keratinizing Acanthoma)

Intracutaneous cornifying epitheliomas (keratoacanthomas) arise from the outer portion of the hair follicle.

They usually occur in relatively young, purebred dogs. Most are solitary, but generalized forms exist. Norwegian Elkhounds and Keeshonden are predisposed to the generalized form.[25] These tumors often have a central pore filled with inspissated keratinous material. Gentle digital pressure applied to the mass results in expulsion of a gray-white keratinous material. Often, there is diagnostic disagreement among pathologists evaluating these lesions; the most common variant diagnosis for keratoacanthomas is well-differentiated squamous cell carcinoma.[26]

Intracutaneous cornifying epitheliomas are benign and do not recur after adequate surgical removal. In the generalized form, new tumors might develop throughout a dog's life. Orally administered retinoids might be useful in the treatment of multiple intracutaneous cornifying epitheliomas (5/7 complete, and 2/7 partial, remissions in one study).[23] Spontaneous regression has also been reported to occur in a dog with the generalized form.[27]

Canine Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is a common malignant neoplasm in the dog. The etiology usually is not known. Tumors that develop in unpigmented or lightly pigmented skin, such as the abdomen and inguinal areas, are believed to be induced by ultraviolet radiation (sun damage).[28] Occasionally, SCC might be caused by burns, chronic infectious or immune-mediated diseases, or progression from viral papillomas.[11,12,24] In an immunohistochemical study of 40 dogs with SCC, 100% of lesions expressed cyclooxygenase-2 (COX-2).[29] COX-2 has been implicated in the oncogenesis of various human cancers, but the mechanisms leading to upregulation of COX-2 are not known. SCC in the dog can be proliferative, ulcerative, or erosive. The clinical features and management of canine SCC are highly dependent on the anatomic location.

Canine Cutaneous Squamous Cell Carcinoma

Cutaneous SCC might first be diagnosed as a preneoplastic lesion, but it ultimately progresses to an invasive tumor. Metastasis to regional lymph nodes and the lungs is rare.[30] Canine cutaneous SCC is best managed with adequate surgical excision. Preneoplastic lesions might respond to orally administered retinoids,[28] and intralesional therapy with sustained-release cisplatin, 5-fluorouracil, or carboplatin might have a role in the management of some dogs with superficial SCC.[31] Comprehensive surgical excision is the treatment of choice for invasive cutaneous SCC. Radiation therapy for incompletely excised tumors; chemotherapy with platinum drugs, doxorubicin, or gemcitabine; or perhaps treatment with COX-2 inhibitors, can be considered for metastatic tumors, but their efficacy is unproven.

Canine Nasal Planum Squamous Cell Carcinoma

Nasal planum SCC can be treated with comprehensive surgical excision of the nasal planum and premaxilla, but the prognosis is extremely guarded. Case selection is important: in a study of six dogs treated surgically, two recurred in less than 2 months, probably because of incomplete resections.[32] Radiation therapy has been largely disappointing, with 7/7 dogs treated with radiation for incompletely excised tumors suffering recurrences in 8 to 12 weeks in one study.[32]

Canine Digital Squamous Cell Carcinoma

SCC originates from the subungual epithelium, or occasionally from other tissues of the digit, and it is the most common digital tumor in dogs. A breed predilection for large-breed, black-coated dogs—including Giant Schnauzers, Standard Poodles, Labrador Retrievers, Rottweilers, and Flat Coated Retrievers—has been reported.[33] Dachshunds with a black hair coat might be overrepresented.[33] Approximately 80% of digital SCCs invade bony tissue of the third phalanx. Metastases are uncommon initially but can be diagnosed after treatment in as many as 30% of dogs.[33-35] Rarely, dogs might develop SCC on multiple digits, either simultaneously or over time.[33,34] Wide amputation, with disarticulation of the first phalanx and metacarpal/metatarsal bone is the treatment of choice. Overall, <50% of dogs with digital SCC die as a result of their disease, so median survival cannot be determined.[34] In one study, the 1- and 2-year survival rates were 95% and 74%, respectively, for subungual epithelial SCC, and 60% and 40%, respectively, for SCC arising from other parts of the digit.[34] Chemotherapy with platinum drugs, doxorubicin, or gemcitabine, or perhaps treatment with COX-2 inhibitors, can be considered for metastatic tumors, but efficacy is unproven.

Feline Squamous Cell Carcinoma

As with dogs, SCC in cats occurs most frequently in sun-damaged skin and is usually preceded by actinic (solar) keratosis.[24] Viruses might also be underlying etiologies for feline SCC. In one study, 24% of cats infected with feline immunodeficiency virus (FIV) developed SCC.[36] It is unclear whether a direct causal relationship exists or whether the condition is due to outdoor sunlight exposure in these cats. Papillomavirus has been identified in lesions of multicentric SCC *in situ* (Bowen disease).[24,37] As in canine SCC, COX-2 immunoreactivity has been shown in all cases of feline cutaneous SCC,[38] though the mechanisms are unknown. As in dogs, SCC is the most common digital neoplasm in cats.[39] The histologic differentiation of primary digital SCC in cats can be difficult to discern from metastatic pulmonary adenocarcinoma in the digits, so thoracic radiography is recommended if a diagnosis of SCC is returned.[39,40]

Feline Cutaneous Squamous Cell Carcinoma

Cutaneous SCC in the cat usually starts as a crusted area that eventually develops into an erosive or ulcerative lesion. The most common sites are unpigmented areas exposed to sunlight, including the external nares, pinnae, eyelids, and lips. Multiple lesions occur in ≈45% of affected cats.[41] Metastases are rare.

Several treatment options exist for feline cutaneous SCC, including comprehensive surgical excision (pinnectomy, nosectomy), cryotherapy, external-beam radiation, strontium-90 plesiotherapy, photodynamic therapy, topical immunotherapy (imiquimod cream), electrochemotherapy, and intralesional chemotherapy. These treatments are most successful in small (<5 cm), superficial lesions; therefore, early diagnosis and prompt therapy are essential. Small, minimally invasive SCC lesions can be controlled for >1 year in most cats, and long-term control (2-7 years) is possible in 10% to 60%. Treatment of larger (>5 cm) or invasive tumors is disappointing, with control times generally <2 years.[41-48] In all cats, avoidance of sunlight is important to prevent additional lesions.

Feline Multicentric Squamous Cell Carcinoma *In Situ* (Bowen Disease)

Bowen disease is a condition of small, plaquelike, crusted SCC lesions that histologically do not invade the basement membrane. Unlike solar-induced SCC, multicentric SCC *in situ* is found in haired, pigmented areas and might be caused by infection with a papillomavirus.[37]

Lesions are multifocal over the head, neck, thorax, abdomen, and limbs. Occasionally, focal areas of invasive SCC or concurrent invasive SCC lesions might be present.[49,50] When possible, surgical excision is the treatment of choice. Strontium-90 plesiotherapy can be effective for small lesions (<8.5 mm in diameter); multiple overlapping fields are needed for larger lesions.[46] Due to the multicentric nature of the disease, some cats might need alternative therapies. Imiquimod is an immune-response modulator, and regression of Bowen disease lesions treated with this cream has been reported.[50] Therapy with orally administered retinoids is variably successful.[12]

Basal Cell Tumors (Basal Cell Epithelioma)

Basal cell tumors (basal cell epitheliomas) are benign neoplasms that arise from the basal cells of the epidermis. They are the most common skin tumor affecting the cat.[51] The tumor previously classified as basal cell tumor in the dog has been reclassified as trichoblastoma. Basal cell tumors usually are solitary, firm, rounded, and well-circumscribed. Occasionally, they might be cystic. Basal cell tumors often are pigmented, which can lead to a clinical misdiagnosis of melanoma. Adequate surgical excision is the treatment of choice.

Basal Cell Carcinoma

Basal cell carcinomas usually are solitary and similar to basal cell tumors; they are often pigmented brown or black. This tumor is locally invasive; therefore, clinical management should include wide surgical excision. In most cases, local excision is curative. Animals with local recurrence[52] and/or metastases rarely have been reported.[53] Adjunctive radiation therapy can be considered when adequate surgical margins cannot be achieved.

Trichoepithelioma

Trichoepitheliomas are benign neoplasms from the hair follicle sheath. They are relatively common in the dog and uncommon in the cat. Surgical excision is the treatment of choice. Malignant trichoepithelioma with lymph node and lung metastasis has rarely been reported.

Follicular Stem Cell Carcinoma

Follicular stem cell carcinoma is an uncommon epithelial tumor in the dog that has not been reported in other species.[54] Tumors previously referred to as *sebaceous carcinomas* now are named *follicular stem cell carcinomas.*[54] They show areas of apocrine or trichoepitheliomatous (hair follicle) differentiation or both. The biological behavior has not been well described, but lymphatic invasion is noted in some tumors, and metastases have been reported.[54]

Pilomatricoma

Pilomatricomas are uncommon, benign tumors that arise from the hair follicle. They usually are solitary and well circumscribed. On cut section, the tumor consists of several layers of gray-white chalky tissue. Surgical excision is the treatment of choice. Malignant pilomatricomas have been reported rarely; lymphatic invasion is seen histologically, and metastases to bone, lymph nodes, lungs, skin and the nervous system might occur.[55]

Trichoblastoma

Trichoblastomas are common benign tumors that predominately derive from primitive hair germ epithelium. This neoplasm was previously classified as basal cell tumor. Trichoblastomas are generally solitary and can be pigmented. Surgical excision is curative.

Other Follicular Tumors

Other uncommon follicular tumors (tricholemmoma, trichofolliculoma, dilated pore of Winer, and warty dyskeratoma) are benign lesions, and adequate surgical excision should be curative.

Sebaceous Gland Tumors

Sebaceous gland tumors are derived from sebocytes, produce sebum (an oily white fluid), and are among the most common skin tumors in dogs. Predisposed breeds include English Cocker Spaniel, Cocker Spaniel, Samoyed, Siberian Husky, Cock-A-Poo, Alaskan Malamute, West Highland White Terrier, Cairn Terrier, Dachshund, Miniature and Toy Poodle, and Shih Tzu. These tumors are uncommon in cats.

Histologically, sebaceous gland tumors are classified as sebaceous hyperplasia, epitheliomas, adenomas, or, rarely, carcinomas. The lesions are wartlike or cauliflower-like in appearance and can occur throughout the body, including on the eyelids. They usually are solitary, but multiple sebaceous gland tumors can occur. Tumors previously referred to as *sebaceous carcinomas* in the literature are now named *follicular stem cell carcinomas* (see above).[54]

Surgical excision is the treatment of choice for all types of sebaceous gland tumors. Local recurrence is rare, but up to 10% of dogs might develop lesions at other sites.[56] Dogs with sebaceous hyperplasia might respond to therapy with orally administered retinoids.[23] Sebaceous carcinomas appear to have a low potential for metastasis.[56]

Hepatoid Gland Tumors (Perianal Gland Tumors)

Perianal gland tumors arise from canine circumanal glands, which are nonsecretory, modified sebaceous glands.[57-60] These tumors are discussed in ch. 278.

Sweat Gland Tumors (Apocrine Gland Tumors)

Sweat gland tumors in dogs and cats commonly occur in the inguinal or axillary regions. These tumors have various clinical presentations, including solitary nodular masses or a diffuse, inflammatory, and ulcerative, plaquelike growth. Cats with a histologic diagnosis of apocrine gland carcinoma of the digit might actually

have digital metastases from a pulmonary carcinoma.

Most sweat gland tumors are histologically malignant carcinomas, and >20% might have evidence of lymphatic or vascular invasion.[61-63] Wide surgical excision is the treatment of choice. In two case series, <2% of canine sweat gland carcinomas developed distant metastases, possibly in association with vascular invasion.[61,62]

Ceruminous Gland Tumors

Ceruminous gland tumors originate from modified apocrine sweat glands in the external ear canal. Chronic otitis externa might be a predisposing factor (see ch. 237).[64] Common clinical signs associated with ear canal tumors include the presence of a mass, aural discharge, odor, pruritus, and pain. Neurologic signs, including Horner's syndrome and vestibular disease, might also be present. Radiographs of the skull and/or CT are important imaging modalities that should precede surgery. Careful evaluation of the mandibular and periauricular lymph nodes is essential.

Ceruminous gland adenomas can be managed by conservative surgical resection. For ceruminous gland carcinomas, however, comprehensive surgical excision, including ear canal ablation and lateral bulla osteotomy, is the treatment of choice. A 42-month median remission, 25% recurrence rate, and 75% 1-year survival rate are associated with such treatment, compared to a 10-month median remission, 40% recurrence rate, and a 33% 1-year survival rate with lateral ear resection alone.[65] Complete ear canal ablation with lateral bulla osteotomy in 7 dogs resulted in 0 recurrences over a 36 month follow-up, compared with recurrence within 4 months in 3/4 dogs treated with a more conservative lateral ear canal resection.[66] Radiation therapy can be used as an adjunct to incomplete resection. A median progression-free interval of 40 months and a 56% 1-year survival rate were achieved in six cats and five dogs treated with radiation therapy after incomplete resection of ceruminous gland adenocarcinoma.[67]

Anal Sac Adenocarcinoma

Anal sac adenocarcinomas arise from the apocrine glands in the ventrolateral aspects of the anus. They occur almost equally in female and male dogs but are rare in cats.[68] Up to 30% of anal sac adenocarcinomas are detected incidentally on a routine physical examination, underscoring the importance of complete rectal examination on routine exams. Twenty-five percent to 50% of anal sac adenocarcinomas produce parathyroid hormone–related protein (PTHrP), leading to hypercalcemia of malignancy[68,69] (see ch. 297 and 352); hypercalcemia generally resolves quickly after resection of the primary tumor, but supportive therapies (e.g., intravenous fluids, corticosteroids, and/or bisphosphonates) might be needed in some cases until surgery can be done or when hypercalcemia cannot be controlled with surgery alone. Metastases generally arise in the iliac lymph nodes, although distant metastases might also be seen in the liver, spleen, lungs, bones, and other sites. Occasionally, extension from the iliac lymph nodes into the lumbar vertebrae may occur.[69] The diagnosis and treatment of these tumors[70,71] are discussed further in ch. 278.

Tumor size generally is an important predictor of survival of dogs with anal sac adenocarcinoma. Dogs with small tumors (<2.5 cm diameter) and no metastases have an excellent prognosis (median survival ≈3.5 years[73]) after surgical excision. For tumors >2.5 cm in diameter, the survival time with surgical excision alone is ≈1.5 years.[73] In a study of 24 dogs with anal sac tumors ≥10 cm, survival times were <1 year.[74] The rate of local recurrence after surgical excision of anal sac adenocarcinoma is approximately 50%. It is unclear whether this correlates with incomplete histologic margins,[69,70] but adjunctive radiation therapy for dogs with incompletely resected tumors might improve the outcome.[75]

Forty percent[69] to 80%[70] of dogs with anal sac adenocarcinoma have metastases to the iliac lymph nodes at initial diagnosis, but anal saculectomy and sublumbar lymphadenectomy can still confer a median survival time of ≈2 years.[76]

It is unclear whether paraneoplastic hypercalcemia of malignancy or E-cadherin (a transmembrane protein that mediates adhesions between epithelial cells and the extracellular matrix) influences the outcome of dogs with anal sac adenocarcinoma.[67,73,74,77]

Anticancer agents most widely evaluated include cisplatin, carboplatin, doxorubicin, mitoxantrone, actinomycin, and melphalan,[70,73-75] but the exact role of chemotherapy for this disease is not known. Evidence suggests that toceranib phosphate has biologic activity against canine anal sac adenocarcinoma (see

below, and ch. 341).[78] Indications for chemotherapy and/or receptor tyrosine kinase inhibitors might include nonresectable tumors, metastatic disease, or even evidence of lymphatic invasion, and additional studies are needed to assess this.

Round Cell Tumors

Round cell tumors also may be called *discrete cell tumors.* Cytologically, they appear as individually oriented round cells that have no obvious attachments to each other. Round cell tumors include lymphoma, mast cell tumors, plasmacytomas, histiocytomas, and transmissible venereal tumors. Occasionally, melanomas and basal cell tumors might mimic round cell patterns. In some cases, the type of tumor is not readily distinguished cytologically; a biopsy of the lesion should be submitted for histopathologic analysis. If the cell lineage is still not determined, immunohistochemistry or special stains can be performed. Examples include CD3/CD4/CD8 (T-cell lymphoma), CD21/CD79a (B-cell lymphoma), CD-117/Toluidine blue/Giemsa (mast cell tumor), MUM1/RF4 (plasma cell tumor), CD 18 (histiocytoma) and Melan A/PNL2/S100 (melanoma).

Lymphoma, Mast Cell Tumor, Histiocytoma, and Transmissible Venereal Tumors

These tumor types are discussed in ch. 344, 349, 350, and 351, respectively.

Plasmacytoma

Cutaneous plasma cell tumors (cutaneous extramedullary plasmacytomas) usually are solitary, and common locations of occurrence are the digits, lips, pinnae, oral cavity, and rectum.[78,79] The majority of cutaneous plasmacytomas in the dog are benign and are unrelated to multiple myeloma (see ch. 344). The behavior of canine plasmacytomas does not seem to have any relationship to the degree of histologic atypia or pleomorphism.[79,80] Additional information is available under Myeloma-Related Disorders (ch. 344).

The treatment of choice for cutaneous plasmacytomas is surgical excision. Local recurrence might be associated with incomplete margins.[79] Radiation therapy (see ch. 340) can be considered for nonresectable tumors, but information is limited.[81,82]

Most plasma cell tumors reported in cats are systemic (myeloma-related disease), so testing is indicated as described for multiple myeloma (see ch. 344).[83] Solitary cutaneous plasmacytomas in cats should be excised. Adjunctive chemotherapy with predniso(lo)ne and alkylating drugs (i.e., melphalan, chlorambucil, or cyclophosphamide) is recommended if the disease is multicentric. As in dogs, radiation therapy can be considered for the treatment of a nonresectable cutaneous lesion.

Melanocytic Tumors

Melanoma

The etiology of cutaneous melanomas in dogs and cats is unknown, but breed predilections in dogs suggest a genetic basis. Breeds reported to be at risk include Scottish Terriers, Airedales, Boston Terriers, Cocker and Springer Spaniels, Boxers, Golden Retrievers, Standard and Miniature Schnauzers, Irish and Gordon Setters and Doberman Pinschers.[24] In dogs, lesions usually are solitary and are brown to black in appearance. Common sites include the eyelid, muzzle, trunk, interdigital skin, and subungual epithelium (nail bed). Digital melanomas are the second most common digital tumor in dogs, after SCC.[33] In cats, the most common pigmented cutaneous tumor is a basal cell tumor. However, melanomas also are black. Common sites in cats include the pinnae, nose, and neck.

The biological behavior of cutaneous melanomas can be benign or malignant. Of critical importance is the location of the tumor. As a general rule, tumors arising from haired skin are benign. Those arising from mucocutaneous junctions are malignant, the only exception being those arising on the eyelids. Melanomas of the digit can be highly malignant, and malignant melanomas commonly spread via lymphatics to draining lymph nodes and the lungs. Metastases to distant sites such as the liver, spleen, brain, heart, and bone marrow occasionally occur.

In dogs, traditional histologic criteria of malignancy appear to be appropriate for diagnosing malignancy in tumors of melanocytic origin, but no single feature or pattern of features always correlates with outcome.[84-86]

Histologic mitotic index appears to be generally predictive of biologic behavior.[84,87-89] A mitotic index of <3 per 10 high-power fields appears to be associated with benign behavior.[87,93] It is difficult to predict the biologic behavior of cutaneous melanomas in cats based on mitotic index, because 25% of malignant tumors can show no mitotic figures.[90]

The treatment of choice for cutaneous melanomas in both the dog and the cat is surgical excision. A median survival of 26 months and a 2-year tumor-related death rate of 10% occurred in 59 dogs where the mitotic index of the tumor was <3, compared to a median survival of 7.5 months and a 2-year tumor-related death rate of 73% in 26 dogs where the mitotic index was ≥3.[87] With digital melanomas in dogs, >50% metastasize.[33,35] A median survival time of 12 months has been reported for dogs treated by amputation of the affected digit.[33,34,85] Other studies have reported median survival times of 18 to 24 months.[87,88]

The prognosis for cats with cutaneous melanomas is guarded. In one study of 57 cats with these tumors, metastases were documented at initial diagnosis in 11 (19%). Forty-five cats were treated by surgical excision, and 22 of these animals developed local recurrence or metastases.[91]

Coarsely fractionated radiation therapy is useful for treating dogs with oral melanoma and might be beneficial for local control of nonresectable cutaneous melanomas in dogs and cats.[92]

Also, a clinical response to treatment with carboplatin can be seen in dogs with oral melanomas. Therefore, this might be considered as an adjunct therapy in dogs with digital melanomas or in dogs and cats with malignant or nonresectable tumors or metastatic disease.[93,94] Finally, a xenogeneic DNA canine melanoma vaccine is commercially available (Canine Melanoma Vaccine, Merial) (see ch. 341). The product immunizes with human DNA encoding tyrosinase, the enzyme essential for melanin synthesis. Long survival times have been reported in dogs in clinical stage II (tumor 2-4 cm in diameter) or stage III (tumor >4 cm in diameter or with local lymph node metastasis) oral melanoma with adequate local control (i.e., with surgery and/or radiotherapy) treated with the vaccine. However, reliability of vaccine efficacy data is severely hampered by lack of randomized clinical trials.[95-97]

A xenogeneic tyrosinase DNA vaccine was safe when used in conjunction with local and regional disease control in a group of 58 dogs with malignant digit melanoma. Overall median survival time was 476 days, with a 1-year survival rate of 63%. The xenogeneic vaccine used in the study was of murine DNA origin, unlike the commercially available product, which is of human DNA origin. However, the authors believe that the immune response and therefore response to vaccine treatment should be the same.[98] Canine melanoma vaccine might have a role in the management of malignant cutaneous melanomas, but this has yet to be determined.
